CHAPTER

52 Anal Carcinoma

Jennifer Yon-Li Wo, Theodore Sunki Hong, Matthew D. Callister, and Michael G. Haddock

INCIDENCE

In 2015, there were an estimated 7270 new cases and 1010 deaths attributable to anal squamous cell carcinoma,[1] representing approximately 2% of gastrointestinal malignancies in the United States.[2]

BIOLOGIC CHARACTERISTICS

Prognostic factors predictive for local control and survival are size, extent of the primary tumor, and regional lymph node involvement.

STAGING EVALUATION

Staging should generally include a complete history and physical examination, anoscopy with biopsy, complete blood cell count, liver function tests, serum creatinine levels, chest radiograph, and computed tomography (CT) scanning of the abdomen and pelvis. Positron emission tomography (PET) imaging should be considered.

Endoscopic ultrasound may be used to evaluate the depth of invasion.

PRIMARY THERAPY

Definitive radiotherapy and concomitant 5-fluorouracil (5-FU) and mitomycin-C are appropriate treatment for most patients with anal cancer. Five-year survival rates range from 40% to 80%.

Local control with anal preservation is achieved in more than 95% of patients with tumors less than 2 cm in size and in 60% to 75% of those with larger tumors.

ADJUVANT THERAPY

Adjuvant radiotherapy and concurrent chemotherapy are indicated for those rare patients who are managed initially with abdominoperineal resection but have primary tumor extension beyond the anal sphincter or metastases to regional lymph nodes.

Approximately 60% of patients with persistent or recurrent local disease after radiotherapy plus chemotherapy may still be cured with abdominoperineal resection.

LOCALLY ADVANCED DISEASE

Radiotherapy and concurrent chemotherapy are effective in patients with large primary cancers with or without invasion of adjacent organs. Two thirds of patients with locally advanced primary tumors maintain sphincter function.

Patients with positive nodes have a 5-year survival of 40% to 60%.

PALLIATION

Palliative chemotherapy with 5-FU and mitomycin C in patients with metastatic disease is associated with a 50% response rate.

Brain and osseous metastases may be effectively palliated with hypofractionated radiotherapy.

Carcinoma of the anal canal accounts for about 1.9% of all malignant tumors of the digestive system in patients in the United States.[1] Despite the rarity of anal cancer, it is a model for successful oncology research, both in the laboratory and in the clinic. Epidemiologic observations about the increased incidence of anal cancer in some populations, along with advances in molecular biology that have allowed the identification of human papillomavirus (HPV) DNA in most anal tumors, have provided the initial clues to the mechanism of anal carcinogenesis. Retrospective studies have provided important information about the natural history and patterns of spread of anal cancer, as well as hypotheses to test in prospective trials. Prospective randomized trials have been completed successfully and have led to the adoption of a combination of radiotherapy and chemotherapy as the standard of care for patients with anal cancer. Questions remain, however, about the most effective and least toxic regimens of radiotherapy and chemotherapy.

This chapter focuses on the biologic characteristics of anal cancer, the rationale for patient evaluation, treatment recommendations, and results of treatment. Radiotherapy techniques for patients with anal cancer will also be discussed.

ETIOLOGY AND EPIDEMIOLOGY

Anal cancer occurs much less frequently than other types of cancer of the digestive tract. In 2015, there were an estimated 7270 new cases and 1010 deaths attributable to anal cancer,[1] representing approximately 2% of gastrointestinal malignancies in the United States.[2] In the United States, the annual incidence is 0.47 per 100,000 white men and 0.69 per 100,000 white women.[3] The annual incidence among African Americans is higher: 0.57 per 100,000 men and 0.78 per 100,000 women.[3] Overall, 87% of patients diagnosed with anal cancer are non-Hispanic whites, 5% are African American, and 3% are Hispanic.[4] The median age at diagnosis is 62 years.[4] Thus, the typical American patient with anal cancer is a white woman in her seventh decade of life.

Epidemiologic studies from the United States, Europe, and Australia have reported an increased incidence of anal cancer in the past 30 to 40 years.[5-7] Within the United States, the incidence of anal cancer in the general population has increased over the last 30 years, from 10 to about 20 per million.[5] In a review of the Surveillance, Epidemiology, and End Results (SEER) database from 1973 to 2000, the incidence of anal

cancer in men and women was found to have risen from 1.06 and 1.39 per 100,000 persons to 2.04 and 2.06 per 100,000 persons.[5] In particular, the incidence of squamous cell anal carcinoma has increased dramatically after 1997 for men and women, consistent with the impact HIV has had on the acquisition and persistence of HPV.[8] In England, between 1990 and 2010, there has been a 69% increase in squamous cell anal carcinoma from 0.43 per 100,000 population in 1990–1994 to 0.73 in 2006 to 2010, with effect more marked in women than men.[9] Similarly, the number of new cases of anal cancer in Denmark has doubled in men and tripled in women.[10]

The incidence of anal cancer is higher in urban than in rural populations, and increases in the incidence of anal cancer have been greater in urban than in rural populations.[3,10] In the United States, the increased incidence of anal cancer has been predominantly limited to densely populated regions. Young men account for a substantial proportion of this increase.[8] In Denmark, the median age at diagnosis in men has decreased from 68 to 63 years, whereas in women, it has remained constant at 66 to 67 years.[10]

Association with HIV Infection

At least part of the increased incidence in young men can be explained by the observation that men who have sex with men (MSM) are at increased risk for the development of both anal intraepithelial neoplasia (AIN) and anal cancer, particularly among patients with HIV.[11-15] The population at highest risk for anal cancer appears to be MSM (odds ratio [OR], 17.3),[16] and in particular in the subset of these men who are HIV-positive. A meta-analysis of 53 studies found that prevalence of anal cancer (45.9 versus 5.1 per 100,000 men) was significantly higher among MSM who were HIV-positive as compared to HIV-negative.[11]

With the introduction of highly active antiretroviral therapy (HAART), although the incidence of some AIDS-associated cancers, including Kaposi's sarcoma and non-Hodgkin's lymphoma, have decreased in incidence, the incidence of anal cancer has not declined.[21-24] Two large cohort studies from England and France recently demonstrated no significant difference in the standardized incidence ratio (SIR) for development of invasive anal cancer with the introduction of HAART.[23,24]

The incidence of anal cancer is markedly increased in both men and women who have AIDS. The relative risk (RR) estimated from a linkage analysis of cancer registries and AIDS registries is 63, and it is higher for homosexual men (RR, 84) than for heterosexual men (RR, 38). The increased risk is also apparent during the 5-year period before an AIDS diagnosis. The absolute risk of anal cancer in patients with AIDS is 1 per 1000.[25]

Risk Factors

The pathogenesis of anal cancer is multifactorial. A diagnosis of anal cancer represents the result of an interplay of multiple environmental and host factors. Patients with epidermoid anal cancer are more likely than control patients to have had a previous diagnosis of malignant disease, including cancers of the vulva, vagina, or cervix and lymphoma or leukemia. Patients with anal cancer who are diagnosed before age 60 years are at higher risk of subsequent development of malignant diseases of the respiratory system, bladder, vulva, vagina, and breast, but they are not at increased risk for subsequent development of colon or rectal cancers.[26] Overexpression of the c-*myc* oncogene has been implicated in the pathogenesis of both anal squamous cell neoplasia and breast cancer.[27,28] This finding, along with an observed pattern of second malignant diseases and prior malignant diseases in patients with anal cancer, suggests a multifactorial pathogenesis and common oncogenetic risk factors. These factors may include sexually transmitted viruses, environmental carcinogens such as cigarette smoke, immunosuppression, and genetic susceptibility.[26]

Anal cancer and cancers of the female genital tract share a common pathogenesis.[29] In the embryo, the anal and cervical canals are both derived from closely related anlagen.[30] Women patients with anal cancer are more likely than women with colon or stomach cancer to have had a prior diagnosis of cervical intraepithelial neoplasia.[29] An association between anal cancer and the number of lifetime sexual partners has been reported in women.[31] Case-control studies have also found an association between anal cancer and some sexually transmitted diseases.[17,31-33] This association, along with the increased incidence in young homosexual men, strongly suggests an etiologic factor for anal cancer associated with increased sexual activity.[3]

Among sexually transmittable infectious agents, HPV has been the most thoroughly studied potential causative agent. Although there are more than 60 types of HPV, those most commonly associated with benign genital condylomata acuminata are HPVs 6 and 11, whereas HPVs 16, 18, 31, 33, and 35 are associated with malignancy or high-grade dysplasia.[34] Several investigators have also reported an association between genital warts and anal cancer in men and women.[32-36] The development of anal warts in both sexes has been linked with the practice of anal intercourse.[32]

The likelihood of finding HPV DNA in specimens of anal cancer varies according to patient demographics and laboratory technique. Patients with HPV-associated anal cancer are 10 years younger on average than patients with reportedly HPV-negative cancers.[37] In addition, HPV-associated anal cancer has been reported more frequently in Europe and South America than in South Africa and India.[38] When in situ hybridization techniques are used to analyze biopsy specimens of anal cancer, the rate of HPV DNA detection ranges from 17% to 73%.[34,37]

Exposure to HPV may be a risk factor even for patients in whom HPV DNA is not detected in the carcinoma specimen. Serum IgA antibodies to a peptide antigen from the E2 region of HPV 16 have been found in 89% of patients with anal cancer compared with only 24% of controls.[37] In another study, antibodies to HPV 16 capsids were elevated in 55% of patients with anal cancer compared with 3% of controls. Antibodies to HPV-capsid antigen were detected in an equal number of cancer specimens from patients whose HPV DNA was negative or positive (as assessed by in situ hybridization), which suggests that some patients presumed to be HPV-negative had been exposed to HPV.[40]

HPV infection and anal cytologic abnormalities are common in patients with HIV infection.[12] Patients who are HIV-positive with HPV DNA found in anal biopsy specimens seem to have a high rate of cytologic abnormalities. In one study of 12 patients who are positive with HIV without AIDS, 11 patients (92%) with normal cytologic findings but with HPV DNA found in anal mucosa later had cytologic abnormalities at 17-month follow-up.[41]

Although the true influence of HPV in anal carcinogenesis is uncertain, some laboratory findings point to the involvement of the HPV E6 and E7 proteins. These findings include the observation that the *E6* and *E7* oncogenes are consistently expressed in tumor cells but that normal E6 and E7 regulatory mechanisms are absent.[43] In addition, the E7 protein of HPV 16, in cooperation with the E6 protein, is able to transform mammalian cells in vitro while blocking *E6* and *E7* gene function, which results in reversal of the malignant

HPV DNA is more likely to be detected with polymerase chain reaction analysis. Studies comparing both techniques have found that polymerase chain reaction techniques detect HPV DNA in 78% to 85% of patients, whereas in situ hybridization techniques find HPV DNA in only 17% to 50% of the same patients.[34,39]

Additionally, recently published data of 34,189 individuals infected with HIV and 114,260 individuals not infected with HIV in the North American AIDS Cohort Collaboration on Research and Design (NA-ACCORD) from 1996 to 2007, the unadjusted anal cancer incidence rates were 131 for MSM who were infected with HIV, 46 for other men who were infected with HIV, and 2 for men who were uninfected with HIV per 100,000 person-years.[15] Although in most areas of the world, anal cancer is more common in women than in men of all age groups,[17,18] in areas with a relatively high proportion of MSM, however, anal cancer may be more common in men. For example, in San Francisco, the incidence of anal cancer in white men more than doubled from 0.53 per 100,000 in 1975 to 1.2 per 100,000 in 1989,[3] and in Los Angeles, anal cancer has become more common in men than in women younger than age 35.[19] A study of Danish MSM living in registered "marriage-like partnerships" identified an incidence of cancer double what was expected, which could be accounted for by HIV-related cancers, including Kaposi's sarcoma, non-Hodgkin's lymphoma, and anal cancer. The relative risk ([RR] of anal cancer in this population was 31, and anal cancer appeared to be associated with a positive HIV status.[20]

Many patients with AIDS most likely die of opportunistic infections before anal cancer is manifested. Although the impact of effective antiretroviral therapy on the incidence of anal cancer is not yet clear,[42] further increases in the incidence of anal cancer may be observed in patients with AIDS as survival time is prolonged.[41]

phenotype.[43,44] Interactions of HPV oncoproteins with known tumor suppressor gene products have been reported. The E6 protein of HPV 16 and HPV 18 forms stable complexes with the p53 protein product of the *P53* tumor suppressor gene.[45-47] The cellular p53-E6 protein complex results in a lack of appropriate G1 arrest and subsequent genomic instability. The E7 protein also forms complexes with the retinoblastoma gene product and with p107, p130, p33, cdk2, and cyclin A. E7 also activates the cyclin-A promoter and overrides two inhibitory functions that restrict the expression of cyclin A and cyclin E.[44]

Some evidence suggests that infectious agents other than HPV may contribute to anal carcinogenesis. Associations have been found between the development of anal cancer and a history of syphilis or gonorrhea in men[33,48] and between anal cancer and *Chlamydia* and herpes simplex virus type 2 in both sexes.[31,32] In a study of patients in and around San Francisco, herpes simplex virus DNA was detected in 3 of 15 patients with invasive anal cancer and in 3 of 4 patients with high-grade intraepithelial neoplasia.[39] No Epstein-Barr virus or cytomegalovirus DNA was found in the tumor specimens of the 15 patients with anal cancer. Further studies are needed to determine whether these and other sexually transmitted agents are involved in anal oncogenesis or are merely surrogate markers for probable HPV infection.

Chronic immunosuppression is associated with an increased risk for anal malignant disease. Renal transplant recipients have an increased incidence (as high as 100-fold) of carcinoma of the vulva or anus.[49,50] These cancers occur at an earlier age than they do in the general population.[49] Renal transplant patients also have an increased incidence of cutaneous neoplasia and viral warts. Those with a high susceptibility to cutaneous malignant disease (four or more skin cancers) are more likely to have HPV DNA-associated skin cancer and are more likely to have an anogenital malignant tumor.[51] The increased incidence of anal malignant disease in patients who are HIV-positive is most likely caused in part by chronic immunosuppression.

A number of authors have reported an association between anal cancer and cigarette smoking.[31,32,35,52] When compared with a control group of patients with colon cancer, both men and women smokers were found to have an increased risk of anal cancer.[32]

Although in the past, chronic inflammation or irritation from benign anal conditions (e.g., hemorrhoids, anal fissure, fistula, or inflammatory bowel disease) had been associated with anal cancer,[18,53-55] recently published case controlled series have failed to demonstrate an association between benign anal conditions and anal cancer.[35,56] A Danish population-based study found that patients with anal fissure, fistula, perianal abscess, or hemorrhoids were at increased risk for anal cancer; however, the RR for invasive anal cancer was highest in the year immediately after a diagnosis of benign anal pathology, and it declined from a high of 12 the first year to 1.8 after 5 or more years. Thus, despite a temporal association between the diagnosis of benign anal lesions and the diagnosis of anal cancer, this suggests that a so-called benign anal condition is often a symptom or misdiagnosis rather than a cause of anal cancer.[56]

PREVENTION AND EARLY DETECTION

Prevention of anal cancer should include educational efforts about the causal link of sexually transmitted HPV infection with malignant diseases of the anogenital tract. Recommendations of the 1996 National Institutes of Health Consensus Panel on cervical cancer prevention are also applicable to anal cancer and include encouragement to delay onset of sexual intercourse.[58] Barrier methods, such as condoms, do not prevent HPV transmission.[59] The panel also recommended development of an effective vaccine to prevent transmission of HPV, and a subsequent Phase III clinical trial provided encouraging results in this regard.[60-62]

In a randomized trial of 4065 healthy males 16 to 26 years of age, a quadrivalent vaccine was effective in preventing infection with HPV types 6, 11, 16, and 18 and prevented the development of external genital lesions. In the per-protocol population, efficacy against lesions related to HPV types 6, 11, 16, or 18 was 90.4%.[63] A planned substudy of that trial analyzed the impact of HPV vaccine on the development of anal squamous intraepithelial lesion (SIL) in 602 MSM who had a history of five or fewer lifetime sexual partners. Participants with a history or evidence of anal lesions were excluded, as were participants who were HIV positive at enrollment on the protocol. The primary endpoint of the trial was the development of anal SIL associated with HPV types 6, 11, 16, or 18. In the per-protocol population, which included 402 of the 598 men (67%) who received all three doses of vaccine, the incidence of anal SIL associated with HPV 6, 11, 16, or 18 was decreased by 78 percent in those receiving vaccine compared with placebo (1.3 versus 5.8 events per 100 person years at risk). Additionally, there was a 75% decrease in the incidence of high-grade squamous intraepithelial lesion (HSIL) with vaccine (0.8 versus 3.1 events per 100 person-years at risk).[64] As a result of these promising results, in October 2011, the Advisory Committee on Immunization Practices (ACIP) recommended the routine use of quadrivalent vaccine in males aged 11 or 12 years.[65]

Additional preventive efforts should be focused on the treatment of HPV infection, including the development of antiviral agents, targeting of E6 and E7 to block transforming activities, and vaccines to prevent progression of HPV infection.[51,58] Education is also required about the causal role of cigarette smoking in anal and other cancers.

Because of the rarity of anal cancer, efforts at early detection through widespread screening are not feasible. However, screening may be feasible in certain high-risk subsets. Anal intraepithelial neoplasia is a common finding in people who are infected with HPV.[12,41] Analogous to the situation with cervical cancer, where cervical SILs may progress to cervical carcinoma, HSIL may be a precursor to invasive anal cancer.[66-68] Anal cytologic smears have been used to diagnose HSIL in high-risk patients. Because the specificity of anal cytology for the detection of HSIL is low, anoscopy with biopsy is required to differentiate anal condylomata acuminata from HSIL.[66] However, the colposcopic criteria to distinguish low-grade squamous intraepithelial lesions (LSIL) from cervical HSIL have been used to distinguish LSIL from HSIL of the anus in homosexual and bisexual men.[69] This information may allow for a targeted biopsy of suspected HSIL, resulting in increased sensitivity for detection. One study of anal cytology in homosexual and bisexual men reported the sensitivity and specificity for detection of HSIL to be 69% and 59%, respectively, in men who are HIV-positive and 47% and 92%, respectively, in men who are HIV-negative.[68]

BIOLOGIC CHARACTERISTICS

Unlike most gastrointestinal tract malignant diseases, anal cancer is predominantly a locoregional disease, and distant metastasis is relatively rare. Most relapses after curative therapy are located in the pelvis, perineum, or inguinal regions.[70] Only 5% to 10% of patients will have cancer that has spread beyond the pelvis at diagnosis,[53,59,71] and 10% to 30% of patients will have disease relapse at distant sites after curative local therapy.[60,70,72,73] Although chemotherapy is considered a

In a population-based case-control study of patients with anogenital cancers in the Pacific Northwest, 60% of patients with newly diagnosed anal cancer were current smokers compared with 25% of the controls. The risk of anal cancer was positively correlated with both the number of cigarettes smoked per day and the number of years the patient had been a smoker.[52]

Supporting evidence for this view is found in a study of patients treated for benign anal conditions at U.S. Veterans Affairs hospitals. The elevated RR for anal cancer in these patients was most pronounced in the first year after the benign pathologic condition was diagnosed, and it decreased rapidly thereafter until there was no increased risk of anal cancer between year 5 and year 22.[57]

component of standard therapy for anal cancer, its addition has not decreased the number of patients with distant metastases.[71,74,75] As the number of metastatically involved regional nodes increases, so does the risk of distant metastasis.[76] The most common site of distant metastasis is the liver, followed, in variable order, by the lungs, extrapelvic lymph nodes, skin, or bones.[71,75,77-80]

Characteristics of anal cancer that have consistently been correlated with local control and survival are the size and extent of the primary tumor and the status of the inguinal and pelvic lymph nodes.[81-83] The 5-year survival for patients with tumors 2 cm or less in diameter that are treated surgically is about 80% but declines to 55% to 65% when the tumor is 2 cm to 5 cm or to 40% to 55% when the tumor is more than 5 cm.[76,84] The depth of invasion and the size and extent of the primary tumor are prognostic for response to treatment, local control, and survival when patients are treated nonsurgrically with radiotherapy and chemotherapy.[70,75,80,85-88]

The survival for patients with regional lymph node metastases who are treated primarily with surgical procedures with or without adjuvant therapy is about half that observed in similar patients without nodal metastases.[84,89] Similarly, 5-year survival after radiotherapy alone in patients with inguinal lymph node metastases range from 0% to 36% compared with 5-year survival of more than 50% in patients without lymph node involvement.[89-91]

There is relatively little information in the medical literature about the prognostic significance of regional nodal metastases in patients who receive combined radiotherapy and chemotherapy. In a retrospective, recursive, partitioning analysis of patients treated at Princess Margaret Hospital (PMH), patients who are node-positive at 5-year follow-up were found to have a trend toward lower cause-specific survival (CSS) (57% versus 81%; $p = 0.07$).[74] In the European Organization for Research and Treatment of Cancer (EORTC) randomized trial of radiotherapy alone versus concurrent chemoradiation, regional nodal metastases were associated with significantly worse local control ($p = 0.004$) and survival ($p < 0.001$).[82] However, in node-positive patients, the number of involved nodes (≥1), their size (<2 cm or >2 cm), and the extent of involvement (N1, N2, or N3 category) added no further prognostic information.[82] Similarly, in a secondary analysis evaluating the impact of TN category on outcomes for RTOG 98-11, the best outcomes were found among patients with T2-3N0 disease, and the worse outcomes were in patients with T4N0, T3N+, and T4N+ disease. Outcomes for T2N+ patients were intermediate between T3N0 and T4N0.[73]

Patient-related variables that have been evaluated as potential prognostic factors for local control and survival in patients with anal cancer include age, gender, race, performance status, hemoglobin levels, and white blood cell counts. Age probably does not have independent prognostic significance for any endpoint. A retrospective Canadian study found that older patients were treated with less aggressive chemotherapy and were less likely to be offered salvage surgery for recurrence; therefore patients older than 65 years of age were found to be at higher risk for death from anal cancer.[92] An Australian study reported that although requirement for treatment break was higher in elderly patients, chemoradiation was safe and tolerable in elderly patients and provides equivalent disease control rates compared to the younger age group.[93] Conflicting data exist about the impact of gender on prognosis. Several studies have reported no difference in outcome by gender in patients treated with radiotherapy or combined radiotherapy and surgery.[74,91,92,94] However, a trend toward higher survival in women has been reported in some surgical series,[76,84] and in the EORTC randomized trial, female sex was associated with better survival ($p = 0.12$) and local control ($p = 0.05$).[82] Similarly, in recently published analyses of the Radiation Therapy Oncology Group (RTOG) 98-11 and United Kingdom Coordinating Committee on Cancer Research (UKCCCR) study respectively, male sex was significantly associated with poorer locoregional control,[83] disease-free survival (DFS),[81] disease-specific survival,[83] and overall survival (OS).[81,83] Lower survival has been reported in patients with a lower performance status, in nonwhite patients, and patients with higher white blood cell count with anal cancer who received combined-modality therapy.[83,95] A lower hemoglobin level has also been suggested to have an adverse effect on disease-specific survival.[83]

Several histopathologic variables have been evaluated as potential prognostic factors in patients with anal cancer. The histologic subtype (squamous cell cancer versus cloacogenic subtype), tumor cell morphology, extent of differentiation or keratinization, cell size, architecture, and pleomorphism are of no prognostic significance.[74,91,92,94,96] The extent of differentiation may be associated with tumor stage because patients with advanced-stage cancer tend to have tumors that are less differentiated.[76] The depth of invasion of the primary tumor has been reported to have prognostic significance in patients treated primarily with surgical resection.[96] DNA ploidy has also been associated with prognosis in surgically treated patients with DNA aneuploid tumors predictive of an inferior outcome.[96] In a Mayo Clinic study of surgically treated patients, those with aneuploid tumors had inferior survival compared with patients with DNA diploid or tetraploid tumors on univariate analysis. On multivariate analysis, however, DNA ploidy was not a significant predictive variable.[97]

There are currently no clinically useful tumor markers. Despite negative liver imaging, patients with elevated alkaline phosphatase or lactate dehydrogenase are at increased risk for subsequent liver metastases.[98] In one study, reduced expression of $p21^{waf1}$, a cyclin-dependent kinase inhibitor, was associated with shorter OS.[99] Preliminary information suggests that serum antibodies to HPV proteins may eventually be useful as prognostic markers. Elevated serum IgA antibodies to HPV 16 E2:9 peptide have been associated with lower survival rates independent of tumor size.[37] In another study, patients who died of anal cancer were found to have higher levels of IgG against HPV E7:5 peptide than did patients with anal cancer in complete remission or patients who died of other causes.[40]

PATHOLOGY AND PATHWAYS OF SPREAD

The World Health Organization (WHO) classification of malignant epithelial tumors of the anal canal includes squamous cell carcinoma, adenocarcinoma, small cell carcinoma, and undifferentiated carcinoma. Most cases of adenocarcinoma of the anus are actually distal rectal adenocarcinomas with extension into the anal canal. True primary anal canal adenocarcinoma is rare, as is small cell carcinoma of presumed neuroendocrine origin.[18,76] Subsets of squamous cell carcinoma in the WHO system include large-cell keratinizing carcinoma, large-cell nonkeratinizing or transitional carcinoma, and basaloid carcinoma.[100] Although basaloid carcinomas have historically been considered to be nonkeratinizing tumors, most basaloid carcinomas exhibit keratinization and should be considered squamous cell carcinomas.[67]

Although most anal canal malignant tumors are squamous cell carcinomas or squamous cell variants, marked morphologic heterogeneity is characteristic.[67] Classification of epidermoid anal cancers on the basis of morphologic appearance has led to the use of several potentially confusing terms. These include transitional cell carcinoma, basaloid carcinoma, and mucoepidermoid carcinoma. These tumors all arise from the

anal transition zone and are often grouped together as *cloacogenic carcinoma. Mucoepidermoid carcinomas* contain mucous microcysts and are histologically dissimilar to mucoepidermoid carcinomas of the salivary glands. The natural history is identical to that of squamous cell carcinoma of the anus without microcysts. Although sometimes considered to be distinct lesions in the medical literature, cloacogenic carcinoma, transitional cell carcinoma, basaloid carcinoma, and mucoepidermoid carcinoma are all subtypes of squamous cell carcinoma because patients with these various tumor subtypes have similar clinical characteristics and the tumor subgroups do not differ in natural history or response to therapy[18,53,70,101]

Primary anal melanoma is a rare tumor that accounts for only 1% of all anal cancers. Anal melanoma is similar to melanoma of the skin in that it rarely affects African Americans and is characterized by the distant spread of disease.[102] Outcome is poor after wide local excision or abdominoperineal resection, with just a 10% survival in most series at 5-year follow-up.[103]

Pathways of Tumor Spread

Anal cancer tumors spread by direct extension to surrounding tissues, lymphatic dissemination to pelvic and inguinal lymph nodes, or hematogenous spread to distant viscera.[104] At diagnosis, about half of all anal cancers have been found to invade the anal sphincter or surrounding soft tissue. Although Denonvilliers fascia is usually an effective barrier to prostatic invasion in men, direct extension to the rectovaginal septum is a common occurrence in women.[105]

The anal canal has several potential lymphatic drainage pathways. The superficial inguinal nodes are the primary drainage basin for that part of the anal canal distal to the dentate line.[106,107] Lymphatic drainage around the dentate line occurs to perirectal lymph nodes and along the pathway of the inferior and middle hemorrhoidal vessels to obturator and hypogastric lymph nodes. Lymphatic connections also join the anus to presacral, external iliac, and deep inguinal nodes.[108]

Metastatic involvement of pelvic lymph nodes has been reported in 25% to 35% of patients treated primarily with abdominoperineal resection.[53,76] Inguinal node metastases are found in about 10% of patients at diagnosis; the risk depends on the size and extent of the primary tumor.[71,77] The incidence of inguinal node metastases may be as high as 20% for tumors more than 4 cm in diameter and as high as 60% when there is direct invasion of adjacent pelvic organs.[77] Relapse in undissected inguinal nodes has been reported in 13% of surgically managed patients with clinically negative inguinal lymph nodes.[76] Cumulative rates of inguinal relapse among patients treated with definitive chemoradiation without prophylactic inguinal irradiation has been reported in 30% of T3-T4 patients[109] and 7% to 12% of T1-T2N0 patients.[109,110] Prophylactic irradiation may significantly reduce the rate of inguinal recurrence.[109]

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Rectal bleeding is the most common symptom of anal malignant disease. Perineal pain, mass sensation at the anus, and a change in bowel habits are also frequently reported.[18,53,108,111-113] Many patients with symptoms of early anal cancer are diagnosed initially with a benign anal condition, such as hemorrhoids, anal fissures, or fistulae.[18,53]

Most patients with anal cancer are diagnosed at an early stage. A national survey of such patients found that 73% were diagnosed with stage 0 to II cancer, whereas only 8% were diagnosed with stage IV cancer.[4] The interval from the onset of symptoms to diagnosis may be quite prolonged, however, exceeding 1 month in 80% of patients and 6 months in 33%. A study of Norwegian patients with anal cancer found that nearly one third of them had a delay of more than 6 months from onset of symptoms to diagnosis.[91,113] This finding emphasizes the importance of a thorough digital rectal examination in patients with anal symptoms.[56,57,113]

Patient Evaluation

Evaluation of the patient with known or suspected anal cancer should begin with a thorough history and physical examination. The patient should be questioned about anal sphincter function and any history of risk factors (sexual or drug abuse) for HIV infection.

In addition to a complete general physical examination, a detailed examination should be conducted of the abdomen, inguinal region, anus, and rectum. The extent of circumferential involvement of the anal canal should be noted, and documentation should be made of the size, extent, and location of the primary tumor. The size, location, and mobility of palpable inguinal lymph nodes should be noted. Perirectal lymph nodes may be involved metastatically, but these are rarely palpable by digital rectal examination.[91]

Laboratory studies should include a complete blood cell count, measurement of serum creatinine levels, and liver function studies of bilirubin, alkaline phosphatase, lactate dehydrogenase, and glutamic-oxaloacetic transaminase. For patients with HIV risk factors, a determination of HIV status should be made before the initiation of therapy. Although concentrations of serum carcinoembryonic antigen (CEA) are elevated in 20% of patients with anal cancer, posttreatment CEA values have not been found to correlate with clinical outcomes and have not proven useful in patient management.[114] There are no other clinically useful tumor markers for anal cancer.

Radiographic evaluation should include chest radiographs and CT scanning of the abdomen and pelvis. The CT scan is generally inferior to the physical examination for the characterization of primary tumors, but it is useful for the evaluation of the liver and the perirectal, inguinal, pelvic, and paraaortic lymph nodes. Magnetic resonance imaging (MRI) has not yet been proven to be more clinically useful than CT scanning. The depth of invasion of the primary tumor may be evaluated with ultrasonography.[115]

PET imaging is useful in further evaluating the extent of the primary tumor and the presence of regional lymph node metastases and distant metastases, as well as in evaluating the response to therapy.[116-121] A retrospective evaluation of the sensitivity of PET/CT imaging compared with physical examination and CT scanning alone among 41 patients with anal cancer showed that PET/CT imaging detected the primary tumor in 91% of patients compared with only 59% by CT scanning alone.[122] In addition, PET/CT identified positive inguinal nodes in 17% of patients who were found to be clinically negative by CT and physical examination. Another series reports that use of PET during initial staging led to a change in stage in 23% of patients and radiotherapy field changes in 13% of patients.[123] Furthermore, a posttherapy PET scan showing resolution of metabolic activity was reported to be highly associated with improved progression-free survival (PFS) (95% at 2 years versus 22%; $p < 0.0001$).[124] Posttreatment PET/CT demonstrating resolution of metabolic activity performed 3 months compared to 1 month after completion of treatment may yield higher sensitivity (100% versus 66%) and specificity (97.4% versus 92.5%) with respect to predicting outcomes.[120]

Staging

Anal cancer should be staged according to the TNM staging system of the American Joint Committee on Cancer (AJCC)[125] (Table 52-1). Tumors are classified according to their maximum diameter and their invasion of adjacent structures, as determined by the physical examination and any imaging studies.

The AJCC staging system for anal canal cancer is applicable to all carcinomas that arise from the anal canal. Cancers of the anal margin (distal to the anal verge) are staged as skin cancers, but melanoma of the anal canal is excluded. For staging purposes, the regional lymph nodes in the AJCC system are the anorectal, perirectal, lateral sacral, internal iliac (hypogastric), and superficial and deep inguinal lymph nodes.[126]

TABLE 52-1 TNM 7th Edition Staging System of the American Joint Committee on Cancer, 2010

Stage	T*	N†	M
0	Tis	N0	M0
I	T1	N0	M0
II	T2	N0	M0
	T3	N0	M0

	T2	N1	M0
	T3	N1	M0
	T4	N0	M0
IIIB	T4	N1	M0
	Any	N2	M0
	Any	N3	M0
IV	Any	Any	M1

**Tumor category:* Tis, *carcinoma in situ;* T1, *tumor 2 cm or less in greatest dimension;* T2, *tumor more than 2 cm but 5 cm or less in greatest dimension;* T3, *tumor more than 5 cm in greatest dimension;* T4, *tumor of any size invades adjacent organs, for example, vagina, urethra, bladder (Note: direct invasion of the rectal wall, perirectal skin, subcutaneous tissue or the sphincter muscle is not classified as T4).*

†Nodal category: N0, *no regional lymph node metastases;* N1, *metastasis in perirectal lymph node(s);* N2, *metastasis in unilateral internal iliac or unilateral inguinal lymph node(s);* N3, *metastasis in perirectal and inguinal or bilateral internal iliac or bilateral inguinal lymph node(s).*

PRIMARY THERAPY

Surgery Alone

Before the establishment in the 1980s of sphincter-sparing therapy as the standard of care for epidermoid anal cancer, most patients with anal cancer in North America were treated surgically with abdominoperineal resection. Reported 5-year OS after abdominoperineal resection for anal cancer ranged from 25% to 70% (average, 50%).[76,84,127] Locoregional recurrence developed in 25% to 35% of patients and distant metastasis in 10%.[76,84,127] Patients at highest risk for local recurrence (range, 36% to 48%) after abdominoperineal resection are those with extension of the primary tumor beyond the anal sphincter or metastases to inguinal or pelvic lymph nodes.[76] A component of locoregional disease is present in as many as 84% of patients with relapse after abdominoperineal resection.[76] When the inguinal lymph nodes are metastatically involved, 5-year OS after primary surgical therapy is only 10% to 20%.[127] Although abdominoperineal resection is now rarely used initially, it is still useful for treatment of patients with local recurrence after conservative therapy and for management of complications after conservative therapy.[127]

Irradiation Alone or Plus Chemotherapy

High-dose radiotherapy without surgical resection or other adjuvant therapy is an effective treatment for small stage T1 tumors without inguinal adenopathy. Table 52-2 summarizes the local control and survival results from retrospective series of radiotherapy alone for small anal cancers. For patients with anal cancers of 2 cm or less in diameter, 100% local control 5 years after radiotherapy without chemotherapy has been reported in several small series of less than 10 patients each.[74,75,128] In a larger French retrospective series, however, among 66 patients treated with T1 tumors ≤1 cm, 6 developed local recurrence at a median interval of 50 months.[129] Local control rates at 5 years are lower (57% to 76%) in patients with 2- to 5-cm tumors.[74,75,130]

[c]*One patient with tumor >5 cm.*

[d]*Equivalent to 30 Gy in 10 fractions, followed by 15 Gy to 20 Gy with interstitial implant.*

[e]*1979 UICC staging: T1, less than one third length and circumference of anal canal; T2, more than one third length or circumference of anal canal or infiltration of external sphincter.*

In previous editions of the staging system of the Union Internationale Contre le Cancer (International Union Against Cancer [UICC]),[91] primary tumors were classified not by size but rather according to the length and extent of their circumferential involvement with the anal canal. Tumors involving less than one third of the length and circumference of the anal canal were classified as T1 category of disease, whereas those that involved more than one third of the length or circumference or that invaded the external sphincter were classified as T2. T3 tumors involved the rectum or perianal skin, and T4 tumors invaded adjacent structures.

Radiation Alone or Plus 5-FU and Mitomycin C

The only prospective randomized trial to compare radiotherapy alone with the combination of radiotherapy and chemotherapy in patients with node-negative anal cancers 5 cm or less in diameter (T1 to T2, N0) was carried out by the UKCCCR Anal Cancer Trial Working Party.[131] In this trial, 223 of 585 patients had T1 or T2, N0 anal cancer and were randomized to receive 40 Gy to 45 Gy of external beam radiotherapy (EBRT) to the pelvis, followed by a 15-Gy to 25-Gy boost with a perineal field or interstitial implant with or without two 4- or 5-day infusions of 5-FU and a single bolus injection of mitomycin C. Using local control as the endpoint, subset analysis showed a statistically significant advantage for combined-modality therapy for patients with T1N0 or T2N0 anal cancer.[132]

Combined-modality therapy with radiotherapy and chemotherapy is appropriate for most patients with anal cancer and has become the standard of care. Statistics from the U.S. National Cancer Data Base for 1988 and 1993 show that the use of chemotherapy has increased and the use of resection as the primary treatment has declined.[4]

The initial studies that led to the adoption of combined-modality therapy with nonsurgical treatment were conducted at Wayne State University. Before scheduled surgical resection, 30 Gy of radiation in 15 fractions was delivered to the true pelvis, medial inguinal nodes, and anal canal in conjunction with concomitant 5-FU 1000 mg/m^2 every 24 hours for 4 days as a continuous infusion and mitomycin C (MMC) in a single bolus injection of 15 mg/m^2. After five of the first six patients were found to have no residual tumor in the abdominoperineal resection (APR) specimen 4 to 6 weeks after the completion of radiotherapy, surgical resection was subsequently reserved for locally persistent or recurrent disease after radiotherapy and concurrent chemotherapy.[80] Overall, 86% of patients (24 of 28) had a clinical complete response to chemoradiation, and 7 of the 12 patients (58%) who had an APR had a complete pathologic response.[133]

Table 52-3 summarizes the disease control and survival results with concomitant chemoradiation from several series. Local failure after radiation doses of 45 Gy to 60 Gy with concomitant chemotherapy occurred in 11% to 40% of patients, and 5-year OS was 65% to 80%.

Two randomized studies comparing radiotherapy alone with concomitant radiotherapy plus 5-FU and MMC have been performed by the EORTC[82] and the UKCCCR Anal Cancer Trial Working Party.[131] For patient eligibility, the EORTC trial required a locally advanced primary tumor (T3 or T4 category) or involvement of regional lymph nodes, whereas the UKCCCR trial enrolled patients with any stage of disease, including distant metastases. Initial radiotherapy was similar in both trials and consisted of 45 Gy to the pelvis over 4 to 5 weeks. In the EORTC trial, partial responders at 6 weeks after induction therapy were boosted with an additional 20 Gy and complete responders received 15 Gy. In the UKCCCR trial, a 15-Gy to 25-Gy boost was administered to patients with more than a 50% tumor response; patients with less than a 50% response had radical surgery. Concurrent chemotherapy in the EORTC trial consisted of 5-FU 750 mg/m^2 every 24 hours on days 1 to 5 and days 29 to 33 with a single 15-mg/m^2 dose of MMC on day 1. Chemotherapy in the UKCCCR trial consisted of 5-FU 1000 mg/m^2 every 24 hours on days 1 to 4 and days 29 to 32 or 750 mg/m^2 every 24 hours on days 1 to 5 and days 29 to 33, with a single MMC dose of 12 mg/m^2 given on the first day of radiotherapy.

Results of the EORTC[82] and UKCCCR[131] trials are summarized in Table 52-4. The complete response rate 6 weeks after boost radiotherapy was significantly improved with the addition of chemotherapy to radiotherapy (80% versus 54%; p = 0.02) in the EORTC trial. A nonstatistically significant trend toward a higher complete response rate was also reported in

the UKCCCR trial. However, this endpoint was measured 6 weeks after the initiation of therapy compared with 6 weeks after the completion of all therapy in the EORTC trial. In both studies, local control was significantly improved with the addition of concurrent chemotherapy. Local control with radiotherapy alone was surprisingly low (39% at 3 years) in the UKCCCR study. The definition of local failure included tumor reduction of less than 50% 6 weeks after 45 Gy of irradiation, surgery for morbidity, and failure to close a pretreatment colostomy for any reason. Conversely, EORTC investigators considered patients locally controlled even if they had to undergo surgery to achieve a complete response at the completion of radiotherapy. Neither study reported any significant impact of chemotherapy on the incidence of distant metastases or on OS, although absolute survival at 3 years slightly favored the chemoradiation arms numerically in both trials.

The EORTC and UKCCCR trials established combined-modality therapy as the standard of care for patients with anal cancer. Further refinement in the understanding of optimal therapy is provided by the results of a Phase III study conducted by RTOG and the Eastern Cooperative Oncology Group (ECOG). In the RTOG/ECOG study (Table 52-5), patients were treated with radiotherapy (45 Gy to 50.4 Gy in 25 to 28 fractions) and 5-FU and were randomized to receive or not receive MMC.[139] The addition of MMC was associated with fewer colostomies, higher local control, and better DFS. The addition of MMC also significantly increased the risk of major toxicity. Survival was slightly higher in the MMC arm of the study, but the difference was not statistically significant. The chemotherapy regimen in this trial differed from that of the European trials because two doses of MMC 10 mg/m^2 were delivered on day 1 and day 29 instead of a single dose. Two of the four treatment-related deaths in the MMC arm were felt to be caused by a failure to follow protocol dose-reduction guidelines for the second MMC dose.

The biologic basis for improved outcome with the addition of chemotherapy to the treatment regimen is not known. However, the fact that several studies have reported no significant reduction in distant failure with chemotherapy suggests that the effect is predominantly locoregional, possibly because of an interaction with irradiation.[74] For example, in the PMH experience, distant failure occurred in 18% of patients treated with radiotherapy alone, in 17% of those who received MMC and 5-FU, and in 10% of those receiving 5-FU alone.[74,140] Synergistic interactions between irradiation and 5-FU or MMC and between 5-FU and MMC have been demonstrated in mammalian tumor cell lines in vitro.[141] Hypoxic mammalian tumor cells also have an increased sensitivity to mitomycin C in vitro, although whether the hypoxia has any effect when anal cancer is treated with fractionated radiotherapy is not known.[142] Laboratory studies have also shown increased cytotoxicity associated with continuous infusion 5-FU compared with 5-FU delivery by intermittent bolus.[143]

It cannot be assumed that sequential therapy will duplicate the excellent results achieved with concomitant chemoradiation. Complete pathologic response rates 6 weeks after 50 Gy of irradiation, 5-FU, and MMC are in the range of 85% to 95%.[80,144,145] In contrast, only 45% of 42 patients who received

sequential 5-FU and MMC, followed by radiotherapy, had a complete pathologic response.[111]

Radiation Plus 5-FU and MMC versus 5-FU and Cisplatin

In addition to the concurrent use of MMC and 5-FU during radiotherapy, multiple single institutions[134,136,146,147] and prospective Phase II trials[148-150] have reported favorable results with concurrent cisplatin (CDDP) and 5-FU, with or without an induction chemotherapy phase of treatment. A U.S. Gastrointestinal Intergroup Phase III trial (RTOG 9811) was conducted to compare the efficacy of concurrent cisplatin-based therapy with standard MMC-based therapy.[151,152] Six hundred forty-four patients with T2 category or higher (any N category) carcinoma of the anal canal were randomized to two cycles of induction CDDP (75 mg/m^2) and 5-FU (1000 mg/m^2 for 4 days) followed by 45 Gy to 59 Gy of irradiation with two concurrent cycles of the same regimen versus MMC (10 mg/m^2) and 5-FU (1000 mg/m^2 for 4 days) given twice concurrently during radiotherapy (no induction phase). For the cisplatin- and MMC-based arms, 5-year OS was 70.7% and 78.3%, respectively ($p = 0.026$), and 5-year DFS was 57.8% and 67.8%, respectively ($p = 0.006$) (Table 52-6). There was a trend toward statistical significance for colostomy-free survival (CFS), locoregional failure (LRF), and colostomy failure (CF) ($p = 0.05$, $p = 0.087$, and $p = 0.074$, respectively).[152] Based on this trial, a regimen of MMC and 5-FU given concurrently with radiotherapy remains the standard of care for anal cancer. It is unclear whether the delayed use of radiotherapy or difference in radiosensitization of cisplatin compared with MMC played a role in the inferior colostomy rate observed in the experimental arm of this study.

In contrast, the largest Phase III trial, the UK ACT II study, was theoretically a direct comparison of CDDP versus MMC (gave two doses of CDDP versus only one of MMC) and also examined the role of maintenance (adjuvant) treatment. The ACT II trial enrolled 940 patients in a 2 × 2 randomized trial with a control arm of 5-FU (1000 mg/m^2, days 1-4, 29-32) and MMC (12 mg/m^2, day 1) versus an experimental arm of + 5-FU (1000 mg/m^2, days 1-4, 29-32) and cisplatin (60 mg/m^2, day 1 and 29) with a primary endpoint of 6-month response rate.[153] Patients were subsequently randomized to receive either no maintenance versus maintenance therapy of 5-FU (1000 mg/m^2, days 1-4, 29-32) and CDDP (60 mg/m^2, days 1 and 29) to be initiated 4 weeks after the completion of radiotherapy, with a primary endpoint of relapse-free survival (RFS). With a median follow-up of 5.1 years, 90.5% (391/432) patients in the MMC group compared to 89.6% (386/431) in the CDDP group had a complete response at 26 weeks ($p = 0.64$). Overall, toxic effects were similar in each group, although there were more grade-3 and grade-4 hematological toxicities in the MMC arm (26% versus 16%, $p = < 0.001$).[153] Maintenance chemotherapy (chemo) was not associated with an improvement in 3-year PFS (Table 52-6; 74% with maintenance chemo versus 73% without maintenance; HR, 0.95; 95% CI, 0.75 to 1.21; $p = 0.70$). Based on the results of this study, the largest in anal cancer to date, the authors concluded that administration of MMC, in combination with 5-FU and 50.4 Gy RT in 28 daily fractions without maintenance chemo, should remain standard practice because of similar efficacy and toxic effects, fewer cycles of chemo, fewer nonchemotherapy drugs, less time in the chemo suite, less expense, and no risk of neuropathy compared with cisplatin.[153]

Role of Dose Intensification

In patients with locally advanced anal cancer, based on the promising results of a Phase II trial of induction chemotherapy,[149] the role of induction chemo and dose intensification of the radiation boost was evaluated in the UNICANCER ACCORD 03 study.[154] In this study, 307 patients with tumors ≥4 cm or <4 cm and N1-3M0 were randomly assigned by 2 × 2 randomization to receive one of the following: (1) 2 cycles of induction 5FU-CDDP (5-FU 800 mg/m^2, day 1-4, 29-32) and CDDP (80 mg/m^2 intravenously, days 1 and 29), with EBRT (45 Gy in 25 fractions over 5 weeks, 5-FU–CDDP during weeks 1 and 5), and standard-dose boost (SD: 15 Gy); (2) 2 cycles of induction chemo, chemoRT, and high-dose boost (HD, 20 Gy to 25 Gy); (3) chemoRT and standard-dose boost; or (4) chemoRT and HD boost. With a median follow-up of 50 months, neither induction chemo nor dose intensification of the RT boost was associated with improvements in 5-year CFS (76.5% versus 75.0%, $p = 0.37$ for induction versus no induction, and 73.7% versus 77.8%, $p = 0.067$ for SD versus HD, respectively).

Although the primary study endpoint was negative, given the trend toward improved CFS in this study, further dose intensification studies, either with new drugs or new radiation techniques, may be warranted.[154]

Treatment Tolerance

Anal function is preserved in 65% to 80% of patients after sphincter-sparing therapy.[74,75,94,135] The most common indication for abdominoperineal resection is local recurrence or disease persistence because 90% of patients for whom local control is achieved can be expected to maintain a functional anus.[74] Late treatment complications may result in the loss of anal function, and a colostomy may be required to manage complications in 2% to 10% of patients whose cancer is locally controlled.[74,75,77,91,94,128,137,155,156] A Danish multicenter cohort study of 235 patients reported a 5-year cumulative incidence

of therapy-related colostomy of 12%. Of the 12 patients who received therapy-related colostomies not part of an APR, indications included chronic anorectal ulcer, fecal incontinence, bowel obstruction, rectovaginal fistula, perianal skin injury, and anal canal fibrosis.[156]

LOCALLY ADVANCED DISEASE AND PALLIATION

Tumor size appears to have a moderate impact on treatment outcome when combined-modality therapy is used. In the RTOG/ECOG study, 17% of patients with primary tumors 5 cm or more in diameter had positive biopsy findings 6 weeks after completion of therapy compared with 7% of those with a tumor less than 5 cm in diameter ($p = 0.02$). Preservation of anal function was also more likely in patients who had smaller tumors; 11% of patients with T1 or T2 cancer required a colostomy compared with 21% of those with T3 or T4 cancer.[139] Differences in local control have also been reported using tumor diameter cutoffs of less than 5 cm. In a previous RTOG study, local control at 3 years was 84% among patients with tumors smaller than 3 cm and 62% among those with tumors 3 cm or larger.[85] Similarly, local control among patients treated at PMH was 94% for those with tumors of 2 cm or less and 72% for those with larger tumors. No difference in local control was reported between the subgroups of patients with tumors of 2 cm to 5 cm or with larger tumors (>5 cm), unless invasion of adjacent structures was discovered, in which case local control was 62%.[74]

Secondary analyses of the U.S. Gastrointestinal Intergroup RTOG 9811 Phase III trial have been performed to further define prognostic factors for outcomes in patients treated with concurrent chemoradiation. The initial analysis found that a tumor size of more than 5 cm was the only pretreatment characteristic that independently predicted a subsequent need for colostomy (hazard ratio, 1.85; $p = 0.008$).[151]

A subsequent analysis of RTOG 98-11 was performed to determine if the TN category of disease (T2N0, T3N0, T4N0, T2N+, T3N+, T4N+) has an impact on DFS and OS, LRF, distant metastasis, or CF.[73] All endpoints showed statistically significant differences between the 6 TN categories of disease, including OS ($p < 0.0001$), DFS ($p < 0.0001$), LRF ($p < 0.0001$), distant metastasis ($p = 0.0011$), and CF ($p = 0.01$). The best outcomes for OS, DFS, and LRF were found with T2N0 and T3N0 categories of disease (5-year OS, 82% and 74%; DFS, 72% and 61%; and LRF, 17% and 18%). The poorest outcomes were with the T3N+ and T4N+ disease categories (5-year OS, 57% and 42%; DFS, 38% and 31%; and LRF, 44% and 60%). The 5-year CF was best for patients with T2N0 (11%) or T2N+ (11%) disease and worst for patients with T4N0 (26%), T3N+ (27%) and T4N+ (24%) disease.[73]

Preservation of anal function is possible in two thirds to three fourths of patients with locally advanced disease in both RTOG 98-11 (see earlier mention)[73] and PMH series.[74] In the PMH experience, two thirds of patients with tumors that invaded adjacent structures maintained anal function after radiotherapy and chemotherapy, as did two thirds of patients with tumors that involved more than 75% of the circumference of the anal canal.[74] Locally advanced disease is not an indication for abdominoperineal resection in patients who retain some measure of anal function at diagnosis.[74]

Node Involvement

Involvement of the inguinal lymph nodes at diagnosis is associated with a worse prognosis. In the EORTC randomized trial, patients with involved lymph nodes had inferior local control and survival. However, the extent of nodal involvement did not add any prognostic information.[82] In a report from PMH, the 5-year cause-specific survival for patients who were clinically node-positive was 57% compared with 81% patients who were node-negative ($p = 0.07$). Combined-modality therapy was effective in the treatment of patients with involved nodes. In such patients, control of cancer in metastatically involved lymph nodes was achieved 87% of the time.[74] In an RTOG 9811 secondary analysis, 5-year DFS was 64% for patients who were node-negative and only 35% for patients who were node-positive ($p \leq 0.0001$).[157] As noted in the prior section, in a subsequent secondary analysis of RTOG 98-11, the poorest rates of OS, DFS, and LRF were with T3-4, N+ disease.[73]

Radiotherapy without chemotherapy has been used for patients with metastatically involved inguinal lymph nodes, with control of nodal disease reported in 60% to 70% of patients.[77,94] However, survival is poor for these patients with radiotherapy alone (range, 0% to 36% at 5 years), and combined-modality therapy with radiotherapy and concurrent chemotherapy is preferred.[89-91,94]

Salvage Therapy

Patients with local failure after radiotherapy and chemotherapy should be considered for abdominoperineal resection. Local control can be achieved with abdominoperineal resection in as many as 60% of these patients.[74,75,77,88,91,94] Ultimate local control is obtained in more than 90% of patients with anal cancer, including patients who require surgery after radiotherapy for locally persistent or recurrent disease.[77,94]

Patients who have locally advanced recurrent disease that is not surgically resectable for cure may benefit from low-dose reirradiation plus concurrent chemo followed by surgical resection of gross disease and intraoperative radiotherapy (IORT). This aggressive combined-modality treatment approach may result in successful salvage as seen in a recent Mayo Clinic Rochester analysis.[158] Salvage surgical resection and IORT were used in a series of 32 patients between 1993 and 2012 who had either residual ($n = 9$) or recurrent ($n = 23$) disease following primary chemoradiation. Those with recurrent disease received low-dose preop chemoRT before resection or IORT. Five-year OS and DFS were 23% and 17%, respectively.

Palliation

Although anal cancer is predominantly a locoregional disease, 5% to 10% of patients will have disease beyond the pelvis at diagnosis and distant metastases will develop in 10% to 20% after locoregional therapy.[71,74,75] The most common site of distant metastases reported in most series is the liver; metastases to the lungs, lymph nodes, skin, bones, and brain have also been reported.[71,75,77-80] Palliative chemotherapy with 5-FU plus either mitomycin C or cisplatin is associated with a 50% response rate and a median survival of 12 months.[71] Patients with brain metastases, symptomatic osseous metastases, or other localized symptomatic metastases should receive hypofractionated radiotherapy for palliation.

IRRADIATION TECHNIQUES AND TOLERANCE

Traditional Field Design

Radiotherapy field design should be based on an understanding of the spread of anal cancer. Historical results in patients treated by APR show that 35% to 46% had involvement of

pelvic lymph nodes and that 13% to 16% had a relapse in the inguinal lymph nodes.[76,84] Therefore, the pelvic and inguinal lymph nodes should be included in the radiotherapy fields.

A portion of the inguinal lymph node chain is superficial to the femoral head and neck. It is important to use radiotherapy fields that decrease the radiation dose to these structures. Large anteroposterior/posteroanterior (AP/PA) fields that include the inguinal lymph nodes will deliver the full radiation dose to the femoral head and neck. Patients treated in this way may be at risk for radiation-induced fracture.[159] Radiotherapy techniques that treat the lateral inguinal lymph nodes only through anterior fields will minimize the dose to the femoral head and neck. One method is to treat the primary tumor, pelvic nodes, and inguinal nodes with an anterior photon field that encompasses all these structures. The posterior field is designed to treat only the primary tumor and the pelvic lymph nodes. Electron fields are used to supplement the dose to the lateral superficial inguinal nodes that are not included in the posterior photon field (Figure 52-1). Another technique is to use CT-based simulation for optimal delineation of the inguinal lymph nodes and then to use this information to minimize the volume of the femur included within the radiotherapy field.

Target Volumes and Normal Structures

Accurate target and normal structure identification is crucial to advanced treatment planning with three-dimensional radiotherapy or intensity-modulated radiation therapy (IMRT). The gross tumor volume (GTV) represents the maximal extent of the primary tumor and clinically involved lymph nodes based on the combined consideration of the physical examination, endoscopic findings, and diagnostic imaging studies. The clinical target volume (CTV) includes all

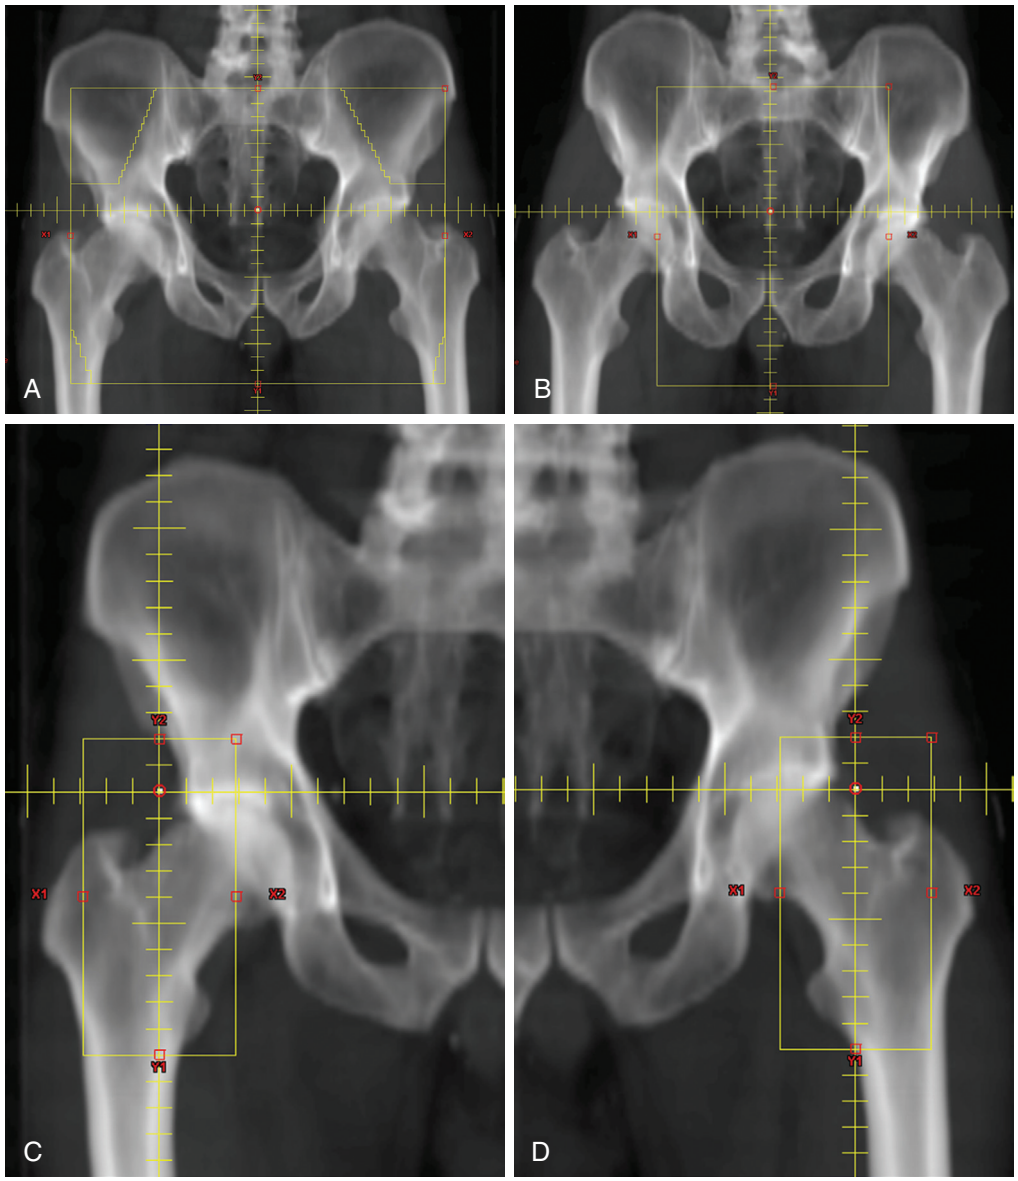

Figure 52-1 Anal cancer fields: Wide anterior **(A)** and narrow posterior **(B)** photon fields. Electron fields are used to give a supplementary radiation dose to lateral inguinal nodes not included in the narrow posterior photon field **(C** and **D)**. The medial border of each electron field is placed at the posterior photon field's lateral exit point on the anterior abdominal wall.

tissues at risk of longitudinal or radial microscopic extension of the primary tumor as well as nodal areas at risk. These nodal regions include the perirectal nodes (including all of the mesorectum to the pelvic floor), inguinal nodes, presacral nodes, and internal and external iliac nodes. Multiple CTVs may be constructed based on differences in planned dose delivery to elective regions of treatment. The superior extent of the elective nodal coverage is generally at least to the iliac bifurcation or to the sacral promontory.

A retrospective review of 167 patients treated at the M. D. Anderson Cancer Center with definitive chemoradiation reported that all regional pelvic failures (21% of relapses) occurred among patients whose superior field border was placed at the bottom of the sacroiliac joint. The authors concluded that a superior field or target border at vertebrae L5/S1 may reduce such recurrences.[160]

In 2009, an RTOG panel reported consensus contouring guidelines and an atlas for elective CTV demarcation in anorectal cancer.[161] This reference serves as an excellent template and resource for lower gastrointestinal cancer treatment planning. Key normal structures that should be identified in the planning process and avoided include the femoral head and neck, bladder, and bowel. Excessive skin exposure should also be avoided in the perineum and groin.

Intensity-Modulated Radiotherapy

Given the close proximity of the bladder, small bowel, femoral heads, and possibly pelvic bone marrow to target regions in the management of anal cancer, the improved conformality of IMRT compared with traditional techniques presents an opportunity for toxicity reduction[162,163] (Figure 52-2). A retrospective review of 53 patients treated at multiple institutions has reported favorable acute toxicity and efficacy rates with early follow-up among 53 patients treated with IMRT and concurrent chemotherapy.[164] More than 92% of patients had a complete clinical response, and acute grade-3 or higher gastrointestinal (GI) or dermatologic toxicities were observed in only 15% and 38% of patients, respectively. RTOG 0529, a Phase II trial of 52 patients treated with dose-painted IMRT and concurrent mitomycin C and 5-FU also shows favorable patient tolerance rates.[165] In this study, patients with T2-4N0-3M0 anal cancer received 5-FU and MMC on days 1 and 29 of dose-painted IMRT, prescribed per stage as follows: T2N0: 50.4 Gy to the anal primary PTV, 42 Gy to elective nodal PTV in 28 fractions; for T3-4, N0-3: 54 Gy to the anal primary PTV, 54 Gy to >3 cm metastatic nodal PTV, 50.4 Gy to ≤3 cm metastatic nodal PTV, and 45 Gy to elective nodal PTV. Compared with the historical benchmarks of RTOG 9811, there was significantly less grade 2+ hematologic toxicity (73% versus 85%; $p = 0.032$), grade 3+ GI or genitourinary toxicity (21% versus 36%; $p = 0.0082$) and grade 3+ dermatologic toxicity (23% versus 49%; $p < 0.0001$), with a favorable early clinical response reported.[165] Treatment interruptions because of toxicity were significantly less with dose painted IMRT with median treatment duration of 43 days compared with 49 days ($p < 0.0001$). Integration of IMRT requires rigorous quality assurance, however, to ensure appropriate target volume coverage, minimize marginal misses, and maximize normal tissue sparing with accurate identification of normal tissue structures. This was evidenced in RTOG 05-29, in that 81% of treatment plans required dose-painted-IMRT replanning on initial review and 46% of plans required multiple resubmissions.[165] Preliminary efficacy outcomes of RTOG 05-29 demonstrated similar 2-year outcomes to RTOG 98-11 (2-year LC: 20% versus 19%, 2-year OS: 88% versus 91%, 2-year DFS: 77% versus 76%, for RTOG 05-29 and RTOG 98-11, respectively).[166] Because of the associated acute toxicity sparing, DP-IMRT will be used as the platform and may allow for radiation dose escalation in future RTOG anal canal trials.

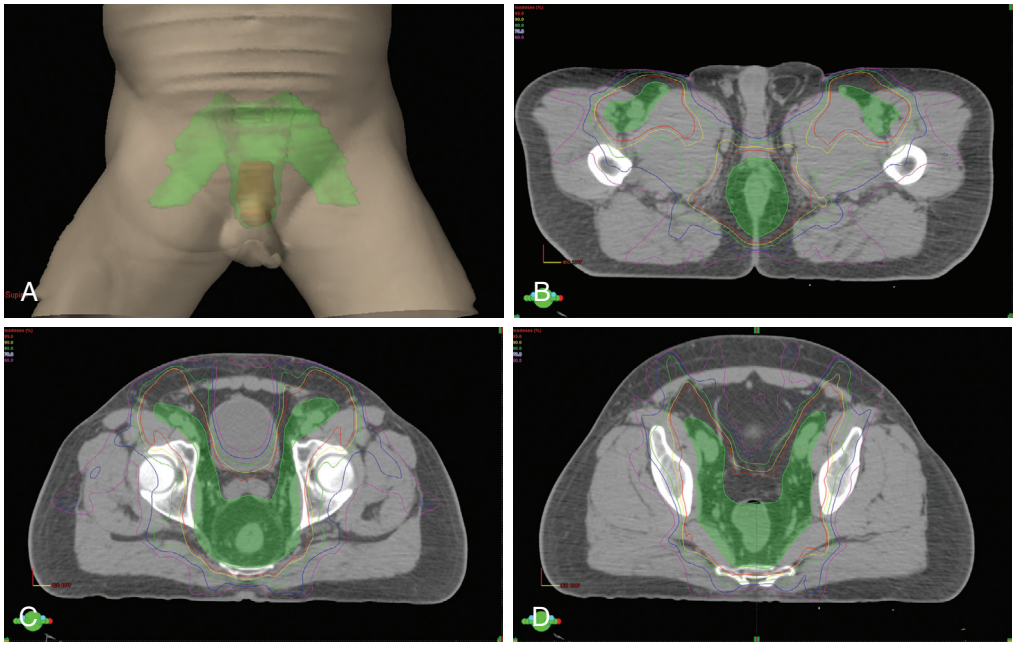

Figure 52-2 Three-dimensional rendering **(A)** of the clinical target volume *(green)* and gross tumor volume in a 65-year-old male with T2N0M0 squamous cell carcinoma of the anal canal. (The planning tumor volume is not shown.)

Radiation Dose and Fractionation

The RTOG/ECOG Phase III clinical trial provided useful information about the most favorable combination of radiation dose and chemotherapy agents.[139] The best local control rates resulted from an aggressive regimen of concurrent chemoradiation (5-FU, 1000 mg/m^2/d on days 1 to 4 and days 29 to 32 of EBRT; MCC, 10 mg/m^2 on day 1 and day 29 of EBRT). The primary tumor, pelvic lymph nodes, and inguinal lymph nodes received a total dose of 36 Gy of EBRT in 20 fractions, followed by a field reduction to include the primary tumor. An additional 9 Gy was administered in 5 fractions, for a total dose to the primary tumor of 45 Gy in 25 fractions. Patients who had residual tumor after 45 Gy received an additional dose of 5.4 Gy in 3 fractions, for a total cumulative primary tumor dose of 50.4 Gy in 28 fractions. The medial inguinal lymph nodes received 45 Gy if clinically negative or 50.4 Gy if clinically positive. This combination of radiotherapy plus 5-FU and MMC resulted in 4-year local control of 84%, which was significantly better than 4-year local control of 66% in patients randomized to receive an identical dose of irradiation plus 5-FU alone ($p < 0.001$).

In the RTOG/ECOG study, 26% of the patients treated with radiation therapy plus 5FU-MMC experienced life-threatening or fatal toxicity, including a 3% treatment-related death rate. It is not yet known whether increasing the radiation dose to more than 50.4 Gy in conjunction with 5-FU and mitomycin C chemotherapy will improve the therapeutic ratio of local control to treatment tolerance. In the subsequent U.S. Gastrointestinal Intergroup clinical trial RTOG 98-11, the recommended final boost dose was 55 Gy to 59 Gy for patients with T3 to T4 disease, positive nodes, or T2 disease with residual disease after 45 Gy.[151,152] Locoregional relapse continued to be a problem even with these slightly higher radiotherapy doses, as noted previously (5-year LRF range of 17% [T2N0] to 60% [T4N+] by TN disease category).[73] In RTOG 05-29 with dose-painted IMRT, recommended final doses were 54 Gy in 30 fractions for patients with T3 to T4 or node positive disease and 50.4 Gy in 28 fractions for patients with T2N0 disease.[165] Preliminary outcomes demonstrate equivalent rates of 2-year local control with this dose fractionation schema compared to RTOG 98-11.[166]

The hypothesis that there will be fewer local failures when the irradiation dose is increased to more than 50.4 Gy with concurrent 5-FU and mitomycin C has not been tested in prospective trials. Three retrospective series have contributed to the formation of this hypothesis. At the University of Texas M. D. Anderson Cancer Center, patients with anal cancer who were treated with radiotherapy and continuous infusion 5-FU 300 mg/m^2 during the entire radiotherapy course had better local control with radiation doses of 55 Gy to 66 Gy (9 of 10 patients) than with lower doses of 45 Gy to 49 Gy (7 of 14 patients).[135] Researchers at the University of Kansas evaluated treatment with or without chemotherapy and found local control of 92% for radiation doses of more than 55 Gy, 77% for 45 Gy to 55 Gy, and 64% for 45 Gy or less.[167] Similarly, a retrospective review from the Medical University of Vienna demonstrated 14% local recurrence with doses of 54 Gy or more compared with 70% with doses of less than 54 Gy among patients with T3 or T4 tumors.[168]

In contrast to dose escalation for locally advanced tumors, more moderate doses of irradiation with chemotherapy may be adequate for early tumors or after local excision of a small tumor. In addition to the original experience with complete responses to 30 Gy reported by Nigro et al,[133] at least two other institutions have reported local control of over 95% with 30 Gy and concurrent chemotherapy among a limited number of patients with early tumors or after local excision.[169,170] Such a strategy has not been evaluated in a prospective clinical trial.

EBRT alone is appropriate for a few patients who are not candidates for combined-modality therapy because of clinically significant comorbid illness or other reasons. A high rate of tumor control has been found in patients with small tumors treated with a radiation dose of 45 Gy in 25 fractions to the pelvis, inguinal lymph nodes, and primary tumor, followed by a boost dose to the primary tumor, for a total cumulative dose of 60 Gy to 70 Gy in 33 to 35 fractions.[86,128]

Nearly all patients who receive concomitant chemoradiation for anal cancer will have perineal skin reactions, and more than half will have confluent moist desquamation. The severity of such acute reactions is influenced by the radiation fraction size and treatment technique. In a PMH study of 50 Gy in 20 fractions (2.5 Gy per fraction), the acute and late toxicities were considered unacceptably high.[74] Less severe toxicity was reported with the same fractionation schedule and a break in treatment or with a fractionation schedule of 48 Gy in 24 fractions.[74] The use of IMRT appears to decrease both severity and volume of perineal skin reactions, hematologic suppression, and gastrointestinal toxicity in single institution and group studies. Improvement in acute treatment-related toxicities with IMRT may lead to decreased requirement for treatment break and shorter overall treatment times.

The overall treatment time may affect the outcome of radiotherapy or chemoradiation. In an RTOG pilot study evaluating 59.4 Gy with 5-FU and MMC that included a planned treatment break, 30% of patients required a colostomy by year 2 compared with only 7% in the RTOG/ECOG randomized trial, which did not use planned treatment breaks.[171] Pooled data analysis of RTOG 8704 and 9811 determined that each increase in treatment duration by 14 days was associated with a 9.4% increase in risk of failure requiring colostomy.[172]

Tumor Regression

Tumor regression may be slow after radiation therapy alone or chemoradiation, with the time to complete regression ranging from 2 to 36 weeks (median, 12 weeks).[74] Preliminary results from a secondary analysis from the ACT II study evaluating optimal time to assess clinical complete response (CCR) found that 29% of patients not in CCR at 11 weeks achieved CCR at 26 weeks. As early surgical salvage would not have been appropriate for these patients, CCR at 26 weeks has been recommended as the optimal timing of response for future trials.[173]

An alternate approach in patients with high risk of local persistence or relapse (T4N0, T3-4N+) would be to use PET-CT response instead of CCR to determine when surgical salvage is indicated. This may lead to better rates of surgical salvage and allow the possibility of local excision instead of APR in select patients.

Most recurrences at the primary site manifest within 2 years of treatment.[74] When concurrent chemotherapy is not used, tumor regression may be even more prolonged. In a French study of 193 patients with anal cancer treated with radiation therapy alone, the mean time to a complete response was 3 months after the completion of therapy, and some patients required as long as 12 months for a complete response.[91] However, the rapidity of the clinical response to therapy may also be prognostic. Another institution from France reported that patients with T3 to T4 tumors who had a tumor reduction of 80% or less at the completion of the first phase of radiotherapy (30 Gy to 45 Gy of EBRT) had 5-year CFS of only 24.8% compared with 65% among patients with a response of more than 80% ($p = 0.002$).[174]

Although routine biopsies have been required 4 to 6 weeks after the completion of therapy in several studies,[80,144,145] routine biopsies should not be performed on patients with regressing or clinically absent tumors. Treatment with 30 Gy to 50 Gy plus 5FU-MMC is associated with negative biopsy findings in 85% to 90% of patients 4 to 6 weeks after completion of radiotherapy.[80,144,145] Because of accelerated repopulation in surviving clonogens, a low-dose radiation boost after a 6-week break is unlikely to provide any benefit. The purported benefit of additional therapy for 7 of 22 patients in the RTOG/ECOG study is more likely a result of continued slow tumor regression after initial therapy than the result of the addition of 9 Gy of irradiation and cisplatin chemotherapy.

Treatment Tolerance

The acute toxicity associated with therapy for anal cancer may depend in part on the radiation fraction size and schedule and how chemotherapy is used. Investigators at PMH reported a decrease from 75% to 40% in acute grade-3 toxicities when the fraction size was reduced from 2.5 Gy to 2 Gy or when a planned treatment break was used.[74] Acute toxicity is markedly higher when MMC is added to 5-FU and radiotherapy. In the RTOG/ECOG trial, 26% of patients who received 5-FU and MMC together experienced grade-4 or grade-5 toxicity (3% treatment-related deaths), compared with only 7% of patients receiving 5-FU (0.7% treatment-related deaths).[139] As noted previously, IMRT appears to decrease the incidence of grade-3 or higher treatment intolerance.[165]

For patients receiving both MMC and 5-FU, the most common life-threatening toxicity is bone marrow suppression resulting in neutropenic sepsis. In addition, essentially all patients will experience a perineal skin reaction.[85] In the RTOG/ECOG study, confluent moist desquamation was reported in 55% of patients treated with this combination.[171] Mild to moderate diarrhea may be experienced by two thirds of patients, and nausea and vomiting by 25% and 15%, respectively.[85]

Late treatment-related complications are usually diagnosed within 2 years of treatment.[90] Asymptomatic or minimally symptomatic perineal fibrosis, telangiectasia, and minor intermittent bleeding from the anorectal region or bladder may be observed.[175] Severe late effects that affect a patient's social life or require surgical intervention have been reported in as many as 15% of patients.[74,78,91] These effects include anal incontinence, intestinal obstruction, chronic diarrhea, chronic pelvic pain, fistula, or bladder dysfunction.[78] Elderly women may be at increased risk for fractures of the femoral head and neck, especially if the radiotherapy fields encompass the entire femoral head and neck in both anterior and posterior treatment fields.[128,159] Late complications may necessitate colostomy for management in 2% to 10% of patients.[74,75,77,91,94,128,156] Whether the use of IMRT will reduce late toxicity remains to be seen.

Late complications of radiotherapy may be more likely when treatment is delivered with fraction sizes larger than 2 Gy.[74] Late complications are also more common in patients with locally advanced tumors; one series reported late effects in 23% of patients with T3 or T4 tumors compared with only 6% of patients with T1 or T2 tumors.[90]

Some investigators have reported that patients who are positive for HIV with anal cancer have reduced tolerance for combined chemoradiation regimens.[176,177] Compared with patients who are HIV-negative, patients who are HIV-positive are more likely to require treatment breaks, hospitalization for acute reactions, and chemotherapy dose reductions.[176,178] In addition, survival of patients with HIV is often limited; one report found a 29% 2-year survival for patients who are HIV-positive compared with 71% at 4 years for patients who are HIV-negative.[176] Although the best treatment strategy is unknown, low-dose chemoradiation in a small series of patients has been reported to result in a satisfactory tolerance and response in patients who are HIV-positive and in patients with AIDS without major opportunistic infections.[178]

The advent of highly active antiretroviral therapy (HAART) in the management of patients who are HIV-positive appears to have led to improved tolerance and treatment outcomes among patients who are HIV-positive. A pooled retrospective analysis from four institutions of 121 patients with anal cancer treated in the HAART era revealed similar clinical complete response rates (≥92%) and OS among patients who are HIV-positive and HIV-negative.[179] However, patients who are HIV-positive were much more likely to fail locally by 5 years (62% versus 13%; $p = 0.008$) and had increased dermatologic and hematologic acute toxicity with therapy. Other institutions have reported successful treatment and acceptable toxicity with standard anal cancer chemoradiation regimens among patients who are HIV-positive in the HAART era,[180-184] but some have also noted inferior long-term local control rates despite excellent initial response rates.[185]

TREATMENT ALGORITHM AND FUTURE DIRECTIONS

Figure 52-3 is a diagnostic and treatment algorithm for patients with newly diagnosed anal cancer.

Future investigations in the clinical management of anal cancer should be focused on improving efficacy among patients with locally advanced disease but also reductions in acute and long-term morbidity from therapy. The continued advances in treatment target definition, radiation conformality (e.g., IMRT), and accuracy of radiotherapy delivery through image-guided radiation therapy (IGRT) afford the opportunity for the prospective study of dose escalation among patients with locally advanced disease at presentation. In addition, these technologies provide opportunity for reducing treatment toxicity by limiting the dose to the genitalia, femora, bladder, bowel, and bone marrow, as has been demonstrated with early clinical experience.

Though RTOG 9811 demonstrated a reduction in severe acute hematologic toxicity with the experimental cisplatin-based arm, there is an opportunity for study of newer cytotoxic, radiosensitizing agents in an attempt to improve efficacy or reduce chemotherapy-related side effects. In addition, the incorporation of biologic agents with treatment has the potential to improve efficacy. There is no role for maintenance chemotherapy after definitive chemoradiation at this time.

Advances in imaging may also improve therapy and medical decision making in the management of anal cancer. As discussed, PET/CT imaging improves the initial staging of anal cancer and may aid in evaluation of the response. The value of early reimaging with PET as a predictor of response to therapy and possibly to guide selection of the total radiotherapy dose and earlier surgical salvage (local excision, APR) has not yet been investigated.

Despite the rarity of anal cancer, major advances in the laboratory and clinic have led to an increased understanding of anal neoplasia that has improved treatment outcomes. As pathways leading to anal carcinogenesis are more fully described and the influences of HPV and other infectious agents are better defined, expanded research efforts focusing on prevention will be possible. However, further advances in the prevention and treatment of anal cancer will require continued commitment to prospective trials.

Overview

Anthony L. Zietman

Since the publication of the last edition of this textbook, the field of genitourinary oncology has continued to change dramatically. It has truly become a field that is intensely multidisciplinary, and radiation oncologists, often substantially outnumbered in the multidisciplinary clinic, must be masters of the published data. Genitourinary oncology has become one of the areas in which practicing radiation oncologists are likely to spend a substantial proportion of their time and one that they cannot choose to ignore.

Developments in genitourinary oncology illustrate the best and some of the more problematic aspects of contemporary medicine. There is much research in areas of spectacular technologic advance, but too much has been widely adopted without sufficient and rigorous scientific evaluation. New drug therapies are being rapidly added to practice but how best to incorporate them with existing therapies and radiation remains an urgent need. Randomized trials are being performed, but they often struggle to overcome decades of therapeutic prejudice. This overview provides highlights of the field that are reviewed in greater detail by the authors of the following chapters.

PROSTATE CANCER

Prostate cancer, along with breast and lung cancers, continues to be the most common type of cancer seen by practicing radiation oncologists. This situation reflects the explosion in early case detection through the widespread use of the prostate-specific antigen (PSA) blood test and the successes of therapy. The incidence peaked in the early 1990s, a few years after the introduction of PSA because the prevalence of the disease in the previously unscreened population was reduced. As predicted, the rate fell, but never to baseline levels. It now holds steady at more than twice the original annual incidence, and the detection rates far exceed the death rates.

It is becoming clear that prostate cancer is being detected in many more men than require treatment.[1] Because we still struggle to sort the "tigers" from the "pussycats," radiation oncologists and urologists have been erring on the side of caution and treating most patients who are diagnosed with prostate cancer.[2] This will change in the near future because of widely expressed concerns by patients, physicians, and policy makers about overtreatment to the point that prostate cancer has come to be regarded as the "bad boy" of the U.S. healthcare system. Randomized trials are being published that call into question many of our assumptions of the last 30 years.

In the years ahead, biomarkers and radiologic advances will likely evolve that, combined with PSA testing and Gleason grading, will be able to determine who does and who does not require treatment. When that happens, the caseload will decline, and oncologists will be able to concentrate their energies and their effective therapies on the patients who need them. Active surveillance for low-risk prostate cancer is now a mainstream approach that is gathering advocates. What the role of radiation oncologists will be in following these patients is yet to be determined and will, in part, define the way we practice in the future. Will this role default to us, to the urologists, or back to primary care? More than one third of patients who elect for active surveillance end up requiring therapy and many of these, being older patients, choose radiation. Thus, it is incumbent on radiation oncologists to remain involved.

Whether patients require treatment at the time of diagnosis or at some later stage one question that remains central is: Which is the most effective therapy? External beam radiation therapy (EBRT) has progressed substantially over the last two decades. In 1999, the Patterns of Care Study showed that most radiation oncologists in the United States were using three-dimensional conformal techniques. These, in turn, have been replaced by other forms of EBRT, such as intensity-modulated radiation therapy (IMRT), and more recently, by proton beam and stereotactic techniques.

Prospective trials have shown that increased radiation doses yield higher cure rates and that highly conformal techniques are the only safe ways to give these doses.[3,4] This is a superb example of practice changing on the basis of strong evidence. Whether the more recent evolutions in delivery systems offer dosimetric gains that are of significance remains controversial, but the now-routine use of patient-reported outcomes in radiation therapy trials will answer the question. The use of image guidance has gained widespread acceptance, and few centers currently deliver prostate treatment without it. The next decade will be spent evaluating the patient-reported benefits of these technical advances and integrating them with advances in anatomic and functional imaging to develop boost techniques for subtotal prostate irradiation.

The substantial technical improvements have made EBRT a much more lengthy and expensive process. As a result, alternative approaches have been proposed in an attempt to reduce the social and economic burdens. One such method is hypofractionation. In the past, proponents of its use were considered "heretics," but evidence now suggests that hypofractionation may be beneficial because prostate cancer may have a low α/β ratio.[5] Better targeting may now even allow for extreme, and thus patient friendly forms of hypofractionation. These concepts are being tested in randomized trials in the United States, Canada, and Europe. Such investigations are vital because many centers are using this approach without a clear understanding of its biologic implications and risks. Uncertainties remain about the most appropriate doses particularly at the extremes of hypofractionation. Also popular

has been low-dose-rate and high-dose-rate (HDR) brachytherapy, which have many proponents and a body of favorable evidence. Despite this, these therapies are sliding out of favor in competition with other novel radiation and nonradiation approaches.

Patients with early prostate cancer have a disease that is so likely to be cured that quality-of-life issues become important for survivors. Appropriate instruments are being used to report on such issues at an increasing rate, and it is evident that effects on quality of life will become one of the important factors influencing patients and physicians in choosing therapy in the years ahead.[6]

For locally advanced disease, there have been tremendous efforts by the large U.S. and European cooperative groups to perform trials, answer questions, and determine standards of practice. The role of androgen therapy combined with EBRT has become better defined. Results with radiation alone for low-risk disease are sufficiently good that these patients probably do not need androgen therapy[7]; intermediate-risk disease probably does require androgen therapy but only a short neoadjuvant course[7,8]; and high-risk prostate cancer certainly needs it for years in a manner akin to breast cancer.[8,9] The role of pelvic lymph node irradiation in locally advanced disease is one that will not go away. RTOG 94-13 has suggested that there may be a small disease-specific survival advantage when it is given, and newer technology is being used to treat the lymph nodes in a fashion that results in less severe side effects than in the past.[10] Active trials are addressing the use of high-dose irradiation in addition to androgen deprivation, and now with novel forms of androgen deprivation also chemotherapy. These represent a brave new frontier in the management of men with a disease that indisputably needs more effective therapy.

Despite the now stable incidence of prostate cancer and the increase in active surveillance the number of patients managed surgically continues to increase, in large part, riding a wave of enthusiasm for robotic technology. A significant proportion of these patients experience a subsequent failure and postoperative radiation is now a large part of the contemporary radiation oncologist's practice. Large randomized trials have clearly shown that irradiation has a role in the postoperative management of prostate cancer. It is becoming widely accepted not only in salvage treatment but also in adjuvant treatment.[11,12]

Prostate cancer now joins breast and testicular cancers and lymphoma as an exemplary field for clinical research. One trial builds on the "shoulders" of the next, and piece-by-piece, knowledge is accumulated to create a clearer picture of management. Prostate cancer also has become a model in its multidisciplinary approach. Through brachytherapy and combined-modality treatment, radiation oncologists, urologists, and medical oncologists have developed a new and productive spirit of cooperation.

BLADDER CANCER

Bladder cancer is a disease for which substantial gains have been made. A growing body of supportive evidence has made the multimodality approach to bladder preservation a recognized alternative to radical cystectomy.[13] The Radiation Therapy Oncology Group (RTOG) continues to refine treatment techniques in a series of trials optimizing the doses of irradiation and chemotherapeutic agents. In the United Kingdom and northern Europe, there has been much work on better defining the treatment volume, and randomized trials are answering questions about nodal treatment and the value of whole bladder versus partial bladder irradiation. There is interest in daily image guidance for this highly mobile tumor because the most severe side effects of bladder cancer treatment are gastrointestinal rather than genitourinary complications. Any method radiation oncologists can find to tighten target volumes and reduce the volume of small bowel treated will be a step forward for patients with bladder cancer. Several new studies look at improving the tolerance of chemoradiation through altered fractionation and gentler chemotherapy.

Several molecular markers and potential molecular targets have emerged in bladder cancer and are creating new avenues for clinical research. Future trial group research will likely be focused on using markers to better select patients for bladder preservation and on the interaction of targeted therapies with chemoradiation.

With all the progress, why is multimodality treatment with organ conservation not more popular with patients and urologists? The urologists have traditionally been the gatekeepers, and their belief that the bladder must be removed rapidly to maximize the chance for cure is strong, as is the belief that an irradiated bladder functions poorly and that superficial and invasive local failures are common and difficult to manage. The section of this chapter on bladder cancer summarizes the data that may be used by radiation and medical oncologists to argue for organ conservation as an alternative to immediate cystectomy for the willing patient. Recent high-profile randomized trials from the United Kingdom and the United States looking at radiation therapy with and without chemotherapy will likely strengthen the argument of those proposing organ preservation.[14,15]

TESTICULAR CANCER

Seminoma is one of the most radiation sensitive of all tumors, and radiation oncologists take particular pride in being able to promise a high probability of cure. There are few cancers for which cure rates exceed 95%, as they do in stage I to II seminoma. For 40 years, adjuvant irradiation has been the principal player alongside orchiectomy, but more recently, there has been a stepwise retreat in its use. Large volume irradiation has a long-term legacy in the treatment of young male patients. Long ago, the mediastinal field was dropped because of concerns about cardiac toxicity and because improved chemotherapy offered effective salvage in cases in which it was needed. Recent concerns revolve around radiation-induced tumors.[16] Conformal techniques are now routinely used to spare some normal tissue, and in a series of British and Canadian randomized trials, substantial reductions in target volume and dose have been tested and validated.

Since the first edition of this book appeared, the standard adjuvant treatment in Europe has shrunk from a full "dog-leg" field treated to 30 Gy down to a paraaortic field alone treated to only 20 Gy.[17] Trials have looked at single-agent carboplatin as an alternative to irradiation, and it has been found to be effective, although its long-term effects are unknown.[18] In Canada, recognizing that most men with small tumors were disease free after orchiectomy, a policy of surveillance became commonplace, with treatment deferred and given only to those who ultimately prove to have stage II disease. In Chapter 55, Warde documents these changes and the discussions that the contemporary radiation oncologist must have with any newly diagnosed patient. The recent story of irradiation in seminoma mirrors that of irradiation in Hodgkin's disease in that the search for the dose that is "as low as we can go" has been driven by the success of the treatment.

KIDNEY AND URETERAL CANCERS

Renal cancer, cancer of the renal pelvis, and cancer of the ureter have traditionally been the preserve of the surgeon.

There has been a tremendous stage shift in renal cancer with the routine discovery of small, incidental tumors on abdominal computed tomography (CT) scans performed for other reasons. Development of partial nephrectomy, laparoscopic nephrectomy, and percutaneous ultrasound ablation has provided effective therapy that cannot be matched by any medical or radiation therapy alternative.

Although renal cell cancer is recognized to be relatively insensitive to radiation, irradiation has a role to play in locally advanced or metastatic disease. It may be considered as an option after resection of disease with positive margins or after resection of an isolated local recurrence. Intraoperative irradiation may be used as a supplement to EBRT to deliver the high doses required for local tumor control without causing excessive bowel toxicity. In metastatic disease, irradiation to a high dose has an important role in maintaining the quality of life of patients who may live for many years. Stereotactic irradiation has become commonplace for the treatment of brain metastases, and this technique allows for the delivery of the high doses needed to ablate disease in this common site of spread. Because patients are now living longer with the development of effective targeted agents, it is likely that these techniques will be in high demand for the management of metastases outside the central nervous system (CNS).

Cancers of the renal pelvis and ureter are different from renal cell adenocarcinomas. Because they are transitional cell in origin, they behave more like bladder cancer and are more sensitive to irradiation and cisplatin-based chemotherapy. Organ-sparing approaches are not used, however. There is little gain in function or quality of life for preserving a kidney or ureter when another exists, and surgery is the mainstay of treatment. Chemoradiation may offer some assistance when the disease is locally advanced or has spread to nearby lymph nodes.

PENILE CANCER

Penile carcinoma is another cancer for which organ conservation may be expected to be popular. In Chapter 57, Crook and Mazeron demonstrate that penile cancer may in many ways be regarded like any other skin cancer but in one way it stands apart, and that is in its high propensity for nodal spread. They also show that effective organ-sparing radiation treatment is possible. Treatment is technically challenging, and in the United States, where men are circumcised and the disease is rare, there is little accumulated experience. However, treatment by brachytherapy or EBRT follows simple first principles, and it is not beyond the reach of any skillful radiation oncologist.

CHAPTER

53 Prostate Cancer

Jeff M. Michalski, Thomas M. Pisansky, Colleen A.F. Lawton, and Louis Potters

INCIDENCE

There was an estimated 220,800 new cases of prostate cancer in the United States in 2015 and 27,540 deaths. Although the incidence of new cases has been relatively stable since 1994 because of prostate-specific antigen (PSA) screening, the rate of death has been declining as a result of earlier diagnosis and treatment. One in six American men will develop prostate cancer during their lifetime.

BIOLOGIC CHARACTERISTICS

PSA, clinical tumor stage, and tumor grade are predictive of extraprostatic tumor extension, lymphatic and hematogenous metastasis, and therapeutic outcome. These factors may be combined to improve the accuracy of predicting disease-related survival.

STAGING

The tumor (T), nodes (N), and metastasis (M) (TNM) classifications may be determined by clinical examination, diagnostic imaging, and pathologic examination of prostatectomy and lymphadenectomy specimens.

Digital rectal examination (DRE), with or without ultrasound, Gleason score of the biopsy, and PSA form the basis of the clinical staging workup. Total body bone scan and pelvic imaging with either computed tomography (CT) or magnetic resonance imaging (MRI) are selectively used in high-risk patients.

PRIMARY THERAPY

The selection of radiation therapy (RT) and radical prostatectomy as primary therapeutic modalities is based on life expectancy, comorbidity, tumor-related characteristics, and patient expectation with regard to quality of life issues.

In clinically localized disease, several years of observation are required to measure the impact of a particular treatment on the natural history of the disease. RT provides outcomes for patients with organ-confined disease that compare favorably with expected survival duration and is an alternative to radical prostatectomy.

Three-dimensional and intensity modulated external beam RT allow radiation dose to conform to the target, while minimizing exposure of nontarget (e.g., rectal and bladder) tissues.

Transperineal ultrasound guided brachytherapy provides a means for accurate radioactive source placement. Long-term cancer control and survival are comparable to radical prostatectomy.

ADJUVANT THERAPY

Risk factors for postprostatectomy local tumor recurrence include tumor involvement of surgical margins, seminal vesicles, or pelvic lymph nodes. Adjuvant RT improves local tumor control, disease-free, metastasis-free, and overall survival (OS).

LOCALLY ADVANCED DISEASE

External beam radiation therapy (EBRT) is considered the preferred primary treatment modality. The addition of neoadjuvant androgen deprivation (AD) to EBRT improves local tumor control and progression-free survival (PFS) rates. AD as adjuvant therapy to EBRT diminishes the risk for local tumor recurrence and metastatic disease relapse. Improved survival duration may also be observed, particularly for patients with high-grade tumors.

PALLIATION

EBRT effectively relieves symptoms resulting from locally progressive disease or metastases. Systemic radiotherapy with radium-223 (^{223}Ra) improves survival and reduces the risk of skeletal fractures, spinal cord compression, and other adverse skeletal events.

Prostate cancer is an important health issue that provokes considerable debate among healthcare professionals, agents of the healthcare policy, patient advocates, insurers, and other third-party payers. The high prevalence of prostate cancer coupled with the variable natural history and multiple treatment approaches encourages deliberation as to the appropriate approach to the population of men that may confront this illness. In this context, the radiation oncologist may engage in discussion with primary care physicians, urologists, and other healthcare professionals concerned for the welfare of patients with prostate cancer.

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

In 2015, an estimated 220,800 Americans were diagnosed with prostate cancer, accounting for 28% of all newly diagnosed cancers in men.[1] It appears that one in six American men will develop a clinically recognized invasive prostate cancer during his lifetime. Ninety percent of cases are expected to be diagnosed with local or regional stage disease for which the 5-year relative survival rate approaches 100%.

A broad base of knowledge relevant to multispecialty interaction and detailed information regarding the current controversies is essential for a productive dialogue. Furthermore, the clinician should interpret existing medical literature with a critical view and should strive to contribute to clinical research efforts that will ultimately improve the care of patients with this disease.

The age-adjusted annual incidence rate increased 66% overall between the periods of 1975 to 1979 and 1987 to 1991.[2] This change largely reflected the increased detection of localized, rather than regionally advanced or metastatic, prostate cancer cases. In recent years, the incidence of newly diagnosed cases has dropped 1.9% per year from 2001 to 2009.[1] The recent decrease in the incidence of prostate cancer may reflect stabilization related to PSA screening. Prostate cancer remains the second-leading cause of cancer death in men with an estimated 29,720 deaths in 2013. As with the incidence of newly diagnosed cancers, there has been a 40% drop in prostate cancer death rates over the past two decades. The annual death rate from prostate cancer was 38.56 in 1990 compared to 23.6 deaths per hundred thousand men during the years 2005 to 2009.[1]

Etiology

Cohort and case-control studies are the two principal methods used to ascertain the etiology of cancer.[6] Several reports describe various host-related and environmental factors that appear associated with prostate cancer (eBox 53-1), but it is not yet understood which factors directly initiate or promote prostate carcinogenesis. As discussed by several authors,[7,8] long-term androgen exposure, which is required for normal prostatic development and for cancer growth and maintenance, advanced age,[9] race/ethnicity,[10-12] and familial history of prostate cancer[13,14] are presently viewed as the most likely risk factors. Other associations such as diet, body mass index, energy balance, and physical activity are becoming more suspect.[15-19]

Hormonal Factors

Although several lines of investigation suggest the importance of hormones in the promotion of prostate cancer, their mechanism of action and interactions are not clearly understood. Animal studies indicate that chronic testosterone exposure markedly enhances the effects of carcinogens on prostatic tissues.[20] Furthermore, both benign prostatic hyperplasia (BPH) and prostate cancer simultaneously develop under androgen stimulation, and some reports suggest that men with benign hyperplasia are at increased risk for development of prostate cancer.[21,22] Various authors also report that men with prostate cancer have alterations in serum androstenedione, dihydrotestosterone (DHT), sex hormone–binding globulin, or testosterone,[23-26] which was also noted to vary according to race and ethnicity.[25,26] Despite these associations, circulating androgens do not fully explain the development of prostate cancer and downstream effects in target tissue may be more relevant.[27] Testosterone is the main circulating androgen, but it is converted to DHT in prostate and other peripheral tissues by 5α-reductase. DHT binds the androgen receptor leading to nuclear translocation and activation of transcriptional and androgen responsive genes. The activity of 5α-reductase is different in various ethnic groups and may partially explain the variable incidence and aggressiveness of prostate cancers by race.[26,28]

Age

Age may be the single most important factor associated with prostate cancer because most elderly men have histologic evidence of cancer in the prostate gland,[4] and the rate of clinical detection is a direct function of age.[1] Although several causes may be invoked such as senescence of the immune system, higher levels of oxidative stress, prolonged exposure to carcinogens, and impaired response to DNA damage, an exact explanation for this association is lacking.

Hereditary Factors

Twin studies suggest that heritable factors account for a proportion of prostate cancer risk.[29] Several investigators observed familial clustering of prostate cancer and suggested that genetic constitution may increase susceptibility to the disease.[13,14] It has been estimated that as many as 5% to 15% of prostate cancer cases are hereditary or familial,[30,31] and they are typically diagnosed at an earlier age than sporadic cases.[30] Carter et al describe an increased risk of the disease, a greater number of affected relatives, and an earlier age of onset with the familial type compared with the sporadic form.[13] The age-adjusted risk of developing prostate cancer in the setting of a familial predisposition is approximately twice that of the general population but may be greater (i.e., 5- to 11-fold), depending on the number of affected first-degree relatives.[13,32]

Racial and Ethnic Variations

Prostate cancer incidence is characterized by marked racial and ethnic variation that is dependent on geographic factors.[1] For example, a 30- to 50-fold difference in the incidence of the disease is observed between black men and native Asians.[34] In the Health Professionals Follow-up Study, African American race was strongly associated with a risk of developing prostate cancer.[35] However, a complex interaction between race and ethnicity and environment exists. For example, the incidence of cancer in a particular racial or ethnic group (e.g., Japanese) tends to shift toward that of the population in the geographic area to which that group immigrates (e.g., the United States) as the group assimilates to its new environment and culture.[36] Furthermore, certain racial and ethnic groups (e.g., blacks) present with more-advanced prostate cancer and appear to have a stage-adjusted outcome that is worse than for other members of their society (e.g., whites).[37,38] Racial variations of hormonal, dietary, genetic, and perhaps socioeconomic factors may account for such findings,[10,26,28,39,40] but definitive evidence in this regard is lacking, and further research is necessary to clarify the association between race and ethnicity and prostate cancer risk.

Dietary Factors

The role of dietary factors in prostate cancer pathogenesis is difficult to discern because research in this area is confounded by complex interactions with other potential risk factors. There are striking racial or ethnicity and geographic variations in prostate cancer incidence that may have a dietary basis. In particular, a high-fat diet appears to correlate with prostate cancer incidence and mortality,[8,15,39,41] whereas ingestion of retinol,[42] certain carotenoids (e.g., lycopene),[8,43] phytoestrogens,[44] and vitamin D may be protective.[45] The influence of other vitamins (e.g., vitamin E) and minerals (e.g., zinc) is uncertain.[8] In a large prospective cohort study of American men, Sinha reported an association of processed and red meat with the total prostate cancer incidence and the incidence of locally advanced disease.[46] Other dietary factors such as α-linolenic acid are associated with increased risk of prostate cancer, whereas tomato-based products containing lycopene have been associated with reduced risk.[35,47] It has been suggested that a diet high in fruit and vegetable intake is associated with a lower rate of prostate cancer.[48] The Health Professionals Follow-up study demonstrated and association for tomato sauce, the primary source of bioavailable lycopene, and a lower risk of prostate cancer.[47] In the Selenium and Vitamin E Cancer Prevention Trial (SELECT) investigators identified an association of high serum levels of long chain omega-3 polyunsaturated fatty acids and the development of prostate cancer.[49]

The incidence of incidental (or latent) prostate cancer observed at autopsy examination and the incidence and prevalence of clinically manifest prostate cancer increase substantially with age.[1,3,4] Information from the Surveillance, Epidemiology, and End Results (SEER) Program indicates that approximately 1.8% of American men between ages 40 and 59 years had a clinical diagnosis of prostate cancer, whereas 15% of men 60 to 79 years old would have prostate cancer by the time they attained this age. Although the prevalence of incidental carcinoma does not exhibit marked geographic variation, the regional disparity in the antemortem clinical expression of the disease and the cancer mortality rate of prostatic carcinoma is noteworthy.[3,5] North America, Australia/New Zealand, Western and Northern Europe, and the Caribbean have a much higher incidence of this disease than Asia.[5]

eBOX 53-1 Potential Risk Factors for Prostate Cancer

Advanced age
Benign prostatic hyperplasia
Diet (e.g., fat intake)
Familial history of prostate cancer
Histologic precursors (e.g., prostatic intraepithelial neoplasia)
Hormonal factors (e.g., serum testosterone)
Occupational exposure (e.g., cadmium)
Race or ethnicity (e.g., black)
Sexual behavior (e.g., multiple partners)
Sexually transmitted disease (e.g., herpes virus)
Tobacco use
Vasectomy

A meta-analysis of 13 case-control and cohort studies determined a relative risk in first-degree relatives of 2.5 (95% confidence interval [CI], 2.2 to 2.8).[14] The highest risk was in relatives of cases diagnosed before 60 years of age. The risk of developing prostate cancer was 3.5-fold greater in men with two affected relatives.[14] Candidate susceptibility genes like *RNASEL*, *ELAC2*, and *MSR1* have been identified in cases of heritable prostate cancer,[31] whereas mutations in these genes are rare in the more common sporadic forms of the disease.[33]

Some vitamins, minerals, and other micronutrients have been implicated as having a protective role in prostate cancer. An association between low levels ultraviolet light exposure and prostate cancer mortality rates led to the hypothesis that vitamin D insufficiency may play a role in prostate cancer risk.[50] In contrast, the European Prospective Investigation into Cancer and Nutrition (EPIC) showed no significant association between circulating levels of 25-hydroxyvitamin D and risk of prostate cancer.[51] Giovannucci hypothesized that high dairy and meat consumption increase risk of prostate cancer by lowering 1,25(OH)2D.[52] Indeed, there may be important interactions with vitamin D and calcium that may influence the risk of developing prostate cancer. In the Health Professionals Follow-up study a high dietary calcium intake was associated with an increased risk of prostate cancer.[19] Halthur suggests that high serum levels of calcium in young overweight men may be a marker for a decreased risk of developing prostate cancer.[53] EPIC reported an increase risk of prostate cancer with dairy proteins and dairy calcium.[17] The Nutritional Prevention of Cancer Study Group tested selenium supplementation as a preventative agent for a number of cancers. Clark reported a 63% reduction in the incidence of prostate cancer with oral selenium supplementation.[54] Similarly, a secondary analysis of the Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study showed a 32% reduction in the incidence of prostate cancer.[55]

Body Habitus

Although studies have failed to consistently show that obesity is related to prostate cancer incidence, a study of more than 400,000 men (Cancer Prevention Study II) showed that men with higher body mass index (weight versus height) had an increased risk of prostate cancer death as compared to men with a lower body mass index.[15,16] The mechanism through which obesity might cause prostate cancer or a higher mortality from prostate cancer is complex but is thought to be related to a state of hyperinsulinemia that leads to higher levels of insulin-like growth factor and available sex steroids (androgens).[56]

Precancerous Lesions

Certain atypical epithelial lesions may be precursors of prostate cancer, and their presence in a prostatic biopsy may serve as a risk factor for this condition. These lesions may now be classified into two categories: prostatic intraepithelial neoplasia (PIN) and atypical adenomatous hyperplasia.

Of the two categories, PIN represents the putative precancerous end of the morphologic continuum of cellular proliferation and is more strongly associated with prostate cancer.[76] Two grades (low and high) are recognized, with high-grade PIN considered a precursor of invasive carcinoma.[76,77] Studies suggest that PIN predates prostate cancer by 10 years or more, with low-grade PIN first emerging in the third decade of life.[78] PIN is often found in proximity to carcinoma, and its presence warrants search for invasive carcinoma.[79] Davidson et al[80] noted that 35% of patients with PIN had prostate cancer identified on subsequent biopsy, which is consistent with the results of other studies.[81] These results suggested that PIN was a likely and strong risk factor for prostate cancer that warrants close surveillance and follow-up.[82,83] However, in the Prostate Cancer Prevention Trial the incidence of a new cancer diagnosis on repeat prostate biopsy was as high as 35% even in the absence of high-grade PIN.[84] Specific molecular findings associated with high grade PIN may be able to predict which men may have invasive cancer on repeat biopsies. In a study of biopsy specimens expressing Alpha-methylacyl-CoA racemase (AMACR), there was a 5.2 times greater incidence of cancer on repeat biopsy compared to high-grade PIN without AMACR positivity.[85] AMACR overexpression was also more often identified in high-grade PIN adjacent to cancer than high-grade PIN lesions distant from cancer in prostatectomy specimens.[86]

PREVENTION AND EARLY DETECTION

Prevention

Prostate cancer is an androgen-dependent tumor with a prolonged latency between initial malignant transformation and clinical expression, features well-suited to disease prevention efforts.[3] Progression from tumor inception to invasive carcinoma often takes decades, allowing sufficient time for intervention.[87] Chemoprevention strategies that use high-risk target populations have the greatest potential to identify promising agents in a time-efficient manner.[88] The results of focused studies such as these can then be confirmed in large-scale trials applied to the general population. The ability to alter the hormonal environment of the host provides an excellent opportunity to interrupt the multistep process that results in clinical expression of the disease.[3] Advances in our understanding of the process of carcinogenesis and the availability of promising new chemopreventive agents, including those producing reversible AD, have the potential to favorably affect the morbidity and mortality of prostate cancer in the foreseeable future.

Luteinizing hormone–releasing hormone analogs (e.g., goserelin, leuprolide) reduce luteinizing hormone and (secondarily) testosterone levels. The long-term use of these agents may cause anemia, atrophy of reproductive organs, diminished muscle mass, loss of libido, and vasomotor instability, which limits the utility of these agents for chemoprevention in the general population. Nonsteroidal antiandrogens (e.g., flutamide, bicalutamide) competitively bind to androgen receptors in target tissues. These agents are tolerated in patients, although adverse effects may include gastrointestinal (GI) disturbance, gynecomastia, hot flushes, and a metabolic syndrome.

Intracellular 5α-reductase converts testosterone to DHT, the hormone responsible for prostate epithelial proliferation. DHT has greater affinity for the androgen receptor and is the primary agonist leading to prostate maintenance and growth. Three isoforms of 5α-reductase have been identified with various levels in different tissues. Type 1 is expressed in BPH and its expression is greatly increased in prostate cancer, especially high-grade tumors.[89] Type 2 5α-reductase expression is decreased in PIN and some early cancers but is increased in metastatic and recurrent prostate cancer.[89] The role of type 3 5α-reductase is less defined. Competitive inhibitors of 5α-reductase (e.g., finasteride and dutasteride) suppress intraprostatic DHT to castrate levels. The Prostate Cancer Prevention Trial (PCPT) was initiated to test the efficacy of finasteride as a chemoprevention agent in men at low risk of having prostate cancer.[90] This placebo-controlled Phase III trial randomized 18,882 eligible men (older than 55 years, normal DRE, and PSA levels <3 ng/mL) to finasteride (5 mg daily) or placebo for 7 years. There was a 25% reduction in the prevalence of prostate cancer over this 7-year period from 30.6% in the placebo group to 18.6% in the finasteride group.[90] Of note, however, is that more aggressive tumors, Gleason score 7-10, were more common in patients who took finasteride, 37% of all tumors and 6.4% of all men on the finasteride arm versus 22% of all tumors and 5.1% of all men on the placebo arm. The increase incidence of high-grade cancers seen in the PCPT trial has been a topic of great debate. The investigators have argued that the increase in high-grade cancers is a result of a detection-bias related to the reduced volume of prostate tissue and therefore a greater ratio of cancer to benign tissue. Furthermore, there was no dose effect from the finasteride with no significant increase in worse cancers with higher cumulative doses of the drug.[91] The PCPT study was not designed or powered to detect differences in cancer-specific survival or OS. Finasteride did reduce urinary symptoms compared to placebo, but there were also significantly more adverse sexual side effects.[90] A reduced volume of ejaculate, erectile dysfunction, loss of libido, and gynecomastia were more common in the finasteride group ($p < 0.001$), but urinary urgency, frequency, retention, urinary tract infection, and prostatitis were less common with finasteride ($p < 0.001$).[90]

The Reduction by Dutasteride of Prostate Cancer Events (REDUCE) trial, a Phase III study testing inhibition of 5α-reductase with dutasteride.[92] Dutasteride blocks both types I and II 5α-reductase suggesting it may be more effective at preventing the development of prostate cancer. The REDUCE trial is a randomized trial of placebo compared with dutasteride 0.5 mg administered daily to evaluate it as a chemopreventive agent for prostate cancer. The use of dutasteride was associated with a 22.8% lower risk of being diagnosed with prostate cancer 4 years after study entry. However, like the PCPT trial, the REDUCE trial has not shown a decrease in the incidence of prostate cancer death nor all-cause mortality. It may be that these medications decrease the likelihood of detecting clinically insignificant cancers but do not reduce the incidence of potentially fatal disease.

Different factors may be at play in the carcinogenesis of nonagressive cancers and the evolution of disease to an aggressive form.[57] Taller height was associated with in increased risk of fatal prostate cancer in the Health Professionals Follow-up study.[35] Height may be a surrogate for dietary and hormonal influences that may affect the risk of prostate cancer.

Other Lifestyle Factors

Research regarding other lifestyle factors such as tobacco use, alcohol consumption, physical activity level, sexual behavior, and sexually transmitted diseases has provided mixed findings with regard to the importance of these factors in prostate cancer pathogenesis.[15,16,18,35,58-67] Previous infection with *Trichomonas vaginalis* has been associated with an increase risk of aggressive prostate cancer.[67] Vigorous physical activity was associated with a lower risk of fatal prostate cancer in the Health Professionals Follow-up study.[35] In a meta-analysis including more than 88,000 cases, Liu reported a reduction in the incidence of prostate cancer with physical activity, particularly occupational activity.[68] Likewise, the EPIC study showed that only occupational and not leisure activity was associated with a reduction in prostate cancer risk.[18] Although the results of these studies may be affected by the fact that several lifestyle factors may be simultaneously interacting and difficult to separate, nevertheless, this research increasingly suggests that there may be an effect for at least some of these etiologic factors.

Environmental Exposure

A link between environmental or occupational exposure to carcinogens and development of prostate cancer has also been explored, but establishing a correlation and identifying a causative agent(s) have been difficult. For example, laborers in heavy industry, rubber manufacturers, and newspaper printers may have a somewhat higher incidence of prostate cancer,[69] but this association is weak, and its significance remains uncertain. Exposure to cadmium, as from cigarette smoke, nickel-cadmium batteries, or certain paints, has been implicated as a carcinogen because cadmium workers have more aggressive prostate cancers and an increased cause-specific mortality.[70] A clear association between these factors, environmental or occupational exposure, and prostate cancer is conjectural, and further study is required before firm conclusions can be formed.

Vasectomy

Some investigations suggested that vasectomy increases androgen levels[71] or produces an immunologic reaction[72] that might promote prostate carcinogenesis. However, John et al[73] and Sidney et al[74] could not confirm this association in large cohort studies. Furthermore, the National Institutes of Health determined that information regarding a putative association between vasectomy and prostate cancer was not convincing and that a causative relationship had not been established.[75] Therefore, vasectomy should not be considered a prostate cancer risk factor.

The association of dietary consumption or serum levels of selenium and α-tocopherol and a low rate of prostate cancer has suggested that dietary supplements of these nutrients may protect men from the development of this disease.[55] Despite this association, two prospective Phase III clinical trials did not show a reduction in the incidence of prostate cancer with vitamin or selenium supplementation. In the SELECT trial, there was no significant reduction in prostate cancer incidence related to either selenium or vitamin E supplementation.[93] The SELECT enrolled 32,400 participants to a Phase III randomized, double-blind, placebo-controlled trial with a 2×2 factorial design. The study was designed to determine the efficacy of selenium, vitamin E, or a combination of the two to prevent prostate cancer. In this trial, an increase of 1.17 relative risk of developing prostate cancer was associated with taking vitamin E, although there was no significant change in the risk when taking selenium or the combination. The Physicians' Health Study II enrolled 14,641 male physicians and randomized them to receive vitamin E and C supplements daily. Neither vitamin E nor C supplementation reduced the risk of prostate or other cancers.[94]

Early Detection

Considerable controversy surrounds the use of early detection programs for prostate cancer. Some argue that early detection efforts are too costly and will lead to the recognition of an increased number of clinically insignificant tumors because autopsy studies demonstrate a high prevalence of incidental tumors in older men.[5,87] Likewise, a study of prostate cancer discovered in organ donors found incidental prostate cancer in one third of men age 60 to 69, and 46% in men older than age 70.[95]

Contributing further to the arguments against prostate cancer screening are the limited sensitivity and specificity of PSA, DRE, and ultrasound in diagnosing cancer. Although DRE has high specificity for prostate cancer, it has a low sensitivity profile and is not considered an effective detection tool on its own.[96] In contemporary series, PSA testing with a threshold of 4.0 ng/mL has a sensitivity of only about 20%.[97] Although the sensitivity of PSA testing could be improved by lowering the threshold value for all men this would compromise the specificity and increase the detection of clinically insignificant cancers. Early detection strategies have also been criticized for exaggerated improvements in cancer-specific survival related to an early detection bias. In an early report, the use of PSA resulted in a diagnostic lead time of approximately 5 years[98,99] and longer in the detection of earlier-stage and lower-grade tumors.[100] Data from the European Randomized Study of Screening for Prostate Cancer (ERSPC) and SEER registry suggest the lead-time bias could range from 5.9 to 7.9 years.[101] Included in the debate over prostate cancer screening are the risks of overdetection and overtreatment. Overdetection occurs when men are found to have disease that would have remained silent and contributed no morbidity in his lifetime. Overtreatment occurs when an intervention plays no role in extending a patient's life or preventing morbidity from the illness. The real challenge for clinicians involved in the management of prostate cancer is the identification of clinically significant disease.

Arguments in support of prostate cancer screening include the 36% reduction in prostate cancer deaths seen between 1990 and 2005.[1] This trend began shortly after the introduction of PSA testing and statistical models suggest that PSA testing contributed to this decline.[102,103] Furthermore, PSA testing is responsible for the migration of prostate cancer diagnoses to earlier and more curable stages.[1] These findings, as well as data from studies suggesting a survival benefit to treatment for early cancers support a role for early detection and treatment. The Swedish randomized trial of surgery versus watchful waiting demonstrated an improvement in disease-specific and overall mortality in men undergoing radical prostatectomy for early stage disease.[104] In the United States, an observational cohort of 44,630 men from the SEER data suggests a survival advantage with active treatment for low- and intermediate-risk prostate cancer in men age 65 to 80 years.[105] Countering those arguments are the results of the randomized Prostate Cancer Intervention versus Observation Trial (PIVOT) that failed to show a survival benefit to early surgical treatment for early stage prostate cancer in the PSA screening era.[106] In that trial of 731 men with localized prostate cancer, the 10-year survival rate was 53.0% in men assigned to radical prostatectomy and 50.1% in those assigned to observation ($p = 0.22$). Furthermore, the prostate cancer specific death rate was not significantly different between the two arms.

Early data from three prospective randomized trials seeking to measure the benefit from prostate cancer screening contribute to this screening controversy.[107-110] The U.S. Prostate, Lung, Colon and Ovary (PLCO) Screening Trial registered 76,685 men at 10 study centers to determine the impact of annual PSA and DRE on the cause-specific mortality for cancers in each of these organ sites.[110] The primary exclusion criteria were a history of a PLCO cancer, current cancer therapy, and more than one PSA blood test in the 3 years before study enrollment. Subjects in the screening group were offered annual DRE for 4 years and annual PSA testing for 6 years. A PSA of more than 4.0 ng/mL or a DRE with nodularity or induration were considered suspicious for prostate cancer and patients with these findings were advised to seek diagnostic evaluation. With a median follow-up of 13 years, although there were 12% more cancers diagnosed in the screened group, there was no reduction in prostate cancer mortality.[110] The cumulative mortality rates from prostate cancer were 3.7 and 3.4 deaths per 100,000 person-years in the screened and control arms, respectively. The European Randomized Study of Screening for Prostate Cancer (ERSPC) recruited 182,160 men between the ages of 50 and 74 years from seven European countries.[109] They were randomized to undergo PSA screening once every 4 years or to a control group that did not get PSA screening. There was country-to-country variability in enrollment criteria and screening regimens: age of eligibility, case selection criteria, thresholds for PSA, and the inclusion of DRE in the screening assessments. PSA values as low as 3.0 ng/mL were considered abnormal and would prompt referral for further testing. Of 162,388 eligible men enrolled 6693, prostate cancers were diagnosed in the study group compared to 5396 (20% fewer) in the control group. With a median follow-up of 11 years, the adjusted rate ratio of prostate cancer death in the screened arm was 0.79 (95% CI, 0.68 to 0.91, $p = 0.001$).[109] This represents a relative risk reduction of 21% in favor of screening. In this trial, the number of men that would need to be screened to prevent one prostate cancer death is 1055. More importantly, 37 men would need to be treated to prevent each prostate cancer death.[109] A population-based screening trial was conducted in Sweden.[111] The Goteberg trial prerandomized 20,000 men born between 1930 and 1940 before inviting half of them to participate in PSA screening. PSA was drawn at time of study entry in the invited group and every 2 years thereafter up until the age of 70. In the men invited to screen, 7758 of 9952 (76%) had at least one PSA drawn. Unlike the PLCO trial where as many as 44% of enrollees had prior PSA testing, the Goteberg population had fewer than 3% previously screened. This trial showed a greater reduction in prostate cancer mortality compared to either the ERSPC or the PLCO trials. The relative risk of prostate cancer death in the screened population was 0.56 in the Goteberg study compared to 0.80 in the ERSPC and no reduction in the PLCO trials. Finally, the Prostate testing for cancer and Treatment (ProtecT) trial in the United Kingdom and its companion screening trial has enrolled hundreds of primary care centers and 225,000 patients to help address the value of screening and treatment for early-stage prostate cancer.[112] Primary results of these studies are expected in 2016 with a median follow-up of 10 years.

There are important differences in these screening trials that help explain to apparent differences in conclusions. The U.S. PLCO trial enrolled a group of men in whom as many as 42% of cases underwent previous screening effectively reducing the prevalence of cancer relative to that of a completely unscreened population. This prescreening allowance is emphasized when looking at the Goteburg study where nearly a quarter of the patients were diagnosed at their first screening visit. In addition, over the period of the PLCO trial 52% of nonscreened men had PSA testing, contaminating the control group. The follow-up of 11 years for prostate cancer mortality is relatively short for a group of men with screened cancers. The heterogeneity of eligibility and screening criteria in the ERSPC trial make it challenging to determine the exact

population that would benefit from screening. The Goteberg study included younger men, had a lower PSA threshold, an interval of 2 years between testing, a higher rate of biopsy for men with a positive screen PSA, and less contamination because of prior or ongoing PSA testing in the control arm. This trial may be more indicative of the true value of unbiased PSA screening. The ProtecT trial has also seen less than 10% of the men in the nonscreened arm having their PSA tested making this also a "clean" study for determining the benefits, or otherwise, of screening.

One criticism of published trials of PSA screening is the use of singular thresholds to prompt further diagnostic evaluation. Because serum PSA levels directly correlate with age in men without prostate cancer, several investigators sought to improve the diagnostic accuracy of PSA by defining the normal test range as a function of age and race (eTable 53-1).[113-118] El-Galley et al[118] studied the clinical impact of age-specific reference ranges in 2657 men who underwent prostatic biopsy. Analysis of the sensitivity, specificity, and positive predictive value profiles supported use of age-specific reference ranges because of increased detection sensitivity in younger men and increased specificity in older men.

Newer biomarkers are currently being explored to complement or replace PSA for screening. Prostate Cancer Antigen 3 (PCA3) is a noncoding RNA whose expression is restricted to the prostate and is not expressed in any other normal human tissue or tumor.[130] PCA3 RNA is highly overexpressed in 95% of tumors compared to normal or BPH tissue with up to 66-fold upregulation of PCA3 in cancer compared with normal prostate tissue. Because cancer cells with high PCA3 levels are shed from the prostate into urine, PCA3 RNA can be measured not only in prostate tissue specimens but also in urine and in urine sediments after a DRE. In a correlative biomarker study conducted in the control arm of the REDUCE prevention trial, elevated urinary PCA3 scores were associated with positive biopsy rate ($p = 0.0001$) and correlated with biopsy Gleason score ($p = 0.0017$).[131] In recent studies gene alterations involving androgen regulated *TMPRSS2* and *ERG* transcription factor genes were identified in patients diagnosed with prostate cancer.[130] *ERG* is regarded as a key prostate cancer oncogene. Similar to PCA3, *TMPRSS2-ERG* gene rearrangement can be detected in urine after a DRE. The detection of *TMPRSS2-ERG* fusion in urine has greater than 90% specificity and 94% positive predictive value for prostate cancer detection. Given the high specificity of the test, fusion status in men who are ERG-positive may serve as a viable biomarker to establish disease presence or absence.

Screening Recommendations

The controversy in prostate cancer screening is evident when the current recommendations from various professional societies are reviewed. The American Cancer Society (ACS) previously recommended annual DRE and PSA testing in men older than 50 years of age with a life expectancy of at least 10 years. In 2009, following the publication of the interim results of the PLCO and ERSCP trials, the ACS no longer supports routine testing for prostate cancer. The ACS does support healthcare professionals discussing the potential benefits and limitations of early detection with an *offer* to test with annual PSA and DRE beginning at age 50 in men who are at average risk of prostate cancer and a life expectancy of more than 10 years[132] (http://www.cancer.org/cancer/prostatecancer/detailedguide/prostate-cancer-detection). In African American men and men who have a first-degree relative diagnosed with prostate cancer the discussion should take place at age 45. In men with more than one first-degree relative with prostate cancer the process could begin at age 40. If no prostate cancer is detected as a result of screening the interval for PSA testing can be extended to once every 2 years if the PSA is less than 2.5 ng/mL. The American Urological Association (AUA)[133] strongly recommends shared decision making for men age 55 to 69 years that are considering PSA screening and proceeding based on a man's values and preferences. The AUA discourages PSA screening in men age older than 70 years or who have less than a 10- to 15-year life expectancy. Based largely on the findings of the PLCO and ERSCP studies, the U.S. Preventative Services Task Force (USPSTF) concluded that the benefits of screening for prostate cancer are uncertain and the balance of benefits and harms cannot be determined.[134] The USPSTF does not recommend screening for high risk or other specific populations as none of the trials were powered to detect differences in these subgroups.

PATHOLOGY AND PATHWAYS OF SPREAD

Anatomy

Prostatic anatomy is readily understood by using the urethra as a reference point. The verumontanum is a major anatomic landmark and protrudes from the posterior prostatic wall at the midpoint of the urethra. Most prostatic ducts and the ejaculatory ducts empty into the urethra in this region, whereas the periurethral glands empty throughout the length of the urethra. Immediately proximal to the verumontanum is the müllerian remnant, the utricle, an approximate 0.5-cm length of epithelium-lined cul-de-sac. A circumferential sleeve of muscle surrounds the entire urethra and is composed of the proximal preprostatic smooth muscle sphincter, which prevents retrograde ejaculation, and a distal sphincter of striated and smooth muscle at the apex that is essential for urinary control.

The prostate is composed of three zones: peripheral, central, and transition. The peripheral zone includes approximately 70% of the prostatic volume and is the most common site of PIN and carcinoma. DRE often includes a description of the prostatic lobes based on palpation of the median furrow, which divides the peripheral zone into the right and left halves. The central zone is a cone-shaped area that includes the base of the prostate and encompasses the ejaculatory ducts; it represents approximately 25% of the volume of the prostate. The transition zone is the smallest component of the normal prostate, accounting for approximately 5% of the gland, but it usually enlarges as men age as a result of BPH and may grow to dwarf the remainder of the prostate.

The prostatic capsule consists of an inner smooth muscle layer and an outer covering of collagen, with marked variability in the relative amount of each in different areas. At the apex, acinar elements are sparse and the capsule is ill-defined. As a result, the prostatic capsule cannot be regarded as a well-defined anatomic structure with constant features.

The nerve supply of the prostate is furnished by paired neurovascular bundles along the posterolateral edge of the prostate. Autonomic ganglia are clustered near the neurovascular bundles, and small nerve trunks arising at this site penetrate the capsule to form an extensive network within the gland.

The primary blood supply of the prostate is furnished by the internal iliac artery, and the venous drainage is directly into the prostatic plexus, which eventually empties into the internal iliac vein. This route may account for hematogenous metastases, most often in osseous sites.

The lymphatics of the prostate and the seminal vesicles were detailed through anatomic dissections described by Rouvière.[135] Lymphatic drainage of the prostate originates in an extensive intraprostatic network that coalesces to form a subcapsular system and henceforth coalesces into a periprostatic lymphatic network and the four pedicles of the collecting

Additional attempts to improve the screening accuracy of PSA measurements are based on the observation that serum PSA level depends on cancer volume, tumor differentiation, and the amount of benign prostatic tissue.[120] To account for coexistent BPH, the concept of PSA density (PSAD) was introduced by Benson et al.[121] PSAD is the total serum PSA value divided by the volume of the prostate gland, as determined by transrectal ultrasound (TRUS). PSAD appears most useful for patients with a total serum PSA level in the range of 4 ng/mL to 10 ng/mL, particularly when palpable prostatic abnormalities are absent. In this setting, it is believed a PSAD of 0.15 ng/mL/cm^3 or more best identifies men in whom prostatic biopsy should be considered.[122,123]

Because the proportion of PSA complexed to α_1-antichymotrypsin is greater in patients with prostate cancer than in men with benign prostatic disease, the ratio of free-to-total (i.e., percent free) PSA will be lower in men with prostate cancer and may help discriminate between benign and malignant prostate conditions.[124-128] Although the free-to-total PSA ratio can be applied to any serum PSA level, performing a free PSA determination improves the specificity for prostate cancer detection when the total serum PSA range is approximately 3 ng/mL to 10 ng/mL.[126,129] To determine the optimal cutoff point that may warrant prostatic biopsy, various free-to-total PSA ratios were examined for their association with prostate cancer.[128,129] A multicenter clinical performance study demonstrated that a free-to-total PSA ratio of less than 7% was highly suspicious for cancer, whereas a free-to-total PSA ratio of above 25% was rarely associated with malignancy.

trunks: the external iliac, hypogastric (or internal iliac), and posterior and inferior pedicles that terminate in the external iliac (including the obturator), presacral, and hypogastric lymph nodes, respectively. The lymphatics of the seminal vesicle originate in the mucous and muscular networks and give rise to the superficial plexus, which culminates in the lymph nodes of the external iliac system. Modern surgical series of extended pelvic lymph node dissections report involved lymph nodes commonly in the obturator fossa, external and internal iliac regions.[136,137] These sites account for nearly 85% of lymph node metastases in prostate cancer.[137] Another 15% of involved nodes can be identified in the presacral, paravesicular, and pararectal sites.[137]

Histology

The prostatic epithelium consists of three main histologic types: secretory, basal, and neuroendocrine cells. Despite having the lowest proliferative activity of the epithelial elements, secretory cells produce PSA, prostatic acid phosphatase (PAP), acid mucin, and other secretory products. The basal cells form a flattened layer of cells surmounting the basement membrane at the periphery of the glands. These cells possess the highest proliferative activity of the prostatic epithelium and are thought to act as stem or "reserve" cells that repopulate the secretory cell layer.[138] Basal cells, selectively labeled with antibodies to high-molecular-weight keratin (e.g., 34βE12), are used to differentiate benign acinar processes from adenocarcinoma, which lacks a basal cell layer. Neuroendocrine cells are the least common epithelial cell type and are often not identified in routinely stained sections.

The seminal vesicles have a variable anatomic distribution, portions of which may occasionally be found within the prostatic capsule where they may be mistaken for prostatic nodularity or induration on examination. The cells of the epithelial component have large, irregular hyperchromatic nuclei with coarse chromatin and prominent nucleoli that often show nuclear abnormalities.

Pathology of Prostate Cancer

Prostatic Intraepithelial Neoplasia

PIN represents the putative precancerous end of the morphologic continuum of cellular proliferation within prostatic ducts, ductules, and acini.[76,139] The histologic diagnosis requires both cytologic and architectural abnormalities, and lesions displaying some but not all such changes are considered atypical. PIN is designated as low grade or high grade, based on relative nuclear and nucleolar enlargement. The continuum culminating in high-grade PIN, and henceforth in early invasive cancer, is characterized by basal cell layer disruption, loss of markers of secretory differentiation, nuclear and nucleolar abnormalities, increased proliferative potential, and variations in DNA content (i.e., aneuploidy).[140-142] Rubin described *TMPRSS2-ERG* fusion genes in PIN intermingled with invasive cancer carrying the same fusion pattern. Using antibodies specific for ERG rearrangements, they observed ERG oncogene overexpression in high-grade PIN but not in adjacent benign prostate tissue.[143] Virtually all measures of phenotype and nuclear abnormality by computer-based image analysis reveal similarities between PIN and invasive cancer, in contrast with normal and hyperplastic epithelium.[77] The recognition of PIN should serve as an indication for a thorough search for invasive cancer because of their close association.[76,139]

Histologic Appearance

Gross identification of prostate cancer may be difficult or impossible, and definitive diagnosis requires microscopic examination. In radical prostatectomy specimens, cancer is often multifocal, with a predilection for the peripheral zone. Tumor foci must be at least 5 mm in greatest dimension to be grossly apparent and appear yellow-white with a stony-hard consistency caused by stromal desmoplasia or inflammatory processes.

The minimal criteria necessary to establish a diagnosis of prostate cancer in biopsy material are described by Algaba et al.[144] Approximately 99% of prostatic cancers are adenocarcinomas that have a microscopic appearance consisting of a proliferation of small acini with multiple patterns. Evaluation of small acinar proliferation of the prostate can be a diagnostic challenge, particularly when the suspicious focus is small. Diagnosis relies on a combination of architectural and cytologic findings that may be enhanced by ancillary studies such as immunohistochemistry. Architectural features include irregular glandular contours that deviate from the smoothly rounded contours of normal prostatic glands. The fact that glands are usually regular in shape is useful because malignancies often exhibit an irregular and haphazard arrangement. Noting variations in gland size can also be of value, and comparison with adjacent normal prostatic glands may be useful. Atypical cytologic features are also important for the diagnosis of cancer because nuclear and nucleolar enlargement is seen in the majority of cells suspicious for cancer.

The basal cell layer is critical to the diagnosis of adenocarcinoma because an intact basal cell layer is present at the periphery of benign glands, whereas a basal cell layer is entirely lacking in carcinoma. However, small foci of adenocarcinoma clustered around larger glands, which have an intact basal cell layer, may occasionally compound diagnostic difficulty, and it may be useful to employ monoclonal antibodies against high-molecular-weight keratin (HMWK) to evaluate the basal layer. Alpha-methylacyl-CoA racemase (AAMCR) is preferentially expressed prostate cancer[145] and P63 is an important marker for basal cells[146] that aid in the immunohistochemical diagnosis of prostate cancer. Other ancillary histologic features that may aid in diagnosis include acidic mucin in the acinar lumen, eosinophilic crystalloids, and microvascular invasion. Inflammation should be noted when evaluating small glandular proliferation because reactive atypia may result or may be seen in the setting of prior RT, infarction, or other conditions.

Morphologic Variants

Several unusual morphologic variants (e.g., mucinous, prostatic duct, small cell, and transitional cell carcinomas) of prostatic carcinoma have been identified but account for less than 10% of cases. These tumors are usually associated with typical acinar adenocarcinoma and rarely occur in pure form. It is important to recognize the special variants and to understand the criteria that distinguish them from benign mimics. Although data are limited, the clinical behavior and prognostic significance of the morphologic variants may differ from typical prostatic adenocarcinoma.[147]

Grading

The Gleason system, based on a Veterans Administration study of more than 4000 patients, has become the global standard for grading prostate cancer (Figure 53-1). The Gleason system is based on the degree of glandular differentiation and an overall pattern of tumor growth at relatively low microscopic magnification.[148] Five patterns of growth are recognized and numbered in order of increasing aggressiveness. Because tumors may display variable histology, two patterns are recorded for each case: a primary or predominant pattern (Gleason 1-5) and a secondary or lesser pattern (Gleason 1-5). The Gleason score is the sum of the primary and secondary

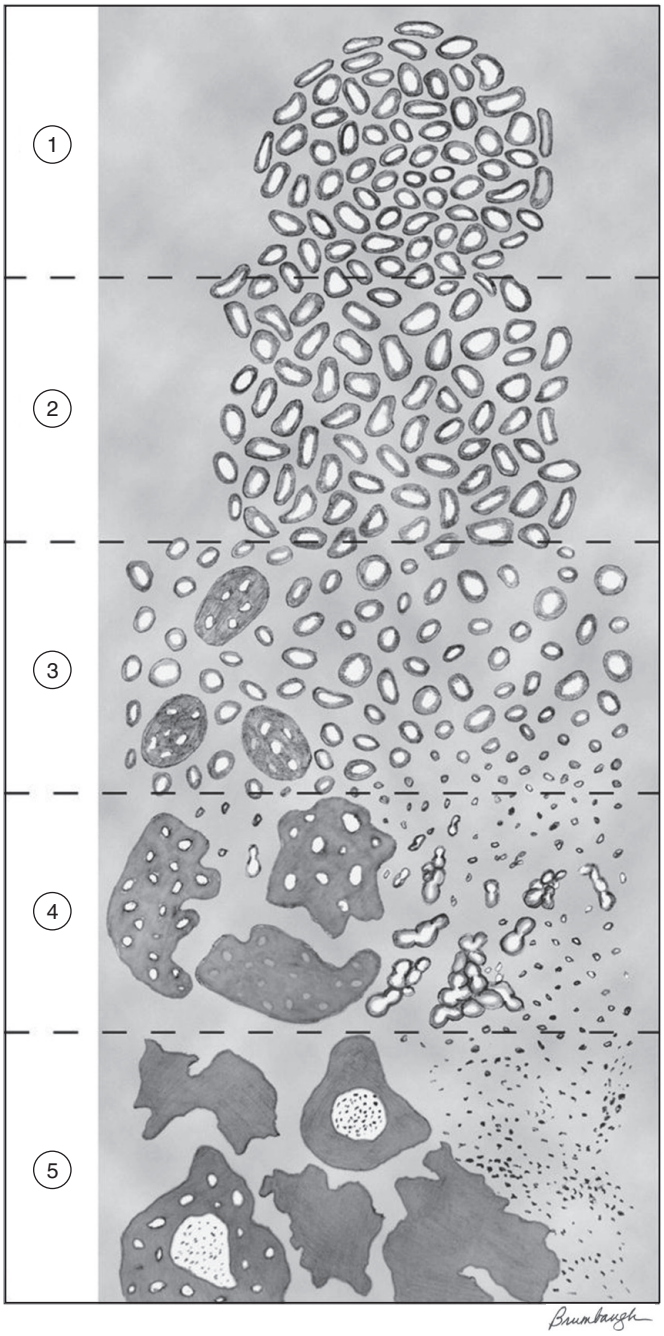

Figure 53-1 Schematic drawing of modified Gleason grading system. *From Epstein JI, et al: The 2005 International Society of Urological Pathology (ISUP) Consensus Conference on Gleason Grading of Prostatic Carcinoma. Am J Surg Pathol 29:1228–1242, 2005.*

patterns and ranges from 2 to 10. If only one pattern is present, the primary and secondary patterns receive the same designation. Gleason noted that more than half of prostate cancers contain two or more patterns,[149] and Aihara et al[150] found an average of 2.7 different Gleason grades in a series of prostatectomy specimens. Interobserver and intraobserver variability has been reported with the Gleason and other grading systems, and Gleason noted exact reproducibility of score in 50% of needle biopsies, and >1 score in 85% of cases.[149]

In 2005, the International Society of the Urological Pathologists held a consensus conference to update the guidelines for Gleason scoring.[151,152] The modifications were felt to be necessary because of the evolving roles of PSA screening and TRUS-guided biopsy techniques on the diagnosis and identification of cancer in needle core specimens. For example, the Gleason scoring system predated the use of immunohistochemical staining for basal cells. Many of the grade 1 + 1 = 2 adenocarcinomas diagnosed in the past would now be considered adenosis because of an intact basal layer. Furthermore, it was made clear that Gleason score 3 or 4 should rarely be applied to ultrasound-acquired biopsies because these are rarely present in the peripheral zone but more typically found by transurethral resection of the prostate (TURP) of the transition zone. In addition, the finding that a cribriform pattern is more aptly included as a Gleason grade-4 pattern has shifted some Gleason score 6 cases to Gleason score 7. These changes have resulted in a grade migration over the past decade that has paralleled the stage migration witnessed as a result of PSA screening.[153] In a review of 1240 radical prostatectomy specimens, the modified Gleason scoring system resulted in upgrading of patients with classic Gleason 6 cancers 34% of the time. Patients with tumors upgraded to Gleason 7 indeed had worse biochemical and metastatic disease progression than patients whose tumors remained Gleason 6.[154]

Although a correlation exists between the needle biopsy tumor grade and that found in the prostatectomy specimen, a higher grade (i.e., more poorly differentiated) is identified in approximately one third of cases.[148,155,156] The correlation is strongest for the primary Gleason pattern, but the secondary pattern also provides useful predictive information, particularly when used to create the Gleason score.[148] The incidences of undergrading and understaging are decreasing related to stage migration as well as the elimination of Gleason scores 2 to 4 biopsy specimens.[157,158] In a series of 1455 men undergoing radical prostatectomy at Johns Hopkins, Fine and Epstein reported 80.0% accuracy of biopsy Gleason scores of 6 or less on final surgical pathology.[158] For patients with biopsy Gleason scores of 7 or greater, 25% were less than Gleason score 7 on final pathology. Whereas in the past downgrading of high grade cancers was uncommon at radical prostatectomy, one quarter to one half high-grade cancers are now downgraded at surgery.[158-163]

Pathologic Staging

The criteria for assigning pathologic classification and stage were developed by the American Joint Commission on Cancer (AJCC) and the International Union Against Cancer (Tables 53-1 and 53-2).[164,165] Currently, the AJCC 7th edition is in use.[164] The details of handling, processing, and recording histologic findings of biopsy, radical prostatectomy, and nodal dissection tissue specimens are described in detail by the Association of Directors of Anatomic and Surgical Pathology.[166] Thorough examination of radical prostatectomy (RP) specimens is critical for tumor classification and should allow accurate determination of pathologic stage, Gleason score, tumor volume, and surgical margin status. Pathologic stage is assessed by determining the presence or absence of extraprostatic extension (EPE), seminal vesicle invasion (SVI), and lymph node involvement (LNI).

Extension of cancer beyond the edge or capsule of the prostate is diagnostic of EPE. The identification of tumor cells in fat is the only reliable way to diagnose EPE on needle biopsy specimens.[166] In radical prostatectomy specimens, designation of EPE requires identification of tumor cells admixed or abutting fat or extending beyond the dense smooth muscle of the prostate to involve the loose connective tissue or less compact smooth muscle outside the prostate.[166] Difficulty is occasionally encountered in the presence of a dense desmoplastic response in extraprostatic tissue, particularly in cases treated

TABLE 53-1 American Joint Commission on Cancer TNM Staging Classification

Classification		Definition
PRIMARY TUMOR (T)		
Clinical		
Tx		Primary tumor cannot be assessed
T0		No evidence of primary tumor
T1		Clinically inapparent tumor neither palpable nor visible by imaging
	T1a	Tumor incidental histologic finding in 5% or less of tissue resected
	T1b	Tumor incidental histologic finding in more than 5% of tissue resected
	T1c	Tumor identified by needle biopsy (for example, because of elevated PSA)
T2		Tumor confined within prostate[a]
	T2a	Tumor involves one-half of one lobe or less
	T2b	Tumor involves more than one-half of one lobe but not both lobes
	T2c	Tumor involves both lobes
T3		Tumor extends through the prostate capsule[b]
	T3a	Extracapsular extension (unilateral or bilateral)
	T3b	Tumor invades seminal vesicle(s)
T4		Tumor is fixed or invades adjacent structures other than seminal vesicles, such as external sphincter, rectum, bladder, levator muscles, or pelvic wall
PRIMARY TUMOR (T)		
Pathologic (pT)[c]		
pT2		Organ confined
	pT2a	Unilateral, one-half of one side or less
	pT2b	Unilateral, involving more than one-half of side but not both sides
	pT2c	Bilateral disease
pT3		Extraprostatic extension
	pT3a	Extraprostatic extension or microscopic invasion of bladder neck[d]
	pT3b	Seminal vesicle invasion
REGIONAL LYMPH NODES (N)		
Clinical		
Nx		Regional lymph nodes were not assessed
N0		No regional lymph node metastasis
N1		Metastasis in regional lymph node(s)
Pathologic		
pNx		Regional nodes not sampled
pN0		No positive regional nodes
pN1		Metastases in regional node(s)
DISTANT METASTASIS (M)[e]		
M0		No distant metastasis
M1		Distant metastasis
	M1a	Nonregional lymph node(s)
	M1b	Bone(s)
	M1c	Other site(s) with or without bone disease

[a]*Tumor found in one or both lobes by needle biopsy, but not palpable or reliably visible by imaging, is classified as T1c.*
[b]*Invasion into the prostatic apex or into (but not beyond) the prostatic capsule is classified not as T3 but as T2.*
[c]*There is no pathologic T1 classification.*
[d]*Positive surgical margin should be indicated by an R1 descriptor (residual microscopic disease).*
[e]*When more than one site of metastasis is present, the most advanced category is used. pM1c is most advanced.*

TABLE 53-2 American Joint Commission on Cancer Stage Grouping for Prostate Cancer

Anatomic Stage/Prognostic Groups*					
Group	**T**	**N**	**M**	**PSA**	**Gleason**
I	T1a-c	NO	MO	PSA < 10	Gleason ≤ 6
	T2a	NO	MO	PSA < 10	Gleason ≤ 6
	Tl-2a	NO	MO	PSA X	Gleason X
IIA	T1a-c	NO	MO	PSA < 20	Gleason 7
	T1a-c	NO	MO	PSA ≥ 10 < 20	Gleason ≤ 6
	T2a	NO	MO	PSA ≥ l0 < 20	Gleason ≤ 6
	T2a	NO	MO	PSA < 20	Gleason 7
	T2b	NO	MO	PSA < 20	Gleason ≤ 7
	T2b	NO	MO	PSA X	Gleason X
IIB	T2c	NO	MO	Any PSA	Any Gleason
	T1-2	NO	MO	PSA ≥ 20	Any Gleason
	T1-2	NO	MO	Any PSA	Gleason ≥ 28
III	T3a-b	NO	MO	Any PSA	Any Gleason
IV	T4	NO	MO	Any PSA	Any Gleason
	AnyT	N1	MO	Any PSA	Any Gleason
	Any T	Any N	M1	Any PSA	Any Gleason

**When either PSA or Gleason is not available, grouping should be determined by T stage and either PSA or Gleason as available.*

by AD. Perineural invasion may exist in the absence of EPE. The anterior muscle is an uncommon site for EPE; this is observed only with large tumors involving the transition zone. Reporting EPE at the apex is challenging because of the vague boundaries of the capsule in this region. Most patients (57% to 81%) with EPE have involved surgical margins,[167] which predicts a worse prognosis.

Positive surgical margins are defined as cancer cells touching the inked surface of the prostatectomy specimen. Care must be taken to avoid interpreting ink within tissue crevices created by postoperative handling of the specimen as margin positivity. It is important to note that the status of the surgical margin is not explicitly included in pathologic staging, and pathologists and clinical investigators should describe surgical margin status separately from EPE. Positive surgical margins can be present in the absence of EPE because of capsular incision (pT2+ disease).

Seminal vesicle invasion is a pathologic finding associated with an increased risk for disease relapse[168,169] and occurs when tumor extends into the region where vas deferens and seminal vesicle converge at the prostatic base.[170] Direct tumor growth from this location along the ejaculatory duct complex or through the prostatic capsule may result in seminal vesicle invasion. This mechanism accounts for the observations that tumor volume is often greatest at the prostatic end of the seminal vesicle in the vicinity of the vas deferens,[170] that involvement of both seminal vesicles is a common finding,[169] and that isolated deposits of prostate cancer remote from the ejaculatory duct complex are observed in only one eighth of seminal vesicle specimens involved with tumor.[169] Microscopic involvement of the bladder neck is not a pT4 designation. Patients with microscopic bladder neck invasion have a prognosis similar to those with seminal vesicle invasion and should be designated pT3a.[164,171]

Postirradiation Histology

For approximately 18 to 24 months after EBRT, and perhaps longer for interstitial implantation, needle biopsy of the prostate in the absence of clinical disease progression is of limited value because of delayed and continuing tumor cell death.[172]

After this period, needle biopsy is associated with a lower level of diagnostic error that is minimized by obtaining multiple specimens.[173-175] Histologic changes of prostatic radiation injury include acinar atrophy, shrinkage and distortion, marked cytologic abnormalities of the epithelium, basal cell hyperplasia, stromal fibrosis, and a decreased ratio of acini to stroma.[172] Vascular sclerosis is also prominent and may involve small and large vessels. Although a definitive method to assess tumor viability after RT does not exist, PSA and PAP expression persists,[176] suggesting that tumor cells capable of protein production retain the potential for cell division and spread.[177,178] Keratin 34αE12 expression also persists and is often of value in separating treated adenocarcinoma from some of its mimics. AMACR staining may be lost in nonneoplastic epithelium but can persist in residual tumor cells. Proliferative cell nuclear antigen (PCNA) may improve the sensitivity and specificity of a postirradiation biopsy. Negative PCNA staining in an otherwise positive biopsy predicts (83% to 97% for eventual resolution of tumor, whereas positive PCNA staining is correlated with a local failure in 49% to 79% of cases.[177] Grading of cancer following RT can be problematic.[179,180] Squamous metaplasia is common and the acini have nuclei that are large and hyperchromatic with conspicuous nucleoli. The tumor may show loss of architectural features suggestive of higher grade. Cancer grading after RT has yielded conflicting results: some observers noted no difference in pretherapy grade or behavior,[172,181] whereas others found increased grade.[182] There is better success at applying a postirradiation Gleason score in cases where the radiation treatment effect is minimal. If considerable treatment effect is seen, then grading is problematic.[179,180]

Effects of Androgen Deprivation

AD of normal, hyperplastic, and dysplastic epithelial cells causes acceleration of programmed cell death (i.e., apoptosis), with fragmentation of tumor DNA, emergence of apoptotic bodies, and inhibition of cell growth. Global glandular atrophy can be seen but it tends to be more prominent in the peripheral zone.[179] Furthermore, there is reduced nuclear size, loss of nucleoli, chromatin condensation, nuclear pyknosis, and cytoplasmic vacuolation.[183,184] However, grading may be misleading and is to be avoided.[184] AMACR, PSA, PAP, and keratin 34αE12 immunohistochemistry are useful in identifying carcinoma because AMACR, PSA, and PAP are retained and 34αE12 remains negative. Expression of neuroendocrine differentiation markers (e.g., chromogranin, neuron-specific enolase), remains unaltered, whereas proliferative activity, as measured by Ki67 (MIB-1) or PCNA immunoreactivity, is reduced after AD.[179,184]

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

Molecular Biology

As our understanding of the molecular biology of prostate cancer grows, it is conceivable that treatment can become personalized with agents that specifically target the genomic or metabolic characteristics of a particular patient's cancer. Increasing focus is given to the role of the androgen receptor (AR) in the tumorigenesis, treatment, and prognosis of prostate cancer.[187] Androgens, along with multiple coregulatory factors, activate the AR leading to transcription of AR target genes promoting the growth of normal and neoplastic prostate tissue. The ETS family of genes is transcription factors that are involved in a variety of functions including cellular differentiation and cell cycle control. Several ETS factors have been implicated in carcinogenesis through gene rearrangements. Tomlins et al have identified recurrent gene fusions of two ETS transcription factors, ERG and ETV1, to the *TMPRSS2* gene.[188] In their initial series, the *TMPRSS2-ERG* gene rearrangement was identified in 47% of clinically localized prostate cancers. *TMPRSS2* is expressed in normal luminal epithelial and neoplastic prostate tissue and is strongly induced by androgen in androgen-sensitive prostate cell lines. *TMPRSS2-ERG* fusion gene can be detected in a proportion of high-grade PIN lesions and that this molecular rearrangement may be an early event that precedes chromosome-level alterations in prostate carcinogenesis.[189] The importance of the TMPRSS2-ERG fusion as an early event in the development of prostate cancer is supported by the homogenous distribution of the fusion gene in a prostate cancer, the absence of the fusion in benign prostate tissue, and the association of *TMPRSS2-ERG*–positive cancers associated with the same fusion in high-grade PIN lesions.[190] Mutation or changes in AR expression may account for the development of androgen-independent prostate cancer. ERG overexpression, mediated through *TMPRSS2-ERG* fusion, contributes to development of androgen-independence through disruption of AR signaling. Yu found that ERG inhibits AR expression and activity and induces repressive epigenetic programs that contribute to AR and cancer progression.[191] Unfortunately, early clinical data has not shown the TMRPSS2-ERG status to be predictive of response to radiation therapy.[192]

As acknowledged, slightly less than half of all prostate cancers harbor rearrangements of the ETS transcription factor family. Other common genome rearrangements include SPOP mutant and the serine peptidase inhibitor Kazal type 1 (SPINK1) overexpressing subtypes. The SPOP gene encodes for the substrate-recognition component of an ubiquitin ligase. This protein affects a variety of pathways, including hedgehog, c-Jun-N-terminal kinase, and components of steroid receptor signaling. Inhibitors of these pathways are being tested for prostate cancer activity. Likewise, the fact that epidermal growth factor receptor (EGFR) mediates part of the oncogenic properties of SPINK1 provides a rationale for EGFR inhibition in these tumors.

Predictive Factors

Pathologic Endpoints

The therapeutic efficacy of RT and RP depends on the accurate determination of tumor burden and the risk of subclinical disease. Despite the clinical impression of disease confined to the prostate gland, occult tumor extension through the prostatic capsule or involvement of seminal vesicle(s) or regional lymph nodes is common at the time of diagnosis. Compared with surgical-pathologic stage, the clinical staging of prostate cancer frequently underestimates disease extent, and many patients are "upstaged" after RP with pelvic node dissection.[193] Among patients thought to have prostate confined disease by clinical assessment, variable proportions of patients will be found to have extracapsular extension (ECE), SVI, or lymph node involvement at the time of prostatectomy with the likelihood of these findings correlated with pretreatment characteristics such as T category, Gleason grade, and PSA level[194] (eTable 53-2). Because these findings may have considerable importance for selection of an appropriate therapeutic strategy (e.g., radioactive seed implantation or RP versus EBRT), several investigators studied the association between readily available pretherapy factors and the pathologic endpoints of extraprostatic tumor extension, SVI, and pelvic LNI.

Extraprostatic Extension

EPE is a pathologic feature that is associated with a worse outcome following RP.[196-200] Several pretherapy tumor-related

The PCPT has provided important information about the impact of 5α-reductase inhibitors on the histological appearance of prostate cancer. The initial report of the PCPT suggested that the rate of high-grade tumors was increased with the use of finasteride. Subsequent reports suggest that the drug may have reduced the volume of benign prostate tissue and low-grade cancer thereby increasing the likelihood of identifying higher grade disease.[185,186]

From Eifler JB, Feng Z, Lin BM, et al: An updated prostate cancer staging nomogram (Partin tables) based on cases from 2006 to 2011. Br J Urol 111:22–29, 2012.[195]

EPE, *Extraprostatic extension;* LN+, *lymph node involvement;* OC, *organ confined;* PSA, *prostate-specific antigen;* RP, *radical prostatectomy;* SV+, *seminal vesicle involvement.*

factors are associated with EPE, and these include clinical tumor stage,[193] pretherapy serum PSA value,[193] prostatic biopsy tumor grade,[193] microvessel density (i.e., neovascularity),[201] and percent of biopsy containing cancer.[201] Although any of these factors may be individually used to estimate the likelihood for EPE, the accuracy of such estimates is enhanced by combining those factors that independently contribute to the predictive model.[193,194,202] The extent of EPE is associated with the risk of clinical failure. Epstein reported significantly worse rates of progression with established ECE compared to pathology specimens that had just a few malignant glands outside the capsule.[198] Wheeler defined extensive EPE as tumor extending more than one high-power field outside the capsule on more than two separate sections.[197] Both focal and extensive EPE were significantly associated with other adverse findings such as seminal vesicle involvement and lymph node metastases as well as a lower progression-free probability (73% and 42%) compared to no progression in the absence of any capsular invasion.[197]

In the PSA era, Partin et al[203] were among the first to use multivariate statistical analysis to identify pretherapy variables associated with EPE in patients who underwent RP and demonstrated that clinical tumor stage, Gleason score of the diagnostic biopsy, and serum PSA level independently correlate with this finding. The combination of these factors was used to develop probability estimates, which were displayed as a nomogram and later incorporated into clinical practice guidelines for patient management. Kattan et al[202] conducted a separate validation study that confirmed that the nomogram discriminated well between men with organ-confined disease and those in whom the disease extended beyond the prostate gland. The updated Partin nomogram eTable 53-2 may be useful for predicting the probability of organ-confined status,[195] but any estimation should consider the confidence of the prediction, as indicated by the associated 95% confidence intervals, for the combination of factors relevant to the new patient under consideration.

Seminal Vesicle Invasion

SVI is a pathologic finding associated with an increased risk for disease relapse.[168,169,196,204] The adverse prognostic impact of SVI is exceeded only by lymph node metastases.[205] In a multiinstitutional study of 6740 patients undergoing RP, Baccala reported 10-year biochemical relapse-free survival of 77.2% without SVI compared to 25.6% with SVI.[204] Several investigators have correlated pretherapy tumor-related factors with SVI as a means to identify patients with a high likelihood for this condition.[169,193,202,204,206-209] These studies demonstrate that clinical tumor stage, tumor grade of the diagnostic biopsy specimen, percentage of cancer in the biopsy, and serum PSA level are associated with SVI in a statistically significant manner.

Although serum PSA level was the best single predictor, Partin et al[193] noted that clinical tumor stage and Gleason score contributed to SVI risk estimation and so were among the first to combine these factors to develop nomograms for clinical use. Thereafter, Diaz et al used this information to create a prediction equation.[210] However, Kattan et al[202] applied the original SVI nomogram of Partin et al[193] to an independent data set and concluded that the nomogram was suspect, particularly in the areas of high predicted probability, and ill-suited to clinical application. In the RP series reported by Baccala, the biopsy Gleason score and clinical stage T3 were more predictive of SVI than PSA.[204]

In response to Kattan et al, Partin et al performed a multiinstitutional analysis in which updated nomograms were developed and validated.[211] Although this provides useful information, patients were only assigned to the most advanced and mutually exclusive pathologic category based on the findings of the RP and PND specimens for the analysis. Furthermore, all these data are derived from patients selected for radical prostatectomy and may underestimate the true extent of disease in men not considered suitable for surgery. Although these nomograms may be appropriate for the surgical candidate, the risk of SVI may be underestimated with this approach, and caution is necessary in using the revised nomogram for other purposes (e.g., RT target volume definition).

Nodal Involvement

Clinical T category, prostatic biopsy tumor grade, and serum PSA level are also associated with pelvic LNI, and a combination of these factors may be used to predict the probability of LNI in the patient with a new diagnosis of clinically localized prostate cancer.[193,206,212,213] Partin et al[193,203] incorporated these factors in a LNI predictive nomogram. Kattan et al[202] were not able to validate the LNI nomogram in a separate group of patients and suggested that the nomograms were not broadly applicable. As a result, Partin et al[211] used a different mathematical method to analyze a larger and more diverse study population and provided revised nomograms to estimate the probability of LNI.[193,194]

Clinical Endpoints

Factors predictive of clinical endpoints may be grouped according to whether they are patient related, are intrinsic to the neoplasm (i.e., tumor related), or are treatment related. It is essential to recognize that a factor may have importance only in certain patient subsets (e.g., those with clinically localized disease) but not in other settings (e.g., metastatic disease). Furthermore, different endpoints may be considered (e.g., local tumor control, metastatic relapse, biochemical relapse [BCR], cause-specific or overall mortality), and a particular factor may have significance for some, but not all endpoints.

Patient-Related Factors

Patient age had been identified as a prognostic factor in older series of patients managed with surgery, RT or expectant management.[215-219] These reports have offered conflicting results suggesting that younger patients did better with expectant management in some series[216,220] whereas older patients fared worse in others.[215] Similarly, some series suggest a worse prognosis with surgery or radiation therapy for younger patients[217,219,221-223] whereas others do not.[224-230] A meta-analysis of 34 studies with more than 27,000 patients did not show an association between age and outcome in the PSA era.[231] Parker speculated that PSA screening may have eliminated the impact of age on prognosis because of less delay in diagnosis, improved measures of outcome, a screening related age-specific lead-time bias, and an interaction between age and tumor grade.[231]

Racial and ethnic disparities for the outcome of patients after diagnosis and treatment exist for many malignancies, including prostate cancer. African Americans are more likely to be diagnosed with advanced stage and higher grade prostate cancer than whites or non-African American minorities.[1] The survival rate of African American men is inferior to that of non-Hispanic white men with localized prostate cancer.[38,232] The reason for these disparities are unclear and may be related to variations in genetics, nutrition, socioeconomic status, clinical and surgical staging procedures applied to different races, or access to care or inherent differences in cancer biology. SEER data has shown a difference in the rate of radical prostatectomy and surgical staging being performed in African American men with localized prostate cancer.[233]

The presence of coexistent medical ailments (e.g., ischemic heart disease) in a patient with prostate cancer may have a significant impact on treatment decisions. These comorbidities

In a series of 588 men undergoing RP with an extended pelvic lymph node dissection, Briganti identified the percentage of positive biopsy cores as being the single-most important factor predicting LNI.[214] In a multivariate analysis, clinical T-category, primary biopsy Gleason grade and percentage of positive cores were independent predictors of LNI. They developed a nomogram that could identify men who could be spared an extended pelvic lymph node dissection.

In a secondary analysis of RTOG clinical trial data where eligibility and treatment guidelines were prescribed according to study specifications, Roach reported that the observed inferior survival of black Americans was likely related to their presentation with more advanced disease and not resulting from inherent biological differences in their cancer.[234] In a review of SWOG trials, the survival of African American men with advanced stage prostate cancer was worse than all other patients, even when corrected for differences in socioeconomic status.[235] Two other studies suggest that even when effects of age, presenting PSA, Gleason score, and stage are controlled, a difference in PFS persists.[236,237] Moul demonstrated differences in outcome in men treated with radical prostatectomy in an "equal access" medical system (i.e., the U.S. military).[238] There is recent evidence for differences in presentation and outcome for Hispanic men with localized prostate cancer,[239] but few to no reliable estimates exist for the Native American, Native Alaskan, Asian or Pacific Islander populations. Therefore, it appears that some evidence suggestive of biologic differences in patient subgroups is emerging.

may determine whether or not a patient is a candidate for an aggressive surgical intervention or whether the patient should be treated at all. These nonprostate cancer–related treatment selection criteria have a profound impact on outcome reporting that are unrelated to the effectiveness of any specific treatment strategy. Several instruments are available to quantify the severity of comorbidity.[240] The selection of a particular management approach based on overall health status has important implications in interpreting and comparing outcomes, because OS and, perhaps, CSS estimates will be influenced.[240-243] The selection of a particular management approach based on overall health status has important implications in interpreting and comparing outcomes, because OS and, perhaps, CSS estimates will be influenced.[240-243] A nomogram has been described that may allow estimation of life expectancy and aid physicians and patients in choosing treatment strategies.[240]

Tumor Category

The anatomic extent of prostate cancer is an important tumor-related factor predictive of patient outcome. Studies consistently demonstrate the association of primary tumor category with several endpoints in patients with localized disease. Cause-specific survival (CSS) and OS are directly related to the extent of the primary tumor in both RT[244-246] and expectant management[216,247,248] series. The probability of local tumor control[249] and the risk of clinical,[245,250] metastatic,[249,251] and biochemical relapse[225,227,228,246] are influenced in a similar manner. Increasingly T category is combined with other prognostic factors (e.g., initial PSA, tumor grade) to define prognostic groups and report outcomes. Despite this, T-category remains an important factor in selecting optimal local therapy.

Surgical Margins

Modifications to surgical technique have resulted in an improvement in the rate of positive margins with an open prostatectomy technique[252]; however, even with laparoscopic and robot-assisted procedures the rates of positive margins remain as high as 50% and 28%, respectively.[253] In a systematic review and meta-analysis, Tewari abstracted data from more than 400 articles representing 286,876 RPs. After adjusting for preoperative variables, robot-assisted RPs had lower rates of positive margins compared to nonrobot-assisted RPs but not open RPs.[254] Positive margins are typically located at the apex (48%), rectal and lateral surfaces (24%), bladder neck (15%), and posterior pedicles (10%).[167,255] The presence of a positive surgical margin (PSM) increases the likelihood of biochemical relapse, local recurrence, and the need for salvage therapies.[256-258] In a series of 11,729 men undergoing radical prostatectomy between 1990 and 2006, Boorjian reported PSMs in 31% of cases.[256] Patients with positive margins had a biochemical relapse-free survival (bRFS) rate of only 56% compared to 77% ($p < 0.0001$) and a local RFS of 89% compared to 95% ($p < 0.0001$) in patients with negative margins. In some series, patients with PSMs also had a significantly worse systemic RFS, CSS, and OS. In a pooled series of 7816 patients from eight academic urology centers, the presence of a PSM increased the risk of biochemical relapse by 3.7-fold.[258] When combined with risk factors such as high Gleason score or initial PSA, the presence of positive margins is more predictive of clinical failure.[259,260]

It had been suggested that an apical positive margin may actually represent an artifact in the processing of prostatectomy specimens and it may not carry as great a prognostic significance as margins involved elsewhere.[261,262] Analyses of randomized trials evaluating the role of adjuvant radiation therapy failed to show any differences in outcome by site of surgical margin involvement.[263,264]

The extent of surgical margin involvement has been reported to carry prognostic significance.[265-269] In a series of 2468 patients, Lake reported that even focally positive margins (≤3 mm) in patients with organ-confined disease conferred a significant decrease in disease free survival (DFS).[267] The 10-year DFS for patients with organ confined disease was 84%, 64%, and 38% with negative, focally positive, and extensively positive margins (>3 mm), $p < 0.0001$.[267] The data argue strongly that the presence of a PSM has a profound impact on patient prognosis and such patients should be considered for adjuvant therapy.

Nodal Involvement

Tumor spread to regional lymph nodes is associated with a particularly poor outcome following radiotherapeutic or surgical management alone.[268-273] The prognostic significance of the number of involved nodes was identified in some.[273-277] In a series of more than 10,000 patients treated with radical prostatectomy, Boorjian reported that the risk of systemic cancer progression was three-fold greater with one positive node, and another two-fold greater with two or more. One positive node increased the risk of cancer-related death four-fold and when two or more were involved the risk was another two-fold higher.[273] Briganti reported a significantly better 15-year CSS in patients with one or two positive nodes (84%) compared to patients with more than two positive nodes (62%).[277] Schmid et al[275] found that patients with micrometastasis (i.e., ≤5 mm in largest dimension) had significantly better PFS and OS compared with patients with more extensive nodal involvement. In contrast, Srignoli et al[278] found no difference in the risk of subsequent distant metastasis. Cheng et al[279] reported that the risk of distant metastasis in patients with regional nodal involvement was directly proportional to nodal cancer volume, and it was the best predictor of 5-year metastasis-free survival.

Tumor Grade

Long-term case series of EBRT,[227,245,280,281] brachytherapy,[282-284] RP,[285-288] and expectant management[216,247] uniformly identify tumor grade as a strong predictor of disease relapse and mortality in clinically localized prostate cancer. Studies consistently demonstrate that patients with a poorly differentiated tumor (i.e., grades 4 to 5 or Gleason score ≥7) have an increased risk of metastatic disease progression and reduced OS and disease-specific survival (DSS).[247,249,281,289] For the patient with clinical T1 or T2 disease, tumor grade has greater predictive value than does the distinction between T1 and T2 categories.[216,227,249,282,284,288] The association of tumor grade with metastatic relapse[227,249,250] and OS[249] is preserved when pretherapy serum PSA level is considered. Although tumor grade is also associated with DFS and freedom from clinically evident disease relapse,[217,227,290,291] its impact on local tumor control after EBRT is less certain, as some reports noted an association,[244,249] whereas others did not.[290] PSA level (i.e., biochemical control) following local therapy is impacted by tumor grade. Multivariate analysis of pretherapy tumor-related factors for in RT[227,228,249] and surgical[287,289,292] series confirms the significance of tumor grade as a predictor for biochemical relapse.

The relative amount of high-grade cancer in biopsy and surgical specimens predicts for clinical and biochemical outcomes.[293,294] In patients with Gleason score 7, a primary component of Gleason grade 4 (4 + 3) has been associated with a higher rate of metastatic, biochemical, and clinical progression than a primary Gleason grade 3 component (3 + 4) in both surgical[295-298] and RT series.[299] However, although some series demonstrate that the presence of the higher primary Gleason grade is correlated other adverse prognostic factors such as tumor volume, SVI, or positive surgical margins,[297,300] it is not

Albertsen et al applied three comorbidity assessment instruments (i.e., the Kaplan-Feinstein and Charlson indices and the index of coexistent disease) to a cohort of men with localized prostate cancer to assess the impact of comorbidity on patient survival. Although the index of coexistent disease had a marginally better predictive value, each instrument was predictive of age-adjusted survival when corrected for the effect of Gleason score.[240] The risk of death from causes other than prostate cancer (i.e., competing causes) strongly correlated with the severity of comorbidity, and a weak association with prostate cancer–related (i.e., cause-specific) mortality was also noted. Additional research is essential to quantify the confounding effect of comorbidity in the setting of prostate cancer outcomes reporting.

Van Oort reported a higher rate of biochemical relapse in patients when the length of a PSM was more than 10 mm compared to smaller margins.[265] In a series from the Mayo Clinic, Kausik did not detect a difference in relapse rates in patients with EPE and one versus more than one positive margins.[266] In a series of 1712 RP patients, Mauermann reported 10-year bRFS rates of 82% for patients who are margin-negative, 72% for patients with single positive margins, and 59% for patients with multiple positive margins ($p < 0.0001$).

independently associated with a worse outcome in some surgical[297] or RT series.[301-303] Increasingly it is being recognized that tertiary patterns of high-grade adenocarcinoma (Gleason grade 4 or 5) negatively impact prognosis.[294,304-306] Gleason score 7 cancers with any higher grade tertiary pattern have a prognosis following radical prostatectomy that is indistinguishable from patients with a Gleason score 8.[304]

Prostate-Specific Antigen

An abundant literature attests to the importance of the pretherapy serum PSA level as an independent and highly significant predictor of therapeutic outcome.[227,230,249,285,287,307,308] In general the pretreatment PSA level is a measure of tumor volume, although one must also consider the relative PSA contribution from the normal prostate tissue and the fact that some tumors, especially the poorly differentiated ones, may not produce PSA commensurate with the tumor burden. In assessment of post-RT outcome, Landmann and Hunig[309] were the first to draw attention to this association, which was confirmed by the detailed statistical analysis of larger study populations.[227,230,250,251,310,311] Furthermore, the prognostic significance of PSA is not limited to patients treated with RT because similar observations appear in surgical reports.[285,287,289,312,313]

Pretreatment PSA is one of the strongest individual predictors of biochemical relapse.[249,282,285,287,307,314] The effect of pretreatment PSA on outcome increases in a continuous fashion.[228,249] Zagars et al described a relationship between pretherapy PSA and clinical or biochemical relapse after RT.[249] In this series, there was a significant difference in the risk of relapse for pretherapy PSA categories of 4.0 or less, 4.1 to 10.0, 10.1 to 20.0, and more than 20 ng/mL, which was 16%, 34%, 51%, and 89% at 6-year follow-up, respectively. D'Amico described a risk grouping based on pretreatment PSA, Gleason score, and clinical stage.[315] A slightly modified risk group category has been adopted by the National Cancer Center Network and is used for reporting outcomes and to assist in treatment decision making (Table 53-3).[316] Most institutional and other large series now report outcomes by risk stratification group.

The rate of change of the PSA over time may have important diagnostic and prognostic implications. Carter et al reviewed the outcomes of men participating in the Baltimore Longitudinal Study of Aging for up to 39 years. PSA velocity measured 10 years to 15 years before a diagnosis of prostate cancer was correlated with prostate cancer-specific survival 25 years later.[322] The prostate cancer specific survival was 92% in men with a PSA velocity of 0.35 ng/mL per year or less compared to 54% with a PSA velocity of more than 0.35 ng/mL per year ($p < 0.001$). D'Amico reported that the risk of prostate cancer death in men undergoing radical prostatectomy[323] or EBRT[324] because localized prostate cancer was higher if the PSA velocity was more than 2.0 ng/mL per year. Against these observations are the prospective data from the large screening and prevention trials. The ERSPC trial found that PSA velocity did not improve cancer detection and the PLCO model for cancer detection was not significantly affected when velocity was excluded from the algorithm.[325,326] The PCPT found that velocity did not contribute independent prognostic information and the Scandinavian SPCG4 trial determined that PSA changes before diagnosis were not predictive of fatal prostate cancer.[84,327]

PSA doubling time (PSADT) is as a useful tool to estimate prognosis and guide treatment decisions. Derived from the same data as PSA velocity (PSAV), which measures the absolute rate of change, PSADT is calculated as the slope of PSA measurements over time. PSADT represents the relative rate of PSA change over time and is the time needed for the PSA value to double. PSADT takes into account the exponential nature of prostate cancer growth and requires logarithmic conversion using the formula:

$$PSADT = \frac{\log 2x(T2 - T1)}{\log PSA2 - \log PSA1}$$

A number of PSADT calculators are available for use on handheld computing devices or from web pages (www.nomograms.org, www.nomogram.org). Klotz has proposed that PSADT be used as a factor in the selection of patients for active surveillance.[248] A PSADT of 3 years or less is associated with an 8.5-fold greater risk of biochemical failure after definitive treatment than longer PSADT. Hanks et al[328] used PSADT as a pretherapy predictive factor in patients treated with EBRT and found that a PSADT of less than 12 months adversely affected therapeutic outcome. Most reports have focused on posttreatment PSADT to predict the clinical outcome of patients with biochemical relapse after RT[229,290,329-333] or surgery.[332-335] Although there is considerable individual variation, a local tumor recurrence tends to correlate with a longer PSADT (median, 12 to 14 months), whereas a shorter PSADT (median, 4 to 6 months) is observed for metastatic relapse.[311,336] The posttreatment PSADT in patients that have failed treatment with RT is similar to that observed in surgical patients.[337]

After RT, residual prostatic epithelial cells may produce PSA under androgenic stimulation, and serum levels of PSA may be detected even in the absence of prostate cancer.[338] The post-RT nadir PSA (nPSA) level is considered to be a predictive variable similar to pretherapy factors.[227,331,339-341] The nPSA correlates with pretherapy PSA level, tumor grade, and clinical T category[341,342] but is an independent predictor associated with biochemical or clinical relapse,[311,339,340,343] and with local and metastatic tumor control.[317,331,340] Alcantara reported a 10-year distant metastasis rate of 4% versus 19% in men with a 12-month nPSA of ≤2 ng/mL versus >2 ng/mL, $p < 0.0001$.[342] Zelefsky reported the incidence of distant metastases was 10.3% and 17.5% at 10 years in men that had a 2-year nadir

TABLE 53-3 National Cancer Center Network Prostate Cancer Risk Grouping

Relapse Risk	T Category	Grade	PSA (ng/mL)	Comments
Very low risk	T1a	GS ≤ 6	<10	Fewer than 3 biopsy cores positive, ≤ 50% cancer in each involved core, PSA density < 0.15 ng/mL/g
Low risk	T1-2a	GS = 2-6	<10	All three factors
Intermediate risk	T2b-2c	GS = 7	10-20	Any one of the three factors
High risk	T3a	GS = 8-10	> 20	Any one of the three factors
Very high risk	T3b-T4	Any	Any	
Metastatic	Any T	Any grade	Any PSA	N1M0 or NanyM1

Although numerous studies relate pretherapy PSA level to biochemical relapse, reports using clinical endpoints are not as abundant.[249,250,317] Nonetheless, Crook et al[318] affirmed that local tumor recurrence correlated with pretreatment PSA in patients in whom serial post-RT prostatic biopsies were performed. Zagars et al[249] reported a similar finding in a study population in whom post-RT prostatic biopsies were generally obtained to identify an otherwise unknown source for biochemical relapse. Studies with long enough follow-ups to document clinical disease relapse, local and distant, are now being reported and correlate clinical endpoints with pretreatment PSA levels.[227,285,291]

In an effort to improve the prognostic accuracy of pretherapy serum PSA many investigators have examined derivatives of the serum PSA including PSAD (a correction for benign prostate gland volume) or PSA kinetics (velocity of rise or doubling time). Zentner et al[317] evaluated PSAD (i.e., the PSA value divided by prostatic volume) in patients treated with EBRT. Patients with a PSAD of 0.3 ng/mL/cm^3 or less had a 100% DFS probability at 30 months, whereas the estimate for patients with PSAD of more than 0.3 ng/cm^3 was significantly worse (62%). Others have not shown this association and PSAD does not appear to add significantly to the utility of serum PSA level as a predictor of outcome after EBRT, and it is not routinely used as a prognostic factor.[319-321]

value of ≤1.5 ng/mL versus >1.5 ng/mL, $p < 0.002$).[340] Although nadir level can be used to predict the relative likelihood of failure after radiation, there is no absolute level which can determine success or failure after this therapy. Kuban et al in a multiinstitutional study of 4839 patients treated by EBRT for prostate cancer demonstrated that progressively lower nadir levels were associated with incremental improvement in PSA DFS with an 8-year rate of 75% with a nadir <0.5 compared to only 12% with a nadir ≥4.0.[227]

PSA Failure Definitions after Local Therapy

PSA is commonly being used to assess outcome after local therapy because clinical failure, especially following treatment of localized disease, takes years to develop. In evaluating new treatment methods and techniques, it is desirable to obtain comparative efficacy information as soon as possible. Therefore, a consistent, reliable, and accurate method of using PSA as a marker for failure is necessary.

PSA failure definitions following surgery or radiation therapy must use different criteria because of the inherent effect on the prostate by each of these modalities. Because the goal of radical prostatectomy is to remove all prostatic tissue, a detectable PSA level after surgery has been correlated with outcome. Although an undetectable PSA is desirable, the possibility of residual benign glands capable of producing low levels of serum PSA has been suggested. The PSA level is very low, in the 0.1 ng/mL to 0.4 ng/mL range, and is representative of a small amount of prostate tissue left behind.[312,344,345] Although these levels have been correlated to postoperative relapse, further proof of progressive disease is evidenced by a subsequent rising PSA. Cutpoints of 0.2 ng/mL and 0.4 ng/mL have been proposed to report biochemical failure following surgery. In each case, patients with PSA values greater than the cutpoint have higher rates of subsequent rising PSA or clinical failure.[312,344,345] The AUA has recommended defining biochemical relapse as an initial serum PSA ≥0.2 ng/mL with a confirmatory PSA >0.2 ng/mL.[346] For irradiated patients, a rising PSA is the criteria for relapse that is often used because a low target PSA value, especially soon after treatment is not specific in predicting clinical failure.[347,348] This is because the prostate remains intact in irradiated patients and it takes a median of nearly 2 years for the PSA to reach the nadir, or lowest level.[349] Simultaneous with this gradual declining process, a PSA "bounce" can occur, mimicking failure because the bounce is a PSA rise but one secondary to a benign cause, likely prostatitis.[350-352] Therefore, the definition of PSA relapse after radiation must take both of these factors into account to minimize false-positive failure reporting.

The American Society of Radiation Oncology (ASTRO) held a Consensus Conference in 1996 for the purpose of devising a PSA-based failure definition after EBRT, which would standardize outcome reporting. The ASTRO definition for biochemical failure is characterized by three consecutive PSA rises with the time of failure backdated to halfway between the PSA nadir and the first PSA rise.[353] After several additional years experience in the PSA era and more sophisticated statistical analysis, criticisms of the ASTRO definition were brought forward and alternative definitions that were more sensitive and specific were advocated.[347,354] Problems with the original PSA definition included biases associated with back-dating and the time necessary to collect three consecutive rises. The original ASTRO consensus also did not consider the use of neoadjuvant or adjuvant hormone therapy nor did it include data from alternative radiation techniques such as permanent or temporary brachytherapy.

A second Consensus Conference sponsored by both ASTRO and RTOG was held in 2005 at the RTOG's semiannual meeting in Phoenix, Arizona.[355] A panel representing radiation and surgical specialties as well as clinical trials groups formulated a revised consensus statement, commonly referred to as the "Phoenix" or nadir + 2 definition. The revised definition states that a PSA rise of 2 ng/mL or more above the nadir PSA (defined as the lowest PSA achieved) is a biochemical failure. The date of failure is the date at which that PSA value is determined "at call" and not backdated.[355] Patients not meeting these criteria but who undergo salvage therapy such as AD, prostatectomy, brachytherapy, or cryosurgery are considered failures at the time of a positive biopsy or when salvage therapy is initiated. Based on clinical outcomes reported by Kestin, the original ASTRO definition had a sensitivity of 51%, specificity of 78%, positive predictive value of 31%, and a negative predictive value of 88%. The Phoenix definition has a sensitivity of 64%, specificity of 78%, positive predictive value of 36%, and a negative predictive value of 92%.[354,355] Another important point stressed at both consensus conferences is the minimum follow-up necessary to use these definitions. The stated date of control should not be more than 2 years short of the median follow-up time. For example, to report a 5-year biochemical control rate, the median follow-up should be at least 3 years. The original ASTRO definition still has important utility because it can be used to compare results to prior publications. The consensus panel encouraged reporting results using both the Phoenix and ASTRO definitions.[355] The interval to biochemical failure by the Phoenix definition is important in predicting the future development of distant metastases or prostate cancer mortality. Patients experiencing a rising PSA to the nadir + 2 within 18 months of treatment have a significantly higher rate of death from prostate cancer.[356]

Predictive and Prognostic Models

The previous sections on prognostic factors emphasized the interactions many of them have with each other as it relates patient outcomes. Furthermore, comparing treatment between modalities or between institutions and series is complicated by the fact that the patient populations vary considerably between them. It has become increasingly important to use models to account for variable prognostic factors and allow more meaningful comparisons between heterogeneous populations of patients. Models that are predictive describe the likelihood of a finding or event, irrespective of time, whereas prognostic models describe the likelihood of an even over time.

Risk groupings are relatively easy to use and are based on a limited number of clinical variables that allow categorization of patients by their likelihood of recurrence. One of the most commonly used risk grouping was described by D'Amico to estimate the biochemical outcome of men following radical prostatectomy, EBRT, or interstitial brachytherapy.[315] Patients are classified into three categories based on their presenting PSA, Gleason Score, and clinical stage; low risk (stage T1c, T2a, and PSA ≤10 ng/mL and Gleason score ≤6), intermediate risk (stage T2b or Gleason score = 7 or PSA >10 and ≤20 ng/mL) or high risk (stage ≥T2c or PSA >20 ng/mL or Gleason score ≥8). Additional risk groupings have been developed by the National Cancer Center Network (NCCN), University of California–San Francisco (UCSF), and Johns Hopkins University[193,316,358] and are discussed on the Expert Consult website.

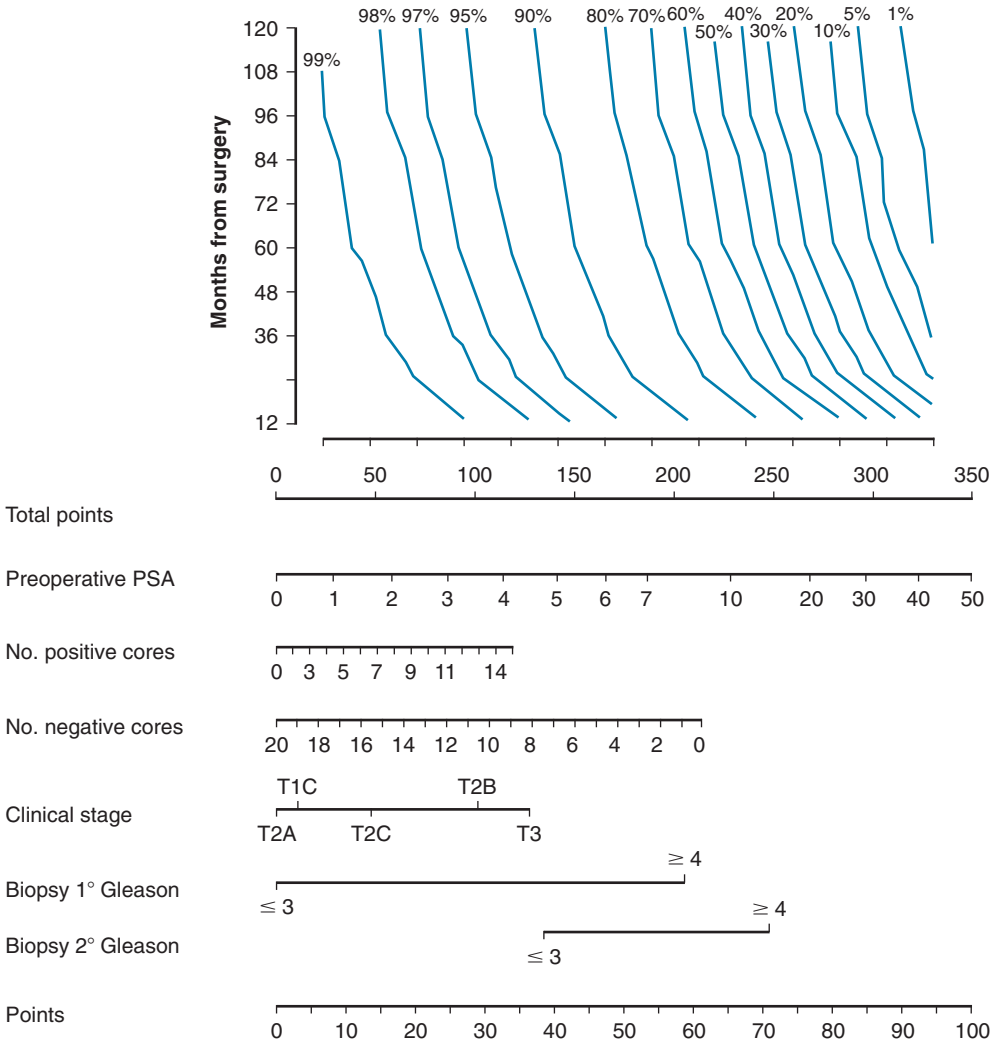
Numerous nomograms have been developed to calculate risk of positive biopsies on screening exams, estimate pathological stage, predict biochemical control before surgery,[359] EBRT,[360] or brachytherapy[361] as well as the risk of prostate cancer progression after local therapy.[362,363] Examples of nomograms for predicting biochemical disease-free survival (bDFS) following radical prostatectomy and EBRT are presented in Figures 53-2 and 53-3.

In a multiinstitutional series, Buyyounouski reported a 10-year estimate of prostate cancer death of 26.2% compared to 55.9% if the interval to biochemical failure were more than 18 months compared to less than 18 months, respectively.[357]

Numerous models exist to assist decision making in many aspects of prostate cancer screening, diagnosis, staging, and treatment. These models include nomograms, risk groupings, probability tables, and artificial neural networks. Each of these predictive models vary on their levels of discrimination, calibration, generalizability, and complexity. Discrimination describes the ability to identify patients that will or will not experience the outcome of interest. Calibration refers to the ability to generate predictions that closely approximate observed outcomes. That is, given a risk of x% experiencing an event then close to x% actually experience it. Although there are methods to internally validate them, ideally predictive models should be externally validated by a data set other than that used to create the model. This validation step speaks to the generalizability of the model, how likely the prediction is to be accurate in similar groups of patients at different centers or at different points in time. When using predictive and prognostic models it must be understood that the data is often unique to the population used to derive the model.

The NCCN has adopted a similar classification for treatment recommendations except T2b-T2c is considered intermediate risk and T3a-T4 represent high-risk tumor stages.[316] The UCSF group has described a risk grouping model that includes the percentage of positive biopsy cores and patient age. The cancer of the prostate risk assessment (CAPRA) score is calculated by assigning points to increasing risk factors. Unlike the D'Amico grouping, the PSA is divided into five discrete categories. The CAPRA score may range from 0 to 10 although 0-1 and 7-10 groups are often combined. The CAPRA score has been validated as a useful tool to predict outcomes following radical prostatectomy.[358] One problem with risk groupings is that each category may contain a heterogenous population and continuous variables are converted into categorical variables, thereby removing the information about the actual value. It also assumes each variable carries equal weight in contributing to patient outcome. Probability tables have been used to estimate pathological findings following radical prostatectomy and are commonly used in multidisciplinary settings to estimate the risks of ECE, SVI, or lymph node metastases. Partin popularized the use of probability tables based on a series of more than 5000 men undergoing radical prostatectomy at Johns Hopkins University.[193] The Partin tables combine serum PSA, clinical stage, and biopsy Gleason score to predict the pathological stage in four groups; organ-confined disease, established ECE, SVI, or lymph node involvement. The outcomes are considered mutually exclusive so the tables tend to underestimate the risk of ECE or SVI because a significant proportion of patients with LNI will also have these findings.[193,194] Nomograms are graphical calculation devices that incorporate at least two continuous or categorical variables. Risk points are determined by identifying the value of variables of interest on axes corresponding to a given prognostic factor. The risk points are then summed and used to estimate the combined effect of the predictors on the expected outcome. Nomograms often use Cox proportional hazards or modified logistic regression to correct for variable impact of incremental changes across a broad range of values to predict endpoints.[356] Nomograms can be adapted to web-based or handheld personal data assistant applications to quickly and conveniently calculate predicted outcomes (www.nomograms.org and www.nomogram.org).

Complementary to these models used to predict the likelihood of a staging outcome or clinical endpoint, nomograms have been developed that are used for estimating 10-year life expectancy to gauge the appropriateness for curative therapy in patients that may be better suited for conservative management approaches. Likewise, there are models that can estimate the likelihood of complication-free survival following surgery or radiation therapy.



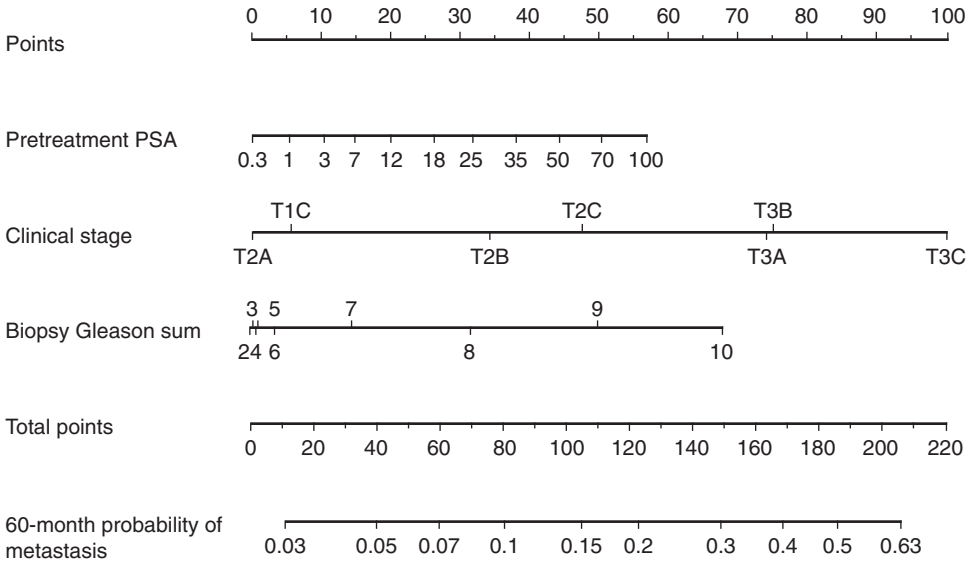


Figure 53-2 Preoperative nomogram estimating the 1- to 10-year progression-free probability after radical prostatectomy alone.
Instructions for physician: Locate patient's preoperative prostate-specific antigen (PSA) on the Preoperative PSA axis. Draw a straight line down to the Points axis to determine how many points toward disease recurrence that patient receives. Repeat this process for each of the remaining variable axes. Sum the points for each predictor and locate this sum on the Total Points axis. Draw a line straight up from the Total Points axis until it intersects with the horizontal line drawn from Months from Surgery, corresponding to the time point in the future within which the risk of recurrence is wished to be calculated. The progression-free probability can be estimated at 12 to 120 months after radical prostatectomy. The slanted vertical line that crosses this intersection point corresponds to the calculated progression-free probability within that point in time after radical prostatectomy.
Instructions for patient: Mr. X, if we had 100 men exactly like you, we would predict <predicted probability from nomogram × 100> percent to remain free of disease progression at <specified months from surgery> following radical prostatectomy alone.
Data from Stephenson AJ, et al: Preoperative nomogram predicting the 10-year probability of prostate cancer recurrence after radical prostatectomy. J Natl Cancer Inst 98:715–717, 2006.

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Clinical Symptoms and Signs

Most patients with early-stage prostate cancer are asymptomatic because most cancers arise in the peripheral zone of the gland. However, a tumor may arise in the transition zone or may extend from a peripheral location to encroach on the prostatic urethra and produce obstructive symptoms. The resulting symptoms, commonly referred to as prostatism, initially consist of urinary hesitancy, diminished force of stream, intermittency, and a sense of incomplete voiding. Thereafter, the bladder detrusor muscle may lose compliance, and irritative symptoms such as urgency, frequency, nocturia, dysuria, and incontinence may develop. Although acute urinary retention may ensue, it is no more likely to occur in the patient with prostate cancer than in the general population.[364,365] Indeed, the constellation of obstructive symptoms now referred to as lower urinary tract symptoms (LUTS) are commonplace in the elderly male population[366] and are often associated with BPH or other mechanical or functional disorders of the urinary bladder. Hematuria, which may result from tumor involvement of the prostatic urethra or bladder trigone, and hematospermia are uncommon signs of prostate cancer and should prompt further investigation to identify their etiology.

Local extraprostatic tumor spread is often asymptomatic and may not be apparent on physical or radiologic examination. However, extensive disease involvement of the periprostatic tissues may produce symptoms as a late manifestation of the disease process. Denonvilliers' fascia is a barrier to rectal

Physician instructions: Locate the patient's PSA on the PSA axis. Draw a line straight up to the Points axis to determine how many points toward recurrence the patient receives for his PSA. Repeat this process for the other axes, each time drawing straight up to the Points axis. Sum the points for each predictor and locate this number on the Total Points axis. Draw a line straight down to find the patient's probability of metastasis within 60 months.

Patient instructions: "Mr. X, if we had 100 men exactly like you, we would expect *<predicted percentage from nomogram>* to develop metastasis within 5 years following conformal radiation therapy. This prediction assumes you may need hormonal therapy, and that you might die of another cause first."

Figure 53-3 Nomogram for 60-month *EBRT* probability of metastasis after EBRT, recognizing the potential for death from other causes. *PSA*, Prostate-specific antigen.
Data from Kattan MW, et al: Pretreatment nomogram that predicts 5-year probability of metastasis following three-dimensional conformal radiation therapy for localized prostate cancer. J Clin Oncol 21:4568–4571, 2003.

involvement, but symptoms similar to those of a primary rectal cancer, such as hematochezia, constipation, or intermittent diarrhea, reduced stool caliber, or abdominopelvic pain, may occur. Renal impairment as a result of prolonged bladder outlet obstruction or from tumor involvement of the bladder trigone or periureteral tissues may cause hydronephrosis and symptoms or signs because of fluid retention or electrolyte imbalance. Invasion of the neurovascular bundles, urogenital diaphragm, or penile corporeal bodies may result in impotence, perineal pain, or priapism, respectively.

The pelvic, axial, and proximal regions of the appendicular skeleton are the most common sites of metastatic disease spread. Based on the distribution of uptake on radionuclide bone scan, the vertebral column (74%), ribs (70%), pelvis (60%), femora (44%), and shoulder girdle (41%) are the prevailing sites of involvement in patients with osseous metastases.[367] Although approximately one third to one half of those with bone metastases may be asymptomatic, pain in these areas is commonly described or may be elicited through examination of the skeletal system. The extent of osseous metastasis and the presence of symptoms[368] are associated with responsiveness to therapeutic intervention and survival. Pathologic fractures are uncommon but may affect the femora, humeri, and vertebral column. Extension of tumor into the epidural space or compression of nerve rootlets or peripheral nerves may cause neurologic deficits. Spinal cord compression is characterized by motor weakness, sensory changes, and bladder and bowel dysfunction. Its presence is considered an oncologic emergency that requires prompt recognition and treatment to avoid permanent disability.

Tumor involvement of pelvic or paraaortic lymph nodes is usually asymptomatic, and clinical signs, such as edema of the abdominal wall, genitalia, and lower extremities, are rarely apparent unless bulky nodal disease is present. Although metastases to other anatomic sites (e.g., adrenal glands, liver, lung, and skin) are described,[369] symptoms or signs resulting from functional compromise are uncommon. Paraneoplastic syndromes, including Cushing's syndrome, the syndrome of inappropriate antidiuretic hormone secretion and abnormalities of serum calcium levels, and hematologic manifestations (e.g., anemia, disseminated intravascular coagulation) may also be present in the patient with advanced metastatic disease.[370]

History and Physical Examination

A thorough history and physical examination are fundamental components of patient evaluation and may be instrumental in directing further diagnostic and staging procedures. In particular, detailed inquiry regarding urinary status, sexual function, and skeletal symptoms identifies the patient's baseline condition and may prompt further investigation and therapy. Assessment of comorbid illness may have relevance to therapeutic decision making, and the family medical history may identify other family members at high risk for developing prostate cancer.

A complete physical examination is essential and may reveal metastatic disease or other clinically important conditions. Careful DRE of the prostate forms the cornerstone of the physical examination and is instrumental in tumor staging. The examination may be performed in the lithotomy, knee-chest, lateral prone (Sims), or standing position with a well-lubricated, gloved index finger. The examiner should measure the craniocaudad and transverse dimensions of the gland and determine its overall consistency, sensitivity, and mobility, as well as the presence and size of any firm or elevated areas. Typically, an area of prostate cancer is quite hard, may or may not be raised above the surface of the gland, and is surrounded by compressible prostatic tissue. However, an area of prostatic induration per se is not pathognomonic of cancer because induration may be the result of prostatic calculi, infection, infarction, granulomatous prostatitis, or nodularity as a result of BPH. Although DRE is important in staging, it is not particularly accurate in screening. In a meta-analysis of 13 prostate cancer screening studies, the pooled sensitivity, specificity, and positive predictive value for DRE were 53.2%, 83.6%, and 17.8%, respectively.[371] The lateral rectal sulci and the urogenital diaphragm are also examined to determine whether extraprostatic tumor extension is present. Although the normal seminal vesicles are too soft to be palpated as discrete structures, firmness extending superior to the prostate gland suggests SVI, and further investigation may be warranted.

Staging

Whitmore[372] is credited with developing the first widely accepted stage groupings for prostate cancer, and the general concepts set forth were later incorporated into the AUA system.[373] Subsequently, the Organ Systems Coordinating Center of the National Cancer Institute initiated a process to align the Whitmore-based groupings and the TNM system. This and other efforts led to development of the AJCC TNM classification and stage groupings,[374] which were unified with the Union Internationale Contre le Cancer in 1987.[165] This system retains the general organizational scheme of prior systems and conforms to the TNM rules applied to tumors originating in other sites.

The AJCC TNM classifications and the stage groupings for prostate cancer are shown in Tables 53-1 and 53-2, respectively. Clinical staging involves primary tumor assessment with DRE, complete general examination to determine disease extent, serum PSA determination, and diagnostic imaging (including TRUS). The regional lymph nodes are defined as those confined to the true pelvis (i.e., those lying below the bifurcation of the common iliac arteries) and include the obturator, external and internal iliac, and sacral lymph node groups. All information available before definitive therapy may be used for clinical staging. Pathologic staging requires histologic examination of the prostatoseminovesiculectomy and pelvic lymph node specimens; presence of EPE, SVI, and margin status, as well as the extent and location of involved lymph nodes should be specified.[151]

Diagnostic Imaging

Ultrasonography

TRUS is an important tool in prostate cancer diagnosis and may be used to identify abnormalities of the prostate gland and seminal vesicles for staging purposes. Although the typical sonographic appearance of prostate cancer is an area of diminished echogenicity (hypoechoic) in the peripheral zone of the gland, between 14% and 29% of patients with prostate cancer have an isoechoic tumor that cannot be reliably distinguished from normal prostatic tissue.[375-377] Furthermore, among prostate cancer screening participants with a hypoechoic finding on TRUS that prompts further evaluation, only 17% to 31% have a diagnosis of cancer established by needle biopsy of the prostate.[375-377] Color or contrast-enhanced Doppler TRUS improve the sensitivity and specificity of prostate cancer detection.[378]

Several investigations address the ability of TRUS to detect extraprostatic tumor extension, which may affect tumor stage, by correlating ultrasound observations with the findings from histologic examination of the prostatoseminovesiculectomy specimen.[379-383] In a series of 200 patients with clinical T3a disease, TRUS was not remarkably different than DRE in detecting EPE.[380] Histopathological examination of prostatectomy specimens confirmed unilateral T3a disease in 49.5% of cases detected by DRE and 55.7% detected by TRUS.

Despite limitations, tumor extension into the seminal vesicles may be appreciated by TRUS as echogenic abnormalities and by anterior displacement and enlargement of this structure. TRUS-guided biopsy may be appropriate if predicted rates of SVI by preoperative nomograms are high and a treatment decision would change based on this finding. TRUS is also valuable in assessing patients for prostate brachytherapy. Prostate gland volume and the presence of prominent median lobe tissue are important considerations for radioactive seed implantation.

Computed Tomography

CT imaging has little value in assessing intraprostatic anatomic changes because of the primary tumor because the neoplasm usually has the same attenuation as the normal prostate gland. In the presence of EPE, the periprostatic fat planes may become indistinct, or there may be deformity of the bladder base, obliteration of the normal angle between the seminal vesicle(s) and the posterior aspect of the bladder, or asymmetric enlargement of a seminal vesicle. However, caution must be exerted in interpreting these images because they may be an artifact of biopsy or the plane between seminal vesicles and bladder may be obscured by rectal distention. Furthermore, EPE is often microscopic and cannot be detected with CT scanning. This observation largely accounts for the low sensitivity of this procedure (24%), which limits its utility in staging the primary tumor.[383]

Diagnostic CT scanning of the abdomen and pelvis for lymph node staging of newly diagnosed prostate cancer infrequently yields valuable information. CT imaging can detect only abnormalities in lymph node size that may result from extensive tumor involvement. As a result, the diagnostic sensitivity of this procedure with respect to lymph node assessment is poor (~25%),[383,384] and the routine use of this test is of little value in assignment of regional node stage in low-risk patients.[385-388] The American College of Radiology (ACR) and the AUA restrict their recommendations on the use of abdominal and pelvic CT scans for staging to locally advanced and high-risk patients.[133,389]

Magnetic Resonance Imaging

In staging prostate cancer, T1-weighted (T1WI) sequences provide high contrast between water density structures (e.g., prostate gland, seminal vesicles) and fat and are particularly useful for evaluating the periprostatic fat and veins, neurovascular bundles, perivesical tissues, and lymph nodes. MRI should be obtained at least 4 to 6 weeks after biopsy to prevent biopsy-related hemorrhage from causing artifacts. The T2-weighted image (T2WI) sequences demonstrate the internal zonal anatomy of the prostate and the architecture of the seminal vesicles. Prostate cancer is typically a focal, peripheral region of decreased signal intensity on T2WI surrounded by a normal (high-intensity) peripheral zone. Transition zone

The Radiology Diagnostic Oncology Group prospectively evaluated preoperative TRUS in 219 patients who underwent RP.[379] Among 85 patients considered to have disease confined to the prostate gland, 43 (51%) had extraprostatic tumor extension, whereas 50 of 134 patients (37%) with suspected extraprostatic disease did not have this confirmed by histologic examination. Overall, the sensitivity and specificity of TRUS in identifying extraprostatic disease were 66% and 46%, respectively, and the test accuracy was only 58%. Based on these results, these investigators concluded that TRUS is not sufficiently accurate to assist in staging early-stage prostate cancer, mainly because of its limitations in identifying microscopic extraprostatic disease spread. In a prospective, multiinstitutional study of 263 patients who underwent radical prostatectomy, preoperative clinical staging by TRUS and DRE was compared with pathologic staging.[381] Overall, TRUS was not significantly better than was DRE in predicting ECE.

Terris et al[382] demonstrated the feasibility of obtaining ultrasound-guided preoperative bilateral seminal vesicle biopsies. Among 73 patients with prostate cancer suitable for prostatectomy, biopsy showed tumor involvement adjacent to seminal epithelium (i.e., a pathognomonic finding) in 8 patients; all of these instances were confirmed following examination of the surgical specimen. Eleven of 133 negative preoperative seminal vesicle biopsies had involvement with cancer, resulting in a false-negative rate of 8%.

Huncharek and Muscat[386] analyzed the CT results of 425 patients with newly diagnosed prostate cancer and found that only 12 patients (3%) had radiologic evidence of adenopathy. Because patients with adenopathy had higher serum PSA levels, these authors concluded that CT scanning was not indicated in the patient with a PSA value under 20 ng/mL, wherein fewer than 1% had adenopathy. Other investigators noted a similar association between serum PSA level and radiologic and histologic findings and likewise concluded that CT imaging for nodal assessment should be reserved for patients with higher (>20 ng/mL) PSA values.[384,387] Fine-needle aspiration cytology may further enhance the specificity and accuracy of CT-based pelvic node evaluation, particularly in intermediate- and high-risk patients.[388]

(TZ) cancers are more challenging to detect because the signal characteristics of the TZ and prostate cancer overlap. Occasionally, nodules of BPH may have similar signal characteristics. ECE can be identified by a contour deformity with an angulated margin, an irregular bulge, a breech of the capsule with direct tumor extension, obliteration of the rectoprostatic angle, or asymmetry of the neurovascular bundles. SVI is characterized by contiguous low signal tumor extension from the base of the prostate, tumor extension along the ejaculatory duct, asymmetric decreased signal of the seminal vesicles, or decreased conspicuity of the seminal vesicle wall on T2WI.

Based on a low sensitivity, specificity, and accuracy a 1.5T body-coil MRI alone may not an accurate method for prostate cancer staging.[379] Over the past decade technologic advances and the introduction of high magnetic field (3T) and multiparametric imaging protocols have allowed for higher MRI resolution and improved staging accuracy. Endorectal coil MRI has been shown to have superior spatial resolution and contrast than 1.5T body-coil images. In addition, the simultaneous use of other clinical information in pretreatment nomograms enhances the value of MRI in predicting seminal vesicle invasion and organ-confined disease.[389,390] Therefore, endorectal-coil or 3T MRI may be best applied in conjunction with the DRE, Gleason score, and pretherapy serum PSA findings in select patients with intermediate- or high-risk prostate cancer.

Dynamic contrast enhancement (DCE)-MRI may visualize neovasculature associated with prostate cancer. DCE-MRI shows earlier and more intense enhancement of prostate cancer than normal peripheral zone tissue. Padhani has shown that DCE-MRI could reliably distinguish tumor from noncancerous prostate.[393] Diffusion-weighted imaging (DWI)-MRI capitalizes on tumor cell density restricting the motion of water molecules. DWI-MRI alone may not provide superior localization or staging information than T2WI, but it has shown some utility as a biomarker predictive of histologic grade.[394]

Magnetic resonance spectroscopy (MRS) can assess cellular metabolism and aid in distinguishing prostate cancer from benign intraglandular changes. Loss of a citrate peak and gain in the choline/creatine peak on MRS has been correlated with the presence of prostate cancer (Figure 53-4).[396] Although it has been hoped that MRS would improve the diagnostic accuracy and staging of prostate cancer, a clinical trial by the ACR Imaging Network (ACRIN) showed no benefit to MRS over standard MRI alone.[397]

Multiparametric MR imaging (mp-MRI) includes a high resolution T2WI along with at least two functional MR techniques (DCE-MRI, DWI-MRI, or MRS). Combining these techniques improves both diagnostic and staging accuracy. Both the ACR and the European Society of Urogenital Urology have described mp-MRI as useful tools to characterize tumor stage and biology.[389,390]

As in CT imaging, interpretation of pelvic MRI images for lymph node metastases relies on lymph node size. Pelvic MRI may also identify bone metastases and confirm the malignant nature of abnormalities identified on bone scan.

Nuclear Medicine Imaging

Bone Scans

Clinically apparent metastatic disease is limited to bone in 80% to 85% of patients with prostate cancer metastases and is observed in a pattern that correlates with the distribution of hematopoietic marrow in the adult. Radionuclide bone scan appearance of metastases may range from a solitary focus of radionuclide uptake to the "super scan," wherein the entire skeleton is uniformly affected. Recognition of the latter condition, distinguished by the lack of renal uptake and excretion of the radionuclide, is important because the scan may otherwise be interpreted as normal. Although the bone scan is a sensitive imaging tool, various other conditions, such as arthritis, bone fracture, and Paget's disease, may also result in uptake of the radionuclide. In certain situations, standard bone radiography or tomography, CT, or MRI may be required to determine the nature of the findings noted on bone scan.

Since the advent of serum PSA testing, Chybowski et al[400] were among the first to evaluate the utility of obtaining a routine bone scan in the pretherapy evaluation of the patient with newly diagnosed prostate cancer. These investigators conducted a retrospective evaluation of 521 randomly selected patients and correlated clinical T category, tumor grade of the diagnostic biopsy specimen, acid phosphatase, PAP, and PSA serum levels with bone scan findings. The probability of a bone scan showing metastatic disease was most strongly associated with and was directly proportional to the serum PSA level, as illustrated in Figure 53-5. Only 0.3% of patients with a pretherapy PSA of 20 ng/mL or lower had a positive bone scan at presentation.[400] Based on a retrospective analysis of 853 consecutive patients, Briganti et al developed a classification

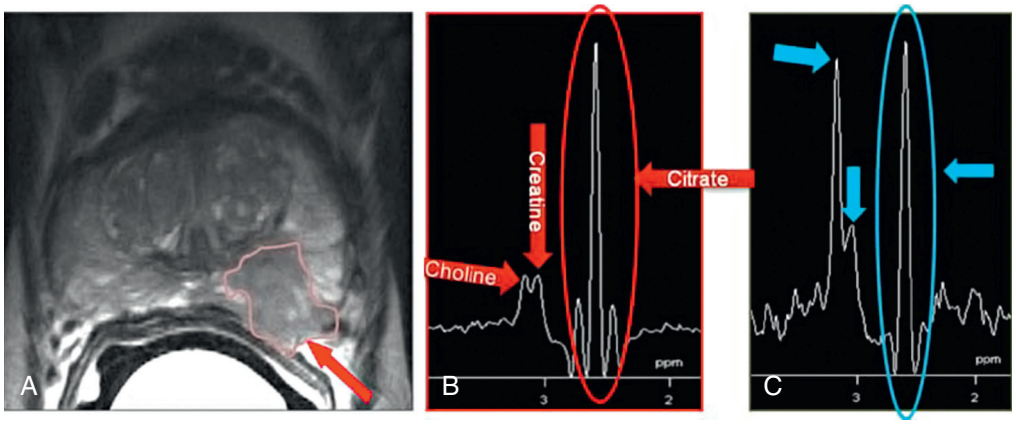

Figure 53-4 A 65-year-old man with stage T3a Gleason 4 + 3 prostate cancer at the left peripheral zone (PZ). **(A)** On the axial T2WI at mid-prostate level in the left PZ there is a low signal lesion *(outlined)* with obliteration of the recto-prostatic angle and extracapsular extension *(arrow)*. **(B)** Magnetic resonance spectroscopic imaging (MRSI) of the normal right side shows low choline + creatine, whereas on **(C)** MRSI of the tumor shows high choline + creatine. The choline peak of tumor is as equally as high as the citrate peak.
From Barentsz JO, Richenberg J, Clements R, et al: ESUR prostate MR guidelines 2012. Eur Radiol 22:746–757, 2012.

In a prospective study of 82 patients, Futterer reported that using an endorectal–pelvic-phased array coil significantly improved anatomical details, staging accuracy, and specificity. Local staging accuracy, sensitivity, and specificity using a pelvic-phased array coil alone were 59%, 54%, and 62%, respectively, although using a combined endorectal–pelvic-phased array coil, local staging accuracy, sensitivity, and specificity were 83%, 65%, and 98%, respectively.[391] High-field (3T) MRI scanners improve the sensitivity and specificity for the nonoperative staging of localized prostate cancer.[392] In a prospective study of 32 patients undergoing 3T endorectal MRI before radical prostatectomy the accuracy, sensitivity, and specificity of local staging were 94%, 88%, and 96%, respectively, for two experienced radiologists, and 81%, 50%, and 92%, respectively, for a less-experienced radiologist.

In a prospective study of 32 patients, Bloch demonstrated a mean sensitivity, specificity, positive-predictive value, and negative-predictive value or 86%, 95%, 90%, and 93%, respectively for predicting ECE by two experienced readers.[395] Although DCE-MRI needs to be validated in larger multiinstitutional studies, it appears to be a promising imaging tool for prostate cancer staging.

Citrate levels in prostate adenocarcinoma appear to be grade dependent. Preliminary data suggest that there is a strong linear relationship between a decrease in citrate levels and the elevation of choline with cancer aggressiveness.[396]

Harisinghani et al have described the intravenous ultrasmall superparamagnetic iron oxide (USPIO) lymphotropic nanoparticles in normal saline to enhance MRI imaging of lymph nodes.[398] Macrophages in lymph nodes involved with cancer do not take up the particles and provide contrast to detect metastases. For lymph nodes that were considered normal by standard MRI criteria, the sensitivity of detecting tumor by this method was 96%. In a meta-analysis of USPIO MRI examinations, the per lymph node sensitivity and specificity were 0.90 and 0.96, respectively. The highest sensitivity and specificity for the studies included in the meta-analysis were for prostate cancer.[399]

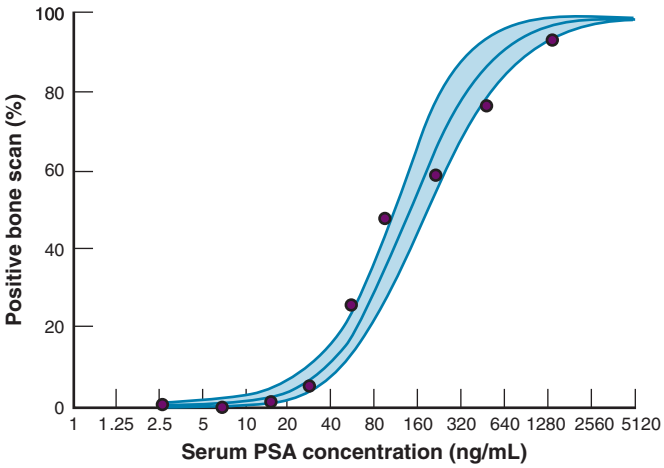

Figure 53-5 Results of bone scintiscan findings as a function of pretherapy serum prostate-specific antigen (PSA) level; 95% confidence intervals are *shaded*.
From Chybowski FM, Larson Keller JJ, Bergstralh EJ, et al: Predicting radionuclide bone scan findings in patients with newly diagnosed, untreated prostate cancer. Prostate-specific antigen is superior to all other clinical parameters. J Urol 145:313, 1991. Copyright 1991, with permission from American Urological Association.

and regression tree model predicts the frequency of a positive bone scan. According to this tool, a staging bone scan should be considered only for patients with a Gleason score >7 or with a PSA >10 ng/mL and palpable disease.[401] A bone scan is not routinely required in the staging evaluation of the patient without skeletal discomfort if the pretherapy serum PSA level is 10 ng/mL or less.

Radionuclide bone scintigraphy may also be of value in the posttherapy assessment of the patient with prostate cancer. The onset of skeletal symptoms, particularly in association with a rising serum PSA profile, should prompt radioscintigraphic investigation. However, posttherapy serum PSA monitoring is apt to identify tumor relapse before the occurrence of symptoms because biochemical relapse may antedate development of bone scan abnormalities by several months.

Monoclonal Antibody Imaging

111-Indium (^{111}In)-labeled capromab pendetide (ProstaScint) is an antibody directed against a prostate-specific membrane antigen.[404] The image performance of ProstaScint has been assessed in the pretherapy evaluation of patients with clinically localized prostate cancer who are considered at high risk for disease spread to regional nodes and in the posttherapy setting when occult residual or recurrent disease is suspected. Surgical series suggest the diagnostic accuracy in the 70% range.[405,406] In the setting of a rising PSA following prostatectomy, ProstaScint imaging has been used to evaluate patients for the presence of local or lymph node recurrence of disease following prostatectomy. The reported value of ProstaScint imaging has been inconsistent with some investigators reporting improved patient selection and outcomes for salvage therapy of a presumed localized recurrence,[407,408] whereas others have reported no difference in outcome in patients with localized versus distant tracer uptake.[409-411]

Positron Emission Tomography (PET) Imaging

PET imaging uses positron-emitting isotopes conjugated to compounds to detect physiological or pathological processes. The most common PET agent used to date is ^{18}F Fluorodeoxyglucose (FDG), a glucose analog that is taken up by upregulated glucose transporters in many cancers. FDG-PET imaging in prostate cancer has been disappointing with poor sensitivity and specificity for local and regional staging.[412,413] Newer PET imaging agents using ^{18}F or ^{11}C labeled methionine, acetate, or choline are showing promise in the primary staging of high-risk prostate cancers and in the evaluation of patients with biochemical relapse.[414] Unfortunately, used as imaging agents to assess disease relapse, the level of PSA associated with the detection of regional or metastatic disease may exceed 2 ng/mL.[415] This high level of PSA makes salvage therapies less useful as the burden or location of disease may exceed that for which radiation therapy could be considered curative.

PET bone imaging with ^{18}F sodium fluoride appears to have superior sensitivity to traditional ^{99m}Tc bone scans. Even-Sapir et al compared Tc-99m planar bone scan, single-photo emission computed tomography (SPECT), F-18 Fluoride PET, and F-18 Fluoride PET/CT in 44 patients with either localized high-risk or metastatic prostate cancer.[416] F-18 Fluoride PET/CT was significantly more sensitive and specific than bone scintigraphy ($p < 0.001$) and more specific than PET alone ($p < 0.001$).

Laboratory Evaluation

Prostate-Specific Antigen

PSA is a serine protease produced by normal prostatic acinar and ductal epithelial cells and by neoplastic cells of prostatic origin.[406,417] It is detectable in the serum in a form immunologically identical to that purified from prostatic tissues and may be elevated in patients with benign (e.g., prostatic hypertrophy, prostatitis) or malignant disorders of the prostate gland.[406] Although PSA exists in several forms in the serum, the PSA–α_1-anti-chymotrypsin complex predominates, whereas the free (noncomplexed) form of PSA is less abundant.[124,418]

Serum PSA levels may exhibit interassay (run-to-run) and physiologic (i.e., intraindividual) variation that must be considered in interpreting serial determinations. Physiologic variation refers to the difference in PSA levels observed when a second sample is obtained from the same patient within a few weeks of the initial sample. For physiologic variation, the ratio difference variation is significantly greater than the interassay variation, is inversely related to the PSA level, and may be as high as 0.298 (95% CI).[419] This means, for example, that a serum PSA of 4 ng/mL can increase to 5.2 ng/mL (4.0 × 1.298) and still remain in the range of physiologic variability.

The serum half-life of PSA is approximately 2.2 (±0.8) to 3.2 (±0.1) days,[420] which means that several weeks are required for serum levels to return to baseline after prostatic manipulation or for a nadir value to be reached after prostatectomy. Although digital examination of the prostate, prostatic massage, TRUS, ejaculation, and cystoscopy have an insignificant effect on the serum PSA level, prostate biopsy causes an immediate PSA elevation (median, 7.9 ng/mL) that requires several weeks to return to baseline.[421-423] TURP also causes PSA elevation (median, 5.9 ng/mL), with a median of 17 days required to arrive at the new baseline value.[423] Because the production and secretion of PSA are androgen dependent, AD therapy often results in a striking reduction in the PSA level,[424] which should be considered in interpreting serum PSA values in this setting.

Acid Phosphatase

Abnormally high serum PAP levels correlate with clinical T3-4 disease, higher tumor grade, and pretherapy serum PSA.[245] However, serum PAP determinations add little to current patient evaluation in either the pretherapy or posttherapy setting.

In a series of 239 patients evaluated with bone scan for biochemical relapse after radical prostatectomy, Dotan et al reported an incidence of bone metastases of 4%, 36%, 50%, and 79% with trigger PSA values of 0-10, 10.1-20, 20.1-50, and above 50 ng/mL, respectively.[402] In a multivariate analysis, PSA slope, PSA velocity, and trigger PSA were all significant factors for predicting a positive bone in the evaluation of biochemical failures after prostatectomy. Using CaPSURE registry data on 292 patients that had failed either radical prostatectomy (66%) or radiation therapy (34%), Choueiri reported that age (<60, 60-69, ≥70), imaging type (bone scan, CT, or MR), trigger PSA (≤5 ng/mL versus >5 ng/mL), and PSADT (<10 months versus ≤10 months) were associated with positive scans. They concluded that followup imaging studies are least useful when the PSA is ≤5 ng/mL and PSADT is ≥10 months.[403]

PET labeled acetate may be a marker for fatty acid synthase, which is upregulated in some prostate cancers. Likewise, PET labeled choline is preferentially taken up by prostate cancer with upregulated choline kinase leading to incorporation of phosphatidylcholine in tumor cell membranes.

The sensitivity and specificity for detection of bone metastases was 70% and 57% for planar bone scan, 92% and 82% for bone SPECT, 100% and 62% for F-18 Fluoride PET, and 100% and 100% for F-18 Fluoride PET/CT, respectively.[416] The authors concluded that F-18 Fluoride PET/CT is a highly accurate imaging modality for the detection of bone metastases in patients with high-risk prostate cancer.

As already stated, pretherapy serum PSA is an important prognostic factor in predicting outcome after treatment for prostate cancer and should play an important role in consideration of treatment options. In general, the higher the PSA level, the more likely that the tumor is outside the capsule and into the seminal vesicles or lymph nodes, which has major impact on the choice of therapy.[227,249,360,425]

Although also produced in nonprostatic tissues, the glandular epithelium of the prostate is the dominant source of acid phosphatase in humans. The prostate-specific form of this enzyme (i.e., PAP) is distinct from other isoenzymatic forms and is influenced by hormonal factors, and its expression is altered in the androgen-deprived state. Since the introduction of assays for serum PSA, acid phosphatase testing has declined in frequency.

Staging Workup

The ACR[426] and the NCCN have established guidelines for the pretherapy staging of patients with a recently established diagnosis of prostate cancer. The scheme proposed by the NCCN is displayed in Figure 53-6[316] and may be used for guidance. However, individual clinical circumstance may require departure from these guidelines because independent medical judgment is necessary to meet needs unique to a particular situation.

PRIMARY THERAPY

Expectant Management

Expectant management is a clinical strategy wherein immediate therapeutic intervention is not pursued when the diagnosis of prostate cancer is first established. With this approach, treatment is withheld until the time of disease progression or the development of symptoms. Expectant management is used throughout the world, and it is considered a satisfactory alternative to the use of primary RT or RP by its proponents. Under a program of watchful waiting, noncurative treatment would be offered at the time of progression and would consist primarily of hormonal therapy to induce tumor regression and alleviate symptoms.[216,427,428] Increasingly, an alternative expectant management strategy, active surveillance, is replacing watchful waiting. Whereas the goal of watchful waiting is to avoid treatment, the goal of active surveillance is to individualize patient care and treat only those men who have a clinically significant cancer and avoid the risk of treatment related morbidity in men whose cancers are unlikely to progress.

The rationale for expectant management related to the natural history of the condition, the age and comorbidity of the incident population, the perceived need (or lack thereof) for therapeutic intervention, and health-related quality of life issues. PSA screening has resulted in an increased rate of prostate cancer overdiagnosis. Overdiagnosis refers to the lead time bias in establishing a diagnosis of cancer that would otherwise not be detected during a man's expected life span. Overtreatment occurs when an intervention plays no role in extending a patient's life or preventing morbidity from the illness. Furthermore, incidental (or latent) prostate cancer is often found on autopsy examination of the prostate gland, and although particularly common in the elderly,[5,87] is observed in as many as one third of men in their fourth and fifth decades.[4] The key to a successful expectant management strategy is the proper selection of patients who have indolent disease or comorbidities that would impact their expected survival relative to the natural history of the prostate cancer.

The Scandanavian Prostate Cancer Group-4 trial comparing radical prostatectomy to watchful waiting has been updated.[438] Radical prostatectomy was associated with a 12.7% decline in the cumulative incidence of death. At 18 years, 56.1% of patients died in the RP arm compared to 68.9% in the watchful waiting group. The cumulative incidence of prostate cancer death was reduced by 11.0%. The men that had the largest reduction in prostate cancer death related to RP were those younger than 65 years and those with intermediate-risk disease. Even men older than 65 showed a reduction in the incidence of distant metastases with RP.

The North American Prostate Cancer Intervention versus Observation Trial (PIVOT) compared the effectiveness of radical prostatectomy to observation in men with localized prostate cancer detected by PSA screening.[106] Although it fell short of its target accrual of 2000 men, it enrolled 731 patients with T1-2NxM0 adenocarcinoma of the prostate. With a median followup of 10 years, 47.0% of men assigned to surgery

Several studies demonstrate that many localized prostate cancers have an indolent course that may support the use of expectant management for this condition. In particular, the prognosis appears quite favorable for the patient with a small-volume, low-grade tumor identified incidental to transurethral resection (T1a category) for BPH.[429,430] However, the distinction between T1a and T1b is important because the risk of disease progression and disease-specific mortality is highly dependent on tumor volume and grade.[430-432]

One of the largest studies of expectant management was reported by Chodak et al,[216] who collected patient and disease characteristics from several nonrandomized institutional series and from a population-based study to evaluate the outcome of expectant management in patients with localized prostate cancer. The expectant management approach in this study was watchful waiting with no attempt to implement curative local therapy in these patients. The investigators identified 10 studies published during the preceding decade and obtained original data on 828 patients from 6 of them. In this meta-analysis, multivariate regression analysis identified tumor grade as the most significant factor associated with DSS. Based on their observations, the authors concluded that localized prostate cancer is a steadily progressive disorder but that observation with delayed hormonal therapy is a reasonable approach for some men with low-grade disease.

Although single-institution series include patients selected for expectant management on the basis of advanced age or life-limiting comorbidity, population-based studies may minimize this potential source of bias. Johansson et al[427] described a group of 300 consecutive patients diagnosed with T1-2 category prostate cancer at the Örebro Medical Centre, a hospital serving a geographically well-defined population. Among these patients, 223 patients with predominantly low-grade tumors were treated with exogenous estrogen or orchiectomy if symptomatic tumor progression occurred. By the time of last evaluation, extraprostatic tumor extension or metastatic disease had developed in 36% and 17%, respectively. Although the 15-year PFS (45%) and OS (21%) rates were rather low, the high 15-year DSS (79%) appeared consistent with the results of several single-institution investigations.[433,434] However, in an update of this study, the prostate cancer mortality rate increased from 15 per 1000 person-years during the first 15 years to 44 per 1000 person-years beyond 15 years of follow-up.[427] Although most cancers had an indolent course during the first 10 to 15 years after diagnosis, follow-up from 15 to 20 years revealed a substantial decrease in PFS (from 45% to 36%), survival without metastases (from 77% to 51%), and prostate CSS (from 79% to 54%). Therefore, these findings support early curative therapy for patients with an estimated life expectancy of more than 15 years.

Other population-based studies from Sweden have not confirmed the high 10-year to 15-year DSS rate observed in the series from the Örebro Medical Centre.[427] For example, Aus et al[435] identified all patients with an antemortem diagnosis of nonmetastatic prostate cancer treated with primary hormonal (63%) or deferred (36%) therapy who died in Göteborg, Sweden, between 1988 and 1990. Among 301 such patients, the cause of death was related to prostate cancer in 149 (50%), and for those surviving at least 10 years, 63% died from this disease. The initial T-category and grade were associated with the prostate cancer–related death rate. Although only 10% of patients with T1a tumors died of prostate cancer, 47% to 53% of patients with T1b-T3 tumors, and 70% of patients with T4 lesions died secondary to their malignant disease. Forty-three to forty-eight percent of patients with grade-1 and grade-2 tumors and 60% of patients with grade-3 lesions died of prostate cancer. Furthermore, 58% of patients underwent transurethral prostatic resection, 22% underwent an upper urinary tract procedure (e.g., pyelostomy) because of urinary obstruction, and 35% received palliative irradiation.[436] Norlén[437] noted similar findings in an evaluation of 44,300 patients with prostate cancer, representing 99% of all newly diagnosed cases, reported to the Swedish Cancer Registry between 1960 and 1978. Survival rates were adjusted for mortality in the general population and were expressed as relative survival, which estimates the likelihood of dying of prostate cancer. Among patients with prostate cancer, the relative survival was 51%, 34%, and 17% after 5, 10, and 20 years of observation, respectively, representing an excess death rate of approximately 8% per year.

died compared to 49.9% undergoing observation ($p = 0.22$). The death rate from prostate cancer or treatment was 5.8% in the men undergoing surgery compared to 8.4% assigned to observation ($p = 0.09$). Only in the subset of men with a presenting PSA of more than 10 ng/mL was there a significant reduction in all-cause mortality. This study lends support to the position that observation is an acceptable course of managing early stage prostate cancer.

Active Surveillance

Unlike watchful waiting, active surveillance strategies attempt to individualize the decision to recommend treatment based on a patient's risk of cancer progression in his lifetime. The key to a successful active surveillance strategy is the accurate identification of patients with clinically insignificant cancer, a rational follow-up plan, and early intervention criteria. Epstein introduced biopsy criteria to predict an insignificant cancer: Clinical T1c (non-palpable), PSA density <0.15 ng/mL, no Gleason pattern 4 or 5, fewer than three positive cores, and <50% cancer per involved core.[439] In an analysis of 237 patients with nonpalpable (T1c) prostate cancer treated at Johns Hopkins University, the Epstein criteria predicted for organ-confined disease in 91.6% of cases.[440] The other 8.4% that fulfilled the Epstein criteria had evidence of extraprostatic disease. In a European validation study of the Epstein criteria, Jeldres examined a cohort of 366 patients.[441] In that series, 20% of patients that fulfilled the Epstein criteria had unfavorable findings at radical prostatectomy such as Gleason score 7 or nonorgan-confined disease.[441] Consequently, as many as 20% to 25% of patients predicted to have insignificant cancer by the Epstein criteria may be expected to have nonorgan-confined disease.[442] The risk of missing a clinically significant cancer and avoiding necessary treatment in a potentially curative patient is the primary reason that active surveillance has not been more broadly adapted.

To accurately identify truly clinically insignificant cancers, many active surveillance series have included additional selection factors to the Epstein criteria. These have included an absolute PSA <10 ng/mL[443,444] or <15 ng/mL,[445,446] or fewer than 33% positive cores.[443] Although clinical validation has not been established, Shukla-Dave has reported the utility of incorporating MRI and MRS into nomograms to predict for clinical significant disease.[447] The receiver operating characteristic area under the curve for the nomogram was 0.54 compared to only 0.726 for the best clinical nomogram that did not include MR imaging data, $p < 0.0001$.

While on active surveillance, clear criteria need to be described for patient follow-up. All published series to date include repeated DRE, PSA, and repeated prostate biopsies. The interval for DRE varies from every 3 to 6 months for the first 2 years, to every 6 months after 2 years. PSA testing frequency ranges from every 1 to 3 months for the first 1 to 2 years and then every 6 months thereafter. Recommended biopsy intervals vary from every 6 or 12 months during the first year, then annually or biannually thereafter. Likewise, the indications for treatment should be well defined before advising an active surveillance strategy. Common criteria for implementing therapy include a change in PSA kinetics, such as an increase in PSA velocity or a decrease in the PSA doubling time to less than 2 or 3 years.[248] Clinical progression of a palpable or ultrasound detected nodule or a rebiopsy pathology with any Gleason pattern 4 or 5 with more than two cores involved or more than 50% of any core involved with prostate cancer is also used as a trigger to implement treatment.

Several single-institutional studies suggest a role for active surveillance in the management of men with low-risk and low-volume prostate cancer including Toronto Sunnybrook Hospital[250] ($n = 450$), Royal Mardsen[448] ($n = 326$), UCSF[445] ($n = 321$), and Johns Hopkins[449] ($n = 407$). The optimal selection criteria for active surveillance remain to be defined, as well as the frequency of follow-up exams, such as DRE, PSA, and repeat biopsy. The criteria for which to initiate active therapy vary from series to series and the long-term impact on prostate CSS and quality of life remains to be determined. eTable 53-3 summarizes the inclusion criteria for eight series reporting on their results of active surveillance, and eTable 53-4 shows the surveillance protocols practiced at each of these centers. The criteria for moving from active surveillance to treatment vary by series but include rising PSA, accelerated PSA kinetics, progression on DRE, worsening Gleason score, or increase in cancer volume by biopsy.[448] Lately, the change in PSA velocity and PSA doubling time have been questioned as to whether or not they portend a worsening state of disease.[450] In these series of active surveillance, the prostate cancer-free survival approaches 100%.

Increasingly, active surveillance strategies are being endorsed by oncologic specialty societies and networks, including the NCCN and AUA.[316,318,458-461] Currently, three randomized clinical trials are under way in North America, Europe, and the United Kingdom to evaluate the role of active surveillance relative to treatment.

Local Therapy

There are two well established primary modalities to manage patients with localized prostate cancer: RP and RT. There are no modern randomized clinical trials comparing these two modalities. Two older trials that attempted to make this comparison were compromised by methodological flaws.[461,463] Although the trial conducted in the United States suggested an advantage to surgery, the study was underpowered and did not analyze patients strictly by their study randomization.[461] With 10 years of follow-up, a smaller Japanese Phase III trial did not show a significant difference in OS or prostate CSS rates.[463] Neither of these trials took place in the PSA era nor did they employ modern staging and treatment techniques. Recent attempts to complete randomized clinical trials in the United States and United Kingdom comparing surgery to RT or brachytherapy have been unsuccessful.[464,465]

In clinically localized prostate cancer, several years of post-treatment observation are necessary to measure the impact of a particular treatment on outcome. Biochemical endpoints such as a detectable or rising PSA are imperfect surrogates for ultimate cancer control. Many biochemical definitions of failure require prolonged follow-up to ascertain failure and that may precede clinical failure by several years.[291,355] As a result, comparisons of outcomes between modalities and series that use different biochemical endpoints can be problematic. Careful attention must be paid to the specific biochemical or clinical endpoint as well as the length of follow-up when reviewing outcome analyses.

Lacking prospective randomized clinical trials comparing surgery and RT, it is necessary to rely on large single-institution and multiinstitutional studies to compare long-term DFS. In a series that included cases from the Hospital of the University of Pennsylvania and the Joint Center for Radiation Therapy in Boston, D'Amico reported the results of 1872 patients treated with localized prostate cancer by surgery (888 cases), permanent seed brachytherapy (218 cases), or EBRT (766 cases). The 5-year biochemical outcomes (ASTRO definition) were not significantly different by modality for patients with low-risk disease but patients with intermediate- and high-risk disease fared worse with brachytherapy compared to either EBRT or surgery.[315] In a case control study of 490 cases, Fletcher reported that the combination of brachytherapy and EBRT

The largest and most mature prospective series of active surveillance to date is that of the Toronto Sunnybrook Hospital with 450 patients and a median follow-up of 6.8 years.[248] The criteria for active surveillance initially included all favorable risk patients (i.e., Gleason score 6 or less, PSA 10 ng/mL or less) and for patients older than 70 years with a PSA up to 15 ng/mL or Gleason scores up to 3 + 4 was allowed. After 2000 the study strictly limited enrollment to favorable-risk patients. The criteria for implementing treatment were PSA doubling time of 3 years or fewer, histological upgrading and repeat biopsy, or clinical progression on DRE. Initially a PSA doubling time of 2 years or fewer was used but was increased to 3 years when it became apparent that only 10% of patients were identified as higher risk necessitating treatment. Patients had a PSA every 3 months for the first 2 years and every 6 months thereafter, as long as the PSA was stable. A repeat biopsy was performed at 6 to 12 months after enrollment and repeated every 3 to 4 years until the patient reached the age of 80 years. Overall 83% of patients had a Gleason score 6 or less and 13% had a Gleason score 3 + 4 = 7 at study entry. The 10-year prostate cancer-free survival rate was 97.2%. Overall 30% of patients had evidence of progression to higher risk categories and were offered therapy. Of 117 patients treated, the PSA failure rate from treatment was 50%, but this represented only 13% of the entire study cohort.[248]

From the Royal Marsden Hospital, Van As reported the results of 326 men managed with active surveillance.[446] Inclusion criteria for their study were clinical T1-T2a, Gleason score <7 (3 + 4), PSA <15 ng/mL, and <50% of biopsy cores positive. Treatment criteria were PSA velocity of >1 ng/mL per year, Gleason score ≥4 + 3 or ≥50% cancer involvement in any involved core on repeat biopsy. With a median follow up of 22 months, they have reported no prostate cancer deaths and 20% of their patients have moved to active treatment.

Dall'Era reported the UCSF experience of 321 men selected as having PSA ≤10 ng/mL, no Gleason pattern 4 or 5, clinical stage T2a or lower, PSA density of <0.75 ng/mL, and fewer than 33% positive cores involved with cancer.[443] Patients were offered treatment if they had a repeat biopsy Gleason score ≥7 or any increase in cancer volume on repeat biopsy or a rising PSA. With a median follow up of 3.6 years, 37% of patients met at least one criterion for treatment. Overall 38% had higher grade cancer on repeat biopsy and 26% had a PSA velocity of >0.75 ng/mL. Seventy-eight of the 321 men (24%) received treatment and there have been no prostate cancer deaths reported to date. They reported that 13% of patients chose therapy despite no evidence of disease progression.

The Johns Hopkins University experience of 407 men with a median age of 65.7 years has been reported by Carter.[455] All patients met the Epstein criteria for clinically insignificant cancers. With a median follow up of 3.4 years, 59% remain on active surveillance and 25% underwent active treatment with curative intent. No patient has died of prostate cancer in that series.

It is worth noting that men often experience anxiety as a result of their diagnosis and fear of disease progression. A randomized clinical trial from Sweden comparing treatment to watchful waiting showed no difference in quality of life in men at 5 years. Worry, depression, and anxiety were equally common in each group.[456] In an early analysis of 129 patients enrolled on the Dutch Prostate Cancer Research International Active Surveillance study (PRIAS), van den Bergh reported that the majority of men scored better than reference values in the domains of decision, depression, generic anxiety, and prostate cancer specific anxiety.[457] These data suggest that when informed, men willingly accept active surveillance as a management strategy.

The NCCN strongly recommends active surveillance for men with a short life expectancy.[316] The NCCN cites the observation by Lu-Yao[462] that the prostate cancer-specific death rate for men on an active surveillance strategy has dropped by 74% in the decade between 1992 and 2002 largely because of earlier diagnosis and the identification of more indolent cancers through PSA screening. The AUA guidelines[458] and the American Cancer Society (ACS)[459] both recommend that patients be informed of active surveillance as an alternative to a curative intervention. The Standard Treatment Against Restrictive Treatment (START)[460] trial in North America, the Prostate Cancer Research Interactive: Active Surveillance (PRIAS)[444] trial in Europe, and the PROstate TEsting for Cancer and Treatment (PROTECT)[112] trial in the United Kingdom are actively following patients. These studies will help bring clarity to the issues surrounding expectant management and early stage prostate cancer.

The North America Phase III Surgical Prostatectomy versus Interstitial Radiation Intervention Trial (SPIRIT) and the Medical Research Council PR06 trials closed prematurely because of poor patient accrual.[464,465] The ProtecT trial[112] randomized patients screened patients diagnosed with cancer to undergo surgery, RT, or active surveillance. Nearly half the men accepted randomization and the first report of this study is expected in 2015.

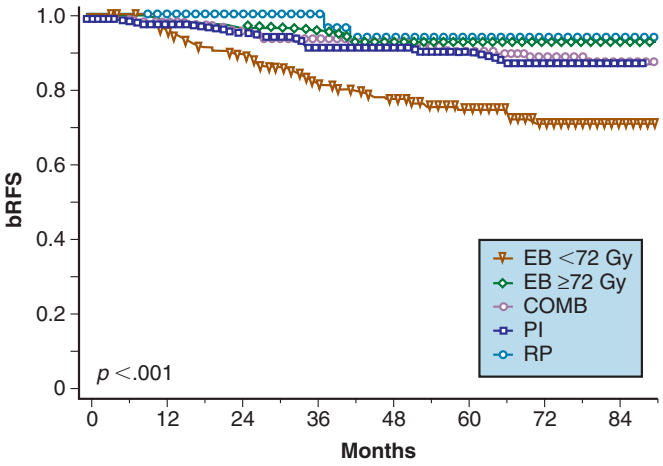

Figure 53-7 Biochemical freedom from recurrence for patients treated with permanent prostate brachytherapy (PI), external beam (EB) radiotherapy by dose (EB <72 Gy and EB ≥72 Gy), radical prostatectomy (RP), and combined methods (COMB).
Data from Kupelian PA, Potters L, Khuntia D, et al: Radical prostatectomy, external beam radiotherapy <72 Gy, external beam radiotherapy > or = 72 Gy, permanent seed implantation, or combined seeds/external beam radiotherapy for stage T1-T2 prostate cancer. Int J Radiat Oncol Biol Phys 58:25, 2004.

yielded statistically superior bDFS (PSA > 0.2) than either brachytherapy alone or RP.[466] Vicini reported the combined results of 6877 men with low- and intermediate-risk prostate cancer treated at seven institutions with a diverse set of modalities including permanent radioactive seed brachytherapy, temporary high-dose rate brachytherapy, EBRT, neutron therapy, and RP. Once corrected for prognostic variables, the 5-year biochemical outcomes were similar between institutions and modalities.[467] Kupelian reported outcomes of 1682 men from the Cleveland Clinic undergoing EBRT (628 cases) or RP (1054 cases).[468] The 8-year bDFS (PSA > 0.2) for the RP patients was 72% compared to 70% for the patients receiving EBRT (ASTRO definition). In a multivariate analysis, while clinical stage, pretreatment PSA, biopsy Gleason Score, year of therapy, and the use of neoadjuvant AD were independent predictors of survival, age, race, prior TURP, and treatment modality (surgery or RT) were not associated with outcome.[468] A pooled analysis of 2991 patients from the Cleveland Clinic and the Memorial Sloan Kettering at Mercy Medical Center showed comparable 5-year bDFS for patients receiving EBRT with doses in excess of 72 Gy, brachytherapy, a combination of EBRT and brachytherapy, or RP (Figure 53-7).[469] A retrospective analysis from the SEER registry of 60,290 men treated for localized prostate cancer found prostate cancer-specific mortality at 10 years was 1.3%, 0.5%, and 3.7% for RP, brachytherapy, and no definitive therapy, respectively.[470] In a multivariate analysis both surgery and brachytherapy resulted in better prostate cancer-specific and all-cause mortality than no definitive therapy. The magnitude of the survival benefits from surgery and brachytherapy were similar.[470]

Two recent series have suggested a higher rate of distant metastases and worse survival in men undergoing RT compared to RP for high-risk prostate cancer.[243,471-473] Each of these series had an imbalance of prostate cancer risk factors and comorbidities that contribute to the observed inferior outcomes with RT. In the Swiss experience, EBRT techniques and total doses were not specified, but the period of the study preceded the availability of both three-dimensional conformal radiation therapy (3DCRT) and intensity-modulated radiation therapy (IMRT).[243] That patients undergoing surgery appear to have better all-cause mortality points to the underlying selection bias in surgical series. Patients with preexisting comorbidities are not routinely selected for radical surgery because of the risk of morbidity and mortality from anesthesia and the operation itself. Attempts to correct for these comorbidities have been problematic. Although no differences in prostate CSS have been identified, no explanation for death from other causes satisfactorily explains the worse OS in men undergoing either EBRT or brachytherapy.[472,473] It is likely that unaccounted health issues such as obesity, smoking, hypercholesterolemia, and hypertension contribute to worse survival in men unable to tolerate RP.[474] Furthermore, as will be discussed later in this chapter, adjuvant hormone therapy, which is considered a standard of care for patients with high-risk disease receiving RT, was not routinely administered to patients in either of those series.

To summarize, RT and surgery must be considered as equal treatments for localized prostate cancer in terms of cancer control. Treatment decisions need to take into account patient health, the impact of treatment on his quality of life, and access to therapy. A thorough discussion of these treatment options, as well as active surveillance if appropriate, needs to be presented to all patients at the time of diagnosis.

Radiation Therapy

General Principles

Radiation therapy has been used as curative therapy for clinically localized prostate cancer for nearly a century. With the advent of megavoltage teletherapy systems in the 1960s, EBRT became a standard therapeutic approach for men with nonmetastatic prostate cancer. Over the past two decades, important advances in EBRT delivery methods such as 3DCRT, IMRT, image guided radiation therapy (IGRT), stereotactic body radiation therapy (SBRT), and proton beam RT have contributed to an improvement in the therapeutic ratio for men with prostate cancer. Similarly, brachytherapy methods improved with advances in imaging modalities, treatment planning software, and delivery methods for localized prostate cancer. At present, the radiation oncologist has several radiotherapeutic options available to apply to the management of men with prostate cancer.

Organ-Confined Disease

The literature contains few prospective, comparative clinical trials relevant to the treatment of patients with clinical T1-2 prostate cancer. Most reports were derived from single-institution observational case series in which a predetermined therapeutic approach and follow-up schedule were not established, and retrospective medical record review was used to assess efficacy and toxicity. Because the interpretation of observational case series presents certain problems,[475] statements about the utility of any treatment method, particularly compared with an alternative strategy, should be viewed with caution. In this context, the ensuing discussion emphasizes the experience from selected centers of urologic excellence and large multiinstitutional studies because these sources present a relatively broad perspective on the results achieved across the spectrum of radiotherapeutic practice.

Conventional External Beam Radiation

Conventional EBRT refers to a treatment planning method wherein the prostate and other target tissues are identified by the anatomy of surrounding structures (e.g., bony landmarks and contrast-enhanced viscera). The availability of modern imaging modalities, particularly CT and MR, coupled with RT treatment planning computers allowed for precise localization

of the prostate gland and other target tissues with respect to the treatment beam. Thus, accurate three-dimensional (3D) target volume definition was made possible, and individualized RT field definitions were devised to conform dose distributions (i.e., conformal RT) to the shape of the target volume(s). Without the benefit of conformal radiation techniques, radiation doses generally could not exceed a prescribed dose of 70 Gy without an associated increase in the rate of bowel or bladder toxicity.[476] Even more importantly, IMRT is a technique that uses multiple beam angles and CT-based computer planning to conform the dose to the prostate as closely as possible, thereby sparing the nearby normal structures. During IMRT a part of the radiation field is blocked or modulated at a specified times and locations to optimize radiation fluence to the target yet limit the dose to adjacent critical structures, in this case, the bladder and the rectum. This modulation can be accomplished with a multileaf collimator or with compensation filters. Image-guidance with in-room CT, x-ray or other methods of tumor localization should accompany IMRT to assure the tight radiation dose distributions are covering the intended target. With dose escalation and treatment intensification with hypofractionation, SBRT methods are being explored.

Results with Conventional EBRT. Before the advent of PSA screening and conformal radiation therapy, the 5-, 10-, and 15-year OS rates associated with definitive RT for T1-T2 prostate cancer were approximately 80%, 60%, and 35%, respectively.[245,478,479] Because significant comorbid illness may reduce life expectancy, CSS is a more appropriate endpoint to assess the efficacy of a particular treatment strategy. CSS probabilities following conventional RT in the pre-PSA era ranged from 55% to 80% at 5 years and 35% to 70% at 10 years.[245,478,479] In general, CSS is higher than OS, which emphasizes the importance of comorbidity in assessment of therapeutic outcome.

Although survival is a crucial and unequivocal endpoint, patient mortality (and, through inference, therapeutic efficacy) is strongly affected by underlying host- (e.g., age, comorbidity) and tumor-related (e.g., tumor grade) factors that may influence selection of a particular management approach. Therefore, complete and permanent eradication of the primary tumor (i.e., local tumor control) may be a more direct measure of radiotherapeutic efficacy. However, local tumor control is not consistently defined in the literature, and definitive evidence regarding the ability of EBRT to attain complete tumor ablation is difficult to obtain. Although most reports defined local tumor control as the absence of a progressively enlarging prostatic abnormality or of signs or symptoms suggesting local tumor recurrence (e.g., hematuria, urinary obstruction), there is considerable disparity between clinical assessment and the results of post-RT prostatic biopsy,[480,481] and few investigations adequately address this issue. Strategies to improve local tumor control in the current era include dose escalation with conformal EBRT, IMRT, proton therapy, SBRT, interstitial brachytherapy with or without EBRT, and the addition of AD therapy.

Relatively few RT series evaluated regional nodal tumor relapse, but fewer than 3% of patients had this identified as a site of disease relapse.[245,478] However, the reported probability of regional nodal relapse was likely an underestimate because serial radiologic imaging was not routinely performed during post-RT patient follow-up. Therefore, the mortality associated with regional nodal relapse has not been defined.

Median life expectancy after appearance of metastatic disease is approximately 2 to 5 years.[245,291] The rate of distant metastasis in men treated with primary RT without long-term androgen suppression ranges from 11% to 28%.[363] A nomogram to predict the rate of distant metastases at 5 years has been constructed and validated.[363] Heightened awareness for the development of metastases may be important in the presence of local tumor recurrence because patients with this condition are at particularly high risk for subsequent metastatic relapse.[482-486] Whether tumor-related factors (e.g., tumor grade) that predispose to local recurrence place patients at risk for harboring subclinical metastases at presentation, or whether persistent disease at the primary site results in secondary tumor dissemination, is uncertain. Yorke et al[487] proposed that more than half of metastases originate in association with local recurrence, and Coen et al[485] reported a late wave of distant metastasis following local failure, suggesting that improved control of the primary tumor may enhance long-term survival. There is increasing evidence that improved local tumor control with aggressive local therapy is having a favorable impact on distant metastases rates.[486,488-490]

Biochemical Relapse. More contemporary studies incorporate both pre- and posttherapy serum PSA into outcome analyses to better define prognostic groups and disease-free status. Serial PSA measurements and the endpoint of PSA RFS have become the new benchmark for assessing treatment efficacy. To study long-term outcome after EBRT in the PSA era, six institutions combined data and used the ASTRO PSA failure definition, defined by the Consensus conference in 1996, as the analysis endpoint.[491] Tumor stage, Gleason score, pretreatment PSA level, and PSA nadir after therapy were all established as important factors in outcome. Five years later, a follow-up study with data from nine institutions was completed and ultimately included 4839 patients with T1-T2 prostate cancer treated from 1986 to 1995 with median 6.3 years follow-up.[227] During this study period a conventional technique (70%) was used in earlier years and conformal therapy (30%) more recently. Prescribed radiation doses were those common for that era as well. Sixteen percent of patients were treated to 60 Gy to 65 Gy, 54% to 66 Gy to 70 Gy, 19% to 70 Gy to 72 Gy, 10% to 73 Gy to 78 Gy, and 1% above 78 Gy. Outcome analysis confirmed the prognostic factors established by the first study: T category, Gleason score, pretreatment PSA, and posttreatment PSA nadir[491] and also established dose and year of treatment as independent prognostic variables.[227] PSA disease-free results for patients treated to at least 70 Gy, shown in eTable 53-5 and Figure 53-8, demonstrate the relationship between nadir and eventual biochemical failure. Because of the long-term follow-up available for these patients, up to 14 years, this analysis also showed that of those patients who were PSA disease-free at 5 years, an additional 17% would develop PSA relapse by 10 years, pointing out the late relapsing nature of this disease. Clinical failure and survival analysis (Table 53-4) showed results more encouraging than those with

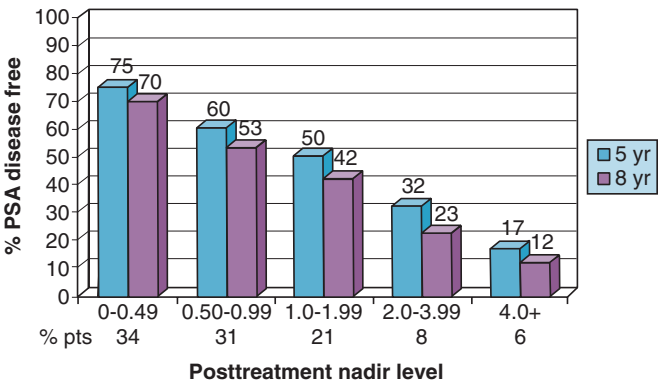

Figure 53-8 The likelihood for long-term local tumor control after external beam radiation is shown as a percentage of all patients determined to be disease free by their PSA nadir level. The percentage of patients achieving each nadir level is given on the *x* axis.

Simultaneous with advances in technology there has been progress in outcome reporting, staging, and risk assessment. Currently, outcome reporting mainly uses PSA after treatment to determine relapse but also uses PSA as a pretreatment factor to classify the disease burden and to categorize patients into prognostic risk groups. Because diagnostic imaging has improved markedly over the last several years, stage migration has also occurred. In fact, there is evidence that the year that treatment was delivered is an independent predictor of outcome in addition to all the other well-known prognostic factors such as T category, grade, RT dose, and technique.[477]

PSA relapse as the endpoint.[492] In studying the relationship of PSA relapse to clinical relapse, this multiinstitutional effort reported that 49% to 78% of patients were clinically disease free at 5 years and 46% to 58% were clinically disease free at 10 years after PSA failure, depending on risk group.[227] bDFS is being investigated as a surrogate endpoint in clinical trials of local therapy because it may fulfill the Prentice Criteria for predicting clinical DFS and possibly OS.[493,494]

Dose Escalation. With PSA outcome reports showing more room for improvement in treatment efficacy than was previously believed, effort was directed toward more conformal treatment techniques, 3DCRT, IMRT, and proton beam therapy to increase the prostate dose while avoiding adjacent nontarget tissues. Several single institutional series have reported outcomes for doses ranging from less than 70 Gy to more than 86.4 Gy.[246,486,489,495,496] Improvement in PSA-DFS and a significant impact on distant metastatic rates have been attributed to dose escalation.[246,486,490,495]

Table 53-5 summarizes five randomized trials that demonstrate a significant improvement in bDFS with EBRT dose escalation.[496-503] Although each of these studies employed conventional or conformal EBRT photon therapy for part or all of the treatment course, the boost treatment in one trial employed a proton beam boost.[501]

It is difficult to draw broad conclusions about the scope of benefit of dose escalation from these prospective Phase III trials. The eligibility criteria were different and the use of AD therapy was required in one trial,[496] allowed by physician discretion for high-risk patients in another trial[497] and not allowed in the others.[498-501] The follow-up duration and the total doses used in the studies also varies. In each of the modern EBRT dose escalation trials,[496-498,501] dose escalation has unequivocally improved bDFS for the populations of patients enrolled in the trials. Within each study, subgroup analyses suggest that some populations benefit more than others. In the MRC trial, all NCCN subgroups benefited from dose escalation.[496] In the Dutch trial, only patients with intermediate- and high-risk disease had improved outcome with higher doses.[497] In the M. D. Anderson trial, the benefit was limited to patients with an initial PSA of more than 10 ng/mL.[498] The Proton Radiation Oncology Group trial showed a significant benefit to both low- and intermediate-risk groups.[501] There were insufficient high risk patients (<5%) to determine the value of dose escalation in that trial. The MRC trial showed an improvement in clinical DFS, 69% compared with 61% (p = 0.03).[496] With a median follow-up of 8.7 years, Kuban reported a significant reduction in the clinical failure rate from 15% to 7% (p = 0.014) with 78 Gy as compared to 70 Gy.[498] Although distant metastases were infrequent, dose escalation improved the distant metastasis-free survival rate from 95% to 99% (p = 0.059). In the patients with NCCN high-risk disease, the reduction in distant metastatic rate from 96% to 83% was significant (p = 0.035). The French trial reported ASTRO biochemical relapse rates of 39% and 28% with 70 Gy and 78 Gy, respectively (p = 0.36).[503] Like the others, there was no clinical or OS improvement.

With a median follow up of 10 years, the MRC trial has not shown a difference in OS. The OS is 71% in both arms despite there being a significant difference in biochemical and disease progression outcomes. Clearly, many patients that develop biochemical or clinical progression will receive long-term AD and other recently approved agents that may prolong survival. Whether the avoidance of the cost and morbidity associated with these salvage systemic therapies is worth the trade off of slightly higher GI side effects will require further examination. RTOG has completed a trial of dose escalation in intermediate-risk prostate cancer that is also powered to demonstrate a survival difference.[504] Follow-up from this and the other randomized trials may help understand the impact that dose escalation has on OS and specific patient subsets. In a systematic review of 38 published studies from 1990 to 2003, an OS benefit to dose escalation in the range of 70 Gy to 80 Gy was demonstrated.[505] In a pooled analysis of four RTOG trials from 1975 to 1992, Valicenti demonstrated that higher radiation dose was a significant predictor for improved DFS and OS for patients with Gleason scores 8 to 10 ($p < 0.05$).[506] After adjusting for other known clinical prognostic factors, a higher radiation dose was associated with a 29% lower relative risk of death from prostate cancer and a 27% reduced mortality rate ($p < 0.05$).

Hypofractionation and Treatment Duration. Preclinical and clinical data have suggested that radiation therapy of prostate cancer may be improved with hypofractionation (higher dose per fraction with a shortened overall course of therapy). Unlike other epithelial cancers, it has been speculated that the alpha-to-beta ratio of prostate cancer is lower than that of its surrounding normal tissues. A low alpha-to-beta ratio would imply a tumor's sensitivity to fraction size and therefore a fraction size of more than the common 1.8 Gy to 2.0 Gy would offer a therapeutic advantage. The early use of hypofractionation was motivated by concerns of cost and resource availability and not related to an expectation of a biological advantage.[507-509] The early suggestion that the alpha-to-beta ratio for prostate cancer is approximately 1.5 came from a computational analysis of patient outcomes that compared men treated with permanent seed prostate brachytherapy to a dose of 145 Gy to a group of men treated with EBRT and conventional fractionation to doses of 70 Gy to 74 Gy.[510,511] Fowler calculated a similar estimate of an alpha-to-beta ratio of 2 Gy with men treated using EBRT and prostate brachytherapy with either iodine-125 (^{125}In) or palladium-103 (^{103}Pd) monotherapy.[512] Brenner completed another alpha-to-beta estimation with a group of men treated on a dose escalation trial using high-dose-rate (HDR) brachytherapy with doses

In their series, irrespective of NCCN risk group, Zelefsky et al reported a 5-year PSA-DFS of 61% with a dose of >70.2 Gy, 74% with 75.6 Gy, 85% with 81 Gy, and 82% with 86.4 Gy.[246] In their highest dose level of 86.4 Gy, they reported exceptional biochemical controls rates of 98%, 85%, and 78% for NCCN low-, intermediate-, and high-risk groups, respectively.[495] In their patients with intermediate- and high-risk disease, high radiation dose was an important and statistically significant predictor for improved distant metastases-free survival.[246] In a multivariate analysis, the Fox Chase Cancer Center group reported that high T category, Gleason score, initial PSA, and low radiation dose were all significant variables associated with the development of distant metastases.[490] In another series of 919 patients treated at the Cleveland Clinic, Kupelian reported that the 7-year distant metastatic rate was 9%, 6%, and 1% for patients treated to a dose less than 72 Gy, 72 Gy to 82 Gy, and 82 Gy or more, respectively ($p = 0.008$).[486]

per fraction ranging from 5.5 Gy to 10.5 Gy.[513] Patients treated with dose escalated hypofractionated HDR brachytherapy had better biochemical control with a calculated alpha-to-beta ratio of 1.2 Gy (95% CI, 0.03 Gy to 4.1 Gy).

An oft-cited criticism of the preceding analyses are the uncertainties associated with retrospective studies in general, as well as the use of data pooled from multiple institutions and the inclusion of brachytherapy where dose heterogeneities are substantial.[515] Furthermore tumor clonogen repopulation[516] and tumor hypoxia[517] may further confound the calculation of accurate alpha-to-beta ratios. Recently, a provocative hypothesis has been put forth suggesting that overall treatment time is an important biological factor related to prostate cancer disease control. Although older, pre-PSA–era series did not show a time factor, an analysis of clinical outcomes from several analyses suggest that a longer overall treatment time was associated with a worse biochemical failure for patients with low-risk prostate cancer.[518,519] Their data raise the question that the benefit of hypofractionation may be partly explained by the shorter overall course of treatment (eTable 53-6).[520]

Prospective randomized trials evaluating hypofractionation for early stage prostate cancer are summarized in Table 53-6. Two older Phase III trials compared standard fractionation to hypofractionation but neither showed an advantage to the shorter course of therapy.[521,522] The short-course regimens were selected for reduced resource utilization and not for radiobiological considerations. The biological equivalent doses chosen for were relatively low and therefore would not have been expected to yield improved outcomes. Several modern Phase III trials were designed on the principle that the alpha-to-beta ratio for prostate cancer is lower than surrounding tissues and that hypofractionation could deliver biologically equivalent doses (EQD2) in the range of 77 Gy to 84 Gy to the tumor.[523-526] These hypofractionation arms were compared to conventional fractionation in 1.8-Gy to 2-Gy daily doses to total doses of 70 Gy to 76 Gy. The first trial from Regina Elena, Italy, was designed to show comparable bDFS but with lower rates of late toxicity.[523,524] Initially reported in 2010, the trial showed a result opposite to what was expected with no difference in 2-year GI toxicity but an unanticipated improvement in bDFS. With further follow up, the differences in biochemical control were no longer significant. A Phase III trial from the Fox Chase Cancer Center compared 76 Gy in 38 fractions of 2 Gy/day to a hypofractionated regimen of 70.2 Gy in 26 fractions of 2.7 Gy/day.[525] It had been hypothesized that the shorter course of treatment would improve the bDFS from 70% to 85% at 5 years. The results from that trial showed no difference with 81% and 85% 5-year bDFS in the short and conventional arms, respectively ($p = 0.745$). Although there were no differences in GI toxicity, patients that had prior urinary obstructive symptoms with an International Prostate Symptom Score (IPSS) score of more than 12 experienced more late genitourinary (GU) toxicity. The authors concluded that there is no disease control advantage with hypofractionation, but fewer healthcare resources would be consumed with hypofractionation, as long as it was limited to patients without prior urinary obstructive symptoms. Finally, early results from a trial at M. D. Anderson Cancer Center (MDACC) compared 75.6 Gy in 42 fractions of 1.8 Gy/day to 72 Gy in 30 fractions of 2.4 Gy/day. Cancer control or PSA outcomes were not reported, but they reported near doubling in the rate of grade-2 or worse GI toxicity from 5.1% to 10.0% and similar rates of grade-2 or greater GU toxicity with 16.5% and 15.8% with conventional versus hypofractionated RT, respectively. Neither difference was statistically significant.[527]

Each of these studies was based upon the premise that the biochemical control rates would be improved with hypofractionation or that the toxicity would be equal or better. Although it appears the short courses of radiation therapy are comparable, noninferiority trials need to establish that this strategy will not result in inferior outcomes over time. Three large Phase III noninferiority trials (Table 53-6) have been completed accrual with more than 5000 cases registered among them. Results from these trials should shed light and inform radiation oncologists about the merits, or lack thereof, of short-course hypofractionated radiation therapy.

Several groups have explored even more aggressive hypofractionation schedules using image guided IMRT or SBRT methods with fraction sizes ranging from 6.7 Gy to 10 Gy. eTable 53-7 summarizes the treatment schedules and 2 Gy equivalent doses.[528-533] The results from these trials show that this extreme fractionation is feasible with rates of bDFS of 90% or better, albeit with short median follow up (Table 53-14). Late toxicity with these ultra-hypofractionated schedules will require long-term follow up to reassure treating physicians that these regimens are both safe and effective.

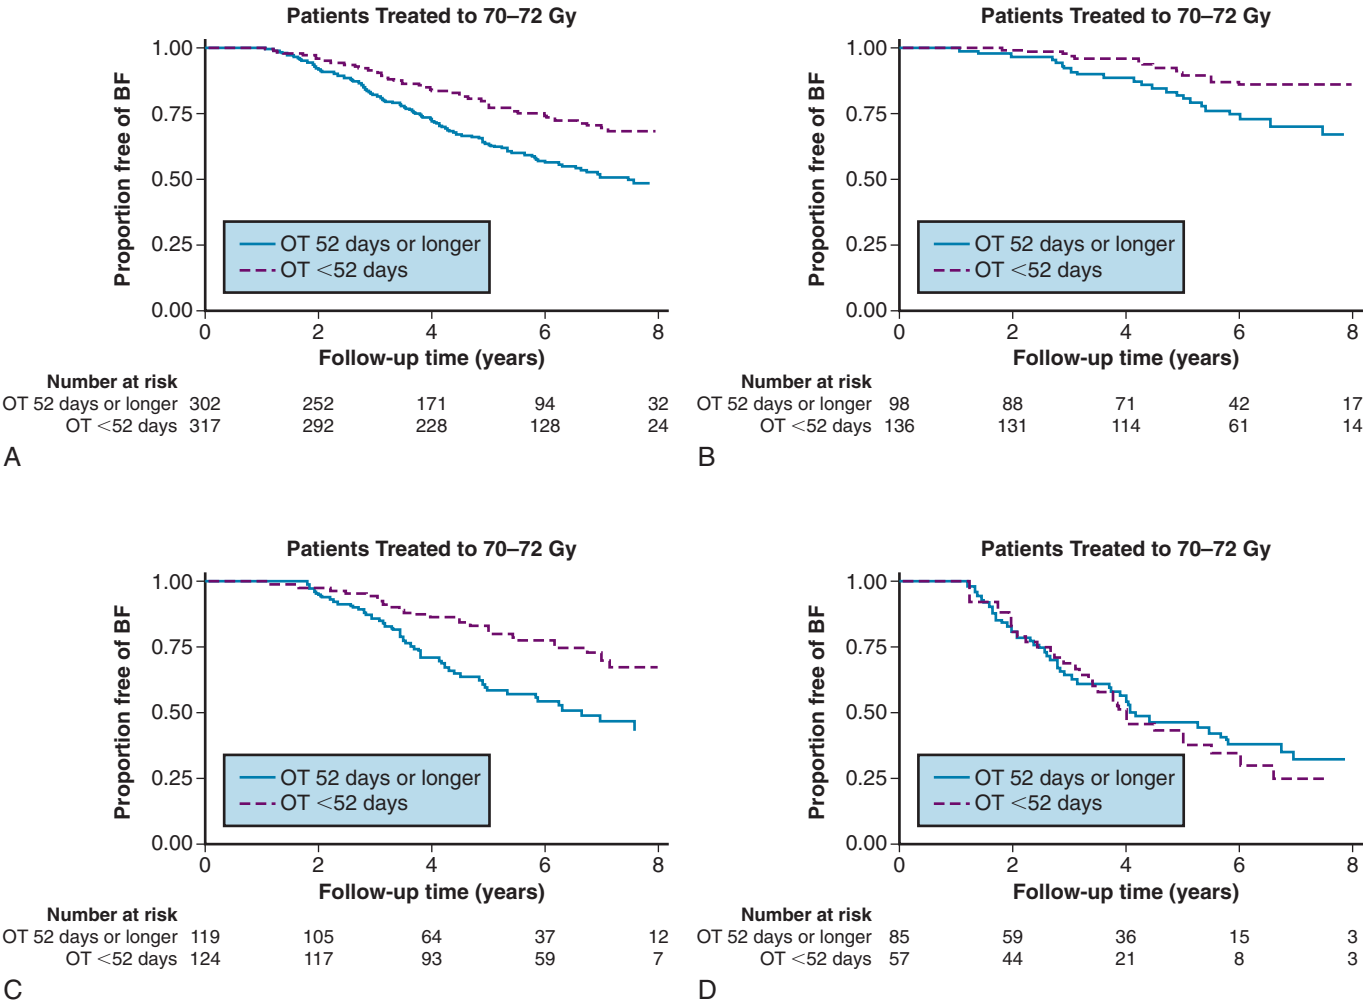
In a series of 3756 patients treated with EBRT that included 185 patients receiving a HDR brachytherapy boost, Williams et al estimated the alpha-to-beta ratio was 2.6 Gy. There was, however, a wide CI of 0.9 to 4.8 Gy.[514]



The Fox Chase Cancer Center defined a nontreatment day ratio (NTDR) as the number of nontreatment days divided by the total elapsed days of the RT course. The larger the NTDR, the more days off or interruptions in treatment were experienced by the patients. The 10-year bDFS of patients with low-risk disease was 82% for patients with a NTDR of <33% compared to only 57% if the NTDR was more than 33% (p = 0.0019).[518] Thames et al confirmed the importance of overall treatment time in a retrospective analysis of 4338 men treated at nine institutions.[519] Overall treatment time was not a factor in biochemical disease control in patients who were treated with EBRT doses less than 70 Gy. However, men with NCCN low- and intermediate-risk prostate cancer who received 70 Gy or higher had 6% loss of bDFS for each additional week increase in overall treatment time. Some of this loss of tumor control could be overcome with an increase in EBRT dose with a 15% decrease in biochemical failure for each 6 Gy increase in dose.[519]

Thames et al analyzed the outcomes of 4839 men treated with EBRT for prostate cancer. In patients that received 70 to 72 Gy, there was a significant improvement in biochemical control if their treatment was completed in fewer than 52 days (eFigure 53-1). This improvement was limited to low and intermediate risk subgroups.

The first Phase I/II trial of SBRT for early stage prostate cancer was reported by Madsen in 2007.[528] Forty men with low-risk prostate cancer received 33.5 Gy in 5 fractions of 6.7 Gy with daily localization had a Phoenix biochemical DFS of 90%. The incidences of late grade-2 or greater GU and GI toxicities were 20% and 7.5%, respectively. Katz reported the largest single-institutional series of SBRT with 304 predominantly low-risk patients.[530] Their first 50 patients received 35 Gy in five 7 Gy fractions and the next 254 patients received 36.25 Gy in five 7.25 Gy fractions. With a median follow up of 30 and 17 months for the low-dose and high-dose cohorts respectively, they reported a low rate of 5% late grade-2 GU toxicities and 2% late grade-2 GI toxicities. Biochemical failure was not reported but they did note that more than 80% of patients achieved a PSA nadir of <1 ng/ml. A PSA bounce of more than 0.2 ng/ml was seen in 16% of their patients. In a pooled series of 1100 patients from eight institutions, King reported a 5-year biochemical DFS of 93% for all patients with a median follow up of 36 months.[536] In a subset of 135 patients with a minimum follow-up of 5 years, the 5-year bDFS was 99% and 93% for low- and intermediate-risk cases, respectively. King reported a significantly lower rate of late rectal toxicity if the therapy was delivered every other day rather than 5 consecutive days (0% versus 38%, $p = 0.0035$).[529] In the series from the University of Texas, Southwestern reported by Boike et al, 1 of the 15 patients treated to a dose of 50 Gy in 5 fractions of 10 Gy suffered a grade-4 toxicity that required a diverting colostomy.[533] Several prospective trials are under way comparing these ultra-hypofractionation schedules to more traditional courses of radiation therapy. In an analysis of Medicare claims, Yu reported that 15.6% of patients receiving SBRT had GU toxicity compared to 12.6% of those that received IMRT.[537] It appeared that urethritis, incontinence, and urinary obstruction were more common in the patients treated with SBRT.

Complications. Complications that occur during or after EBRT can be grouped into four major categories: intestinal, urinary, sexual, and other. Intestinal toxicity occurring during RT manifests as an acute enteritis resulting from the effect of irradiation on the small and large intestine. The severity of this side effect is proportional to the volume of bowel included in the treatment fields but is usually well controlled with antidiarrheal medications and local steroidal type preparations for proctitis. After treatment, any such symptoms typically return to the baseline state within 2 to 4 weeks. However, long-term injury may occur in a small proportion of patients, and this may manifest as persistent diarrhea, tenesmus, rectal/anal strictures, or hematochezia; bowel ulceration, obstruction, or perforation is more uncommon. The RTOG system for late (>90 days after completion of RT) morbidity is shown in Table 53-7 along with a more detailed LENT-RTOG modification used in some studies. A recent review led by the Quantitative Analyses of Normal Tissue Effects in the Clinic (QUANTEC) group addressed the time, dose, and volume relationships associated with radiation related toxicity in the management of a broad spectrum of malignancies. The normal tissue dose constraints recommended by this group are summarized in Table 53-8. Of note, most normal tissue constraints are derived from common fractionation and 3D conformal techniques. The use of hypofractionation and techniques that are more conformal than 3DCRT such as IMRT or proton therapy may require modification of these constraints.

Most patients experience some degree of urinary toxicity during EBRT. The symptoms of cystitis/urethritis are characterized by urinary frequency, urgency, hesitancy, decreased force of stream, and dysuria. These symptoms are usually mild to moderate and resolve 2 to 4 weeks after treatment is completed. Significant long-term urinary sequelae are uncommon, but may take the form of cystitis, hematuria, urethral stricture, or bladder contracture.

Although long-term rectal complications were typically acceptable for lower doses of radiation (<5% ≥ Grade 2 for the 64-Gy to 70-Gy dose range), the use of higher EBRT doses without modification in radiation technique led to an unacceptable level of long-term complications.[476,539,540] Storey et al, using data from the MDACC randomized dose response study with 3DCRT, evaluated the amount of rectum that could be treated to a dose of 70 Gy while still keeping the rectal and bladder complication rates at a reasonable level.[541] This analysis showed that grade-2 and grade-3 rectal complications, which were mainly grade 2, increased with 78 Gy as compared to 70 Gy. According to the latest update, 26% of patients treated to 78 Gy developed complications as compared to 12%

TABLE 53-7 Grading System According to the Radiation Therapy Oncology Group Criteria

Grade	Criteria or Symptoms
RTOG GRADING SYSTEM FOR LATE RADIATION THERAPY MORBIDITY	
1	Minor symptoms requiring no treatment
2	Symptoms responding to simple outpatient management, lifestyle (performance status) not affected
3	Distressing symptoms altering patient's lifestyle (performance status) Hospitalization for diagnosis or minor surgical intervention (e.g., urethral dilatation) may be required
4	Major surgical intervention (e.g., laparotomy, colostomy, cystectomy) or prolonged hospitalization
5	Fatal complication
MODIFIED LENT-RTOG COMPLICATION GRADING SYSTEM FOR LATE RECTAL TOXICITY[538]	
1	Excess bowel movements twice baseline Slight rectal discharge or blood
2	>2 antidiarrheals/wk; ≤2 coagulations; occasional steroids or dilatation; intermittent pad use; regular non-narcotics or occasional narcotics
3	>2 antidiarrheals/d; >2 coagulations; ≤1 transfusion; prolonged daily steroid enemas; hyperbaric oxygen; regular dilatation; daily pads; regular narcotics
4	Dysfunction requiring surgery; perforation; life-threatening bleeding
5	Fatal toxicity

TABLE 53-8 Quantec Organ-at-Risk Dose Recommendations

Organ	Endpoint	Dose (Gy) or Dose/Volume Parameters	Rate (%)	Notes on Dose/Volume Parameters
Rectum	Grade ≥ 2 late rectal toxicity	V50 < 50%	<15	
	Grade ≥ 3 late rectal toxicity		<10	
	Grade ≥ 2 late rectal toxicity	V60 < 35%	<15	
	Grade ≥ 3 late rectal toxicity		<10	
	Grade ≥ 2 late rectal toxicity	V65 < 25%	<15	
	Grade ≥ 3 late rectal toxicity		<10	
	Grade ≥ 2 late rectal toxicity	V70 < 20%	<15	
	Grade ≥ 3 late rectal toxicity		<10	
	Grade ≥ 2 late rectal toxicity	V75 < 15%	<15	
	Grade ≥ 3 late rectal toxicity		<10	
Bladder	Grade ≥ 3 late bladder toxicity	V65 ≤ 50% V70 ≤ 35% V75 ≤ 25% V80 ≤ 15%		Based on RTOG 0415 dose guidelines
Penile bulb	Severe erectile dysfunction	Mean dose to 95% of penile bulb < 50 Gy	<35	
		D90 < 50 Gy	<35	
		D60-70 < 70 Gy	<55	

treated to 70 Gy.[542] However, it was also shown that this complication rate could be minimized by decreasing the amount of rectum treated above 70 Gy. If ≤26% of the rectal volume was treated to ≥70 Gy, grade-2 and grade-3 complications occurred in 13% of patients as compared to 51% of patients if more than 26% of the rectal volume was treated to this dose level. In patients treated with 3DCRT, grade-3 rectal complications, still mainly rectal bleeding but more severe, occur much less frequently (1% to 7% of treated patients).[538,540,541,543] In a preliminary analysis of toxicity in patients enrolled on the high-dose (79.2 Gy) arm of the RTOG randomized trial, Michalski reported significantly higher rates of rectal toxicity if the volume of rectum receiving more than 70 Gy (Rectal V70) or 75 Gy (Rectal V75) exceeded 15% and 10%, respectively (Figure 53-9).[544] In an analysis of patients treated on the Dutch dose escalation trial, Peeters reported an association of fecal incontinence with dose delivered to the distal 3 cm of the anal canal wall, whereas rectal bleeding and high stool frequency were associated with dose to the anorectal wall.[545] Clinical factors associated with complication risk include

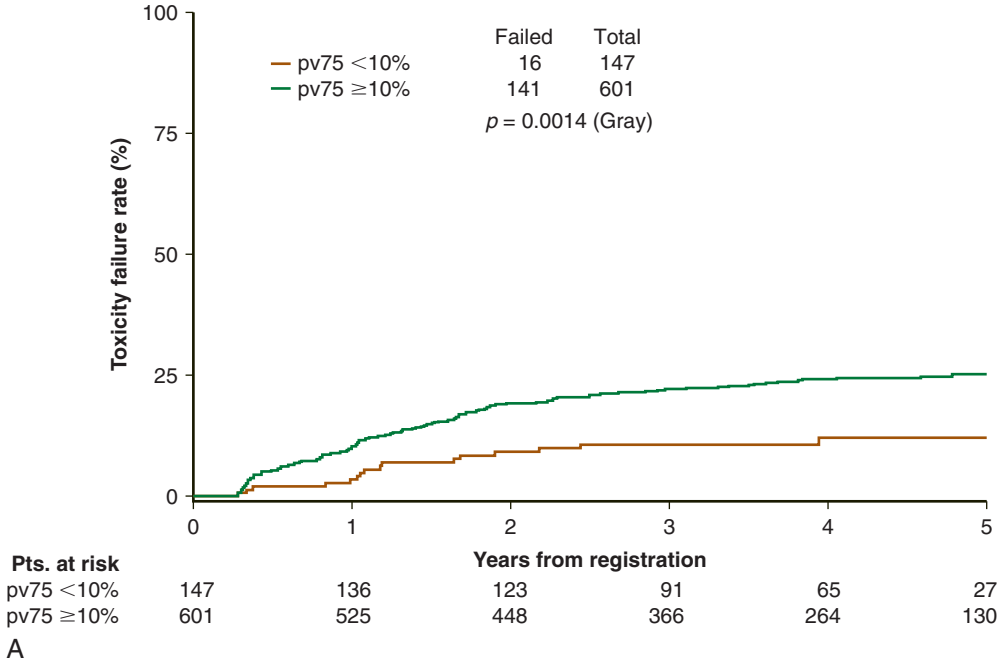

Figure 53-9 Actuarial time to the development of grade 2+ late GI toxicity by dose-volume metrics in patient treated on RTOG dose escalation trial: **(A)** pV70 < 15% or **(B)** pV75 < 10%.
From Michalski, et al: Int J Rad Biol Phys 87:932–938, 2013.

diabetes mellitus, hemorrhoids, inflammatory bowel disease, advanced age, AD therapy, rectum size, prior abdominal surgery, and severe acute rectal toxicity.[546]

A high rate of acute rectal toxicity is now recognized as associated with late RT proctopathy.[544,547-549] In the Dutch randomized dose trial for localized prostate cancer, acute toxicity was an independent significant predictor for late GI toxicity. Zelefsky reported a similar association of acute toxicity to late toxicity in the Memorial Sloan Kettering dose escalation experience.[550] The risk of grade-4 complications, those requiring a major surgical procedure, and grade-5 incidents, those causing the death of the patient, is practically zero and usually related to comorbid conditions.[539,543] In the RTOG dose escalation trial, the incidence of grade-3 or greater late rectal toxicity was significantly greater in patients experiencing grade-2 or greater acute toxicity.[544]

IMRT consistently produces a conformal dose distribution, decreasing the dose to surrounding organs. This has translated into the clinical benefit of decreased toxicity rates despite the delivery of significantly higher doses to the tumor. With a median of 10 years of follow-up, Zelefsky reported that the risk of GI toxicity dropped from 13% with 3DCRT to 5% with IMRT, $p < 0.001$).[550] In the analysis of 748 patients enrolled on the 79.2-Gy arm of the RTOG Phase III dose escalation trial, Michalski reported a significant reduction in grade-2 or worse GI toxicity with IMRT compared to 3DCRT. In the multivariate analysis, IMRT was associated with a 27% reduction in grade-2 late GI toxicity.[544]

The correlation between dose-volume histogram (DVH) and bladder complication risk has not been as straightforward.[551] With 3DCRT, Pollack et al did not see a difference in complication rates when increasing dose from the 70-Gy to the 78-Gy level.[499] In the RTOG dose escalation study, Michalski et al saw a correlation between late bladder complications and the percentage of bladder receiving radiation doses greater than or equal to the defined reference doses of 60 Gy and 65 Gy.[543] In general, the greater the percentage of bladder receiving higher doses, the higher the complication rate. However, there was no dose-volume cut-off above which a complication was more expected as has been seen in rectal DVH analyses. Even more unexpectedly, a higher mean dose to the bladder was a predictor for a lower relative risk of bladder toxicity. An explanation for this might be that bladder complications occur late, as they did in the Massachusetts General Hospital (MGH) proton boost dose escalation study, and the full incidence may not yet have been realized in more recent studies.[552] With 10 years of follow-up, Zelefsky reported that patients receiving a prescribed dose of 81 Gy had a 20% rate of late grade-2 or greater GU toxicity compared to 12% in patients receiving lower doses.[550] There was little difference in the urinary complication rate for 3DCRT versus IMRT. This is likely explained by the fact that much of the toxicity is related to the urethra, which cannot be avoided with either technique. The lack of consistent correlation may be the result of the relative proportion of bladder irradiated, which can change substantially as the treatment course proceeds. As irritative symptoms develop, the frequency of urination increases, which decreases bladder filling and, therefore, total bladder size. This has a direct effect on the percentage of bladder within the treatment field that may differ substantially from that predicted by the initial treatment plan, which is done with a desirably full bladder. In a subsequent series of 268 patients treated to 86.4 Gy, the incidence of grade-2 and grade-3 late GU toxicity was 20% and 1%, respectively.[553] In nearly half the cases, the toxicity resolved with further followup. A DVH analysis demonstrated that hot spots in the bladder trigone were significantly associated with worsening urinary symptoms.[553] They recommended keeping the maximal dose to the bladder trigone to <86.3 Gy with a prescribed dose of 80 Gy in 2 Gy fractions.

Assessment of sexual function after EBRT is complex and may be fraught with difficulty. Potency typically begins to diminish 1 to 2 years after radiation and actuarial analysis appears similar to the natural aging process. Additionally, some patients have compromised potency as a result of concurrent illnesses such as diabetes or arteriosclerosis or as a result of medications taken for comorbid conditions. According to single-institution reports and a meta-analysis, it appears that 50% to 60% of potent patients remain so after EBRT.[554] The specific target tissue for loss of erectile function is unclear, but it has been suggested that either the periprostatic neurovascular bundles or the penile components just inferior to the prostate may be responsible. As part of the QUANTEC project, Roach summarized the risk of erectile dysfunction and the association with mean doses to the penile bulb in excess of 50 Gy.

Other complications including leg or genital edema and osteonecrosis are rare with contemporary techniques. With more conformal radiation, complications appear to be localized.

Of concern, however, are the recent reports on second malignancies associated with radiation for prostate cancer. Although there is a long latency period (5 years to 15 years), this is becoming a more significant consideration because of the younger age at diagnosis, presentation at earlier stages, improved treatment efficacy, and longer average life expectancy. Using SEER data from 1973 to 1993, Brenner et al compared the risk of second malignancy in 51,584 irradiated men to 70,539 who had prostatectomy. There was a fairly small but significant excess risk of solid tumors in men who underwent prostate radiation: 1 in 290 (all years), 1 in 125 for ≥5-year survivors, and 1 in 70 for ≥10-year survivors.[555] The most significant contributors to this increased risk were carcinomas of the bladder, rectum, lung, and sarcomas within the treatment field. Using SEER data from 1973 to 1994 Baxter et al[556] found a hazard ratio of 1.7 for the development of rectal cancers at the irradiated site that did not occur in the remainder of the colon. This 70% increased risk may appear more alarming than it actually is because it translates into 1.4 more rectal cancers per 1000 irradiated men, the same approximate order of magnitude as the risk of having a first-degree relative with colorectal cancer or adding 10 years to ones age. Abdel-Wahab compared the risk of second primary cancers following patients treated with no radiation, EBRT, or brachytherapy.[557] Although the patients who underwent brachytherapy initially had no higher risk of second cancers compared to patients who underwent no radiation, with follow-up beyond 5 years the relative risk of second cancers was similar to patients treated with EBRT.

Particle Beam Therapy

Proton Therapy

Technical Issues. The technical aspects of proton and carbon ion therapy are reviewed in greater detail in the chapters devoted to those technologies. The unique dosimetric feature of the Bragg peak allows relative dose intensity to be applied at deep targets while sparing organs at risk distal to it. Because entrance dose contributes dose to organs proximal to the Bragg peak, most radiation plans for prostate cancer use opposed lateral beams. Just as with IMRT, margins must allow for prostate motion and set-up error. Additionally, because protons are more sensitive to tissue density, extra margin (smearing) must be allowed for inconsistent attenuation in the beam path, such as more bone versus soft tissue, and uncertainties in CT scan densities at planning. Two parallel-opposed lateral beams are typically used for prostate radiation. Range

Historical Perspective. Particle beam therapy has been explored in the treatment of prostate cancer over the last 30 years. In general large, cumbersome, expensive equipment was required to produce the particle beam, set-up and delivery time was lengthy, the process was labor-intensive, and the dosimetry was not tumor conformal, leading to high complication rates with dose escalation because of nearby critical organ tolerance. From the late 1970s through the early 1990s a series of trials were conducted with mixed neutron-photons, proton-photons, and neutrons alone all of which served to study outcomes, both tumor and toxicity, for dose-escalation with particle beam therapy.[500,558,559] Especially for neutron therapy, the increase in dose was largely related to a higher RBE estimated at 4 for the tumor and 3 for normal tissue, which also led to a steep dose-response function for late sequelae.[560] So although mixed photon-neutron therapy showed a survival benefit in one study (RTOG 77-04),[558] and a mixed photon-proton approach produced better local control in poorly differentiated tumors in the MGH trial,[500] the associated toxicity was such that options for dose-escalation with better normal tissue avoidance were preferentially explored. 3DCRT and IMRT with more readily available photons, as well as the application of hormonal therapy to address not only the local but also the metastatic components of treatment failure were applied and refined. As tumor/organ imaging and targeting improved and treatment technology advanced, enthusiasm for particle therapy once again resurged with the hope of decreasing the size of the treatment field and the amount of the nearby normal tissue irradiated. Thus in the current era, proton therapy for prostate cancer is being increasingly more commonly applied and studied and heavy ion treatment with carbon-12 nuclei is being explored. Although data on the comparative efficacy and complications of proton and carbon ion therapy is lacking, several theoretical advantages have been offered. Likewise, there are associated technical trade-offs and concerns that must also be understood.

(depth) uncertainties requiring adequate margin and the slightly higher RBE at the distal end of the Bragg peak prevent using an anterior beam aimed at the rectum. At depth, however, proton beams exhibit significant penumbra affecting the rectum from laterally directed beams.

Studies comparing dosimetry with IMRT with 3D conformal proton therapy have been reported (Figure 53-10).[561,562] The amount of rectum and bladder in the high-dose area are quite similar with both modalities by DVH analysis, allowing for plan optimization and variations in patient anatomy[561,562] There is an advantage for proton therapy for rectal and bladder doses of 30 Gy to 40 Gy or less and for diminished total body doses in the LDR because proton therapy avoids multiple entrance and exit beams (Figure 53-11).[561] (6) The hip dose is 10% to 20% higher with proton therapy, however, because of the use of only two laterally directed beams. The high-dose volume may actually be larger than photons as a result of the need to account for beam attenuation uncertainties and the wide lateral penumbra.

Radiobiology and Second Malignancies. Because protons do not have a much higher linear energy transfer (LET) than photons, the relative RBE is approximately 1.1. Therefore, effects on tumor and normal tissue are assumed to be related to dose and fractionation much the same as for photon treatment. To date, doses and fractionation schedules with proton therapy for prostate cancer have been similar to IMRT. Theoretical benefit in reducing the risk of second malignancy with proton therapy has been proposed.

Clinical Outcomes. To date, outcome reports on proton therapy are sparse, and there are no randomized trials comparing proton therapy to 3DCRT or IMRT. Two randomized trials contained proton therapy as a boost, but the trials were designed as dose comparison studies, and the more recent study included proton therapy in both arms.[500,501] A retrospective review with 10 years follow-up from Loma Linda University contained patients treated with a combination of photons and protons as well as patients treated with protons alone.[564] The dose level was 74 Gy to 75 Gy and the PSA disease-free results were similar to those seen with equivalent doses of photon therapy. Complications to date do not appear to be reduced with proton therapy at comparable dose levels. Preliminary results of a single-arm trial using proton therapy to 82 Gy in 2 Gy fractions showed a grade-2 GI complication rate of 10% and a grade-3 rate of 1%, whereas the respective GU rates were 22% and 7%. There was, in fact, one patient with grade-4 GI and GU toxicity.[565] What this suggests is that unless the urethra and bladder neck are spared, GU toxicity may increase with further dose escalation. Mendenhall reported the early results of three prospective trials of image-guided proton therapy in 211 men treated at the University of Florida.[566] With doses from 78 CGE to 82 CGE, the 5-year cumulative incidences of grade-3 or worse late GI and GU toxicity were 1% and 5%, respectively. The incidence of grade-2 toxicity was not reported but in the previous report it was 4% and 20% at 2 years, respectively.[567] The five year bDFS rates were 99%, 99%, and 76% for the low-, intermediate-, and high-risk NCCN categories. However, in a retrospective study of 27,647 Medicare beneficiaries, Yu reported that compared to IMRT, proton therapy offered no significant difference in the rate of GI or GU toxicity 12 months following treatment.[568]

Future Applications. Pencil beam scanning technology has paved the way for intensity-modulated proton therapy (IMPT). Although most proton centers around the world still use the passive scatter method, which is a 3D conformal approach, it is thought that IMPT holds the key to better directed therapy, possibly to include focal boosting, and the ability to avoid more normal tissue (Figures 53-10 and 53-11).

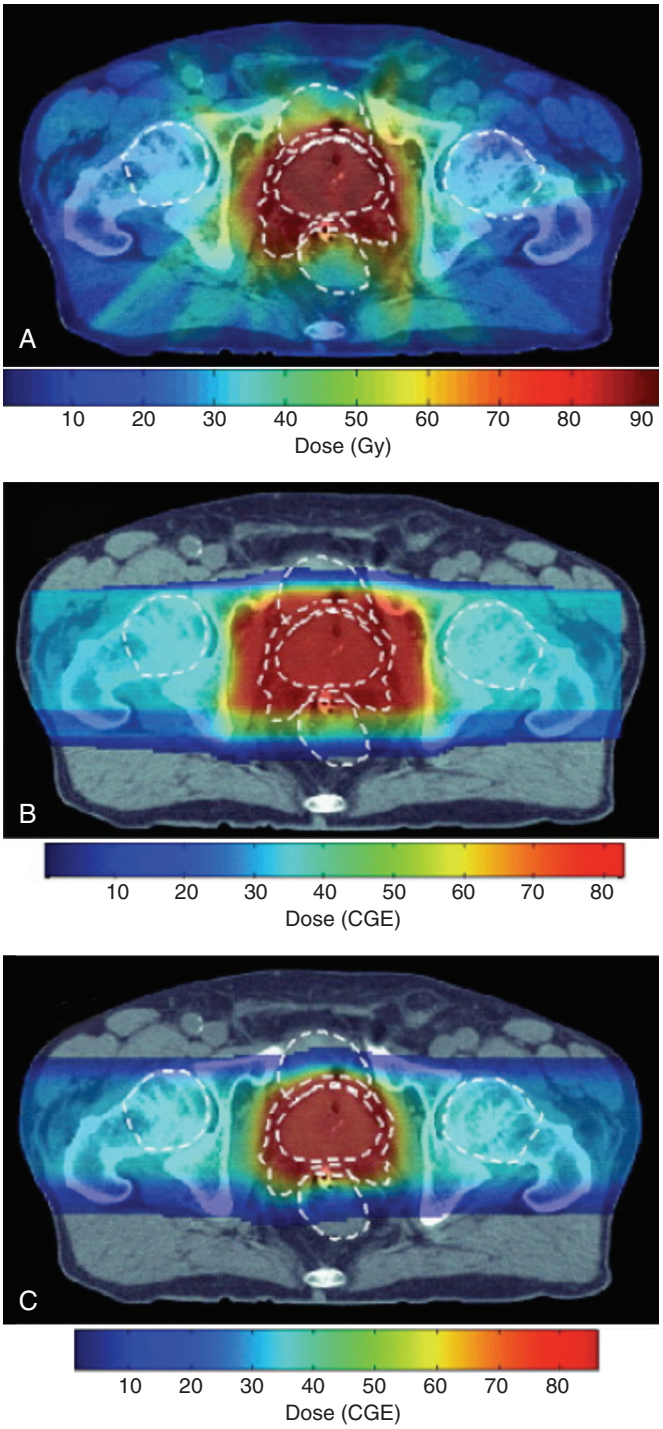

Figure 53-10 Dose distribution in the transversal isocenter section for **(A)** intensity-modulated radiation therapy, **(B)** 3D conformal proton therapy, and **(C)** intensity-modulated proton therapy plans.
From Trofimov A, et al: Radiotherapy treatment of early-stage prostate cancer with IMRT and protons. A treatment planning comparison. Int J Radiat Oncol Biol Phys 69:444-453, 2007.

Studies modeling the risk of second malignancy have suggested that the in-field contribution to this risk is considerably greater than the out-of-field risk from stray radiation and that the in-field risk may be reduced with proton therapy.[563] Of note, however, is the neutron component, which is greater with protons produced by the passive scatter process as compared to 6 MV photons used for IMRT. There is considerable debate over how much more to weight the effect of the neutron component on carcinogenesis. Therefore, the resulting second malignancy rate of one modality versus the other remains debatable because no comparative clinical studies have been reported to date. The impact of patient age is no doubt also a factor in view of the long latency period associated with radiation induced second cancers versus the expected survival of the elderly prostate cancer cohort.

Because the benefit of proton therapy for prostate cancer has been more hypothetical than evidenced-based thus far, cost has become a widely debated issue. Typical proton therapy centers with multiple gantrys carry price tags in the $150- to $200-million range, although single-gantry units may become available for $20 to $30 million. Currently, reimbursement for proton therapy is nearly twice that paid for IMRT. Cost analysis models have not shown proton therapy to be cost-effective by the usual measures even when unproven assumptions are made that this modality will have superior tumor control. Proton therapy proponents argue that as we become technologically more adept with this modality, complication rates will decrease as compared to state of the art photon treatment.

Carbon Ion Therapy. At least one other charged particle is being explored for prostate cancer radiation, the carbon ion. This particle has the advantage of a low LET of approximately 1 in the entrance channel as compared to a LET of 3-4 at the Bragg peak. Accurate targeting is essential for a radiation beam with a high relative biological effectiveness. High LET radiation does have several benefits such as a lower oxygen enhancement ratio making hypoxic tumors more sensitive, less cell cycle dependence, and possible deleterious effects on the microenvironment particularly angiogenesis. Early results from carbon ion trials in Japan show good tolerance and promising 5-year bDFS rates[569,570] With hypofractionated schedules of 66.0 GyE/20 fractions, 63.0 GyE/20 fractions, or 57.6 GyE/16 fractions the cumulative incidences of grade-2 or worse GI and GU toxicities were 1.9% and 6.3%, respectively. The 5-year biochemical and local DFS rates were 91% and 98%, respectively.

Interest in brachytherapy reemerged in the 1970s when Whitmore et al at Memorial Sloan Kettering Cancer Center (MSKCC) in New York established an open, retropubic approach using iodine-125 (^{125}I) seeds.[572] However, trying to uniformly implant the exposed gland did not prove to be the best way to achieve homogenous dose coverage. The 15-year outcomes were disappointing, with only 21% of patients reported controlled. Nonetheless, a retrospective analysis of 110 patients from the original retropubic Yale series with modern, 3D CT-based dosimetric parameters provides insight into the retropubic experience.[573] Several dosimetric parameters were evaluated to determine "cutoff" points that statistically separated these factors by local RFS. When separated by favorable and unfavorable dosimetry parameters, there was a twofold increase in 10-year RFS. More importantly, a comparison of Yale's "inadequate" implants identified a group of patients with local control rates similar to other series from this era that have reported poor outcomes. The experience with the open, free-hand approach suggests that optimal results could be achieved if accurate source placement was accomplished, if dose homogeneity and total dose were adequate, and if patients were appropriately selected.[574]

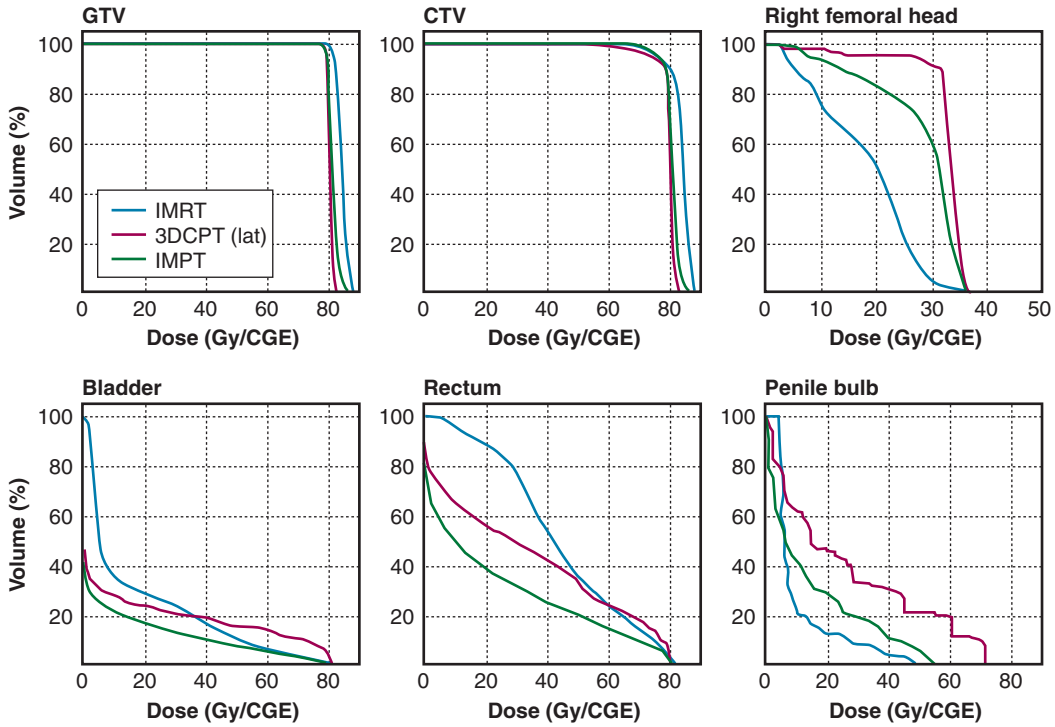

Figure 53-11 Dose-volume histograms for intensity-modulated radiation therapy (IMRT), 3D conformal proton therapy (3DCPT), and intensity-modulated proton therapy (IMPT) plans.
Data from Trofimov A, et al: Radiotherapy treatment of early-stage prostate cancer with IMRT and protons. A treatment planning comparison. Int J Radiat Oncol Biol Phys 69:444–453, 2007.

As always, the goal is to increase the dose while reducing complications.

Brachytherapy

Prostate brachytherapy predates radical prostatectomy, having been introduced in the 1920s with radium needle implants. Later, in the 1960s, radioactive gold seeds were used to treat prostate cancer.[571] Outcomes were poorly reported in the pre-PSA era and, given the complexity of working with radioactive isotopes, its acceptance as a treatment modality was hampered.

A resurgence of prostate brachytherapy occurred in the 1980s because of the transperineal approach developed by Holm et al.[575] This approach adopted in Seattle used a "preplan" to account for the seed placement, whereas in New York a more conservative approach was developed to limit the morbidity of the procedure by peripherally placing seeds to limit central hot-spots.[576] Given the ability for real-time image guidance of implant in situ, excellent results have been obtained with brachytherapy, and both approaches remain active to this day.

Patient Selection. Implantation of the prostate is an attractive option because it concentrates treatment on the prostate and minimizes radiation exposure and morbidity to nearby organs, including the bladder, rectum, and small bowel. Prostate brachytherapy is an outpatient procedure after which the patient may resume 100% of physical activity within 24 hours. The implant serves as the delivery mode of the isotopes, which decay over time and deliver the actual radiation treatment. Prostate brachytherapy can be accomplished with LDR, permanently implanted low-energy, short half-life isotopes such as ^{125}I, ^{103}Pd, and cesium-137 (^{137}Cs) or with high-energy, HDR isotopes such as iridium-192 (^{192}Ir).

The selection of patients for prostate brachytherapy is generally reserved for patients with clinically confined prostate cancer. Similar to other modalities, risk stratification and assessment of pathologic, clinical, and radiographic features best combine to predict for a high probability of organ-confined disease[194]

The selection of brachytherapy as monotherapy versus brachytherapy as a boost with supplemental EBRT has primarily been based on pathologic risk factors. Risk stratification of disease by initial PSA value and Gleason score better predicts outcome and allows for treatment modification to account for those men with high-risk disease. When the risk of extraprostatic disease is high there is the need to combine prostate brachytherapy with EBRT.

The American Brachytherapy Society (ABS) recommends monotherapy for patients with clinical T1-T2a, PSA 10 ng/mL or less and Gleason score 6 or less with the addition of supplemental EBRT for all with higher risk features.[577,578] However, the role for combined EBRT and brachytherapy for patients with intermediate-risk disease remains controversial with some data suggesting that supplemental EBRT may be omitted depending on implant quality and seed placement philosophy.[579]

Brachytherapy is associated with urinary morbidity that may be mild or may be protracted and quite bothersome to the patient. Indwelling catheterization has been reported between 2% and 20% after prostate brachytherapy. Higher rates of acute urinary obstruction date back to older techniques that failed to spare high doses centrally within the prostate. But other factors associated with increased postimplant urinary bother include a high initial International Prostate Symptom Score (>7 to 10) and an enlarged prostate volume.[580] Patients with either or both these factors need to be coached carefully before undergoing permanent brachytherapy. Although it is customary to offer men with enlarged prostates a 3-month course of androgen ablation to reduce the prostate volume, data from Princess Margaret Hospital (PMH)

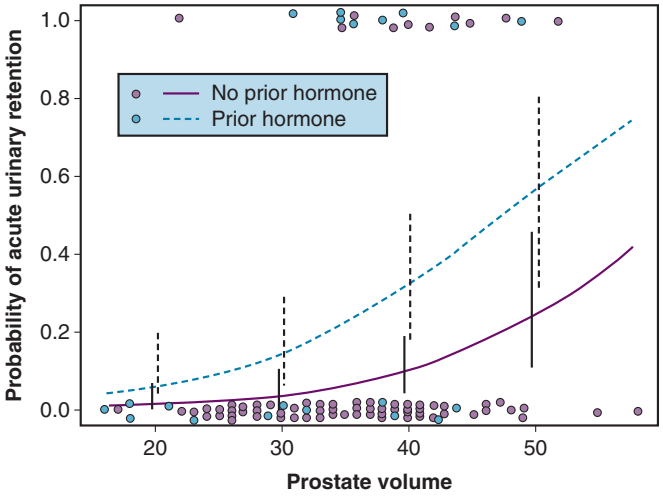

Figure 53-12 Risk of urinary retention according to prostate volume for patients treated with or without hormonal therapy.
Data from Crook J, McLean M, Catton C, et al: Factors influencing risk of acute urinary retention after TRUS-guided permanent prostate seed implantation. Int J Radiat Oncol Biol Phys 52:453, 2002.

suggest that, by doing so, postimplant urinary morbidity is not reduced.[581] Furthermore, the long-term impact on potency of even a 3-month course of androgen ablative therapy needs to be considered. Patients with enlarged prostates and high IPSS values may want to consider EBRT as definitive treatment.

Large prostate size is widely believed to be a relative contraindication to brachytherapy because of technical concerns and the perception that such patients are at higher risk for urinary morbidity. However, contrary to popular perception, several studies have reported that appropriately selected patients with a large prostate can be implanted with acceptable morbidity and with good dosimetry.[582,583] Pubic arch interference may represent a technical problem regardless of prostate size depending on the implant technique used. With the preloaded needle technique, the extended lithotomy position may be difficult to achieve during the planning phase, which may limit needle placement at the time of the implant. With intraoperative planning, patient positioning can be achieved at the time of implant under anesthesia without pubic arch interference.

There appears to be a direct relationship between preimplantation IPSS values and postimplantation urinary obstruction in men undergoing prostate brachytherapy, whether downsized with hormones or not[581] (Figure 53-12). The use of prophylactic α-adrenergic blockers may diminish the impact of a high initial IPSS value.[584] Nonetheless, patients with urinary symptoms should be informed of their risk of urinary retention after implantation.[580,585]

Patients who have been treated for BPH with TURP pose potential problems when treated with permanent prostate brachytherapy. A fresh TURP defect may lead to excessive morbidity and inadequate seed geometry.[586] In general, a preimplant ultrasound evaluation is required for these patients to assess the TURP defect relative to the planned seed locations. Furthermore, it has been reported that patients with a previous TURP may experience prolonged postimplant dysuria and are at risk of urethral necrosis.[587] Current protocols for permanent prostate brachytherapy that place seeds peripherally in the prostate gland do not cause the high rates of urethral necrosis originally reported.[588]

Therefore, past TURP, prostate size, and history of inflammatory bowel disease, all relative contraindications in the past, need to be considered on an individual basis. Patients must also have a patent anus to allow for ultrasonography.

At present, an age-related bias exists within the urologic community, with younger patients being referred more often for radical prostatectomy than either radiation or no therapy. In a recent study from Shapiro et al,[589] men younger than 60 years of age had identical biochemical outcomes at 5 and 10 years compared with patients older than 60 years of age, suggesting that age should not bias prostate brachytherapy as an option in younger men. However, the risk of second primary cancers (SPC) is an important consideration when offering prostate brachytherapy and should be discussed with each patient.

Isotope Selection. Radiobiologic data suggested that isotope dose-rate may be an important factor for treating prostate cancer because different grades of disease with different cell doubling times may have specific sensitivities to either ^{125}I or ^{103}Pd.[592-594] Nevertheless, there have been no data to date to suggest that isotope choice should be based on tumor grade or prostate cancer doubling time.[577] A recent study found that ^{125}I compared to ^{103}Pd brachytherapy followed by EBRT both had an equivalent impact on morbidity and biochemical outcome for patients with clinically localized prostate cancer.[594]

Role of EBRT. The reasons for combining EBRT and permanent prostate brachytherapy are based on the statistical risk of having extracapsular disease associated with Gleason score, PSA, and stage.[193] A prostate implant only provides dose to the prostate with perhaps a 3-mm to 5-mm margin and may include just the base of the seminal vesicles.[595] The "field" effect of EBRT to encompass the seminal vesicles and a larger prostatic margin will potentially encompass the areas at risk for extracapsular disease not treated by the implant.

Patients with T2b cancer or Gleason score 8-10 or PSA >20 ng/mL are recommended to undergo EBRT and implant rather than implant alone.[577] Nonetheless, a review of the literature is not helpful to delineate whether there is a biochemical control difference between these approaches because many centers do not stratify their patients accordingly (Table 53-9).[578,596] Further, detailed pathology studies indicate that the radial extent of extraprostatic cancer extension is almost always 5 mm or less, which is within the confines of a monotherapy brachytherapy dose distribution.[597] If the prostate gland is implanted with a generous periprostatic margin, supplemental EBRT may not improve the outcome in low-, intermediate-, or even high-risk cases.[577,582,598,599]

Results with brachytherapy alone or plus EBRT have been evaluated in several series. In an update of the Long Island experience, Potters et al have shown little difference in PSA-RFS with combined EBRT and brachytherapy versus monotherapy brachytherapy,[579] provided that implant dosimetry is acceptable. Likewise, Blasko et al have identified excellent 10-year BCR in all risk patients undergoing monotherapy brachytherapy. In their study, 230 patients were treated with Pd-103 monotherapy and they reported a 9-yr PSA-RFS of 83%.[283] Forty percent of these patients presented with a Gleason score ≥7 and 24% of the patients had a pretreatment PSA value of >20 ng/mL. These long-term results are as good as any series that routinely use combined EBRT and permanent brachytherapy.[469,598,603] Recently, Shilkrut et al found that EBRT and brachytherapy versus EBRT alone resulted in better outcomes for biochemical failure and prostate cancer specific mortality in patients with high-risk prostate cancer, suggesting that combined modality treatment has a greater impact on CSS and FFBF than EBRT alone in patients with high-risk prostate cancer.[604] Another study found that EBRT with HDR

To that end, it is recognized that radiation exposure is associated with second primary cancers. Several studies have shown an increased risk of bladder and colorectal cancer in men who were treated with radiation for prostate cancer.[556,590] However, these studies were in patients treated EBRT. Brachytherapy, which is highly conformal therapy, appears to have lower SPC risk than EBRT.[557,591]

At the time of the Whitmore implants, ^{125}I was the isotope used and continues to be used for prostate brachytherapy. In the early 1990s, palladium-103 (^{103}Pd) was introduced. With a shorter half-life, it was postulated that ^{103}Pd would be the preferred isotope for higher Gleason score tumors because of their faster tumor doubling time.[593] In 2003, cesium-131 (^{131}Cs) was introduced as a third isotope for prostate brachytherapy; ^{131}Cs has even a shorter half-life than ^{103}Pd, which can offer the advantage of a reduced period to monitor radiation exposure precautions following the implant.

TABLE 53-9 Review of the Literature on Permanent Prostate Brachytherapy Performed as Monotherapy or Combined with External Radiotherapy

brachytherapy boost compared to EBRT alone in the treatment of localized prostate cancer resulted in a 31% reduction in risk of recurrence and a significant improvement in RFS with comparable GI and GU toxicity.[605] There is currently a study by Zelefsky et al (in press) that likewise found improved PSA-RSF and distant metastasis free survival (DMFS) of combination therapy but with EBRT and LDR brachytherapy, instead of HDR, compared to EBRT alone in the treatment of intermediate-risk prostate cancer.[606] The study also found comparable late GI and GU toxicity between the two different treatment modalities.

RTOG 0232 is a Phase III clinical trial that recently closed and sought to compare permanent implants alone to permanent implants plus EBRT in men with intermediate-risk prostate cancer.[607] The results of this study are expected to clarify the role of EBRT in men receiving permanent seed brachytherapy.

Brachytherapy and Androgen Ablative Therapy. With the development of real-time ultrasound permanent prostate brachytherapy in the mid 1980s, the role of combining neoadjuvant androgen deprivation (NAAD) and permanent prostate brachytherapy was to reduce the prostate size if it exceeded 60 grams. This decreases the total isotope activity required and decreases pelvic arch interference.[608] Although this practice has continued, there is data to suggest prostate size is less relevant to implant quality than originally suspected.[583] While some prospective data indicates an improvement in DSS when combining NAAD and EBRT in patients with locally advanced and metastatic prostate cancer,[609] there is no prospective data to support the concept of NAAD as a radiosensitizer for early-stage prostate cancer.[610]

Although Stock et al[611] initially reported on a potential role for combined permanent prostate brachytherapy and hormone therapy, they have subsequently identified that any advantage

TABLE 53-10 Recommendations for Postimplantation Dosimetric Analysis

All patients require postimplant analysis
CT-based dosimetry is recommended (minimum)
Plain radiographs (to verify seed count)
Consistent post implant interval for performing dosimetry
Isodose displays for 50%, 80%, 90%, 100%, and 200%
D90 dose from the dose volume histogram
Additional doses should be reported: D80, D100, V80, V90, V100, V150, V200*
URETHRAL DOSES
Anatomy
1. Contour a volume, not a point or line
2. Catheter or fusion with ultrasound to delineate the urethra
3. Estimation is not accurate
Dosimetric parameters
1. Ur150: (volume in mL of urethra receiving 150% Rx dose)
2. UrD5 (in cGy)
3. UrD30 (in cGy)
RECTAL DOSES
Anatomy
1. Inner and outer wall contour on all CT slices where seeds are identified
2. Dose-percent parameters are too subjective
Dosimetric parameters:
1. R100: (volume of rectum in mL receiving 100% of recommended dose)
2. R150: (volume of rectum in mL receiving 150% of recommended dose)
ERECTILE RECOMMENDATIONS
1. Cannot make recommendations: Weight of evidence toward NVB dose No consensus on location and ability to contour the NVB on CT or ultrasound
2. Recommend study on NVB dosing and contouring
3. Could not support penile bulb dose measurements

From Crook J, Potters L, Stock R, et al: Critical organ dosimetry in permanent seed prostate brachytherapy: Defining the organs at risk. An American Brachytherapy Society Consensus Statement. Brachytherapy 4:186–194, 2005.[616]

CT, *Computed tomography;* D80, D90, and D100, *dose to the respective volume percent of the prostate (D90 represents the minimum dose to 90% of the prostate volume);* NVB, *neurovascular bundle.*

**V80, V90, V100, V150, and V200, volume of the prostate that received the respective dose percent.*

of hormones is negated when postimplant dosimetry is acceptable. Likewise, in the 12-year experience of Potters et al,[282] the addition of hormonal therapy with prostate brachytherapy failed to significantly affect biochemical freedom from relapse when including the impact of the postimplant dosimetry.[282]

Postimplant Dosimetry. Postimplant analysis is an important process and needs to be performed on all patients undergoing permanent prostate brachytherapy (Table 53-10). Single plane pelvic x-rays are insufficient because they do not accurately assess the spatial relationship of the prostate dose and surrounding tissues. Therefore, CT-based dosimetry appears to be the best approach for postimplant dosimetry at this time.[615]

Despite these recommendations, there are several problems with postimplant CT studies that can limit permanent prostate brachytherapy dosimetry. The timing of the study is important because prostate edema may develop acutely following the traumatic insult associated with needle insertion.[618] Early CT scans following the implant may underestimate the prostate dose by up to 10% to 20%.[599] The reported edema half-life is approximately 10 to 14 days so the best time to obtain this study may be 30 days postpermanent prostate brachytherapy.[619] Also, CT scans, may by virtue of pixel size and the location of pelvic and periprostatic muscles, overestimate the prostate size.[620] Lastly, there is tremendous individual variability in drawing the prostate margin, which may overestimate or underestimate the delivered dose.[615] A difference of 1 mm to 2 mm can affect the prostate volume by as much as 30%. Therefore, each clinic needs to set up quality controls to assure that prostate volumes are being appropriately drawn.

These problems aside, Stock et al were able to define the D90 dose as the critical variable to assess permanent prostate brachytherapy (the D90 represents the minimum dose to 90% of the prostate volume). Patients with a D90 dose greater than 140 Gy had a 4-year PSA RFS of 92%, whereas those with a D90 dose less than 140 Gy had a 4-year PSA RFS of 68% (p = 0.04). In a 12-year study, Potters et al[282] identified that the D90% (the D90 dose reflecting the percent of the prescribed dose) was an independent predictor of biochemical freedom from relapse.

Standards have been suggested for postimplant dosimetric analysis of implant quality for the reporting of morbidity.[621] However, many diverse methods of defining the critical organs for morbidity, and of reporting the dose to these organs, are currently evident in the literature. This nonuniformity of approach makes it difficult, if not impossible, to combine data from different centers to establish guidelines for minimizing toxicity.

An expert panel reached a consensus regarding dose parameters that should be tracked to normal tissue(s) when performing prostate brachytherapy. It is hoped that collecting outcomes based on these parameters betters the understanding of normal tissue tolerances and side effects.[616] At this time, there is too little data to make any sound conclusions on any specific data points that will predict the risk of complications and with the advent of real-time, dynamic implants, the role of postimplant dosimetry assessment may become unnecessary.[622]

High-Dose Rate Brachytherapy. HDR remote afterloaded brachytherapy, as an alternative to permanent prostate implants, has been successfully used to treat prostate cancer, but the preponderance of data using HDR for prostate cancer is in men with locally advanced disease. Generally, HDR treatments are combined with EBRT although its application as a monotherapy in patients with low-risk and selected patients with intermediate-risk disease is growing. The ABS recently published consensus guidelines for HDR brachytherapy as a definitive treatment for localized prostate cancer and stated that HDR brachytherapy is an excellent option for the definitive treatment of prostate cancer in any risk category.[613] The consensus statement further recommended that although HDR monotherapy is more established in its role in the treatment of low and intermediate risk prostate cancer, HDR monotherapy for high-risk prostate cancer should still be considered investigational.[613] A recent Phase II study has shown some promising results for HDR as salvage therapy for patients who develop local recurrence in the prostate after definitive EBRT.[623] The study found that in the 42 patients with locally recurrent prostate cancer, with prior EBRT definitive treatment, the treatment with HDR monotherapy as salvage therapy resulted in CSS of 94%.[623]

A recent study found that pretreatment planning with MRI guidance allowed the increased delivery of boost dose to focal tumor volume. This was accomplished by increasing D90 and V150 to the tumor volume using HDR brachytherapy without violating GI or GU constraints.[624]

In patients with high-risk disease treated with EBRT and hormone therapy on the RTOG-9413 study, an improvement was noted when hormones and full pelvic EBRT were used with an EBRT prostate boost.[612] A recent prospective Phase II clinical trial found that the combined effect of EBRT, hormone therapy, and brachytherapy resulted in excellent FFBF.[613] Future studies using permanent prostate brachytherapy may be worthwhile to incorporate a similar approach with adjuvant therapies. Nonetheless, a review of the literature does not appear to demonstrate any synergy based on current practices of combined use of hormones and permanent prostate brachytherapy.[596,614]

Postoperative CT based dosimetric analysis provides detailed information regarding the coverage and uniformity of an implant, affords the ability to compare various intraoperative techniques, and provides a sound basis for future improvement. Although CT determination of prostate volume is widely accepted for EBRT planning, the use of CT for brachytherapy purposes is controversial. The accurate delineation of prostate contours on postimplantation CT may be difficult because of postoperative edema, degradation of the image as a result of implanted metallic seeds, and a possible tendency to overestimate prostate volume from CT compared with transurethral ultrasound. However, a close correlation has been demonstrated for CT and ultrasound determined prostate volumes.[617]

Based on the unpredictable nature of prostatic edema during permanent prostate brachytherapy and its impact on dosimetry, dynamic real-time intraoperative treatment planning systems may ultimately improve the consistency of the D90 dose. Future studies with CT-ultrasound or CT-MRI spatial coregistration (fusion) may better define the prostate margin to determine the delivered dose. In addition, studies on dose heterogeneity will better identify areas within the prostate based on dose that prove to be an independent predictor for toxicity or outcomes.

Modern HDR brachytherapy systems use computer planning programs and robotic delivery systems. During the treatment, a single, high-activity ^{192}Ir source is moved through the implant catheters at 2.5-mm to 5.0-mm intervals. The programmable delivery system controls the amount of time the source stops at a particular location. This is also called the "dwell time." By changing the combination of dwell times, an infinite variety of isovolume dose distributions can be generated. The brachytherapy treatment planning systems can optimize the dwell times based on their location in the implant using computer algorithms. This allows a more homogeneous dose within the implant volume and better coverage of the target volume. Recent advances in treatment planning may provide further refinement of dosimetry by using inverse planning and other dose optimization algorithms. The pretreatment optimization of HDR offers a unique dosimetric advantage over LDR brachytherapy.

In a series of patients receiving either LDR or HDR brachytherapy, Wang reported superior prostate coverage, improved heterogeneity and lower doses to the rectum and urethra with optimized HDR brachytherapy compared to a similar group of men who had permanent LDR implants.[625] HDR brachytherapy dose and fractionation may be an advantage in the treatment of prostate cancer with its hypothetically low α/β ratio.[514] The slow proliferation rate of prostate cancer may be more sensitive to large fraction size and higher dose rates. Indeed, much of the clinical data supporting the low α/β ratio for prostate cancer has been derived from HDR brachytherapy experience.[513,514]

Beside the dosimetric advantages, there are other practical advantages of HDR brachytherapy compared with traditional LDR brachytherapy. Because the HDR source has high activity (typically 10 Curie), a treatment is delivered in a few minutes, similar to EBRT, and is always carried out in the shielded, controlled environment of the HDR treatment room. Between treatments the patient does not need to be isolated and can stay in an unshielded room with other patients. There is no radiation exposure to hospital personnel or to the patient's family members. Because HDR implant is a closed system, there is no risk of seed migration. The effect of postimplant edema can be accounted for by performing dose calculation after the implant.

Brachytherapy Outcomes. Studies reporting long-term outcomes after permanent prostate brachytherapy are mature with more than 10-year outcomes in many men. Without randomized data it is difficult to compare permanent prostate brachytherapy with EBRT or RP. However, by using PSA surrogates to define a successful outcome it appears that permanent prostate brachytherapy is at least equivalent to RP and perhaps slightly better than EBRT.

Long-term data in excess of 10 years support the use of permanent prostate brachytherapy in the definitive treatment of low-risk prostate cancer. Potters et al[282] have reported a 12-year biochemical control rate (bNED) of 81% from a cohort of 1449 patients. Freedom from biochemical recurrence for patients with low-risk disease was 91%. Similarly, Grimm et al showed that the PSA RFS at 10 years was 87% for patients with low-risk disease.[627] Taira recently reported 12-year OS, CSS, and biochemical survival of 72.6%, 98.2%, and 95.6%, respectively out of 1656 men.[628] They also note that for men experiencing biochemical progression, the median time to biochemical failure was 1.9 years compared with 2.4 years for men with a Gleason score of ≤7 and a Gleason score of ≥8 ($p = 0.231$). Although younger patients look for longer-term outcomes, it must be remembered that for permanent prostate brachytherapy, RP and EBRT, outcomes that exceed 10 years to 15 years are pushing against the early experience of PSA screening. Stage and grade migration over time may make long-term data less relevant to the current patient.

Outcomes for men with low-risk disease are excellent, with bNED rates > 90% at 8 years to 12 years.[282] In several studies, implant quality as measured by the D90 dose (the radiation dose that covers 90% of the prostate volume) correlates with outcome. Therefore, the importance of implant quality needs to be emphasized.

For patients with intermediate-risk prostate cancer, Blasko et al[603] identified that the addition of EBRT and permanent prostate brachytherapy was no better than permanent prostate brachytherapy as monotherapy; 5-year biochemical success rate was 85% compared with 84%, respectively. Potters et al[282] also failed to identify an advantage of adding EBRT on Cox regression analysis of intermediate-risk patients. One hypothesis is that poor implant quality, as measured by the D90 dose, can be compensated by the addition of EBRT.

A predictive model for a postimplant nomogram for prostate cancer relapse at 9 years has recently been reported from a large multiinstitutional analysis of 5889 patients who underwent permanent prostate brachytherapy.[629] This study further confirmed the significance of implant dosimetry for predicting outcome. Unique to predictive models, this nomogram may be used a priori to calculate a D90 dose that likely achieves a desired outcome with further validation. Thus, a personalized dose prescription can be calculated for each patient.

In high-risk prostate cancer there appears to be both a dose and radiation field effect associated with permanent prostate brachytherapy. In a multicenter analysis of 3928 patients, Stone et al[630,631] found that patients with high-risk prostate cancer benefited the most from an escalation in the biologically effective doses (BED) compared with the dose typically prescribed to those patients with low-risk prostate cancer.

Long-term biochemical freedom from relapse is reported for permanent prostate brachytherapy from several other centers.[282,283,600,611,633] Although there is little data to correlate clinical outcomes with biochemical outcomes, several studies have compared treatment outcomes between surgery, EBRT, and prostate brachytherapy (alone or combined with EBRT).[469,634] Treatment selection was not a significant factor to predict biochemical outcome except with EBRT doses <72 Gy (Figure 53-7).

Brachytherapy Complications. Many of the side effects associated with brachytherapy are associated with radiation exposure of the urethra, bladder, and rectum. These side effects can have serious quality of life implications and require informed consent from the patient.

In a prospective analysis of the quality of life of patients undergoing primary treatment for their prostate cancer, Sanda et al[635] found that patients undergoing brachytherapy had a significant detriment in urinary irritation or obstruction scores compared with baseline. As noted, factors associated with a greater detriment in urinary irritation or obstruction included a large prostate size and a high IPSS score. In the Sanda study, these factors were not controlled for, suggesting that patient selection remains important.

Similar to patients treated with EBRT and RP, brachytherapy patients were found to have detriments in the domains of sexual function, urinary incontinence, bowel or rectal function, and vitality compared with baseline. Changes in these domains were found to have a subsequent impact on the patient's satisfaction with the overall outcome of the treatment. Yet, for the sexual domain, permanent prostate brachytherapy patients performed better than EBRT and RP.[635]

Treatment-related morbidities following prostate brachytherapy may be acute, subacute, or chronic and affect most commonly the urinary, lower GI, and sexual functions. Many factors have been shown to influence the likelihood of incurring complications and may allow physicians to better select patients suitable for this approach.[580,621,636,637] These reports have also exposed the difficulties in evaluating morbidity due, in part, to the lack of standard assessment methods and potential biases. However, an updated consensus statement of the ABS has outlined standard data points from postimplant dosimetry studies that may better allow the study of dose and normal tissue toxicity (Table 53-10).[616]

Urinary Morbidity and Management. In the immediate postoperative period, patients will likely develop symptoms such as dysuria, frequency, and hematuria (Figure 53-13).[580] The inflammation in the prostate and adjacent tissues may result in weak stream or urinary retention.[637,638] Phenazopyridine is often helpful with dysuria and alpha-blockers, such as tamsulosin, terazosin, and doxazosin, can be prescribed for irritative urinary symptoms such as frequency and weak stream. Hematuria generally improves spontaneously but

Disadvantages of HDR brachytherapy are primarily related to the fractionation schedule. Patients often require an overnight hospitalization in which they are confined to their bed while the transperineal catheters remain in place. In some cases, multiple implant procedures are required to meet the treatment schedule with more than three or four fractions. The HDR procedure may also place a higher demand on healthcare personnel, including the physician, medical physicist, dosimetrist, and nurse, while the implant procedure, treatment planning and optimization, and treatments take place on the same day.

To delineate outcomes in men treated with radiation, a recent study from the UCSF compared endorectal magnetic resonance spectroscopy imaging (eMRSI) responses between permanent prostate brachytherapy and EBRT. For each parameter assessed, permanent prostate brachytherapy outperformed EBRT in both the median time to spectroscopic evidence of disease ablation (24.8 and 32.2 months, respectively) and median time to nadir PSA (38.0 and 52.4 months, respectively).[626]

With new techniques such as dynamic-adaptive permanent prostate brachytherapy, the D90 dose can be controlled intraoperatively. This further negates the need for combined therapy, especially in patients with low- and intermediate-risk disease.

A radiation field effect was also suggested in RTOG 9413. This study demonstrated an advantage in outcomes to whole pelvic radiation plus a cone-down or boost to the prostate, but longer follow-up questions whether nodal radiation is truly beneficial.[632]

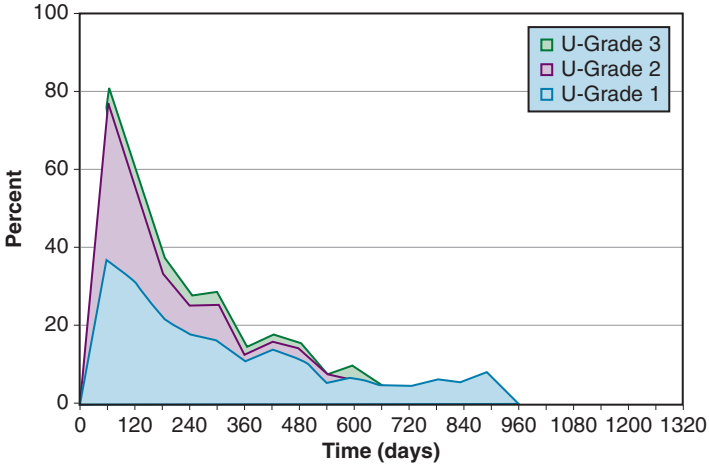

Figure 53-13 Cumulative reported urinary toxicity (i.e., frequency of urination or nocturia) for all patients using the modified Radiation Therapy Oncology Group (RTOG) toxicity scale. U-Grade 1 indicates dysuria, urgency, or bladder spasm requiring no or minimal medical intervention, such as phenazopyridine. U-Grade 2 indicates frequency with urgency and nocturia associated with early obstructive symptoms requiring other α-adrenergic blocker–type therapy. U-Grade 3 indicates obstructive symptoms requiring an indwelling catheter or posttreatment transurethral resection of the prostate (TURP) for symptom relief.
Data from Gelblum DY, Potters L, Ashley R, et al: Urinary morbidity following ultrasound-guided transperineal prostate seed implantation. Int J Radiat Oncol Biol Phys 45:59, 1999.

may cause urine retention requiring bladder irrigation. Patients who develop urinary retention may require catheter placement for an indefinite period of time. Local trauma to the prostate and seminal vesicles can result in hematospermia and orgasmalgia during the first few ejaculatory episodes and may persist for several weeks.

Subacute urinary morbidity develops 1 to 2 weeks after the implant and lasts for several weeks (6 weeks to 12 weeks). Symptoms generally peak approximately 4 weeks to 6 weeks after implant for both ^{125}I and ^{103}Pd.[639] Although these symptoms generally resolve over time, many patients will benefit from alpha-blocking agents.

Any surgical manipulations of the prostate to correct for retention should be considered only after all medical options have been exhausted. Transurethral incision or a transurethral resection of the prostatic urethra for relief of obstructive symptoms can be performed after two to three half-lives of the isotope but is associated with up to a 26% incontinence rate.[641]

Chronic urinary morbidity can occur after 6 months and may include urinary frequency, incontinence, urethral strictures, and urethral necrosis.[642] In addition, improvements in technique that avoid high peri-urethral radiation doses with peripheral seed placement have resulted in fewer severe long-term urinary side effects.[643,644]

A paradox associated with postimplant toxicity is the use of hormonal therapy to reduce the prostate volume for brachytherapy. As noted, Crook et al examined the rate and predictors of acute urinary retention in 150 patients undergoing implant and multivariate analysis showed large prostate volume and prior hormone therapy to be independent predictors of urinary retention. The explanation for this observation may be that cytoreduction of the prostate leaves mainly fibrous tissue as opposed to glandular tissue, which does not allow the gland to accommodate to the acute implant reaction.

Lower Gastrointestinal Morbidity and Management. During the weeks following the implant, there may be changes in bowel habits in the form of diarrhea, constipation, tenesmus, or rectal pressure.[636,647,648] These symptoms generally respond to conservative symptomatic management.

Late injury includes proctitis, rectal ulceration, fistula formation, and incontinence.[648-650] The most common of these is proctitis, which often presents as a painless bleeding that is usually self-limited. Bleeding from proctitis presents late, about 1 to 2 years after implantation and may be exacerbated by constipation. Conservative management is recommended with stool softeners, local steroid creams, or foams. Aggressive measures such as biopsies and laser treatments may precipitate ulceration and fistula formation and should be avoided whenever possible.

The incidence of proctitis has been reported to range from 1% to 12%.[651] Although the 12% proctitis rate reported by Wallner et al represents the early experience with CT-based implants, subsequent refinements of the technique indicate that proctitis rates have decreased to 2% to 6%.[652,653] Synder et al reporting on grade-2 proctitis following ^{125}I implants concluded that the incidence of proctitis was volume dependent for each dose studied.[654] The 5-year actuarial risk of grade-2 proctitis was 5% if 1.3 mL or less of the rectal volume received the prescription dose of 160 Gy, and 17% for >1.3 mL ($p = 0.001$). Others have tried to correlate the risk of proctitis relative to the delivered dose and volume of the rectum with less success.[648] Although there appears to be the suggestion of a dose response, the lack of conformity in the literature makes it difficult to recommend a specific dose to a certain volume of rectum. Further, intraoperative planning systems allow the operator to measure and limit the rectal dose during the case.[655]

Sexual Function Morbidity and Management. Given the impact of erectile dysfunction on quality of life in an ever-younger cohort of patients with newly diagnosed prostate cancer, discussing the impact of sexual function is vital with each patient.

Acute changes in sexual function following permanent prostate brachytherapy include pain with ejaculation and hematospermia. These symptoms generally dissipate over time and correlate with the acute prostatitis that the patient experiences. Erectile dysfunction (ED) following brachytherapy may be multifactorial, as a result of changes to the patient's neurologic, vascular, or psychologic makeup. Zelefsky et al have identified a potential vascular mechanism for impotence following radiation, whereas Merrick et al has examined and tried to correlate the radiation dose to the penile bulb as a mechanism for impotence.[658,659] Other confounding factors include comorbidities such as diabetes, hypertension, and smoking.

There are no prospective data looking at sexual potency following permanent prostate brachytherapy. However, retrospective data indicate a wide range of potency rates following brachytherapy, with as many as 80% to 85% of men younger than age 60 years old remaining potent[628] when treated with implant only versus 29% remaining potent following combination therapy with EBRT, AD, and an implant (Figure 53-14).[660] In a study on 416 patients treated with implant only, Stock et al reported that preservation of potency was 79% at 3 years and 59% at 6 years.[661] In multivariate analysis,

Locke et al reported prospectively on urinary retention in 62 consecutive patients undergoing permanent prostate brachytherapy with or without EBRT.[640] At 1 week, the retention rate was 34% and predictors for retention included prostate size >36 g and the preimplant AUA symptom score >10. The median duration of retention was 70 days with a range of 0 days to 469 days. Others have reported lower retention rates but noted that similar predictors, such as prostate size and preimplant symptoms, affected the overall chance of developing retention.[580,581,637]

The widespread use of the AUA score allows for standardization of certain morbidities and provides an outline of the severity and course of these symptoms. Desai et al reported on urinary toxicity in 117 patients and found a mean doubling of the baseline AUA score, peaking at 1 month following implant and returning to baseline by about 24 months.[645] In a later study from the same institution, Terk et al showed that the pretreatment IPSS was an independent factor to predict urinary retention in a multivariate analysis.[637] Gelblum et al reported urinary toxicity using a modified RTOG scoring system from a large cohort of 693 patients undergoing permanent prostate brachytherapy with or without EBRT.[580] The IPSS scores 1 month after implant were about three times that of the baseline scores. There was no significant difference in AUA scores between ^{125}I and ^{103}Pd at 60 days and 120 days post-implant.

There is much published on the urethral sparing technique to help decrease acute urinary morbidity. Surprisingly, urinary toxicity is greatest in those with large prostates where peripheral seed placement has the greatest impact on lowering the central prostatic dose.[646]

The addition of EBRT to permanent prostate brachytherapy may be a risk factor for increased rectal toxicity. A study by Zeitlin et al reporting a 2.3% fistula rate raises concern that combination therapy may be associated with more rectal injury.[656] This observation was also identified by Brandeis et al in a study comparing quality of life indicators between implant alone and when combined with EBRT.[657] In that study rectal intolerance was significantly higher in those patients treated with combination therapy.

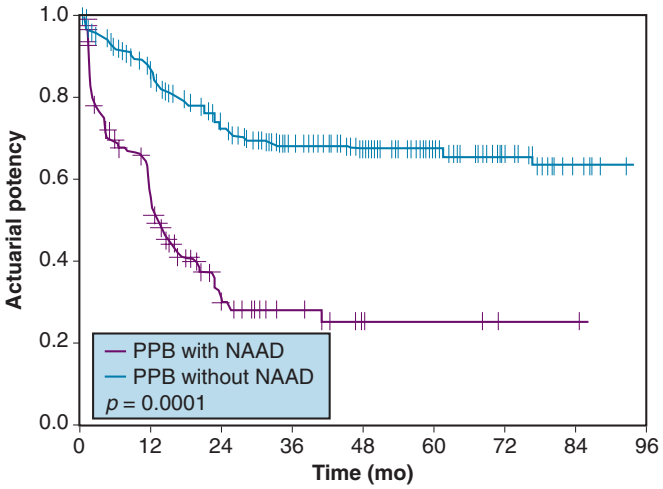

Figure 53-14 Actuarial potency of patients treated with or without neoadjuvant androgen ablation. *NAAD*, Neoadjuvant androgen deprivation; *PPB*, permanent prostate brachytherapy. *Data from Potters L, Torre T, Fearn PA, et al: Potency after permanent prostate brachytherapy for localized prostate cancer. Int J Radiat Oncol Biol Phys 50:1235, 2001.*

pretreatment potency and the implant dose were significant factors for ED post-therapy.

The use of sildenafil and similarly acting agents to treat impotence showed a 62% response rate with patients never having been treated with AD responding more often. Recently, Merrick et al have reported their 7-year actuarial rate of potency preservation of 55.6%.[628] Potent patients were statistically younger ($p = 0.014$), had a higher preimplant International Index of Erectile Function (IIEF) ($p < 0.001$), were less likely to be diabetic ($p = 0.002$), and were more likely to report nocturnal erections ($p = 0.008$).

HDR-Brachytherapy Outcomes. The technique of HDR prostate brachytherapy has been in clinical practice since the 1980s.[662-664] Kovacs et al reported one of the earliest experiences using HDR brachytherapy boost at University of Kiel.[665] Patients selected were mostly those with high-grade.

T2b-T3 lesions who were treated with a combination of split-course EBRT and two 15-Gy HDR treatments. The positive biopsy rate was 18% at 18 months post-treatment. The result was updated at 10 years and 78% of 171 patients remained free of disease at a median follow-up of 55 months. Mate et al at Swedish Medical Center reported their experience with HDR brachytherapy.[666] This group used a more moderate hypofractionated schema with four HDR treatments of 3 Gy to 4 Gy each combined with 45 Gy to 50 Gy EBRT. Pretreatment patient characteristics were stage T1b to T3c, mean initial PSA of 12.9, and Gleason grade range of III to IX. The 5-year bDFS was 84%. In a pooled analysis of 611 patients from the University of Kiel, the Seattle Prostate Institute and the William Beaumont Hospital, Galalae reported 5- and 10-year bDFS rates of 77% and 73%, respectively.[667] Of note, more than half the patients in this multicenter analysis had two or more high-risk features.

Vargas et al at the William Beaumont Hospital reported results of a prospective dose escalation trial using increasingly larger fractions of HDR from 5.5 Gy to 6.5 Gy × 3 to 8.25 Gy to 11.5 Gy × 2 combined with 46 Gy of EBRT in patients with intermediate- and high-risk disease.[668] Assuming an α/β ratio of 1.2, the calculated biologically equivalent doses ranged from 80.2 Gy to 94.2 Gy for the low dose, three fraction group and 99.9 Gy to 136.3 Gy for the high dose, two fraction group. Although the rate of mild grade-1 and grad-2 dysuria was significantly higher with the high-dose group, there were no other significant differences in toxicity for the two groups. The 11.5 Gy × 2 regimen was considered a tolerable regimen. Despite a high frequency of poor prognostic factors, the 5-year actuarial biochemical control rate was 67% and 86% for the low-dose and high-dose groups, respectively. The 5-year clinical DFS was 75.5% and 91.7% for the low- and high-dose arms, respectively.[668]

Early results of HDR implant monotherapy in the management of low risk prostate cancer have been reported.[669,670] The rates of acute urinary and rectal toxicities were reported to be less frequent than with permanent seed implantation using Pd-103 and the rates of chronic urinary frequency and urgency were also less common.[670] bDFS appeared good but the follow-up was too short to claim equivalence to other RT methods.[669,670]

Postirradiation Prostate Biopsy

Although prostatic biopsy had been considered the "gold standard" for determining local tumor control after RT, there is considerable doubt that a positive post-RT biopsy always indicates persistent or recurrent tumor.[318,480,481,484,671-673] Crook et al[671] performed serial prostatic biopsies in a consecutive and unselected group of patients treated with EBRT. TRUS and prostatic biopsy were initially performed 12 months after RT and at 6-month intervals thereafter if the preceding biopsy result was positive or local tumor recurrence was suspected. These investigators concluded that complete post-RT tumor clearance may require more than 2 years, that many patients (more than one third) with an initially tumor-positive or indeterminate biopsy converted to negative on subsequent biopsy. The proportion of indeterminate biopsies decreased over time with 33% at first biopsy to 7% at the fourth biopsy. Positive staining for proliferative markers was associated with an increase in both local and other clinical failures.

Several investigators have found that biopsy results correlated very well with PSA level after radiation,[174,673] and subsequent work on the predictive value of PSA nadir and rising PSA after therapy proved this to be a reliable, noninvasive means of establishing tumor recurrence. Because a rising trend in PSA may herald not only local failure but distant disease as well, situations that call for the documentation of local disease specifically, such as consideration of aggressive local therapy, still necessitate biopsy confirmation.

A few general conclusions about post-RT prostatic biopsy may be made: (1) routine biopsy is justified only in a research setting; (2) the tumor-positive biopsy rate is inversely related to the post-RT interval and appears to plateau at about 3 years; (3) tumor-positive biopsy results more than 2 or 3 years after RT are associated with reduced DFS; (4) tumor-positive biopsy in an asymptomatic patient, particularly in the patient with normal DRE findings and a slowly rising PSA (doubling time at least 10 months to 12 months), is not a mandate for intervention because the disease may take a slow, indolent course.[333]

Surgical Therapy

General Principles

Conventional open radical prostatectomy begins with a low midline incision and mobilization of the peritoneum. Bilateral pelvic lymph node dissection (PLND) precedes RP in patients with sufficient risk of nodal involvement.[193]

Minimally invasive techniques have become popular over the past decade and are largely replacing open prostatectomy in most large U.S. centers. Laparoscopic radical prostatectomy (LRP) follows the same oncological principals as radical retropubic prostatectomy (RRP) with PLND, when indicated, followed by removal of the prostate and seminal vesicles.

During the past few decades, a considerable range of post-RT positive biopsy rates were reported (19% to 93%),[318,480,481,484,671-673] which likely reflected issues relevant to patient selection, interval from RT, biopsy extent, and therapeutic approach. The probability of obtaining a positive biopsy was related to pretherapy T-category, tumor grade, and post-RT clinical examination findings. However, there are potential pitfalls in histologic interpretation of the post-RT biopsy, and the distinction between RT-induced epithelial atypia and residual neoplasm must be established to avoid erroneous histologic diagnosis. A positive biopsy following radiation therapy may be an independent predictor of outcome but in many circumstances these will evolve over time to become negative.

The early history of RP can be traced to Hugh Hampton Young, who first performed the procedure through a perineal approach in 1904 at the Johns Hopkins Hospital. Although initially introduced for BPH some 40 years later, the retropubic technique was later modified for prostate cancer therapy. However, the procedure was accompanied by unacceptable morbidity (e.g., urinary incontinence, erectile dysfunction, and blood loss) until redefined by Walsh et al,[674] Myers et al,[675] and others. Refinements in the procedure gave the retropubic RP certain advantages over the perineal approach and set the stage for broader application and acceptance of this therapeutic modality.[676]

As described by Morgan and Lieber,[677] a "standard" or extended PLND may be performed. Increasingly, extended PLND is recommended to improve staging. Some studies have even suggested a survival advantage although this may be more related to selection of appropriate adjuvant therapies than it is to the removal of micrometastases.[276,316,678] Its margins of dissection are lateral, junction between external iliac artery and vein; inferior, femoral canal; posterior, obturator nerve and vasculature; and superior, bifurcation of the common iliac vessels. Frozen-section histologic examination is performed, and the procedure may be terminated in the presence of nodal disease.

Thereafter, the preprostatic adipose tissue is removed from the prostate to expose the endopelvic fascia, which is incised to separate the levator ani musculature from the prostate. The puboprostatic ligaments are transected to facilitate mobility of the prostatic apex, and the dorsal venous complex and anterior membranous urethra are transected in a manner to preserve the entire distal continence mechanism. The dissection continues by transecting the "pillars of the prostate" and the rectourethralis muscle, and a plane between the prostate and the anterior rectal wall is developed. If the nerve-sparing procedure is performed, the lateral pelvic fascia is incised, and the neurovascular bundles are allowed to fall away posterolaterally. After transecting and securing the pedicles to the prostate, Denonvilliers' fascia is incised to expose the vasa deferentia and seminal vesicles, and the vasa deferentia are transected. The seminal vesicles are dissected from the surrounding tissues, and the plane between prostate and bladder is developed until the longitudinal fibers of the bladder neck are identified. The bladder neck and proximal prostatic urethra are dissected from the prostatic parenchyma, the urethra is transected, and the prostate is removed. Attention is then turned to approximating the distal urethral stump and the proximal urethra at the bladder base to create the urethrourethral anastomosis. The bladder is brought down into the pelvis, the fascia is approximated in the midline, and the skin is closed.

Rather than a large suprapubic incision, LRP methods make use of abdominal insufflation with transabdominal trocars used to introduce laparoscopes and surgical instruments to accomplish the dissection of the pelvic tissues and reanastomosis of the bladder neck to the urethra. LRP is a demanding technique with a considerable learning curve to develop the skills necessary to complete the procedure in a reasonable time with optimum oncological outcomes.[679]

Robot-assisted laparoscopic radical prostatectomy (RARP) gives the surgeon better operative site visualization and more natural hand motions to control the surgical instruments. In a review of insurance and Medicare claims data of 14,727 men undergoing radical prostatectomy between 2003 and 2005, Hu reported the use of minimally invasive techniques rose from 5.4% to 24.4%.[680]

In a similar comparison using SEER data, Hu reported shorter length of stay, fewer surgical complications and strictures with RARP.[681] However, there was an increase in incontinence, ED, and the need for additional cancer therapies such as adjuvant hormones or radiation therapy.

In a systematic literature review and meta-analysis of 79 published reports on the use of RARP between 2008 and 2011, Novara reported a mean positive surgical margin rate of 15% (range 6.5% to 32%).[682] Surgical margins were most commonly present at the prostate apex (5%) followed by the posterolateral margin (2.6%) or multifocal (2.2%). The need for adjuvant therapies was variably reported with series ranging from 0.5% to 23% with a mean value of 4%. There were no significant differences in the rates of positive surgical margins or biochemical relapse by type of prostatectomy, be it RARP, LRP, or RRP.[254,682] RARP was also associated with reduced blood loss and a shorter convalescent period.

Organ-Confined Disease

For patients with a life expectancy exceeding 10 years, RP is generally thought to be an appropriate option if disease is clinically confined to the prostate gland (i.e., stages I to II), although consideration is given to Gleason score and PSA level.[316] However, approximately one half (range, 41% to 64%) of patients thought to have organ-confined disease by clinical assessment have this confirmed by pathologic examination of the surgical specimen,[193,196,202,285] and one third of patients primarily treated with RP undergo additional cancer-directed therapy (i.e., radiation or AD therapy) within 5 years.[683]

Disease outcome after RP is derived from retrospective analysis of study populations from single academic medical centers,[196,285,288,289,684,685] pooled analysis from selected centers,[686] or population-based cohorts[687,688] but is subject to the limitations of observational case series reports as described by Green and Byar.[475] The endpoints of OS, CSS, and metastasis-free survival likelihood from contemporary series of RP (with or without adjuvant or salvage therapy) for patients with clinical stages I to II disease are displayed in Table 53-11. Recent reports indicate that biochemical and clinical failure rates are highly dependent on pretreatment prognostic factors such as T-category, Gleason score, and PSA level as well as surgical findings such as margin status and seminal vesicle and lymph node involvement.[285,684,685,689-691] As an example the series reported by Han et al is shown in Table 53-12. In a series of 1384 patients treated by RARP at the Vattikuti Urology Institute, Menon reported 3-, 5-, and 7-year bDFS of 90%, 87%, and 81%, respectively.[692] Stephenson reported 15-year outcomes of 12,677 patients treated at four academic medical centers. The 15-year prostate cancer specific and all cause mortality rates were 12% and 38%, respectively.[693] It was acknowledged that the exceptionally low rate of prostate cancer mortality may be related to the inclusion of men without a lethal prostate cancer phenotype as well as the effectiveness of modern radical prostatectomy.[285]

Complications

Advances in surgical and anesthetic techniques and in postoperative care reduced intraoperative and postoperative complication rates. The anatomic approach to RP improved hemostasis and visualization during surgical dissection, which reduced the transfusion rate from 77% to approximately 16%.[697,698] Frank rectal injury is uncommon (~0.5%),[697,698] and most patients do not require diverting colostomy because primary closure of a small defect may suffice. Furthermore, myocardial infarction (0.7%), deep vein thrombosis (0.8%), and pulmonary embolism (1%) are uncommon, and less than 0.5% of patients die in the perioperative period.[697,698]

Urinary incontinence is an often-cited complication of RP that typically improves during the first year. Although its precise etiology is not fully understood, the remaining functional length of urethra and preservation of the muscular fibers about the bladder neck are probably critical factors. Depending on the severity of incontinence, it may be managed with protective pads, Cunningham clamp, transurethral collagen injection, or placement of an artificial genitourinary sphincter. Approximately one third (range, 6% to 63%) of patients experience a significant amount of postoperative urinary incontinence,[699-703] and most patients (97%) report some degree of voiding dysfunction.[704] The variation in incontinence rates may result from differences in patient characteristics (e.g., age), surgical technique, and the method through

Complications by technique were compared in Hu's Medicare claims analysis. Men undergoing minimally invasive or perineal radical prostatectomy experienced significantly fewer 30 day complications (14.2% and 14.9% versus 17.5%), anastomotic strictures (6.8% and 8.5% versus 12.9%), required fewer blood transfusions (2.2% and 3.6% versus 9.1%), and had shorter hospital stays (1 and 2 days versus 4 days).[680]

In a contemporary series of 741 patients treated at Yale by Colberg et al, the 5-year bDFS for patients undergoing surgery or brachytherapy were identical for the favorable-risk group (93% versus 92%), intermediate-risk group (70% versus 70%), and the high-risk group (50% versus 52%).[691]

Although to date randomized trials comparing contemporary therapies for definitive treatment of prostate cancer have been nearly impossible to complete, available data suggests that both radiation, either EBRT to current doses or radioisotopic implant, and prostatectomy result in similar outcome for patients with equivalent prognostic factors.[469] Other comparisons by modality are complicated by case selection, intercurrent and comorbid conditions, or lack of appropriate adjuvant therapies.[243,471] Unfortunately, physician bias toward treatment options has been shown to be specialty related.[695,696] Many institutions have attempted to solve this problem through multidisciplinary clinics where patients have the benefit of obtaining consultation from multiple specialists.

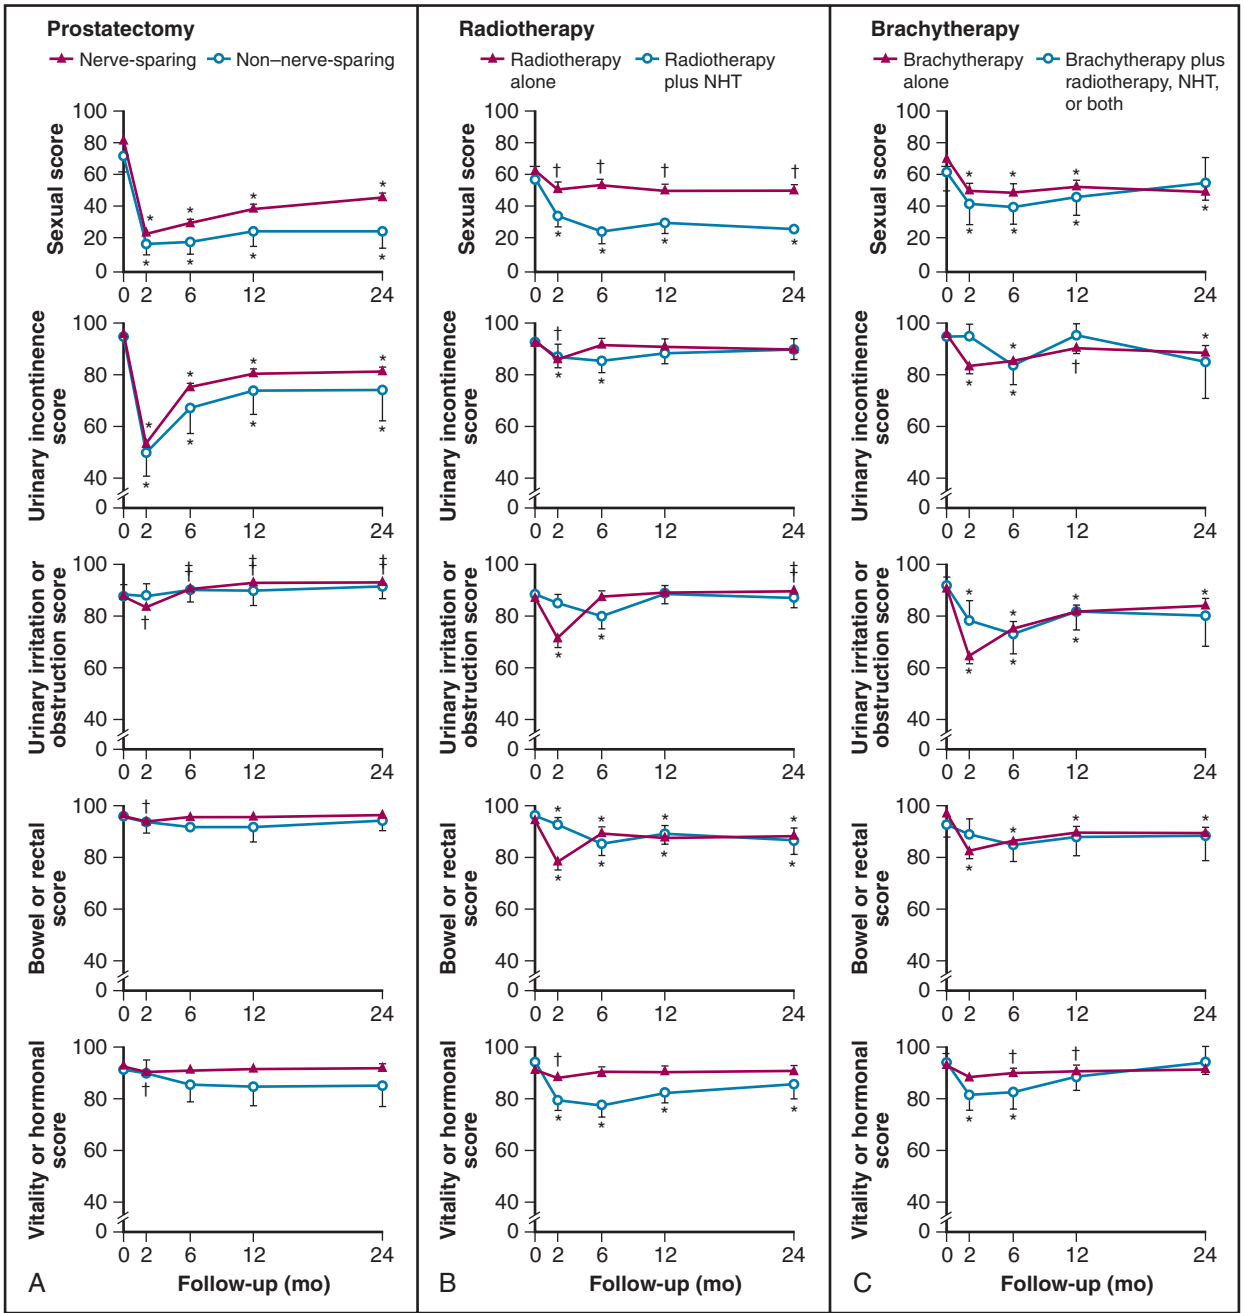
which information was obtained. In systematic review and meta-analysis that included 51 articles published between 2008 and 2011, Ficarra reported the incidence of urinary incontinence (control requiring no pad) following RARP ranged from 4% to 31% with a mean of 16%.[705] Patients with advanced age, large body mass index, comorbidities, lower urinary tract symptoms, and larger prostate volumes were more likely to experience incontinence. Several reports suggest that physician-based assessments underestimate the presence and severity of incontinence,[699,704,706] as patients were hesitant to mention difficulties of this nature to their physician. Bladder neck or anastomotic stricture occurs in approximately 12% (range, 5% to 20%) of patients[699] and may require dilatation or incision to improve urinary flow.



Until recently, there was little awareness of bowel dysfunction as a possible postoperative complication. However, health-related quality of life instruments indicated that one third of patients had impaired bowel function (e.g., diarrhea, rectal urgency),[704] and one in five experienced fecal incontinence.[703] These difficulties often were not appreciated through physician inquiry and reporting[704] and were substantially greater than the expected incidence in a similar age group. Additional research is necessary to determine the cause of this problem so that modifications of surgical technique may be sought to reduce the risk of this complication.

Before introduction of the nerve-sparing procedure, ED was uniformly encountered. However, it was possible to preserve potency once the autonomic innervation of the corpora cavernosa was delineated and the nerve-sparing modification of the RP was made. Walsh et al[701] reported that 68% of men retained potency, which was confirmed by Catalona et al (59%).[707] Patient age, T category, and excision or preservation of one or both neurovascular bundles correlated with the return of sexual function.[700] Population-based studies indicated that 21% (range, 11% to 27%) of patients were potent after RP,[699,701] and 97% of patients reported sexual dysfunction in a survey conducted by Litwin et al.[704] In systematic review and meta-analysis that included 31 articles published between 2008 and 2011, Ficarra reported the incidence of retained potency following RARP ranged from 54% to 90% at 12 months and 63% to 94% at 24 months.[708] Recovery of potency was influenced by age, baseline potency, comorbidities, and the extent of nerve sparing. RARP did appear to have a significant advantage in sparing potency compared to RRP.

Quality of Life

Following the development of validated instruments, such as the UCLA Prostate Cancer Index and the Expanded Prostate Cancer Index Composite (EPIC), quality of life (QOL) assessment has become an important component of posttreatment evaluation.[709,710] Litwin et al[711] were among the first to evaluate QOL in men treated for localized prostate cancer compared men with an age-matched population. Since that time, investigators have generally found that bowel dysfunction is worse following EBRT than after radioisotopic implant or RP.[712-714] This is typically evidenced by urgency, frequency, and bleeding. Urinary function is worse after RP, especially incontinence, although urinary morbidity following implant may be greater than EBRT during the first 12 months.[713,714] Sexual function was similar for RP and EBRT, mainly because of the increasing dysfunction 2 years to 5 years after EBRT, but better for implant patients.[713,714] Additionally, age and comorbidities affected QOL as did the delivery of multiple therapies, especially hormonal therapy. Patient report surveys appear to give a more accurate assessment as compared to physician or chart-based reporting.[704,706]

In a prospective series of 1201 men with localized prostate cancer, Sanda characterized the changes in QOL associated with RP, EBRT, and prostate brachytherapy (BT).[635] Each treatment modality had a negative impact on a man's QOL with a distinct pattern of change in the domains of urinary, sexual, bowel, and hormonal function. After RP, the frequency and severity sexual dysfunction was less severe when a nerve-sparing procedure was used. Urinary incontinence was common after RP with some recovery over time. Likewise, BT was associated with longer lasting urinary morbidity. Figure 53-15 illustrates the time course of onset and recovery for the various QOL domains following each treatment modality. In a French series of 435 patients undergoing RP (n = 127) or brachytherapy (n = 308), Buron described a similar time course of changes in QOL following primary therapy.[715] Impotence

D

Figure 53-15 **A** to **D,** Changes in quality of life after primary treatment for prostate cancer. The graphs show unadjusted changes in mean quality-of-life scores over time for each domain, stratified according to study group. Scores on the Expanded Prostate Cancer Index Composite domains range from 0 to 100, with higher values representing a more favorable health-related quality of life. In the prostatectomy group, non–nerve-sparing procedures consisted of wide excision of both neurovascular bundles. In the radiotherapy group, patients received either external radiation alone or external radiation with neoadjuvant hormone therapy (NHT). In the brachytherapy group, patients received either brachytherapy alone or brachytherapy in combination with NHT, radiotherapy, or both. *Asterisks* designate time points at which scores differed from those at pretreatment baseline by more than half a standard deviation and the comparison was significant ($p < 0.01$, to account for Bonferroni adjustment). *Daggers* designate time points at which differences from baseline were significant but were below the threshold of clinical relevance. *Double daggers* designate mean scores that showed improvement over pretreatment levels. Error bars represent 95% confidence intervals; confidence intervals were symmetric, but error bars are shown as one sided to avoid overlap with mean scores. **D,** Shown are the number of patients for whom sufficient time had elapsed after treatment to enter each follow-up period (including patients who were lost to follow-up) and the corresponding number who completed their prescribed follow-up interview at each time point.

From Sanda MG, et al: Quality of life and satisfaction with outcome among prostate-cancer survivors. N Engl J Med 358:1250–1261, 2008.

and urinary incontinence were more pronounced after RP whereas urinary urgency, frequency, and dysuria were more common after BT. In the Sanda report, patient satisfaction was associated with the change in symptom scores relative to baseline.[635] In a similar prospective study of 435 patients treated by RP, EBRT, or BT in Spain, Pardo reported greater sexual and urinary continence deterioration in patients undergoing RP however patients treated with BT or EBRT had significantly worse urinary irritative-obstructive scores and bowel symptoms.[716] These studies emphasize the importance of patient education and counseling before treatment decisions are made.

LOCALLY ADVANCED DISEASE

Surgery for Locally Advanced Prostate Cancer

Surgery is often more technically difficult in men with locally advanced disease. Among men with very high-risk factors such as a PSA >100 ng/mL, hydronephrosis or pelvic side wall fixation, the perioperative morbidity was much higher than men without these adverse features.[721] In carefully selected individuals and in the hands of experienced surgeons, the complication rate in series of patients with high-risk disease does not appear to be significantly worse than patients with lower risk disease.[722,723] Oftentimes, nerve sparing cannot be achieved leading to higher rates of impotence and urinary incontinence. Nearly 50% of patients will have findings indicating a need for postoperative RT or hormone therapy. In a pooled multiinstitution series of 1366 patients with high-risk disease from eight European centers, Briganti reported that only 505 (37%) had specimen confined disease at RP.[724] Half of the patients received either adjuvant hormone therapy, RT, or both following the RP.

Radiation Therapy

Locally advanced adenocarcinoma of the prostate includes clinical T3 or T4 and bulky T2c tumors. Because these patients have disease that is unlikely to be completely removed surgically the preferred treatment is radiation therapy.

Unfortunately the clinical outcome for such patients with radiation alone is poor with more than half of the patients developing clinically overt metastases by ten years.[245] In addition, given the ability of serum PSA posttherapy to monitor assessment of disease, data shows that the results of RT alone are poor with only approximately one third of the patients showing no biochemical failure at 5 years and approximately 10% at 10 years.[250]

Understanding the poor results of radiation alone, a number of clinical investigators have looked at approaches such as particle beam therapy with neutrons or protons (see the section on particle therapy), EBRT plus HDR brachytherapy with ^{192}I (see brachytherapy section), use of AD with radiation, and chemotherapy in addition to radiation. We will look at these approaches individually.

Androgen Deprivation Plus Radiation

It has been shown that reducing intracellular concentrations of dihydrogen testosterone through the use of AD can induce apoptotic regression of androgen-responsive prostate cancers.[725] Apoptotic regression of androgen-responsive prostate cancers thus, in the context of locally advanced prostate cancer, could help to reduce the primary tumor volume (i.e., cytoreductive therapy), which could improve local control and, therefore, decrease metastatic disease. It may also be helpful in the primary prevention of metastatic disease if used in the adjuvant setting. Extensive work has been done in the arena of AD for locally advanced disease. Although data was emerging showing the addition of estrogen therapy to radiation therapy improved tumor control, the first clinical study to evaluate this in a randomized way was RTOG study 83-07. This study evaluated the efficacy and toxicity of megestrol and diethylstilbestrol (DES) in a Phase II randomized study where patients were assigned to either agent for 2 months prior to and during EBRT.[726] Both the megestrol and DES in addition to radiation resulted in a high likelihood of clearance of the primary tumor (94% to 97%) and local regional tumor control (93% and 94%). Unfortunately there were significant side effects especially in regards to the DES with cardiovascular events. With the development of luteinizing hormone-releasing hormone (LHRH) agonists and nonsteroidal anti androgens, the focus of the investigations within the RTOG changed to these agents.[727] RTOG study 85-19, which used these agents for patients with locally advanced disease, found them to be well tolerated and still resulting in a high rate of tumor clearance (100%).[727]

With a clear indication of a potential benefit by AD therapy to radiation for locally advanced cancers, a number of prospective randomized trials were developed both in the United States through the RTOG and in western Europe through the EORTC. These trials addressed two questions with regard to the use of androgen suppression and radiation. The first question evaluated was the adjuvant question; could radiation therapy and adjuvant AD result in a decrease in distant metastases and increase OS? This question was addressed by RTOG 85-31 (Table 53-13).[728] In this trial patients with locally advanced disease were randomized to EBRT plus indefinite goserelin (started immediately after RT was complete) versus EBRT alone. Treatment included whole pelvis irradiation to 44 Gy to 46 Gy and a boost of 20 Gy to 25 Gy bringing the total prostate dose to 65 Gy to 70 Gy. Ten-year results (Table 53-13) show a benefit across all endpoints including OS. During the same time frame the EORTC performed their own adjuvant trial (22863)[729,730] for locally advanced patients and a small RT and immediate goserelin for 3 years (goserelin started with initiation of RT). The RT included whole pelvis irradiation to 50 Gy with a boost of 20 Gy at 2 Gy per fraction. Results of this trial also showed a benefit to all endpoints including bNED, DFS, CSS, and OS[730] (Table 53-13).

During this same time frame the RTOG addressed the neoadjuvant question with trial 86-10.[731] Could neoadjuvant total androgen suppression (TAS) decrease the tumor burden and thus increase local control with RT? In this trial, patients with locally advanced nonmetastatic disease were randomized to RT alone versus neoadjuvant TAS (flutamide 250 mg three times a day and goserelin acetate monthly for 4 months)[731] for 2 months before and 2 months during RT. Radiation therapy volumes used whole pelvis RT to 45 Gy and a boost of 20 Gy to 25 Gy delivering 65 Gy to 70 Gy to the prostate. Results of this trial have shown statistical improvements in bNED, DMFS and CSS (Table 53-13), but no OS benefit to date.[9]

Another attempt to address the neoadjuvant AD question was performed by the Trans-tasman Radiation Oncology Group (TROG) with protocol 96-01. Patients on this trial had locally advanced disease and were randomized to RT alone (66 Gy in 33 fractions to the prostate and seminal vesicles only) versus 3 months of TAS with goserelin and flutamide 250 mg three times a day starting 2 months before RT versus 6 months of total androgen suppression starting 5 months before RT.[732,733] Five year results revealed a benefit to the six months of total androgen suppression plus RT over RT alone in terms of bDFS, DMFS, CSS and local control. (Table 53-13) The three months of total androgen suppression showed a benefit in terms of bNED and local failure, but not DMFS or CSS.[732,733]

Although there exists a large body of class I evidence to support the routine use of combined EBRT and AD in locally advanced and high-risk prostate cancer, there is scant prospective evidence to support the role of RP. Despite this, there is growing enthusiasm for RP in the management of high-risk disease. One challenge in making comparisons between surgery and RT for locally advanced disease is the ever-increasing use of risk groupings to classify patients. The high-risk category of disease is more commonly determined by Gleason score and less frequently clinical T-category.[717] Furthermore, the specificity of the DRE for clinical staging is low with an approximate 20% to 25% rate of downstaging in RP series.[718] In carefully selected men, the risk of complications is low with RP[718,719]; however, the frequency with which patients will need additional therapies such as adjuvant EBRT is high.[719,720]

Given the evidence of the benefit of AD and radiation therapy in controlling locally advanced adenocarcinoma of the prostate, at least three cooperative trials have examined the optimal duration of AD. The RTOG, the EORTC, and the Canadian PCS IV trial posed this question in three different phase III randomized trials (Table 53-14). RTOG protocol 92-02 randomized locally advanced patients to 4 months TAS (flutamide 250 mg three times a day plus goserelin), 2 months neoadjuvantly and 2 months concurrently with whole pelvis RT (WPRT) 44 Gy to 46 Gy and a boost to the prostate delivering 65 Gy to 70 Gy to the prostate verses the same treatment plus 2 years of additional goserelin.[734,735] Ten-year follow-up is now available for this trial and shows a benefit to the long-term androgen deprivation (LTAD) in bNED, DMFS, and CSS, but not OS except for patients with Gleason Scores of 8 to 10 who did show an OS benefit. The EORTC trial 22961 also looked at the question of duration of AD. In this trial patients were randomized to RT (WPRT to 50 Gy plus a 20-Gy boost totaling 70 Gy to the prostate) and 6 months of Total Androgen Suppression (TAS) (flutamide 250 mg three times a day or bicalutamide 50 mg) and an Luteinizing Hormone Releasing Hormone (LHRH) agonist starting with RT versus the same treatment and an additional 2.5 years of LHRH therapy.[736] Five-year OS and CSS were both statistically improved with the addition of the 2.5 years of LHRH therapy (Table 53-14). Subsequently the Canadian PCS IV trial examined 18 months compared with 36 months in patients with locally advanced disease.[737] In this trial, patients received 1 month of neoadjuvant TAS (bicalutamide and goserelin) then concurrent and adjuvant goserelin for a total of 18 compared with 36 months in addition to RT (44 Gy in 4.5 weeks "whole pelvis" and a prostate dose of 70 Gy in 7 weeks). With a median follow up of 6.4 years, there was no significant difference in prostate CSS or OS between the two arms.[737]

Based on the available data to date, patients with locally advanced nonmetastatic adenocarcinoma of the prostate should receive neoadjuvant and concurrent AD and long-term AD of an additional minimum of 14 months (totaling 18 months of AD).

Toxicity of Androgen Deprivation Therapy

With the need to add AD to RT for patients with locally advanced prostate cancer clearly established, the question of toxicity has to be addressed. Virtually all patients placed on LHRH therapy will have hot flushes, sexual dysfunction, and decreased libido as a result of the decrease in testosterone. In addition with longer duration LHRH therapy, patients can develop increased fat mass, decreased lean body mass, and increased waist circumference.[738] Understanding concerns about weight gain and resultant health issues such as diabetes and cardiovascular disease, several authors have looked at the large randomized trials to understand whether there is truly an increase risk of fatal cardiovascular events with RT and LHRH therapy.[730,731,739] None of these trials, which include RTOG 85-31, 86-10, and the EORTC trial 22863, have shown an increase in fatal cardiovascular events for the RT and AD arm. The follow-up in these trials is long (approximately 10 years on average for living patients) and represent close to 2000 randomized patients. Thus, if there was a significant risk of increased fatal cardiovascular events, it should have been detected. Furthermore, the EORTC protocol 22961 and the RTOG protocol 92-02 showed no difference in fatal cardiac events between the short-course AD versus the longer-term AD arms.[15] Yet some authors have challenged these results.[740,741]

Careful analysis of metabolic changes that occur with 12 months of LHRH therapy has been performed by at least one group.[738] This data reveals a "metabolic syndrome" for LHRH therapy that consists of increased subcutaneous fat, increased serum high-density lipoprotein (HDL), increased adiponectin levels, no change in C-reactive proteins, and insulin sensitivity. This is different than "the metabolic syndrome,"[738] which is characterized by increased visceral fat, decreased serum HDL, decreased adiponectin levels, increased C-reactive proteins, and insulin resistance.

Although there are unquestionably metabolic changes that occur with AD therapy, the LHRH drugs do not appear to cause changes that lead to a significant increase in cardiovascular deaths. Yet, given the weight gain and other changes

TABLE 53-14 Phase III Trials of Duration of Adjuvant Hormone Therapy with External Beam Radiation Therapy for Locally Advanced Prostate Cancer

caused by LHRH therapy, caution is the best approach when considering these therapies in patients with preexisting serious cardiovascular medical histories. Consultation with the patient's cardiologist should be considered.

The other major metabolic concern of LHRH therapy is changes in bone density. Bone loss and the need for baseline bone mineral density (DEXA) scanning is well accepted.[742] Recommended treatment for this potential bone loss includes vitamin D supplements (800 to 1000 IU daily) and calcium supplements (≥1200 mg/day). DEXA scanning should be repeated at 1 year while on LHRH therapy and then every 2 years or as clinically indicated subsequently.[742] Bisphosphonate therapy should be seriously considered for patients going on LHRH therapy if their baseline DEXA scan is consistent with osteoporosis.[742]

Scope of Radiation Therapy

Treatment volumes for locally advanced prostate cancer have included the prostate and seminal vesicles plus a margin along with the pelvic lymph nodes. The vast majority of the large randomized trials have treated in this fashion using doses to the lymph nodes of 45 Gy to 50 Gy (four-field box technique and dose prescribed to isocenter) with a boost to the prostate totaling approximately 70 Gy (isocenter dose).[728,729,731,735,736] Today there is little doubt that the prostate/seminal vesicle dose was too low in these trials because multiple data sets have shown a benefit from dose escalation for these patients.[743] The bigger question regarding the scope of the radiation therapy for this population is whether one needs to treat the pelvic lymph nodes? RTOG 94-13 was designed to answer this question. This trial randomized 1323 patients to whole pelvis radiation therapy (WPRT) versus prostate only radiation therapy (PORT) and neoadjuvant 4 months of TAS verses adjuvant 4 months TAS.[632] Results of this trial showed no difference in WPRT verses PORT and no statistical difference between neoadjuvant TAS versus adjuvant TAS. Unfortunately this trial did show an unexpected interaction between the timing of the TAS and the scope of the radiation therapy.[632] PFS was better with the WPRT and neoadjuvant TAS arm versus the other three arms. But this trial was unable to answer, in a definitive way, the WPRT-versus-PORT question because of the unexpected interactions. Therefore, the question of WPRT versus PORT still needs to be evaluated in a prospective trial. Currently the RTOG is examining the pelvic lymph node radiation question in RTOG 09-24.[744] Until we have more data, WPRT with neoadjuvant and concurrent TAS, and long-term LHRH therapy for at least 14 additional months, remains the standard of care for patients with locally advanced disease.[728,729,735-737,744]

Given the data showing a significant advantage to RT and AD, many practitioners argued that the benefit seen was solely the result of the AD and perhaps RT was not needed. This question has been addressed by two Phase III randomized trials (SPCG-7/SFUO-3) and the Canadian Intragroup Trial. Forty-seven Scandinavian centers participated in the SPCG-7/SFUO-3 trial accruing patients with locally advanced prostate cancer. Patients were randomized to TAS for 3 months followed by AD with flutamide indefinitely versus the same AD plus RT.[745] The addition of the radiation statistically increased the 10-year prostate CSS compared to the AD-alone arm and statistically increased OS with acceptable toxicity rates.[745] The Canadian Intergroup Trial looked at the same question in more than 1000 patients with T3 or T4 tumors or T2 tumors with either PSA >40 ng/mL or PSA >20 ng/mL and Gleason Score 8 disease. All patients received lifelong LHRH agonist or orchiectomy. They were then randomized to RT ("whole pelvis" to 45 Gy in 25 fractions and subsequent boosting to the prostate to 65 Gy to 69 Gy total) or no other treatment.[746] This data also showed a statically significant OS and DSS advantage to AD and RT over AD alone with minimal toxicity.[747] Thus, there should be no question as to the value of radiation therapy in addition to AD therapy for these patients.

Designing the treatment of nodal volumes in addition to the prostate/seminal vesicle volumes has been an area of some confusion, especially in light of the use of IMRT. Even RTOG GU (genitourinary) radiation oncology "experts" had trouble agreeing on such volumes.[748] In an effort to standardize the correct anatomical pelvic lymph nodes to be covered for locally advanced patients, RTOG GU radiation oncologists developed a consensus on the clinical tumor volume (CTV) for pelvic lymph nodes.[749] The nodal groups to be included extend from the L5-S1 interspace (i.e., low common iliac lymph nodes) to the top of the pubic symphysis (obturator lymph node region). Presacral lymph nodes (subaortic only, S1-S3) are also included.

These volumes correlate well with the nodal volumes typically treated with the four-field "box" technique used in all the randomized trials previously mentioned.[749]

Toxicity of Radiation Therapy

Treatment of the pelvic lymph nodes and boosting the primary (the prostate with or without seminal vesicles) is not without toxicity. A review of late sequelae of RTOG protocols 85-31, 86-10, and 92-02 evaluating almost 3000 patients with a median follow-up of 10.3 years for living patients has been reported.[750] All patients received WPRT to approximately 45 Gy and a prostate boost to approximately 70 Gy plus or minus short-term androgen suppression or long-term androgen suppression. The risk of late GI grade-3 or higher toxicity was 4%, 1%, and 3% for RT alone, short-term AD and RT, and RT plus long-term AD, respectively. Late GU grade-3 or higher toxicity was 9%, 5%, and 6% for RT alone, short-term AD plus RT, and RT plus long-term AD, respectively.[750] Grade-5 (lethal) toxicity occurred in 3 patients out of 2906 treated for a risk of approximately 0.1%. Data on late toxicity has been reported for the Phase III Canadian Intergroup Trial (AD versus AD plus RT) showing minimal additional toxicity via the use of radiation in patients with locally advanced prostate cancer.[746,747] These data reinforce the safety of radiation for locally advanced patients and are consistent with other randomized trials of RT plus AD.[730,736]

Role of Adjuvant Chemotherapy

Two randomized trials have shown statistical improvements in survival for patients with metastatic hormone refractory prostate cancer[751,752] with the addition of docetaxel-based chemotherapy. Given these results the RTOG embarked on a randomized trial (99-02) for patients with high-risk nonmetastic prostate cancer. Patients were randomized to RT with long-term AD compared with RT with long-term AD with paclitaxel, estramustine, and oral etoposide.[753] The trial was closed early because of toxicity particularly estramustine-based increased thromboembolic events.[753] Subsequently RTOG protocol 05-21 was opened to test the chemotherapy question. This trial randomized patients with "high-risk" nonmetastatic prostate cancer to RT with long-term AD compared with RT with long-term AD with docetaxel and prednisone. This trial has met accrual and we anxiously await the results. Until we have these results, there is no defined role for cytoxic chemotherapy in addition to RT with long-term AD for patients with locally advanced prostate cancer.

Regional Lymph Node Positive Disease (pN+)

Positive regional (i.e., pelvic) lymph nodes in patients with prostate cancer is a negative prognostic indicator.[754] Although some authors have reported significant long-term survivors from aggressive surgery or radiation approaches,[755,756] the majority of these patients will develop metastatic disease. This fact suggests that occult systemic metastasis likely exist at the time of diagnosis and supports the concept of systemic treatment in addition to any local or local regional therapy. Two data sets are now mature and help the treating oncologist to select appropriate treatment for such patients. The first is a subset analysis of RTOG protocol 85-31.[271] This trial discussed previously, randomized patients with locally advanced adenocarcinoma of the prostate plus or minus pN+ to RT alone (WPRT + a boost to the prostate) versus RT with LHRH indefinitely.[728] One hundred and seventy three patients in this trial had pN+ disease (98 received RT and LHRH and 75 received RT alone). An update of this trial with a median follow up of 6.5 years (9.5 years for living patients) showed a statistical improvement in OS, DSS, and freedom from distant metastasis in favor of RT with LHRH therapy.[757]

The Eastern Cooperative Oncology Group (ECOG) conducted a Phase III trial for patients with pN+ disease, following radical prostatectomy. They were randomized to observation versus immediate hormone therapy (indefinite LHRH or bilateral orchiectomy). The trial closed because of poor accrual, but 98 patients were entered and randomized.[758] At a median follow up of 7.1 years patients receiving immediate hormone therapy had an increase in OS.

Neither of these clinical trials provides the type of level I data necessary to know for certain which is the best approach for pN+ patients. Yet both point to the need for systemic therapy. RTOG protocol 96-08 (which randomized pN+ patients to AD alone versus AD with RT) closed because of poor accrual so the question of the additional benefit of pelvic RT over AD alone remains unclear. It is likely not answerable with a prospective randomized trial. Therefore, given the data available, patients with pN+ disease should be seriously considered for AD in addition to local or regional therapy with radiation or surgery.

Postoperative Radiotherapy

Approximately one third of men with prostate cancer undergo prostatectomy as initial therapy.[759,760] Among patients treated at high-volume academic centers, one quarter to one third are at risk for treatment failure within the ensuing 10 years.[761-764] Postoperative RT is usually administered in three curative situations: the presence of adverse risk factors after complete surgical resection, subclinical disease identified solely by an elevated postoperative serum PSA, or clinically apparent tumor recurrence in the prostatic fossa. When strictly applied, the term *adjuvant* refers to treatment administered to reduce the risk of recurrence when all clinically detectable disease was removed surgically, and this term should be reserved for patients with an undetectable postoperative PSA level.[765] When there is a detectable PSA level after surgery or there is clinical evidence of disease confined to the fossa, the therapeutic goal changes to one of eradicating residual or recurrent cancer, and treatment administered under this condition is referred to as *salvage* therapy.[765]

Adjuvant Radiotherapy

The rationale for adjuvant RT is based on the premise that residual disease in the prostatic fossa is the principal cause of treatment failure,[766] that a substantial number of cancer cells may be present before serum PSA is detectable, and that the greatest opportunity for cure exists when they are fewest in number and localized. Prostate cancer may become more aggressive over time,[767] and this implies that earlier intervention may improve local tumor control and prevent subsequent metastases. Consensus-derived clinical principles encourage preoperative education of patients about adverse pathology findings that increase the risk of cancer relapse and provide indication for postoperative therapy.[765]

Certain factors are associated with a greater risk of disease relapse after prostatectomy. These include higher preoperative PSA,[762,768-770] greater Gleason score,[761,762,768-771] a positive surgical margin,[762,768-770] tumor extension through the prostatic capsule (i.e., EPE),[761,762,771] SVI,[762,768,769,771] and pelvic LNI.[762,768,771] Traditionally, EPE, SVI, or a positive surgical margin are the factors on which a recommendation for adjuvant RT is made.[765,772,773] These risk factors may be combined to provide more individualized estimates for postoperative disease relapse.[761,762,768]

There is an abundant literature of adjuvant RT observational series, and Table 53-15 summarizes outcomes from selected reports.[774-780] It is generally acknowledged that RT improves local tumor control compared to prostatectomy alone,[774,776,778,779] which is reported in ~99% and ~92% of patients with adverse risk factors at 5 and 10 years after RT,

respectively.[774-780] The 5-year and 10-year local control after RP alone is ~85% and ~61%.[774-780] Clinical and biochemical relapse-free rates are also improved with adjuvant RT,[774-776,779-781] which generally reduces the relative risk of relapse by 43% to 88%.[775,776,780] Nonetheless, an estimated one quarter of patients with biochemical relapse only after adjuvant RT has persistent cancer in the prostatic fossa,[782] and this suggests that improved target definition, localization, or dose escalation may improve outcomes.

The impact of adjuvant RT on metastasis-free, OS, and CSS is not clear from the observational studies, because inconsistent findings are reported (Table 53-15).[774,775,777-780] However, this may be the result of differences in patient selection, time trends in disease presentation and therapeutic approach, inadequate patient numbers for conclusive statistical analysis, insufficient follow-up, and the confounding effect of androgen suppression therapy. Nonetheless, reduced metastases and death as a result of prostate cancer rates were observed in some studies with longer follow-up.[778,779,783]

Three randomized clinical trials evaluated adjuvant RT (Table 53-16), and these studies provide the highest level evidence on outcomes. Southwest Oncology Group (SWOG) trial 8794 was the first trial conducted among patients at increased risk of disease relapse (i.e., those with EPE, SVI, or positive surgical margin).[766,784-787] This trial was designed primarily to determine whether adjuvant RT improved metastasis-free survival. Long-term follow-up demonstrated that adjuvant RT improved metastasis-free and OS compared to RP alone with therapy at physician discretion at disease relapse.[784,786] Analysis of metastasis-free survival according to various patient subsets provided no evidence that any particular type of patient should not receive RT.[786] For patients assigned to adjuvant RT, the relative risk of death was reduced by 28% and median survival duration was extended by nearly 2 years.[786] This observation supported the hypothesis that locally persistent cancer contributes to delayed metastatic spread as proposed in the context of primary RT.[787] Additionally, adjuvant RT in this trial was associated with improved freedom from biochemical and local tumor relapse, and reduced use of salvage androgen suppression.[784]

EORTC trial 22911[788-790] enrolled patients with the same characteristics as those of SWOG 8794.[784,786] However, this trial was designed primarily to assess Biochemical Progression Free Survival (bPFS) which was improved in patients assigned to immediate adjuvant RT compared to treatment delayed until disease relapse (Table 53-16). A statistically significant difference favoring adjuvant RT was also noted for locoregional tumor control, and for use of salvage therapy (22% versus 48% by 10 years).[789] Adjuvant RT improved b-PFS in all patient subsets,[789] which did not support a previous conclusion of lack of benefit in margin-negative patients.[790] Although between-group differences in death from prostate cancer or from other causes, or in the incidence of metastases were not observed, the trial lacked a sample size sufficient to identify any such differences.

Although patients with a detectable postoperative PSA level were included in SWOG 8794 (34%) and EORTC 22911 (29%), only patients with an undetectable PSA were evaluated

in the German Cancer Society Arrbeitsgemeinschaft Radiologische Onkologie (ARO) trial 9602 (Table 53-16).[769] As with EORTC 22911, this trial was designed to determine whether adjuvant RT improved b-RFS compared to initial observation. The risk of biochemical relapse was reduced from 46% at 5 years to 23% in patients treated with adjuvant RT, which met the test of significance for the primary endpoint. The trial was not designed to evaluate clinical RFS and OS, so it is unlikely that longer patient follow-up will identify differences in these endpoints.

Studies of adjuvant RT include patients with varied characteristics, so a natural line of inquiry is whether RT benefits all patient subsets. It appears that patients with positive surgical margins,[769,778,779,784,789,790] extraprostatic tumor extension,[769,778,779,784,789,790] SVI,[779,784,789] and possibly pelvic node involvement[778,791,792] derive the greatest benefit. A beneficial effect exists irrespective of Gleason score[769,789,790] and postoperative PSA level,[766,789] or when margins are negative[784,789] or EPE or SVI is absent.[769,789] Inconsistent conclusions from the literature are likely explained by variations in pathology interpretation,[790] patient selection bias, and the small number of patients or events under study. An inability of statistical analysis to identify a significant effect in some studies should not be interpreted necessarily as lack of benefit.

The role of androgen suppression with adjuvant RT is not adequately studied. RTOG 8531 included a subset of prostatectomy patients who were assigned to adjuvant RT or RT with long-term androgen suppression.[793] Improved outcomes were observed with androgen suppression, but such a subset analysis might be considered exploratory rather than definitive. An attempt to study this further was made in RTOG trial P-0011, but it closed prematurely because of inadequate patient accrual. Nonetheless, this issue is being addressed in ongoing trials conducted by the Medical Research Council PR10[794] and the EORTC trial 22043-33041. Androgen suppression alone is the mainstay of adjuvant therapy for pelvic node-positive disease,[795] whereas the addition of RT remains controversial.[778,791,792] An attempt by RTOG randomized trial 9608 to investigate this did not meet with successful accrual, so definitive evidence of benefit is lacking.

Several organizations provide guidelines for postoperative management.[765,772,773,796,797] NCCN (www.nccn.org) and ASTRO/AUA guidelines[765] support adjuvant RT when adverse pathology findings are noted. This view is endorsed by some,[773] and others recommend a discussion between patient and physician,[772,796] or do not advise its routine use.[797]

Salvage Radiotherapy

Biochemical Relapse. The serum half-life of PSA is 3.1 days, so PSA should be undetectable ≥4 weeks after successful prostatectomy. The AUA defines biochemical relapse as PSA ≥0.2 ng/mL with a subsequent value >0.2 ng/mL.[800] Biochemical relapse should prompt a thorough discussion of salvage therapy,[765] yet some suggest that two successive values ≥0.4 ng/mL more strongly correlates with clinically significant disease progression.[801] It is important to note that the efficacy of salvage RT is greatest when PSA is the lowest,[802] and this may help inform the discussion.

The natural history of biochemical relapse varies, and this contributes to discussions about its prevention (e.g., adjuvant therapy) and management. Based on PSA response to salvage RT[766,804-810] and observations from MRI, most such patients have residual cancer in the prostatic fossa.

The kinetics of postoperative PSA (e.g., the PSA doubling time [PSAdt]) has been investigated as a predictor of clinical relapse and mortality.[814-817]) The PSA Working Group provided guidelines for PSAdt calculation, and these include using ≥3 PSA values that are ≥0.2 ng/mL during the past 12 months, values that are increasing only, and values obtained in a setting where testosterone is stable (i.e., not recovering from prior androgen suppression).[818] The relationship of postoperative PSAdt to clinical relapse and mortality exists on a continuum, which may account for the various prognostic groupings that appear in the literature.

Biochemical relapse often prompts a desire to identify the site of disease relapse, despite a typically normal digital rectal examination.[819] Conventional gray-scale TRUS has limited diagnostic accuracy,[820,821] so it should not be used routinely. Although it may be useful to direct prostatic fossa biopsy, biopsy results do not influence significantly the outcome of salvage RT[822-824] because a negative biopsy does not exclude local recurrence and a positive biopsy does not necessarily improve RT outcome. Color and power Doppler TRUS and intravascular microbubble contrast improves accuracy,[825,826] but its role in diagnosis and decision making remains undefined.

Conventional pelvic with or without abdominal computed tomography findings are often non-specific or normal until PSA is substantially elevated.[827-832] Dotan et al constructed a predictive nomogram that may be used to select patients in whom the yield is greatest.[833]

PET uses various radiotracers for cancer imaging, integrated with CT to enhance anatomical localization. 18F-FDG may be used,[834] but 11C-choline may be a more promising agent.[835-838] Radiotracer avidity is most common in nodal, prostatic fossa, and osseous sites, with greater detection rates at higher PSA levels (>1.4 ng/mL),[835-838] and in patients with larger (>1 cm) volume recurrence,[836] or with prior seminal vesicle or pelvic node involvement.[837]

MRI with external and endorectal coil is a useful method to identify postoperative intrapelvic tumor recurrence. A prostatic fossa tumor mass appears iso-intense on T-1 sequences, hyper-intense on T-2, and is early-phase gadolinium enhancing. Endorectal MRI has excellent diagnostic sensitivity (84% to 95%), specificity (89% to 100%), and accuracy (86% to 94%)[841-845] that directly correlates with serum PSA level and prostatectomy histopathology.

Salvage RT Outcomes after Biochemical Relapse. The outcome of salvage RT is described in more than one hundred observational case series reports[765] and a systematic review,[848] but randomized clinical trial results are largely lacking. These series (Table 53-17) provide some insight into outcomes,[780,804-810,816,822,849-855] but cautious interpretation is needed because RT was not administered under ideal conditions (i.e., low PSA level) in all cases. Nonetheless, a substantial proportion of patients had an initial biochemical response,[804,806,809] which suggests that incomplete surgical excision of the cancer is the source of biochemical relapse in most patients. Improved diagnostic evaluation (e.g., endorectal MRI) and IMRT to higher than conventional doses yields promising results[854,856,857] that may be enhanced further with IGRT localization.[858,859] Therefore, the results observed previously may not reflect outcomes expected at present.

Gleason score,[805,807,809,810,816,849,853,854,860] tumor DNA ploidy,[853] persistently detectable postoperative PSA,[805,850] PSA level before RT,[804,806,809,810,816,822,852,853,855,860] PSAdt postoperatively,[806,810,816,822,860] surgical margin status,[810,816] SVI,[804,806,808,816,850,853] pelvic nodal involvement,[810] and delay in initiation of RT[860] are closely associated with the success of salvage RT.

Prognostic factors may be combined to estimate the likelihood that sustained RFS will follow salvage RT.[810,853] Stephenson et al used prognostic factors in a proportional hazards regression to develop a nomogram predictive of RT outcome (Figure 53-16).[810]

Androgen suppression may be given before, during or after salvage RT, but it has been used typically for 2 to 3 months before and then concurrent with RT. Outcomes are presented

Consensus recommendations regarding the selection of adjuvant RT compared with observation with early salvage RT does not exist presently. Some case-controlled series support the notion that adjuvant RT yields improved outcomes,[798] and this gains some support from SWOG 8794.[786] However, these conclusions are not definitive, so the Medical Research Council study PR10,[794] Trans-Tasman Radiation Oncology Group #08.03, Groupe d'Etude des Tumeurs Uro-Genitales, and the Federation Nationale des Centres de Lutte Contre la Cancer are conducting randomized clinical trials to address this issue.

Further guidance may be derived from more individualized estimates of relapse risk in association with male life expectancy.[768,799] The GPSM scoring algorithm (Score = [prostatectomy Gleason score] + [+1 if preoperative PSA 4-10, +2 if PSA 10.1-20, +3 if PSA > 20] + [+2 if seminal vesicle or node involvement] + [+2 if positive surgical margin]) sets out categories of PFS and CSS estimates after prostatectomy.[768] Patients with GPSM score ≥10 are at greater risk for early biochemical relapse and for death from prostate cancer, so patients with greater life expectancy (e.g., ≥10 years) may also benefit most greatly from adjuvant RT. This context may be used to frame a discussion with the patient that balances competing perspectives and uncertainties.

There is the suggestion that low PSA levels result from residual benign prostatic tissue. This does not appear to contribute significantly to biochemical relapse.[803]

Biochemical relapse, however, does not translate universally into clinical expression of disease or excess mortality. A persistently elevated PSA after prostatectomy,[811] shorter interval from surgery to biochemical relapse,[812-814] shorter PSA doubling time,[812-816] higher Gleason[812-815] and GPSM scores,[815] and nondiploid tumor DNA content[815] are associated with progression to metastatic disease and prostate cancer mortality.

Ward et al found that PSAdt was strongly associated with subsequent clinical relapse,[815] with one half to three quarters of patients with PSAdt <12 months having clinical relapse within 10 years. Freedland et al identified PSAdt, Gleason score, and interval from surgery to biochemical relapse as important factors associated with development of metastases and prostate cancer-specific mortality.[814] Most deaths (90%) were attributed to prostate cancer when PSAdt was <15 months, whereas one third of deaths were the result of prostate cancer when PSAdt was ≥15 months. As also noted by Zhou et al,[817] life expectancy was shortest in those with PSAdt <3 months.[814] Although definitive guidelines on its use are lacking, these observations suggest a role for PSAdt when considering salvage therapy.

Postoperative changes may give the false impression of a tumor mass or of retained seminal vesicles.[827] Although a particular PSA level or PSA kinetic parameter does not have sufficient predictive value to trigger an imaging recommendation,[830] an abnormal CT is rare with PSA ≤5 ng/mL to 10 ng/mL or PSA doubling time ≥6 to 10 months.[830,831] Whole-body bone scan is often normal in the asymptomatic patient, particularly with a PSA level ≤10 ng/mL,[830,832] or when the PSA doubling time is >6 months.[831]

Because a normal PET-CT does not preclude a favorable response to salvage RT,[836] best use of this modality requires further study.[836] [111]In capromab prostate-specific membrane antigen monoclonal antibody imaging (ProstaScint) is another nuclear medicine technique. However, it has low sensitivity for detection of local recurrence or metastases, and its results do not predict the outcome of salvage RT.[839,840] Therefore, its use is not recommended routinely.

Studies of multiparametric MRI suggest that combined T2-weighted and dynamic contrast-enhanced images have the highest sensitivity, whereas diffusion-weighted and spectroscopic images do not add greatly to detection.[845] The most frequent sites of recurrence are the vesicourethral anastomosis (50%), retrovesical space (24%), and seminal vesicle region (26%).[841-846] Miralbell et al[847] noted that an approximate 4 cm (length) × 3 cm (diameter) cylindrical volume centered 0.5 cm posterior and 0.3 cm inferior to the vesicourethral anastomosis defined the "ideal" CTV when adapted to exclude nontarget structures (e.g., bladder, rectum, bone). However, tumor recurrence beyond this volume (e.g., at vas deferens transection) may occur,[846] so caution is warranted.

Some studies evaluated pre-RT PSA level using various cutoff values. However, there is a continuous risk of relapse as PSA rises,[810,853] such that each doubling of PSA increases the relative risk of biochemical relapse by approximately 40%. Therefore, an ideal PSA "trigger" for intervention has not been identified.

This nomogram is meant for the patient yet to receive salvage RT, but it is important to note that the results reflect techniques used during the past. Although surgical findings and the postoperative PSAdt represent intrinsic and fixed determinants of prognosis, their contribution to an adverse outcome is lessened when RT is initiated at lower PSA levels.

in only a few observational case series,[810,816,850,861] where criteria for its use were not consistently prescribed. Although its role is controversial,[765] several ongoing clinical trials address its use.

Consensus-based guidelines provide general direction for use of salvage RT.[765,772,773,797] These guidelines state that prescribed dose to the prostatic fossa should be ≥64 Gy,[765,773] but some observational series suggest that a higher dose is beneficial.[854,856,857]

Clinically Apparent Local Recurrence. The distinction between biochemical relapse only and clinically apparent local recurrence has become less clear with the advent of more sensitive diagnostic imaging. Endorectal MRI demonstrated that local recurrences are often located beyond the reach of digital rectal examination and may be of substantial size.[841-845] Thus, clinical detection is a function of tumor location, PSA level, and the frequency and intensity of surveillance.

The efficacy of salvage RT specifically in this setting has been evaluated by relatively few investigators,[822,823,862-868] whose reports often include a heterogeneous and small study cohort. The results of RT (eTable 53-8) suggest that clinically based local tumor control is achieved in ~85% of patients,[862-864,866-868] but the likelihood of bDFS 5 years after RT is considerably less (~25%).[822,823,862,864-868] These observations suggest that DRE lacks sufficient sensitivity to prompt intervention in lieu of a strategy primarily based on PSA monitoring.

More extensive radiological evaluation and fusion of complimentary imaging modalities (e.g., MR and CT) may be needed to provide optimal identification of the mass' complete extent. IGRT[858,859] and highly conformal IMRT may also allow for a significant dose differential in the target volume, and this can be exploited to administer a higher dose within the tumor than in the remaining prostatic fossa. The results of RT achieved to date suggest also a role for neoadjuvant with or without adjuvant androgen suppression to supplement RT.

Adverse Effects

Adverse effects of postoperative RT are similar to those with primary RT and result from incidental irradiation of the bladder, rectum, femoral heads, and erectile tissues, and patients should be informed of these in concert with the potential benefits.[765] Early effects are those that occur during or within 90 days of RT completion, and late effects are those that occur or persist thereafter; the term *chronic* should be avoided because most late effects resolve spontaneously or with minimal intervention. Several observational series[856,878,879] and clinical trials[769,784,788] describe these effects and incidences (not prevalence), but these reports do not necessarily reflect current RT techniques.[856,880] The RT planning and treatment techniques, dose-volumetric parameters, imaging and localization methods, and antecedent surgery influence the incidence and severity of adverse effects. It is essential to document baseline status before RT (e.g., number of daily stools), investigate causation (e.g., proctoscopy), assign attribution correctly (i.e., RT versus not), and monitor the course of these events.

Early adverse effects are limited typically to GU and GI systems, and these tend to be irritative in nature and self-limited. A causal relationship between early and late effects is suggested but not yet irrefutably proven.

The cumulative incidence of late grade-2 or higher (that is, moderate or severe) adverse events likely attributable to postoperative RT is <20% at 5 years[769,878,879]; many adverse effects are not chronic. The 5-year incidence of late grade-2 or higher GI events is <5%,[769,784,856,878] and severe events are less common still (<1%).[769,788,878,879]

It may be difficult to accurately attribute late GU effect causality because both surgery and RT may contribute and their cause is often evaluated incompletely. The incidence of grade-2 or higher late effects is approximately 10%[769,856,878,879] with severe events not likely to arise from RT.[788]

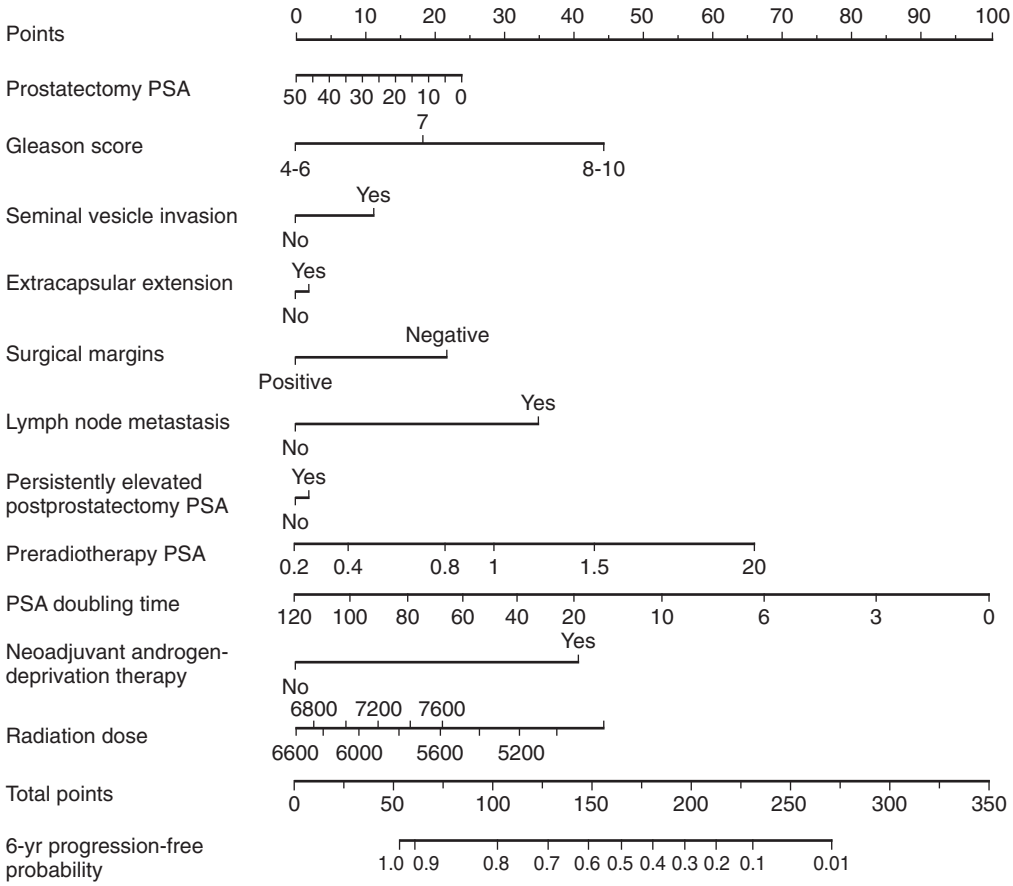
Patient-reported QoL was studied by Moinpour et al in a longitudinal assessment of prostatectomy with or without adjuvant RT.[785] More patients assigned to RT reported urinary frequency throughout the 5-year study period, and bowel symptoms were more common during the first 2 years. This contributed to reduced global QoL during the initial 2 years, but the adjuvant RT group fared better than the surgery only group thereafter.

RTOG trial 9601 assigned patients to prostatic fossa RT with bicalutamide compared with placebo for 2 years, and RTOG 0534 is a three-arm trial of prostatic fossa RT alone versus short-term androgen suppression given before and during prostatic fossa with or without elective pelvic nodal RT. The Japan Clinical Oncology Group 0401 compares bicalutamide to RT with bicalutamide, and the Medical Research Council PR10 includes a comparison of RT compared with RT with 6-month androgen suppression compared with RT with 2-year androgen suppression.[794]

The NCCN (www.nccn.org) supports offering RT in all men with a detectable PSA. This recommendation is provided also by the ASTRO/AUA, the European Association of Urology,[773] the Australian and New Zealand Radiation Oncology Genito-Urinary Group,[772] and the European Society of Medical Oncology (endorsed by the Japanese Society of Medical Oncology).

Acute treatment related dysuria, urgency or frequency, proctalgia, increased daily stools, and (infrequently) hematuria or hematochezia may occur.[788,856] Rectal dose, pelvic nodal RT, diabetes mellitus, hemorrhoids, and androgen suppression or anticoagulant use contributes to acute GI adverse effects, and these factors may be used in a predictive nomogram.[881]

The use of adjuvant (verus salvage) and nonconformal RT and of androgen suppression is associated with increased adverse late effects.[856,878] Late GI adverse events may include increased or urgent stools/tenesmus, proctalgia, hematochezia, mucous discharge, rectal stricture, or fecal incontinence (0.2%).[878]



Late GU events may include bladder neck contracture or urethral stricture (5%),[809,878,879] urgency or frequency, dysuria, or transient hematuria (5%).[809,878,879] Urinary continence is comparable to that which follows surgery alone,[774,777,804,805,866,882] and is typically of a mild stress-induced nature when it occurs.[777] It does not appear that RT diminishes erectile function in men who undergo nerve-sparing prostatectomy,[883] but more comprehensive research is required to address this issue.

Functional and health perceptions did not differ between the groups. Although this study is informative, conformal RT was not used, so it is not certain that these findings can be extrapolated to present-day practice. The experience of Pinkawa et al is perhaps more relevant,[884] because it used a broadly accepted QoL instrument and more modern salvage RT techniques. Reduced urinary function and bother was evident only at end of RT, and reduced bowel function and bother was reported through 2 months, but not thereafter. Lesser bladder distention, bladder D90 ≥ 28% and D50 ≥ 45% was associated with urinary bother at RT end, D90 ≥ 28% was associated with urinary incontinence function and bother subscores at RT end, and D50 ≥ 45% was associated with urinary function and urinary incontinence function score at 12 months. An association between rectal dose-volumetric parameters and QoL endpoints was not identified.

Instructions: Locate Gleason score on the Gleason axis. Draw a line straight up to the Points axis to determine how many points toward disease recurrence the patient receives for his score. Repeat this process for the other 10 disease and treatment axes, each time drawing straight up to the Points axis. Sum the points and locate this number on the Total Points axis. Draw a straight line down to find the patient's probability of remaining free of disease progression.

Figure 53-16 Pretreatment nomogram predicting 6-year progression-free probability after salvage RT.
Data from Stephenson AJ, et al: Predicting the outcome of salvage radiation therapy for recurrent prostate cancer after radical prostatectomy. J Clin Oncol 25:2035-2041, 2007.

Postirradiation Local Salvage Therapy

Surgery for a biopsy proven locally recurrent prostate cancer is an appropriate intervention for selected patients. Because there can be considerable morbidity, an extensive preoperative evaluation to assess surgical feasibility and to exclude clinically overt metastatic disease is warranted. Thus, cystoscopy, examination under anesthesia, CT or MRI of abdomen and pelvis, chest radiography, and radionuclide bone scintigraphy (with or without supplemental skeletal radiography or MRI) may be used to complement the history and clinical examination. Furthermore, the general health condition (i.e., comorbidity) and life expectancy of the patient and the patient's expectations should be considered in concert with the efficacy and morbidity of the procedure. The decision between prostatectomy, anterior exenterative surgery (e.g., cystoprostatectomy), or less invasive procedures (e.g., cryoablation, brachytherapy, or high-intensity focused ultrasound) requires careful preoperative and intraoperative evaluation. A cystoprostatectomy may be indicated in the presence of biopsy-proven bladder neck or seminal vesicle tumor invasion, incontinence from a noncompliant low-capacity bladder, severe RT-induced cystopathy, or pelvic adhesions.[885,886]

Several observational case series described disease outcome after surgical resection for post-RT locally recurrent prostate cancer. The most extensive modern experience was reported by Ward et al who demonstrated that salvage surgery (with or without AD) provided encouraging tumor control and survival rates.[887]

Another alternative to postradiation prostatectomy is cryosurgery, which is the killing of cells via the application of very cold temperatures.[890-895] Several retrospective series have shown reasonable PSA control rates of 30% to 70% at 12 to 20 months with major complications in the 10% range in patients treated with cryosurgery post-RT local failure.[890,892-895]

Brachytherapy has been used as an effective salvage therapy for men who have experienced a local recurrence following either EBRT or brachytherapy.[316,899-905] Second biochemical DFS of 34% to 53% at 5 years[900,902,904] and 54% at 10 years[901] have been reported with permanent seed LDR brachytherapy.

METASTATIC DISEASE

In the past decade several new classes of drugs have been developed to treat prostate cancer. These include

In their experience, there has been a shift away from radical cystoprostatectomy to radical prostatectomy after 1990 such that 82% of salvage procedures are prostatecomies only compared to 54% before that era. The 10-year CSS was 65%.[887] Tumor ploidy, Gleason grade, and pathological stage were strong predictors for outcome. Bianco reported 100 consecutive patients undergoing salvage RP with an overall 5-year PFS of 55%. The 5-year control rate was highly depended on preoperative PSA values with progression free rates of 86%, 55%, and 37% for PSA levels of <4, 4-10, and >10 ng/mL, respectively.[888]

Because RT-induced fibrosis tends to obliterate the usual tissue planes used to establish surgical lines of resection, the increased technical difficulty and morbidity of the procedure result in a general reluctance to perform salvage surgery. The utilization of conformal radiation or brachytherapy techniques appears to make the surgical approach less challenging than older series of salvage prostatectomy.[889] In a series of 100 patients, Stephenson reported a major complication rate of 13% compared to 33% with the rectal injury rate falling to 2% compared to 15% prior to 1993.[886] The rectal injury rate was 5% for prostatectomy patients and 10% for cystoprostatectomy. In the largest published series, the most common complications were urinary extravasation (15%) or bladder neck contracture (22%).[887] Ward noted a decreased need for blood transfusion and a reduced complication rate in patients treated with RP during more recent years, which highlights the importance of the anatomic approach and extent of surgical experience with this situation.[887]

Cryosurgery was first used for prostate cancer in the 1960s and 1970s, but incontinence, urethral necrosis, and fistula were common in because of lack of controlled urethral warming. Subsequently, TRUS guidance and urethral warming were developed.[896,897] Just as for salvage prostatectomy, patients should have biopsy proven locally recurrent disease without evidence of distant metastasis.[890,891] Additionally for patients whose PSA is >5 ng/mL, evaluation of the pelvic lymph nodes via a CT, MRI, or pelvic lymph node dissection is reasonable because salvage radical prostatectomy series report between 20% and 40% of patients as having metastatic disease to the pelvic lymph nodes in this setting.[890,891] In one large series comparing salvage RP to cryosurgery, the cancer control and survival rates were superior for RP over cryosurgery.[898] Cryosurgery remains an option in patients that are not suitable for RP, although properly selecting candidates for this procedure remains a challenge.

Presalvage PSA values of less than 6 ng/mL[901] or less than 10 ng/mL[900] have been associated with better biochemical control rates. Grade-3 or greater GI or GU toxicity rates range from 0% to 47%.[901,902,904-906] The most common late toxicities are urinary incontinence, stricture, or rectal ulcer. An interval from primary RT to salvage brachytherapy of less than 4.5 years has been associated with a greater rate of late complications.[905] HDR brachytherapy has also successfully salvaged patients with local tumor recurrences, although follow-up with this technique has been limited.[903,907]

antiandrogenic agents, cytotoxic chemotherapies, immunotherapies, bone-targeted agents, vaccines, and radiopharmaceuticals. Because many of these new therapies were developed along parallel tracks, the precise impact and timing each of these may have on patients with metastatic disease remains under considerable discussion and investigation. The order with which these drugs have been approved have more to do with regulatory and funding concerns than they have with the ideal sequence of treatment. In the next decade, the optimum combination and timing of these agents will be explored.

Hormonal Therapy

Androgens play a critical role in the health and survival of both normal prostate epithelium as well as prostate cancer. Over the past decade a we have gained a clearer understanding of the role of androgens, the androgen receptor (AR), and the molecular biology of both endocrine and intracrine regulatory processes in the growth of prostate cancer.

Several classes of AD agents are available for medical (versus surgical) castration and include estrogens (e.g., diethylstilbestrol, estramustine), progestational agents (e.g., cyproterone, medroxyprogesterone, megesterol), LHRH agonists (e.g., goserelin, leuprolide, triptorelin, buserelin, histrelin), LHRH antagonists (aberelix, degarelix), and steroidal (e.g., cyproterone, medroxyprogesterone, megestrol) and nonsteroidal (e.g., bicalutamide, flutamide, nilutamide) antiandrogens. There are new classes of antiandrogen agents that specifically target downstream conversion of testosterone to the potent DHT or block its interaction with the AR. Although ~80% of patients with metastatic disease respond to AD,[910] this response is often transient.[911,912] In men with metastatic disease, prostate cancer becomes castrate resistant within 16 months whereas in patients with strictly biochemical progression or failure the time to castrate resistance may be as long as 10 years.[913,914]

Estrogenic therapy lowers LH concentration and thereby reduces serum testosterone levels. Continuous administration of LHRH agonists cause inhibition of LH and FSH release and suppression of testosterone, which reaches castrate levels after 3 weeks. However, LHRH agonists initially produce a significant increase in testicular androgen production, known as the "flare" reaction, which can be inhibited with the administration of antiandrogens. The major side effects of the LHRH agonists include impotence, loss of libido, atrophy of the reproductive organs, and hot flashes. As discussed previously, they can also be associated with metabolic changes that may predispose patients to diabetes, dyslipidemia, or osteopenia. Antiandrogens competitively bind to androgen receptors at the target cell level. This class of drugs blocks the effects of testicular and adrenal androgens.[915,916] Antiandrogens may offer a quality of life advantage over other AD methods because they do not reduce serum testosterone and therefore do not have the marked inhibitory effect on libido and potency apparent with other agents. However, because antiandrogens increase estrogen levels, gynecomastia is a common complication and can occur in as many as 70% of patients. Either prophylactic breast radiation or an anti-estrogen such as tamoxifen is recommended.[917,918]

The role of total androgen suppression (TAS) (i.e., LHRH agonist or orchiectomy and an antiandrogen) has been the subject of considerable investigation. Although Crawford et al[911] and Janknegt et al[919] demonstrated that PFS and OS were improved with TAS, the Prostate Cancer Trialists' Collaborative Group performed a systematic overview, or meta-analysis, of 22 clinical trials and concluded that survival duration was not enhanced with TAS.[912]

There is growing support for the use of intermittent androgen deprivation (IAD) rather than continuous AD. At least three arguments support this strategy over continuous AD including improved QOL because of a reduction in hormone-related adverse events, lower treatment costs, and the possible delay in the development of castrate insensitive disease. In a Phase III trial of continuous versus intermittent AD, Crook reported a median OS of 8.8 years with intermittent AD compared to 9.1 years with continuous AD. The rates of prostate cancer deaths were not significantly different between the two arms. The QOL for patients receiving intermittent AD was improved in the domains of hot flashes, sexual desire, urinary symptoms, and fatigue.[914,920] The optimal duration of treatment while on hormone therapy and the specific triggers for when to reinitiate treatment remain to be defined.

New antiandrogenic agents are undergoing clinical investigation including abiraterone, enzalutamide, and orteronel.[921-923] These drugs appear to have activity in patients previously treated with AD therapies. Several mechanisms for castrate resistance (eBox 53-2) have been identified that may suggest specific strategies to overcome disease progression.[923]

Both abiraterone and enzalutamide have been evaluated in a series of trials for castrate resistant prostate cancer (CRPC) both before and following prior treatments with systemic chemotherapy. The COU-AA-301 trial was a Phase III comparison of abiraterone and prednisone versus placebo and prednisone in men with CRPC that had previously progressed on chemotherapy.[924,925] The median overall survival was significantly increased with abiraterone by 3.9 months (14.8 months compared to 10.9 months). A similar Phase III trial in CRPC patients that had not received prior chemotherapy (COU-AA-302) showed nearly doubling in median survival from 8.3 months to 16.5 months with abiraterone and prednisone compared to prednisone alone.[926] The AFFIRM trial compared enzalutamide to placebo in a similar population of CRPC patients who had progressed following chemotherapy. Enzalutamide was associated with a statistically significant 4.8-month improvement in median survival from 13.6 months with placebo to 18.4 months with enzalutamide.[927] Enzalutamide has also been evaluated in CRPC in the prechemotherapy setting. The PREVAIL study was a double-blind, placebo-controlled trial that demonstrated a 29% increase in survival.[928]

Chemotherapy

Mitoxantrone and prednisone had been approved for CRPC on the basis of improvement in QOL and symptoms related to metastatic disease.[929] Although that combination improved patient reported outcomes, it had no impact on OS. For nearly a decade, little progress had been made in the systemic management of metastatic CRPC. Today, docetaxel-based chemotherapy is considered a standard option for CRPC.[751,752] In a randomized trial of 1006 patients who are castrate-resistant, docetaxel plus prednisone showed a 2.4-month advantage in median survival as compared to mitoxantrone plus prednisone.[752] A similar randomized trial in 770 men with CRPC comparing docetaxel and estramustine to mitoxantrone showed an improvement of time to progression from 3.2 months with mitoxantrone to 6.3 months with docetaxel and estramustine.[751] Additionally a meta-analysis of three randomized trials comparing docetaxel to mitoxantrone showed a reduction in death risk of 8% to 21% with docetaxel which persisted 3 years after the start of therapy.[930] Cabazitaxel is a novel tubulin binding taxane that shows activity in patients previously exposed to docetaxel. In the TROPIC trial, 755 men with CRPC who had progressed on docetaxel were randomized 1 to 2 to receive either mitxantrone or cabazitaxel. In this heavily pretreated patient population, cabazitaxel was associated with a 2.4-month prolongation in median survival (12.7 months versus 15.1 months).[931]

The clinical importance of androgens was established in the early 1940s by Huggins et al,[908] who demonstrated the therapeutic benefit of AD in the context of metastatic disease. The principles and efficacy of AD therapy for patients with advanced and metastatic prostate cancer were well summarized by Schulman et al.[909]

Sex hormone production is regulated by the hypothalamic-pituitary axis. Gonadotropin-releasing hormone is synthesized by the hypothalamus and transported to the anterior lobe of the pituitary gland, where it controls the synthesis and secretion of the gonadotropic hormones, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). The predominant means of controlling FSH and LH levels involve a closed-loop negative-feedback mechanism in which gonadal steroids have the capacity to inhibit FSH and LH secretion. The interaction of circulating LH with its receptor in the target cell results in production of circulating androgens through the following biosynthetic pathway:

Cholesterol → Pregnenolone → 17α-Hydroxypregnenolone → Dehydroepiandrosterone (DHEA) → Androstenediol → Testosterone → Dihydrotestosterone

Under normal physiologic conditions, Leydig's cells account for 95% of testosterone production in adult men, with approximately 5% derived from adrenal androgen production (i.e., androstenedione) and its conversion in peripheral tissues to testosterone. After its diffusion into its target tissue, testosterone is converted to the more potent androgen DHT by 5α-reductase. In turn, DHT forms an intracellular complex with the androgen receptor that targets specific DNA sequences. It is the androgen-responsive genes that determine the balance between cellular proliferation, cell death, and differentiation of the prostatic epithelial cell.

eBOX 53-2 Proposed Mechanisms for Continued AR Signaling in Castrate Resistant Prostate Cancer

Intracrine synthesis of androgens
Amplification and/or overexpression of AR
Overexpression or polymorphism of steroid transporters
Mutation of the AR gene
Constitutively active AR splice variants
Alteration in AR coregulators
Cross-talk between AR and other signaling pathways
Posttranslational modifications of AR
Distinct AR-mediated transcriptional programs

AR, *Androgen receptor.*

Antiandrogens are currently approved for use in combination therapy with an LHRH analogue to provide complete androgen blockade. Their use as a sole means of AD has been investigated.[915,916] At 150 mg/d, bicalutamide appeared to be equivalent to an LHRH agonist or castration in patients with locally advanced but nonmetastatic disease.[915]

Abiraterone is a pregnenolone analog that inhibits CYP17A1 (17 alpha-hydrolase/C17,20 lyase complex) preventing the formation of DHEA and androstenedione thereby lowering the levels of circulating androgen produced by the testes and adrenal glands without causing adrenal insufficiency.[921] The drug is administered with a low-dose corticosteroid to prevent secondary mineralocorticoid excess as a result of an increase in upstream steroids. Orterenol is another testosterone synthesis inhibitor currently being evaluated in clinical trials. Enzalutamide, an androgen receptor antagonist, blocks testosterone binding to the androgen receptor, slows nuclear translocation of the androgen receptor, and inhibits receptor binding to DNA.[922] Like abiraterone, it has shown activity in castrate-resistant prostate cancer suggesting a sustained role of the androgen receptor in castrate-resistant disease. Some studies have shown an upregulation of steroidogenic enzymes leading to an increase in androgen synthesis. In some cases, the Castrate Resistant Prostate Cancer (CRPC) cells can bypass the dominant pathway of the conversion of androstenedione to testosterone and DHT by alternative routes. Enhanced transport of androgen through the cell membrane has been identified. Most importantly, changes in AR expression by mutation or genomic amplification and overexpression may enhance the activity of diminished quantities of intracellular androgen.

Immunotherapy

There are multiple approaches to evoke the host's immune system to respond to metastatic cancer. Sipuleucel-T is an autologous cellular immunotherapy that has prolonged survival a median of 4 months in men with CRPC compared to placebo.[932] This treatment involves obtaining autologous cells by leukopheresis and culturing them in vitro with a protein that couples the vaccine target (prostatic acid phosphatase) to granulocyte-macrophage–stimulating factor. The activated leukocytes are then reinfused into the patient. Approved by the FDA in 2010, Sipuleucel-T represents the first immunotherapy vaccine for the treatment of metastatic cancer.

Systemic Radiotherapy

For the patient with multiple sites of painful osseous metastases, the administration of systemic radioisotopes may be considered. ^{223}Ra is an isotope of radium with a half-life of 11.4 days. It decays by the emission of high energy alpha particles with a short range (<100 μm).

The ALSYMPCA trial was a Phase III placebo controlled randomized trial of ^{223}Ra in CRPC patients with no visceral metastases.[937] Visceral metastases, except lymph nodes <3 cm, were excluded because the agent is not taken up by prostate cancer cells. Patients either previously received docetaxel or were unfit or declined to receive it previously. Radium was administered intravenously at a dose of 50 kBq/kg every 4 weeks for six injections. With 921 patient randomized to ^{223}Ra or placebo in a 2:1 ratio, patients who received ^{223}Ra had a 2.6-month improvement in median overall survival (14.9 months versus 11.3 months). ^{223}Ra significantly prolonged the time to the first symptomatic skeletal event (median, 15.6 months versus 9.8 months).

Strontium-89 (^{89}Sr) is a calcium analogue that is absorbed by the newly forming bone. Approximately 80% of patients experience reduced pain with ^{89}Sr, but only about 10% of patients become pain free.[938]

A prospective randomized trial by Sartor et al has shown samarium-153 (^{153}Sm) to be both safe and effective in the treatment of painful bony metastasis in patients with hormone refractory prostate cancer.[941]

Bone-Directed Therapies

Another option for managing skeletal metastasis in metastatic prostate cancer is the use of bisphosphonates. They bind to exposed bone mineral and diminish the availability of hydroxylapatite crystals for osteoclast mediated resorption. Bisphosphonates can directly inhibit osteoclasts and their precursors. In a Phase III trial of zoledronic acid or placebo in men with asymptomatic or minimally symptomatic CRPC, patient receiving the 4 mg or 8 mg of zoledronic acid every 3 weeks had significantly fewer skeletal related events than men in the placebo group (33.2% versus 44.2%).[942] It also significantly delayed the median time to onset of the first skeletal event to 546 days compared to 464 days. A slight survival benefit accompanied the use of zoledronic acid, but this was not statistically significant. A potential benefit of bisphosphonate therapy is the prevention of osteoporosis caused by prolonged AD use in patients with metastatic disease. Osteoporosis associated with AD causes an increase in skeletal fractures[943] and bisphosphonates could reduce such fractures.

Denosumab is a human monoclonal antibody against the receptor activator of nuclear factor kappa-B ligand (RANKL). RANKL is a tumor necrosis factor cytokine which functions as a key factor for osteoclast differentiation and activation. Denosumab inhibits osteoclast-mediated bone destruction and has been evaluated in men receiving androgen deprivation who are at risk of developing osteoporosis as well as patients with bone metastases. In a double-blind placebo-controlled Phase III trial, Smith et al reported a 5.6% increase in the bone mineral density of men receiving denosumab 60 mg every 6 months compared to a 1.0% loss of density in men receiving placebo.[944] They also experienced a significant reduction in new vertebral fractures (1.5% versus 3.9%) at 36 months. In a double-blind Phase III trial of 1904 men with CRPC, Fizazi compared denosumab 120 mg or zoledronic acid 4 mg, every 4 weeks.[945] Denosumab was better than zoledronic acid for the prevention of skeletal related events. The median time to first skeletal related event was 20.7 months with denosumab compared to 17.1 months with zedronic acid. The rates of adverse events were comparable between the two groups.

Radiation Therapy

EBRT has an important role in the palliative care of patients with symptomatic metastatic disease. Painful osseous metastases are successfully palliated in more than 80% of patients.[946] Dose and fractionation schemes vary, but 30 Gy in 10 fractions or 8 Gy in one fraction are commonly used.[947-949] For patients with multiple sites of osseous pain, hemibody RT may provide pain relief. Either a single fraction or multiple treatments may be given.[950] This treatment technique is gradually being replaced by systemic radionuclides and chemotherapy.[951]

IRRADIATION TECHNIQUES

Primary Therapy

External Beam Irradiation

Before starting EBRT, a comfortable and reproducible (supine or prone) position is established during simulation that allows radiologic imaging to define the appropriate treatment volumes. A prone position may allow greater rectal sparing, particularly in patients with large seminal vesicles.[952] However, the prone position appears to be associated with greater prostate motion from breathing. In the prone position, prostate motion (cranial-caudal) ranged from 0.9 mm to 5.1 mm,[953] and deep breathing resulted in movements of 3.8 mm to 10.5 mm. In the supine position prostate movements during normal breathing were less than 1 mm in all directions. In a randomized study of patient positioning, the supine position was found to be more comfortable and reproducible.[954]

According to current standards, treatment simulation incorporates the use of a patient immobilization device and is done with CT imaging.[955] Immobilization devices reduce variation in daily patient position, thereby improving the accuracy of treatment delivery.[956,957] In the past contrast material may have been instilled into the bladder and rectum to localize the position of the prostate and adjacent organs on planar simulation radiographs; this is unnecessary with CT simulation. A urethrogram can help localize the urogenital diaphragm and, therefore, the apex of the prostate. The prostatic apex is 3 mm to 13 mm above the most proximal aspect of the urogenital diaphragm as defined by the urethrogram.[958,959] Care should be taken not to over inflate the urethra with iodinated contrast as this may distend or move the prostate from its relaxed position.[960,961] Because bladder and rectal filling can cause positional changes in target organs as well as affect the amount of normal tissue irradiated, the amount of bladder and rectal distention should remain as consistent as possible throughout the course of therapy. This is typically accomplished by simulating patients with a full bladder and an empty rectum. In some clinics patients are instructed to modify their diet and consume mild laxatives to minimize rectal distention. A

Other immune therapy approaches include the insertion of cancer cell antigens into viral vectors such as a Pox virus.[933] PROSTAVAC is a vaccine that has three costimulatory molecules that stimulate the immune system and has shown some benefit in delaying progression but has no impact on survival.[934] T-cell function augmentation using anti cytotoxic T-lymphocyte antigen-4 (CTLA-4) antibody may increase T-cell activation, proliferation, and infiltration into tumors, leading to cancer cell death.[935] Ipilimumab is a human monoclonal antibody against CTLA-4 currently being evaluated in clinical trials for CRPC.[936] Ipilimumab has been approved for the treatment of metastatic melanoma. In the randomized Phase II trial of CRPC, patients received ipilimumab with or without radiation therapy to sites of metastatic disease. One objective of the study is to determine whether or not local radiation therapy could augment the immune response through release of circulating tumor antigens following a tumoricidal dose.

^{233}Ra is a calcium mimetic, bound to newly formed bone stroma within the microenvironment of osteoblastic and sclerotic metastases. The large charged alpha-particle causes double-stranded DNA breaks, which result in a highly cytotoxic effect. ^{233}Ra is eliminated primarily in the GI tract and has a favorable safety profile with mild myelotoxicity.

Recent data suggests an improvement in QOL for those patients who have a decrease in pain after ^{89}Sr.[939] The major toxicity of this agent is myelosuppression, so adequate bone marrow reserve is required to safely use this form of RT. Other radionuclides, such as ^{153}Sm, have somewhat less hematologic toxicity.[940]

In the Phase III trial, 152 men with hormone refractory prostate cancer and painful bony metastasis were enrolled in a prospective randomized double-blinded trial comparing radioactive ^{153}Sm versus nonradioactive ^{153}Sm. Randomization was 2:1 to the radioactive agent. The results of this trail demonstrated that 1 mCi/kg of ^{153}Sm is both safe and effective for palliation of painful bony metastases in patients with hormone refractory prostate cancer.[941]

distended rectum may introduce a systematic error in the treatment planning process by compressing the prostate and pushing the posterior wall of the gland forward. Subsequently, during the course of radiation the rectum will empty more completely because of radiation proctitis resulting in a posterior shift of the prostate outside the planning target volume.[962] Three studies have shown an increase rate of biochemical failures in men simulated with a distended rectum.[962-964]

MR imaging complements the delineation of the prostate and seminal vesicles. CT may over estimate the volume of the gland by 27% to 32% and the localization of the prostatic apex is more accurate identified with MR.[958,965,966] The use of MR and CT visible fiducial markers implanted in the prostate before imaging for treatment planning may facilitate and improve the registration of images for treatment planning.

Clinical Target Volumes

Defining the volumes requiring an adequate therapeutic dose of radiation is a fundamental step in the RT planning process. The radiation oncologist must define the treatment volumes, which consist of the primary tumor and its clinically or radiographically evident extensions (i.e., gross tumor volume [GTV]), and regional tissues (e.g., seminal vesicle, lymph nodes) at risk of harboring subclinical tumor deposits (i.e., CTV). The GTV is the prostate gland and any extension of the primary tumor, as determined by clinical or radiologic examinations. The CTV includes GTV and regional sites to which the tumor may spread but that are beyond the limits of clinical detection (i.e., subclinical disease). Determination of CTV should consider pretherapy tumor-related factors correlated with histological findings from surgical experiences (see "Predictive Factors"; "Pathologic Endpoints"). Nomograms and risk categories are helpful to decide whether adjacent uninvolved tissue should be included in the CTV. Margin for possible EPE has been recommended by several authors. In a study of radical prostatectomy specimens, Davis et al demonstrated that EPE was present in 28% of 376 patients.[967] The average radial EPE distance from the prostate capsule was 0.8 mm with a range of 0.04 mm to 4.4 mm. The average radial EPE distance from the prostate capsule was 0.8 mm with a range of 0.04 mm to 4.4 mm. Sohayda reported EPE in 35% of 265 cases extending posterolateral in 53%, lateral in 24%, and posterior in 13%.[968] The 90th percentile of EPE distance was 3.3 mm for patients with clinical T1-2, pretreatment PSA of ≤10 ng/mL and biopsy Gleason score of 6 or less and 3.9 mm for less favorable tumors.

The seminal vesicle(s) may be a site of subclinical tumor extension in patients with clinically localized prostate cancer. The likelihood of SVI may be estimated from predictive models or nomograms.[193,202,210,969] Ultrasound-guided biopsy[382] or endorectal-coil MRI[209,970,971] may be used in the pretherapy evaluation. The role of elective RT of the seminal vesicles in patients with low-risk disease is controversial.[972,973] Nonetheless, the seminal vesicles may be included in the CTV if the risk of SVI is 15% or greater.[202,210,213,612] Exclusion of the seminal vesicles in patients with a low likelihood of SVI reduces the volume of, and RT dose to, nontarget normal tissues (e.g., rectum).[210,973]

Because the extent of SVI is generally within 1 cm of the junction of the seminal vesicles with the prostatic base,[170] inclusion of the entire seminal vesicle within the high-dose target volume may not be routinely required for intermediate-risk disease. In patients with intermediate-risk disease, the proximal 1 cm of seminal vesicle tissue may be included in the high-dose volume. This may be increased if the patient has multiple risk factors. Patients with high-risk disease may require treatment of the entire the seminal vesicles in the high-dose volume, particularly if there is clinical or radiographic evidence of extraprostatic extension or SVI.

The regional lymphatic tissues may be considered a CTV in high-risk situations. Several observational case series suggested that elective nodal irradiation (ENI) contributed a therapeutic benefit for certain patient subsets.[975-978] The RTOG conducted a prospective, randomized trial that evaluated ENI in the pre-PSA era and no improvement in outcome was observed.[979] Results of a contemporary trial, RTOG 94-13, show a higher bDFS rate in patients with a risk of LNI greater than 15%, provided that hormonal therapy was given neoadjuvantly.[612,632] At present, some feel it is appropriate to use models that estimate the risk of pelvic nodal involvement[193,213] and consider ENI when the risk of LNI reaches or exceeds 15%.[612] Whether or not to irradiate pelvic lymph nodes remains a controversial issue. Two additional trials testing the value of ENI are under way by the RTOG. One of them is in the definitive setting with lymph node risk assessed by the clinical factors of PSA, Gleason Score, and clinical stage. The other study is in the salvage setting for men that have a rising PSA following radical prostatectomy.

The goal of ENI of the pelvis is to include the obturator and internal and external iliac lymph nodes. This is often accomplished with a four-field beam arrangement that consists of AP, posteroanterior (PA), and opposed lateral fields or IMRT with five to nine beams. In the past, field margins were typically established through their relationship with certain bony landmarks as follows: (1) superior: L5-S1 interspace; (2) inferior: bottom of ischial tuberosities; (3) lateral: 2 cm lateral to pelvic inlet; (4) anterior: approximately 1 cm anterior to anterior projection of pubic symphysis; and (5) posterior: S3-4 interspace.

The nodal groups to be included extend from the L5-S1 interspace (i.e., low common iliac lymph nodes) to the top of the pubic symphysis (obturator lymph node region) (Figure 53-17). Presacral lymph nodes (subaortic only, S1-S3) are also included. These volumes correlate well with the nodal volumes typically treated with the four-field "box" technique used in all the randomized trials previously mentioned.[749] Complex blocking to shield portions of the small intestine and rectum is recommended. Alternatively, IMRT can be used. A dose of 45 Gy to 50.4 Gy is recommended and is often administered in 1.8-Gy once-daily fractions.[316]

Planning Target Volumes

The planning target volume (PTV) is determined by adding margin to the CTV to account for internal target volume and patient motion, and the field margins are set to conform to the PTV with allowance for the RT beam penumbra and dose build-up effect. These uncertainties can exist day to day (interfraction) and during a single fraction (intrafraction).

Internal movement of prostate, seminal vesicles, and surrounding tissues (e.g., bladder, rectum) throughout the course of EBRT is a well-recognized phenomenon that is a function of bladder and rectal distention and has particular relevance to the design and dosimetric consequences of a tight conformal dose distribution.[980-985] With real time monitor and intrafraction position correction, displacements can be corrected during treatment. Various methods to assess the setup and internal organ localization uncertainty are available including transabdominal ultrasound, in-room cone-beam CT, in-room conventional CT, in-room megavoltage CT, and x-ray imaging of implanted fiducial markers. Some systems are able only to detect prostate position at the start of a treatment whereas others, such as implanted electromagnetic radiofrequency transponders, can monitor position during a treatment session.[986] Chandra et al showed that the prostate would be outside the PTV approximately one third of the time when using a 5-mm margin without daily ultrasound to correct for interfractional prostate movement.[982] Studies have compared

When involved, the extent of involvement of the seminal vesicles may extend as far as 2 cm away from the insertion in the prostate gland.[969,974] Kestin found an excellent correlation between the prognostic features and the probability of seminal vesicle involvement. In 81 patients with positive SVI, the median length of tumor involvement was 1 cm. However, in their entire reported population only 7% of patients had SVI beyond 1 cm.[974]

Defining appropriate lymph node volumes for conformal ENI varies considerably among radiation oncologists.[748] In an effort to standardize the correct anatomical pelvic lymph nodes to be covered for locally advanced patients, RTOG GU radiation oncologists developed a consensus on the CTV for pelvic lymph nodes.[749]

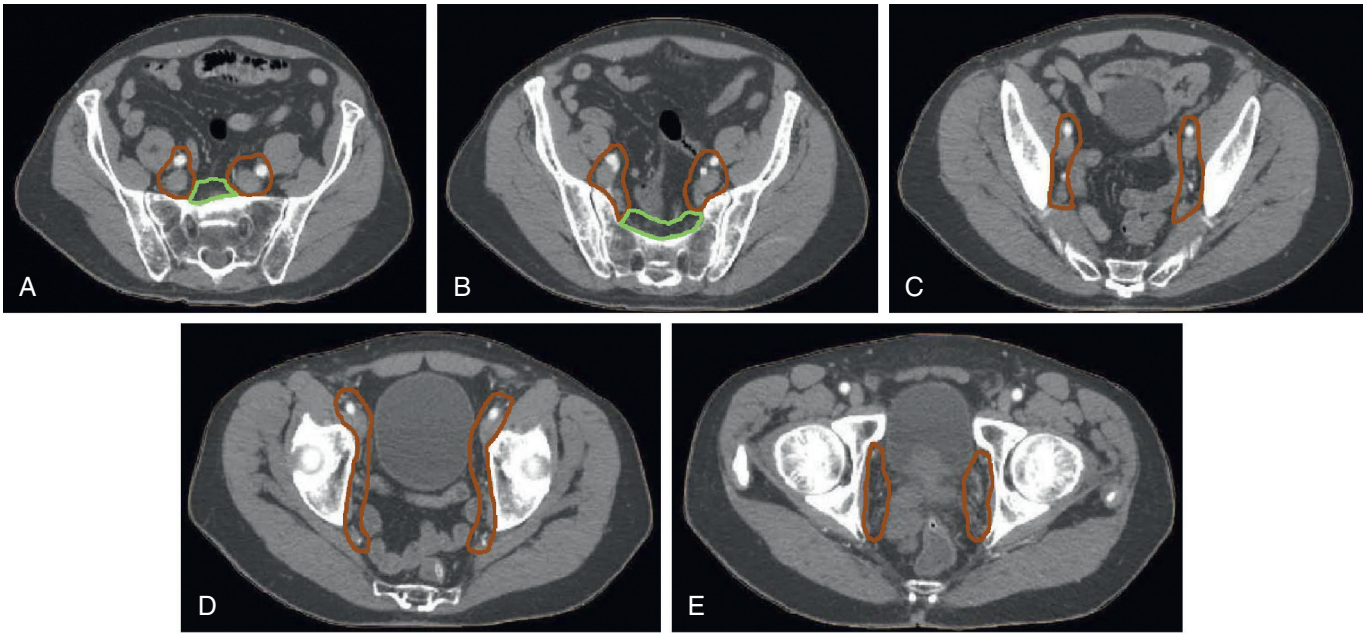

Figure 53-17 Representative pelvic lymph node clinical target volume (CTV) contours from RTOG consensus computed tomography. **A,** Common iliac and presacral CTV lymph node volumes (L5/S1). **B,** External, internal, and presacral CTV lymph node volumes (S1-S3). **C,** External and internal Iliac CTV lymph node volumes (below S3). **D,** End of external iliac CTV lymph node volumes (at top of femoral head, boney landmark for the inguinal ligament). **E,** Obturator CTV lymph node volumes (above the top of the pubic symphysis).

ultrasound to other methods of prostate localization such as cone beam CT (CBCT), megavoltage CT, and fiducial markers with port films.[982,987] Although transabdominal ultrasound systems offer the appeal of being less invasive, fiducial-based systems appear to offer an advantage over ultrasound with respect to the ease of use and the magnitude of residual error.[987] Results tend to vary by approximately 5 mm to 7 mm such that margins of this magnitude are still necessary even when using a method for prostate localization more accurate than port films. Like conventional CT scans, both megavoltage tomographic CT (e.g., tomotherapy) and CBCT offer cross-sectional views of internal anatomy and registration of daily targets to the original simulation CT. Image quality for both these volumetric imaging systems is inferior to simulation CT scans because of the physics of radiation interactions in the Megavoltage (MV) range, a limited field of view or organ motion during image acquisition.[988,989] Despite these deficiencies the images are of sufficient quality to allow daily anatomy-based target localization.[990] The concurrent use of implanted fiducial markers along with MV CT provides a more objective and reproducible determination of target localization.[991] Implanted electromagnetic radiofrequency transponders offer the opportunity to track prostate target position real time. Compared to other imaging techniques, the implanted transponders have a high temporal resolution, which can be used to monitor prostate position continuously during treatment delivery.

Variation in the shape, size, and position of the CTV in relation to the internal fixed point and the position of patient and RT beam in relation to external fixed points are accounted for as the internal motion and set-up margins to establish the PTV; these margins are typically in the range of 0.5 cm to 1.0 cm. Seminal vesicle motion can be greater and more variable than the prostate and may require more PTV margin.

Meijer analyzed serial CT scans on 30 prostate cancer patients and employed deformable image registration techniques to calculate the margin that would be used in the absence of daily imaging and with CT-based methods aligning to boney anatomy or implanted fiducial markers.[993] Without setup correction margins of 11 mm and 15 mm around the prostate and seminal vesicles would be required, respectively. With daily imaging and alignment to bony anatomy the margins could be reduced to 8 mm and 13 mm. With implanted fiducial markers, margins of 3 mm and 8 mm around the prostate and seminal vesicles, respectively, maintained adequate dosimetric coverage to the clinical target volumes.[993] They recommended larger margins at the prostatic apex due to difficulties identifying the inferior border of the prostate.

When using proton beam therapy the thickness of some implanted fiducials may create shadows or artifacts that could lead to underdosing tissue adjacent to the markers. Thin gold fiducials and placement away from known disease in the gland are advised.[994]

Caution should be exercised when reducing margin with improved treatment localization methods. Engels et al reported an increase rate of biochemical failure in a group of men treated with implanted fiducial markers and a margin of 3 mm laterally and 5 mm anterior, posterior, and craniocaudal.[963] This narrow margin, coupled with prostate deformation and dose uncertainty in the penumbra, may have contributed to tumor underdosing. They recommend a PTV margin of 6 mm when using fiducial markers without intrafraction monitoring.

Use of an endorectal balloon during daily treatment may stabilize the position of the gland. Air in the balloon decreases the rectal surface dose by decreasing the electronic equilibrium and buildup at the air–soft-tissue interface. Teh et al reported results of 100 consecutive patients treated with IMRT and an endorectal balloon.[995] Eighty percent had no rectal complaints and 11% and 6% had grade-1 or grade-2 acute toxicity, respectively.

In proton therapy the endorectal balloon is generally filled with water to minimize dosimetric uncertainties related to the lateral penumbra at the prescription depth.

A study conducted at five centers positioned 41 patients over a full course of therapy.[992] The study found that the continuous motion of the prostate was unpredictable and varied from persistent drift to transient rapid movements. Displacements >3 mm and >5 mm for cumulative durations of at least 30 sec were observed during 41% and 15% of treatment sessions.

Techniques for prostate localization prior to each treatment fraction are now available; however, such that margins have been decreased substantially to increase dose and limit normal tissue complications. The magnitude of the margin used for EBRT should be a function of immobilization, localization technique, and the frequency of treatment monitoring.

With air in the balloon, the dose at the air-tissue interface is approximately 15% lower than the dose at the same point without air. The dose builds up rapidly so that at 1 mm and 2 mm away from the interface, the dose is only approximately 8% and 5% lower. The dose to the posterior rectal wall is reduced with the use of an endorectal balloon during the prostate RT. A fluid-filled endorectal balloon is commonly used in patients receiving proton beam therapy because it does not introduce dosimetry uncertainties like fiducial markers can.

Treatment Planning and Delivery

Various EBRT beam arrangements may be used, the most current of which include (1) six-field (right and left anterior oblique, right and left posterior oblique, opposed lateral) 3DCRT techniques and (2) five to nine beam IMRT techniques (Figure 53-18)[251,996,997] or arc-based IMRT methods.

Modern treatment-planning computers also allow display of DVHs to graphically display RT dose to target (i.e., prostate) and nontarget (e.g., bladder, rectum) tissues, and "idealized" treatment plans may be derived through analysis of DVHs and computerized beam optimization. The QUANTEC project has provided DVH parameters that serve as treatment planning guidelines for limiting rectal and bladder toxicity or erectile dysfunction (Table 53-8).[546] In a preliminary analysis of the RTOG Phase III trial of dose escalation for intermediate prostate cancer stricter dose constraints for rectal dosimetry have been identified. Patients with rectal V70 of less than 15% and a V75 of less than 10% were less likely to have grade-2 or greater late rectal toxicity.[544]

The randomized clinical trials demonstrating a bDFS advantage for localized prostate cancer prescribed radiation doses ranging from 74 Gy to 79.2 Gy in conventional fraction sizes of 1.8 Gy to 2 Gy per day.[497,498,501,998] Although each study improved bDFS, there was also an increase in grade-2 or greater late bowel or bladder toxicity. Of note, other than the proton trial, each of these trials employed 3DCRT and not IMRT. It is expected that IMRT will allow safe escalation of dose above 75 Gy without an increase in late GI or GU toxicity.[550,999,1000] Most of the dose escalation trials prescribed treatment to the isocenter, which will deliver approximately 4% lower dose as a minimum to the PTV. In the RTOG dose escalation and hypofractionation trials, the minimum dose to ≥98% of the PTV (V98) was intended to be the study prescription

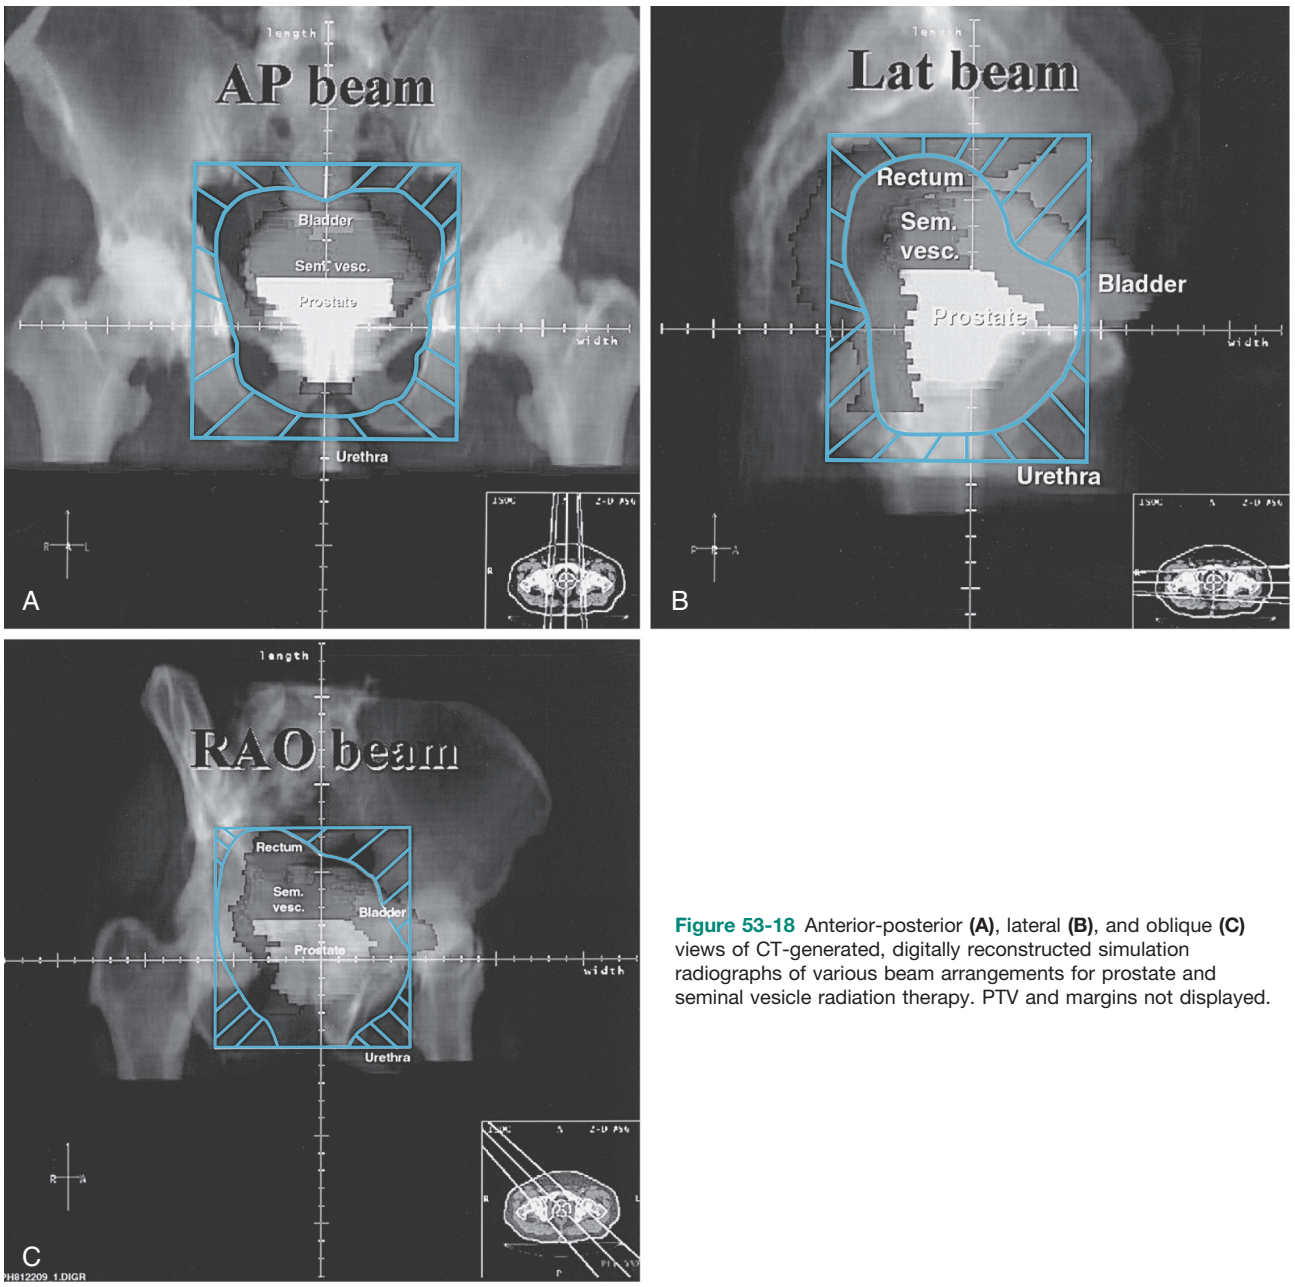

Figure 53-18 Anterior-posterior **(A)**, lateral **(B)**, and oblique **(C)** views of CT-generated, digitally reconstructed simulation radiographs of various beam arrangements for prostate and seminal vesicle radiation therapy. PTV and margins not displayed.

dose. In other words, no more than 2% of the PTV[504,1001] received less than the prescribed study dose.

Brachytherapy

Several techniques for permanent seed brachytherapy have been developed based on prostate imaging. The CT-based method, initially used by Wallner et al, was associated with high rectal and urinary complications, and has largely been discontinued as it does not offer direct intraoperative visualization.[1002]

Most permanent prostate brachytherapy incorporates real-time ultrasonography to visualize the prostate (Figure 53-19). The probe is placed on a fixed stepping device that allows its independent movement relative to the transperineal template. With or without the addition of fluoroscopy, the use of a biplane ultrasound probe allows prostate visualization in sagittal and axial mode for accurate prostate imaging. Others are using real-time MRI techniques to perform permanent prostate brachytherapy.[1003] Most centers use real-time ultrasonography imaging with various techniques. The "Seattle" technique employs the use of a preplan-based on serial axial TRUS performed in lithotomy position in advance of the implant.[586] Based on an approved plan, needles are loaded with I-125 or Pd-103 and spacers, and used in the operating room to correspond with the plan. Needle placement follows the plan with deposition of each successive needle's seeds. Use of fluoroscopy may assist to assure that the needles are positioned against a "zero" plane as a reference position. Several vender specific products have been developed to mimic this process with seed links or strands. An advantage of this approach is that it allows for multiple plans to be developed in advance of the case and that needle placement in the operating room is generally easy and can be performed in a timely manner. The disadvantage of this process is that it remains difficult to achieve the exact position of the prostate relative to the preplan, and that there is no ability to compensate for discrepancies during the case, except to add additional sources at the discretion of the physician.

With advances in software treatment planning systems, Potters et al have reported on a dynamic intraoperative technique that achieves dose conformality based on set parameters for minimum and maximum prostate dose with inverse planning.[655] Using treatment planning software in the operating room, seed location can be determined on actual needle placement, and then followed by dynamic assessment of the dosimetry during the case. Final intraoperative dosimetry appears to correlate to the CT-based dosimetry, with the advantage of using 8% less isotope activity per case (Figure 53-20). Others are using like techniques as the integration of intraoperative computerization and seed planning allows greater flexibility during the case to achieve the implant quality with fewer seeds.[1004-1006]

HDR Brachytherapy

Generally reserved for patients with locally advanced cancers, HDR brachytherapy offers a boost treatment option to EBRT. By placing HDR afterloading needles directly into the prostate gland under real-time ultrasound guidance, a steep dose gradient between the prostate and adjacent normal tissues can be generated that is unaffected by organ motion and edema or treatment setup uncertainties. The ability to control the amount of time the single radioactive source dwells at each position along the length of each brachytherapy catheter further enhances the conformity of the dose. Recent data from several groups performing HDR brachytherapy in patients with locally advanced disease suggest similar tumor control as 3D-conformal EBRT with the added advantages of reduced treatment times, less acute toxicity, and no additional technological requirements to account and correct for treatment setup uncertainties and organ motion.[1007-1009] The issues that remain unresolved with this technique (as with other methods of dose escalation) revolve around the amount of additional dose required to provide optimal tumor control,

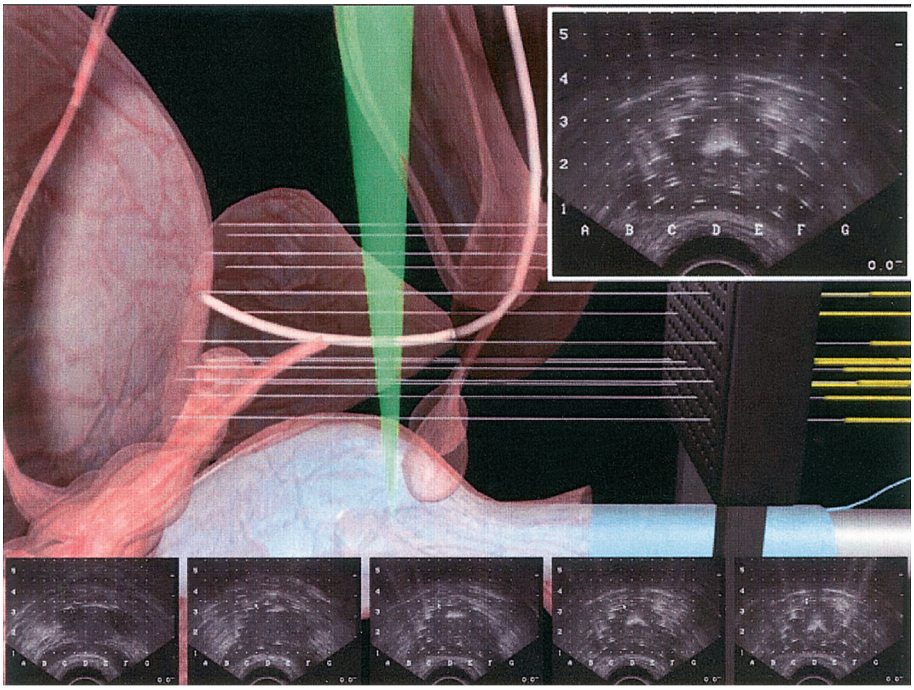

Figure 53-19 Axial-view image of permanent prostate brachytherapy.
Courtesy of Louis Potters, MD, Memorial Sloan Kettering Cancer Center at Mercy Medical Center, Rockville Center, NY.

An alternative technique, originally developed at Mount Sinai, uses an interstitial gun to place each seed individually.[1004] The interstitial gun can be used with a preplan, but is more commonly utilized for a real-time implant, where needle positions can be adjusted as needed. Likewise, use of the interstitial applicator is operator dependent and requires a higher degree of dexterity and ultrasound skills.

There are no studies that have directly compared these techniques. However, it is generally understood that implant quality is similar between the real-time and preplanned techniques.[614]

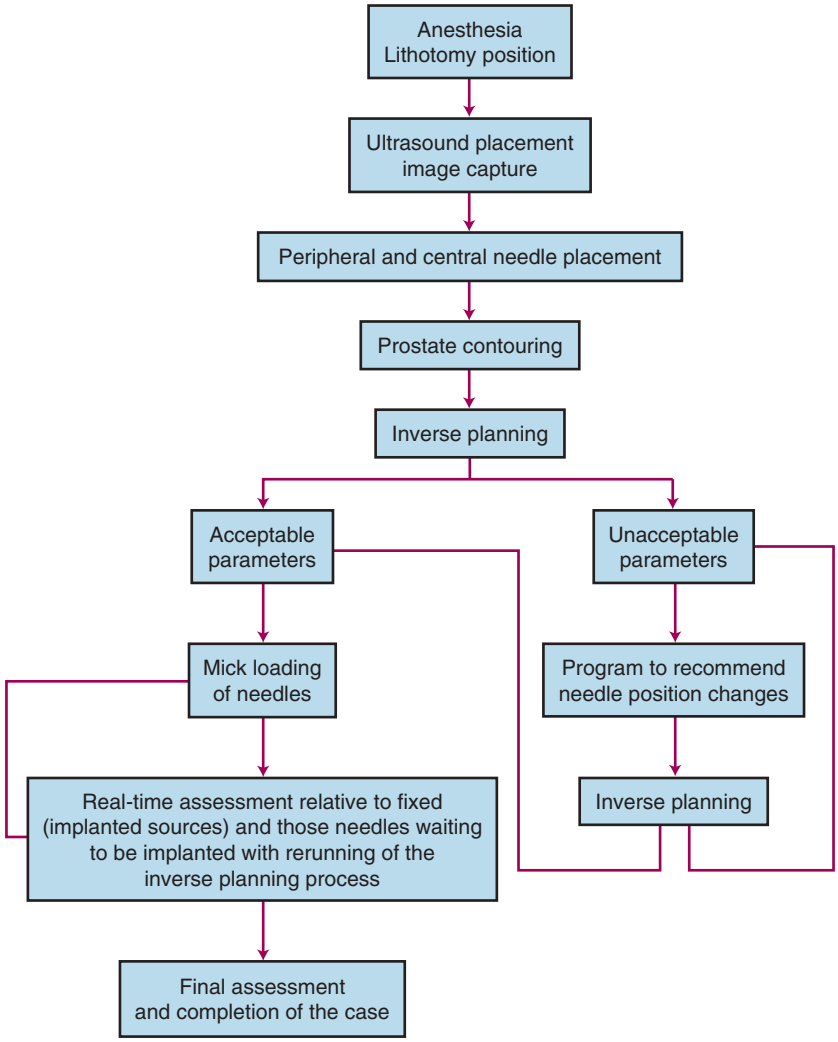

Figure 53-20 Dynamic prostate implant algorithm using treatment planning systems that employ inverse planning techniques.

the role of AD in the management of patients with locally advanced disease, and whether the regional lymphatics should be irradiated. Real-time, conformal techniques control for dose to normal tissues while boosting the prostate, usually in 3 fractions, and better eliminate problems associated with catheter movement between fractions, when performed as a single needle implant.[1010]

Postoperative Irradiation

Treatment Technique

Adjuvant RT typically begins two to four months after surgery when urinary control is improved, and there is wound healing without urinary extravasations or anastomotic stricture. Evidence-based recommendations for pre-RT evaluation are unavailable, but it is prudent to obtain a serum PSA level to assure it is <0.2 ng/mL. Radiological or urological (e.g., cystoscopy) evaluations are seldom warranted, and should be performed only to pursue specific symptoms or clinical signs.

Pelvic nodal RT may be used in the node-positive setting,[1011] but recent series[1012-1015] and clinical trials[488,996,1016] otherwise defined the CTV as the prostatic fossa, and this is the current standard. CT simulation in supine position at ≤ 0.3-cm acquisition spacing with a protocol to assure the bladder is comfortably full and bowels are evacuated is recommended. Bladder contrast may facilitate identification of the vesicourethral anastomosis (VUA), and retrograde urethrography may aid localization of the urogenital diaphragm. However, urethrography may displace tissues superiorly,[961] so this should be accounted for in target delineation. Immobilization of the hips or legs should be considered.

Although guidance may be obtained from preoperative imaging and operative and pathologic findings (e.g., sites of margin involvement), the CTV is determined by the anatomic boundaries of the prostatoseminovesiculectomy as defined by CT or MRI postoperatively (Table 53-18 and Figure 53-21).[1017-1020] The prostatic fossa inferiorly is typically 0.5 cm to 0.8 cm below the VUA,[1018] but the penile bulb is not exposed surgically, so the CTV inferior margin need not extend into it. The superior dissection boundary is the superior surgical clips (if present) or approximately 0.5 cm above the ligation of the vasa deferentia. The anterior surgical plane is along the posterior symphysis pubis and the posterior bladder wall more

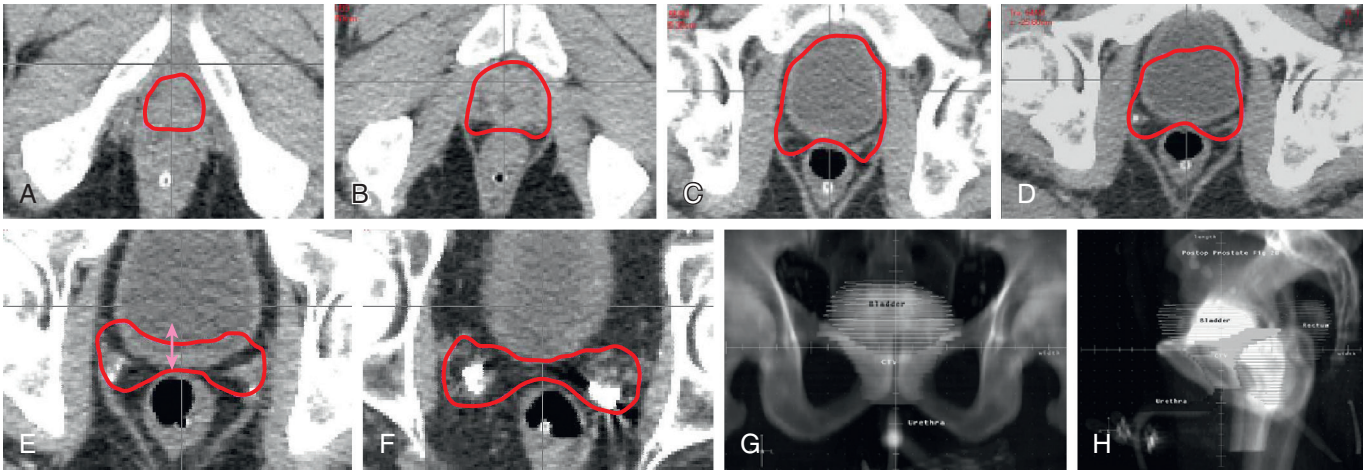

Figure 53-21 Axial CT simulation images from pelvic floor to level of distal vasa deferentia **(A-F)** with delineation of clinical target volume (CTV) and anterior-posterior and lateral radiographs **(G-H)** of CTV for postoperative RT.

TABLE 53-18 Anatomic Boundaries for Postoperative CTV Definition

	Below Superior Aspect of Symphysis Pubis	Above Superior Aspect of Symphysis Pubis
Anterior	Posterior aspect of symphysis pubis	Posterior 1.5 cm of bladder wall
Posterior	Anterior (outer) rectal wall • may form concavity laterally	Mesorectal fascia
Lateral	Obturator internus or levator ani	Sacrorectogenitopubic fascia • obturator internus, if + EPE
Inferior	0.8 cm inferior to VUA or immediately superior to penile bulb • encompass all prostatic fossa clips	—
Superior	—	Seminal vesicle bed as demarcated by clips or distal vas deferens • include residual seminal vesicles (if any), if + SVI

superiorly. The posterior plane follows the anterior rectal wall and levator ani inferiorly and is anterior to the mesorectal fascia superiorly. The mesorectal fascia is the disruption in MRI fat signal or the CT hypodensity anterior to the rectum. Lateral dissection extends along the pelvic fascia, which is visualized as a disruption in MRI fat signal or CT hypodensity medial to the obturator muscle. More superiorly, the boundary is the sacrorectogenitopubic fascia.

The critical normal structures are rectum, bladder, femoral heads, and penile bulb, which are typically defined as solid structures for treatment planning. The outer rectal wall is outlined from the rectosigmoid flexure to the ischial tuberosities, and the femoral heads are delineated through the lesser trochanter. The bladder and bulb are outlined in their entirety. Dose-volumetric constraints on critical normal structures are sufficiently defined for prostate in situ RT,[1021] but are less well defined for postoperative RT. The etiology of RT-induced erectile dysfunction is vasogenic, but a dose-volume relationship has not been reported for postoperative RT. With primary RT, mean penile bulb dose > 52.5 Gy or D_{60} >42 Gy.[1022,1023]

The PTV encompasses the CTV with margins for set-up variation and internal displacement of target tissues. The *x*-(right:left), *y*-(superior:inferior), and *z*-axis (anterior:posterior) margins are derived from daily positional variations of prostatic fossa gold markers or surgical clips.[1024,1025] The standard deviation (SD) of the set-up variation is within 0.6 cm (*x*-axis) and 0.7 cm (*y*- and *z*-axes), and for internal displacement it is within 0.2 cm (all axes). If daily localization methods are not used, the SD of set-up variation and of internal displacement is combined in quadrature, and two SD are used so the CTV is covered in > 95% of treatments. Therefore, the PTV margins are 0.9 cm to 1.2 cm (*x*-axis), 1.0 cm to 1.6 cm (*y*-axis), and 0.9 cm to 1.1 cm (*z*-axis), but they may be reduced with daily image-guidance.[1024,1025]

The observational series (Table 53-15) and randomized clinical trials (Table 53-16) typically prescribed 60 Gy to 64 Gy. However, dose-response analysis suggested that ≥70.2 Gy yielded improved outcomes[1026] when a conformal approach with critical normal structure dose-volumetric constraints are met.[1027,1028] Although more study is needed, provisional dose-volumetric guidance is provided in Table 53-19.

The principles of salvage RT are similar to the adjuvant setting because the prostatic fossa only was treated in most reports (Table 53-17). The CTV is constructed in the same manner (Table 53-18, Figure 53-21), margins are added to define the PTV, and the same dose-volumetric constraints (Table 53-19) may be used in planning. Consensus guidelines recommend that ≥64 Gy should be prescribed to the PTV.[1029,1030] However, more recent literature supports ≥66.6 Gy to 70.2 Gy,[1024,1026] and 75 Gy has been delivered safely with IMRT.[1031]

TABLE 53-19 Dose Volumetric Constraints for Critical Normal Structures in Postoperative RT*

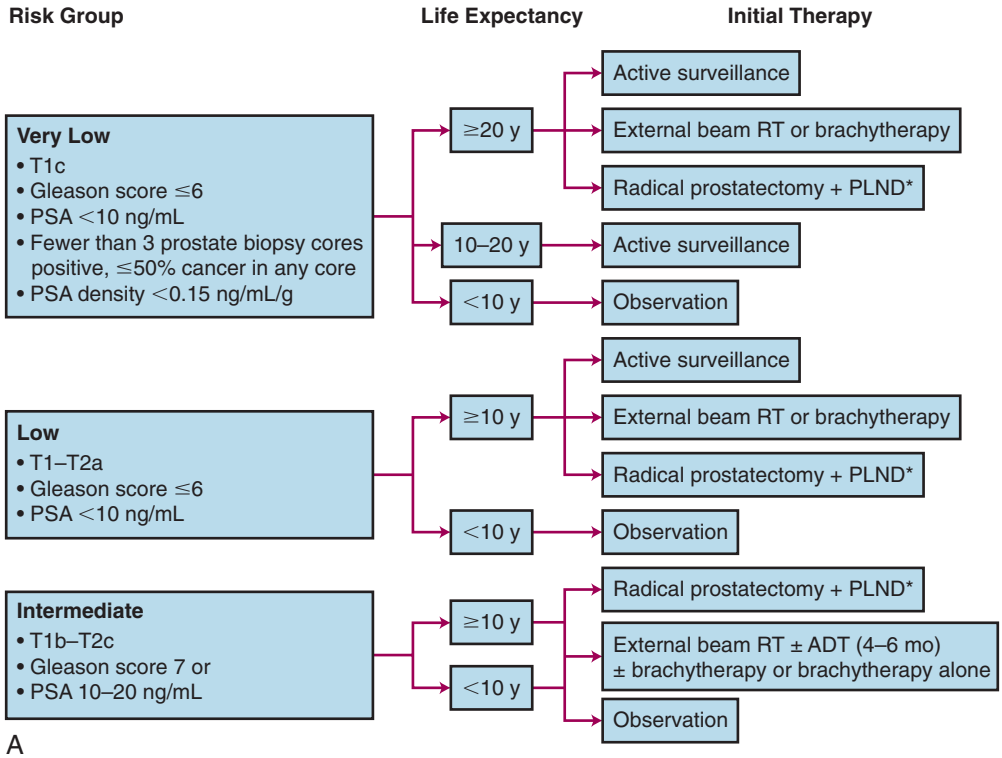
TREATMENT ALGORITHM AND FUTURE DIRECTIONS

Practice guideline development methods were set forth by the Agency for Healthcare Research and Quality.[1032] Multidisciplinary efforts of this nature are centered on analysis of existing scientific outcome and technology assessment studies in an environment of consensus building. Clinical practice guidelines so derived are meant to apply to most, but not all, patients with the specified condition. Nonetheless, it is essential that patient evaluation and management decisions are made in light of all circumstances present in an individual case. In this context, the ACR,[1020,1033-1036] the AUA,[458] the ACS,[459] and the NCCN[316] provided management pathways relevant to pretherapy evaluation, radiotherapeutic care, posttherapy surveillance, and salvage therapy for patients with prostate cancer. Application of these guidelines will not necessarily ensure optimal outcome, so the clinician must exercise independent medical judgment to determine an individual patient's best care program. Likewise, as new studies are reported and more current information emerges, this must drive diagnostic and treatment decisions because formal guidelines are only updated periodically. There has been a rapidly advancing technological revolution in diagnostic imaging and radiation treatment secondary to computer-driven applications which can quickly make adopted guidelines and recommendations obsolete.



The most recent NCCN recommendations are presented in Figure 53-22.[316] In recent years the trend has been toward evidence-based medicine tailored as much as possible for the individual patient. This is especially pertinent in cancer care where studies, both prospectively randomized and retrospective, often provide generalized information for a disease, which can have significantly diverse variables in select populations and individuals. An emphasis has been placed on recommending active surveillance for patients with very-low and low-risk disease, especially those with limited life expectancies. Observation is now recommended for those patients with life expectancies shorter than 10 years with the intent to offer noncurative treatment in the event of a patient developing symptoms or there is a change in the patient's examination or PSA that would suggest symptoms are imminent. Patients with clinically significant disease should be counseled about all their management options. In high-risk and very-high-risk disease, radiation therapy with ADT is recommended over surgical options, which are appropriate only in carefully selected individuals.

Future Directions

The large gap in the rate of prostate cancer death compared to the high incidence of new prostate cancer diagnoses speaks to a significant heterogeneity in the biology of this disease. Understanding which individuals harbor clinically significant disease remains an important challenge for clinical investigation. The value of PSA screening has been questioned because of its low sensitivity and specificity. Better screening assays are being sought to help identify only those men in whom the diagnosis of prostate cancer warrants further evaluation and therapy. Urinary biomarkers such as PCA3 levels appear to complement serum PSA as a screening tool and they appear to correlate with tumor volume and aggressiveness.[1037] Once the diagnosis of prostate cancer is established, genetic screens[1038] for cancer aggressiveness will help identify patients for whom aggressive local or systemic therapy is warranted. Treatment decisions in the future will be driven less by conventional anatomic-based stage grouping but by a broad spectrum of clinical and biological markers that select patients for more individualized therapy.

Radiation oncologists will select treatment volumes, radiation doses and adjuvant therapies that target disease specific sensitivity or host factors to maximize tumor control and minimize side effects that contribute to a decline in quality of life.[1039] Adaptive radiation therapy strategies are currently focusing on tailoring technical aspects of treatment delivery to escalate radiation dose in patients that are best able to tolerate the therapy.[1040] Eventually, assays of normal tissue radiation sensitivity should allow biology based dose and fractionation prescriptions.[1041] The choice between conventionally fractionated as opposed to short-course, hypofractionated RT will be made based upon patient and tumor biology.

Continued investigation on systemic therapies and the interplay between the androgen receptor and hormone sensitivity will allow discovery of more effective AD and chemotherapeutic regimens. The complementary role of local therapies such as RT or surgery, along with new systemic agents in locally advanced and high risk disease is currently undergoing evaluation in clinical trials. Traditional ADT used in conjunction with RT may be augmented by new antiandrogen therapies or cytotoxic drugs such as docetaxel.

CHAPTER

54 Bladder Cancer

Jason A. Efstathiou and Anthony L. Zietman

INCIDENCE

Carcinoma of the urinary bladder is diagnosed in approximately 74,000 people each year in the United States, making it the fourth-most common cancer in men (56,000) and eleventh in women (18,000). Approximately one third will have muscle-invasive disease. About 16,000 (1,100 men, 4,500 women) will die from bladder cancer in 2015. Urothelial (transitional cell) carcinoma has strong etiologic connections with smoking. The less common squamous cancer is more closely associated with chronic inflammation such as *Schistosoma* infection or indwelling catheter.

BIOLOGIC CHARACTERISTICS

The most important predictors of progression from nonmuscle-invading stage to the muscle-invasive stage are high grade, penetration of the lamina propria, and the presence of carcinoma in situ. Once muscle invasion has occurred, the strongest predictors of metastasis and death are bulk of tumor and depth of invasion.

Expression studies and now large-scale sequencing efforts are providing new insights into the landscape of recurrent molecular alterations in bladder cancer and potentially targetable mutations and personalized treatment selection for patients undergoing selective bladder preservation. These include biomarkers prognostic and predictive of response and outcome involved in cell-cycle regulation, apoptosis, proliferation, DNA repair, chromatin regulation, kinase signaling pathways, and hypoxia. These biomarkers continue to be investigated and need further validation.

STAGING EVALUATION AND WORKUP

Painless hematuria is the classic and most common presentation, though irritative voiding symptoms may occur as well. Urine cytology commonly indicates cancer but cystoscopy and transurethral resection is necessary for definitive assessment of the primary tumor.

Magnetic resonance imaging (MRI) may define penetration of the bladder wall and either MRI or computed tomography (CT) scan can evaluate abdominopelvic lymph nodes. The upper tracts must also be evaluated with CT, intravenous pyelogram (IVP), or retrograde ureteroscopy because synchronous tumors are common. Chest x-ray (or CT of the chest) and bone scan are usually obtained to rule out metastatic disease when cancer invades the muscle.

PRIMARY THERAPY

Nonmuscle-invading tumors are managed by transurethral resection of the bladder tumor (TURBT) alone in the case of low-grade lesions and together with intravesical bacillus Calmette-Guérin (BCG) for high-grade, lamina propria invasion, or carcinoma in situ. Over 10 years as many as 50% of the latter group will progress to muscle invasion.

Radical cystectomy with urinary diversion is the United States standard for the management of muscle-invading cancers. There is 90% control within the pelvis, but up to 50% ultimately die of distant metastasis. Radical radiation alone provides only 30% to 40% local control though the use of salvage cystectomy keeps cure rates close to that of primary cystectomy. When limited surgery (TURBT) is combined with radiation and concurrent (often cisplatin-based) chemotherapy, more than 70% of patients keep their native bladders and cure rates are comparable to published cystectomy series. Quality-of-life studies show high levels of satisfaction with the retained bladder.

ADJUVANT THERAPY

Neoadjuvant chemotherapy downstages the primary tumor more than 50% of the time but only adds 5% to 10% to the chance for cure. Adjuvant chemotherapy is commonly used but has proven utility only in the case of node-positive disease.

Adjuvant radiation may be given after cystectomy for locally advanced disease but the benefits need to be better defined.

LOCALLY ADVANCED DISEASE AND PALLIATION

When there is hydronephrosis, extension into adjacent organs or nodal spread, the likelihood of cure is small. Cystectomy or radiation may be used for palliation of voiding symptoms or bleeding, but the mainstay of care for metastatic disease is combination chemotherapy.

Bladder cancer is a chemoresponsive disease. Cisplatin-based regimens give responses in more than 60% of patients and are often quite durable. Other active agents include Taxotere, gemcitabine, and 5-fluorouracil (5-FU)/mitomycin C.

Radiation therapy is effective in palliating painful bone metastases and in alleviating symptoms from brain metastases.

Approximately 70% of all new cases of bladder cancer are early stage and have not yet invaded the detrusor smooth muscle. In the absence of muscle invasion, endoscopic transurethral resection (TUR) with or without intravesical therapy is the therapy of choice, and the radiation oncologist plays only a limited and occasional role. For muscle-invading disease, the most appropriate treatment algorithm remains controversial. Although radical cystectomy has long been the standard treatment in the United States, organ-preserving regimens using radiation with concurrent chemotherapy are comparably effective alternatives in selected patients.

In this chapter, we separately discuss the treatment of nonmuscle-invading and muscle-invading disease. Special emphasis is placed on the development of combined-modality therapy in muscle-invading bladder cancer with and without bladder preservation.

ETIOLOGY AND EPIDEMIOLOGY

Bladder cancer is the most common malignancy involving the urinary system and the second-most common genitourinary cancer. It is the sixth-most common cancer overall; fourth-most common cancer among men and the eleventh-most common cancer among women. It is estimated that there will be approximately 74,000 new cases and 16,000 bladder cancer deaths in 2015.[1] The rates of new cancers and deaths have been fairly stable in men and have been dropping slightly in women in recent years. The reasons for the disparity between the sexes are not well understood. More than 500,000 people in the United States are bladder cancer survivors.

Internationally, incidence rates of bladder cancer vary almost 10-fold. Highest rates occur in western Europe and North America; relatively low rates are found in eastern Europe and several areas of Asia (China, India, Philippines).[2,3]

Cancer of the bladder occurs primarily in older men. Median age at diagnosis of is 73 years. More than two thirds of cases occur among persons age 65 and older. The incidence rate among African American and Hispanic men is about 50% of that among whites. The male-to-female ratio is at least 3:1, approaching 4:1 in whites.[4] Five-year survival rate for all patients is 77% (96% for in situ disease, 69% localized, 34% regional, and 5% distant). Overall incidence and death rates have been relatively stable over the past 10 years.

Risk Factors

Cigarette smoking and various environmental and occupational exposures are the major risk factors for bladder cancer. These substances concentrate in the urine, where the urothelial lining is exposed to their carcinogenic effects. Cigarette smoking is associated with up to 50% to 60% of bladder cancer diagnosed in men and 30% among women in the United States. Occupational exposure among white men accounts for 25% of bladder cancer diagnoses in men and 11% in women. Specific chemicals linked to bladder carcinogenesis include beta-naphthylamine, 4-aminobiphenyl, and benzidine. Evidence also suggests that chlorinated organic compounds formed as a by-product of drinking water chlorination may account for 10% to 15% of cases. Infection with *Schistosoma haematobium* is a well-documented risk factor and an important cause of bladder cancer in developing countries.

Cigarette smoking increases the risk of bladder cancer two- to fourfold. Risk estimates for moderate to heavy smokers range from 2 to 10 compared with nonsmokers.[5-9] Smokers with less functional polymorphisms of N-acetyltransferase-2 (known as slow acetylators) have a higher risk of bladder cancer than other smokers, presumably because of their reduced ability to detoxify carcinogens.

Some studies indicate a reduction in risk by more than 30% within the first year to 4 years after cessation of smoking, and more than 60% 25 years after cessation, but even after 25 years the risk still does not reach the background level of never smokers.[7,9] Smoking cessation may decrease recurrence rates for patients with nonmuscle-invasive disease.[10] Exposure to secondhand smoke in women may be a risk factor for the development of bladder cancer.[11]

In the 1950s, occupational exposures to aromatic amines in the British dyestuff and rubber industries were found to be associated with bladder cancer.[12,13] The mean time from start to exposure to death was 25 years, with the greatest risk for workers who started before age 25. Workers in the leather industry are at increased risk for bladder cancer.[14,15] The increased risk for painters seems to be the result of many known carcinogens in paint such as benzidine, polychlorinated biphenyls, formaldehyde, asbestos, and solvents such as benzene, dioxane, and methylene chloride.[16] Drivers of trucks, buses, or taxicabs are suspected to have an increased exposure to exhaust emissions containing polycyclic aromatic hydrocarbons (PAHs) and nitro-PAHs.[17]

It was first recognized in the 1970s that chlorination of drinking water generates a wide array of halogenated organic compounds. A number of epidemiologic studies investigated the possible association between exposure to these compounds and cancer. A 1992 meta-analysis of these studies found a significant association between exposure to chlorination by-products and bladder cancer.[18] Several studies published subsequently supported this conclusion.[19,20] High levels of arsenic in drinking water have also been linked to the subsequent development of bladder cancer.[21]

Aromatic amines are detoxified by *N*-acetylation. The *N*-acetyltransferase enzyme in the liver is polymorphic, displaying a slow and a rapid acetylator phenotype. The allele that confers a slow acetylator phenotype is assumed to be associated with an increased risk of bladder cancer (relative risk, 1.1 to 1.9).[22]

There are several other well-documents risk factors. Exposure to *S. haematobium* infection is associated with a predominantly increased risk of squamous cell carcinoma of the bladder.[23] Heavy consumption of phenacetin-containing analgesics was linked to cancer of the renal pelvis, ureter, and bladder.[24] Cyclophosphamide, an alkylating agent, and pelvic radiation have also been linked to the risk of bladder cancer.[25-27] Other risk factors include low total daily fluid intake, chronic cystitis, indwelling catheters, recurrent urinary tract infections, and consumption of Chinese herbs containing aristolochic acid.[28,29]

PREVENTION AND EARLY DETECTION

Primary prevention involves identification and avoidance of cancer-causing factors.[30] In public health terms, avoidance and cessation of cigarette smoking is the most effective means available for the prevention of bladder cancer. Decreasing exposure to workplace carcinogens and increasing fluid intake are other useful approaches.

Secondary prevention involves screening individuals at high risk for a particular cancer with the goal of early detection and treatment. Urine cytology as a screening test is low cost and low risk and has excellent specificity > 98% but relatively poor sensitivity, particularly for low-grade tumors (overall sensitivity 34%, with sensitivities for grades 1, 2 and 3 tumors of 12%, 26%, and 64%, respectively).[31] Furthermore, the prevalence of preclinical bladder cancer is probably too low in the general population for large-scale screening programs to be rewarding. Testing for asymptomatic hematuria does not appear to be a useful method for screening. A single test has a low sensitivity. Repeat testing at short intervals, such as weeks, has been advocated but yields unacceptably high rates of false-positive results.[32,33] Overall, screening has not been particularly useful in the detection of bladder cancer and the most recent statement from the U.S. Preventive Services Task Force concludes that the current data are insufficient to make a definitive recommendation on screening for bladder cancer in asymptomatic adults.[34] When urothelial cancer is suspected, noninvasive screening may be performed using cytology, nuclear matrix protein, telomerase, or fluorescence in situ hybridization (FISH) analysis, but the definitive diagnosis is made only by cystoscopy and biopsy.

Chemoprevention involves the administration of a natural or synthetic agent to healthy people (primary) or patients with precancerous conditions who are at high risk for bladder cancer (secondary) to prevent or retard the development or progression of cancer. Retinoids (vitamin A derivatives) as

well as high-dose multivitamins, pyridoxine (vitamin B6), alpha tocopherol (vitamin E), ascorbic acid, polyamine synthesis inhibitors, polyphenols (green tea extract), COX-2 inhibitors (celecoxib), EGFR tyrosine kinase inhibitors (erlotinib), and oltipraz have been or are under investigation as potential chemopreventive agents,[35-45] but nothing definitive has been established at present. Additional studies are under way.

PATHOLOGY AND PATHWAYS OF SPREAD

In the United States, more than 90% of cancers arising in the bladder are urothelial carcinoma (UC), also known as transitional cell carcinoma (TCC). Less common pathologies are squamous cell carcinoma (SCC), adenocarcinoma, and small cell carcinoma, comprising approximately < 10% of bladder tumors, respectively. In Egypt, SCC comprises 70% of all bladder cancers.

Macroscopically, papillary growth is more frequent than solid tumors (approximately 80% versus 20%). Solid tumors are more likely than papillary tumors to be high grade and invasive into the muscularis propria layer.

Although the collective term *superficial cancer* is still commonly used, it is a category that comprises several classes of transitional cell cancers with different rates of recurrence, different rates of progression to muscle invasion, and quite different treatments. The tumors that arise in the epithelium and develop in an exophytic (papillary) pattern are known as Ta tumors. They are usually low grade (I or II), and although they tend to recur, they are considered to be relatively benign lesions that closely resemble the normal urothelium. Although they have more than the normal seven layers of urothelium, they show normal nuclear polarity in more than 95% of tumors and no or only slight pleomorphism. When progression deeper into the submucosa or lamina propria occurs the tumor is described as T1 and carries a higher risk of progression and even of metastasis.

Grade is an important predictor of recurrence and progression for all categories of superficial disease. Pathologic grades I to III (low, intermediate, or high) are based on the number of mitoses, presence of nuclear abnormalities, and cellular atypia. High-grade tumors show loss of polarization of the nuclei and moderate to prominent pleomorphism. Muscle-invasive disease, however, is usually high grade, and depth of invasion is the more important prognostic factor for outcome.

Carcinoma in situ (Tcis) is defined as noninvasive, high-grade, flat cancer confined to the epithelium, which can be localized or diffuse, and it may occur in association with either superficial or muscle-invasive TCC. Tcis can also occur without a concurrent exophytic tumor. Endoscopically, Tcis presents as a friable red area indistinguishable from inflammation and spreads laterally, displacing normal epithelium. Urine cytology is positive in 90% of patients with Tcis because of a loss in the cohesiveness of cells.

In T2 lesions, muscle invasion is present and the probability of nodal and distant spread is increased. T2 disease is divided into superficial (T2a) or deep (T2b) invasion.[46]

SCCs are associated with chronic inflammation or infection with *Schistosoma* and tend to grow as large masses with a high degree of necrosis. In North America they are more commonly associated with chronic bladder irritation or stasis such as a lifelong indwelling catheter. The North American variant has the distinction of higher metastatic propensity.

TCC is often multifocal both in place and in time (polychronotropism). This is a striking characteristic of this disease but the etiology is uncertain. Two of the most commonly held explanatory theories are a genetic field defect with multiple new tumors spontaneously arising or, alternatively, the local reimplantation of tumor cells ("local metastasis). Evidence strongly suggests that tumor reimplantation or submucosal migration is the predominant mechanism. Multifocal tumors as well as upper tract and lower tract lesions arising in one individual demonstrate clonality.[47] Therefore, the entire urothelium needs to be evaluated if a tumor is found.

External and internal iliac chains as well as perivesical lymph nodes are first-echelon lymph nodes. Common iliac, paraaortic, and paracaval lymph nodes are considered second-echelon lymph nodes. Lymph node sampling in patients undergoing cystectomy should include excision of 12 or more lymph nodes.[47]

Bladder cancer can also spread by direct extension or hematogenous metastases. Direct extension can be to the prostate, pelvic side wall, anterior pelvic structures, symphysis pubis, rectum, or sigmoid colon. Hematogenous metastatic spread is most frequently seen to the lung, liver, and bone. Peritoneal metastases are another route of spread.

MOLECULAR BIOLOGY

Newly discovered cellular mechanisms and their associated proteins have become the subject of intense interest. This is partly for what they tell us about the biology of a tumor but also because of their potential role as prognostic markers or therapeutic targets. It has long been recognized that invasive bladder tumors are extremely heterogeneous in nature despite almost always being of high-grade transitional cell morphology because of complex genetic and epigenetic interactions that play a direct role in the initiation and progression of TCC. When the range of genetic alterations is considered, deletions (e.g., loss of tumor suppressor genes) generally arise in early stage disease, whereas gains and amplifications (e.g., activation of oncogenes) may be more frequent in advanced stages of disease. Genetic factors may also modify the risk associated with exogenous agents through activation or detoxification of potential carcinogens. The search to understand the heterogeneity and use it to therapeutic advantage is only just beginning. At the moment the best prognostic indicators we have in bladder cancer are clinical: stage, grade, tumor size, uni- or multifocality, and the presence or absence of either hydronephrosis or lymph node involvement (see later). No molecular biomarker has yet come close to improving on these clinical markers, but it is anticipated that they will in the near future.[48,49] Likely this will involve a combination of multiple independent markers and an individual tumor's gene expression pattern.

Apoptosis and Cell Cycle Receptors

These receptors provide malignant cells with an evolutionary selective advantage. These include cellular immortalization, escape from G1 checkpoint control, loss of DNA damage checkpoints (G2/M), loss of normal DNA repair mechanisms, loss of apoptotic response, and the development of invasive capabilities.[50-52] The *pRb* and *p53* pathways, which involve several common molecules, provide G1 checkpoint control and regulate the response to DNA damage. Though the *Rb* gene itself is only mutated in a few specific cancers it is thought that abnormalities of its function are far more common and transitional cell bladder cancer is one of these.[51,53-55] Disruption of its function is required to overcome the restraint it imposes on cell-cycle progression. The pro-apoptotic tumor suppressor gene eliminates cells with abnormalities in their *Rb* pathways. Thus, tumors commonly have abnormalities in p16 and p14ARF and abnormalities at these loci may also be required to overcome the checkpoints that protect the cell from aberrant stimuli. *p53* mutations, which may be detected by nuclear immunohistochemistry, are present in more than one half of bladder tumors and appear to be related to the progression of

bladder cancer and to outcome following treatment.[53,56-59] A meta-analysis of 168 studies assessing *p53* overexpression showed a weak, although significant, association with overall risk of relapse and mortality.[60] Cooperative group trials of either methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC) chemotherapy or chemoradiation have not shown any clear association between *p53*, *pRb*, or *p16* or status and outcome.[61,62] Other genes that have been studied include *Bax*, *Bcl-2*, *p21*, survivin, and matrix metalloproteinases.[63-70]

Researchers from Germany have suggested that one does not have to analyze the molecular pathways relating to apoptosis to predict response; a measure of the baseline spontaneous apoptotic rate of the tumor may be easier and quite sufficient. High-apoptotic index and high Ki-67 index correlated with improved complete response, local control, and cause-specific survival with a preserved bladder following chemoradiation. The inability to undergo spontaneous apoptosis whether the result of overexpression of *Bcl-2* or survivin appears to predict local failure after irradiation and chemotherapy.[71]

The RAS family of transforming genes is often overexpressed in bladder cancer. Their presence may be related to the original development of the tumor. In a mouse model, farnesyltransferase inhibitors, which inhibit the posttranslational modifications of H-ras, worked synergistically with radiation in reducing tumor relapse.[72]

Growth Factor Receptors

The epidermal growth factor (EGFR) family of receptor tyrosine kinases is known to initiate a complex program of signal transduction events that modulate cell survival, invasion, migration, proliferation, and differentiation. This family has a number of members of which *erb-1* (EGFR) and *erb-2* (Her-2) are characterized the best. The role of these receptors has been studied extensively in recent years in a variety of malignancies and there is evidence that increased activity through this pathway is common.

Both EGFR and Her-2 are commonly overexpressed in urothelial tumors. Numerous studies have investigated expression of Her-2 in bladder cancer using immunohistochemistry and have found overexpression in 30% to 80% of tumors.[60,73-76] There are, however, conflicting data on the relationship between the expression of these receptors with response to treatment and clinical outcome.

An RTOG study evaluated the clinical relevance of EGFR and Her-2 expression as measured by immunohistochemical staining on slides from 73 patients treated on four of the RTOG bladder preservation trials and pointed to a more favorable prognosis in those who overexpress EGFR but a lower complete response rate in patients with TCC who overexpress Her-2.[62] EGFR positivity (EGFR-1 expression identified in 19% of patients) correlated with improved overall survival (OS, $p = 0.044$), disease-specific survival (DSS, $p = 0.042$), and survival with an intact bladder ($p = 0.021$). A trend toward decreased incidence of distant metastases was also associated with EGFR expression. On multivariate analysis, adding tumor stage, tumor grade, whether or not a visibly complete TURBT was done, and patient age to the model, EGFR positivity remained significantly associated with improved DSS. Her-2 overexpression correlated with reduced complete response rates to chemoradiation (50% versus 81%, $p = 0.026$), which remained significant on multivariate analysis. *p53* and *p16* had no prognostic significance. These patients had all been treated with chemotherapy and radiation, and it may be that EGFR has a more direct involvement in improving the response of TCC to these agents than it does other tumors. It will be crucial to elucidate this relationship clearly as a growth factor receptor may be either a favorable or an unfavorable marker depending on the proposed therapy. The RTOG data suggested that targeting the Her-2 pathway may be more profitable than EGFR in the initial therapy of muscle-invasive bladder cancer. There is certainly experimental evidence that Her-2 has an antiapoptotic effect and that tumor radiosensitization can result from targeting this mechanism.[77] RTOG trial 05-24 evaluated the addition of trastuzumab (Herceptin) to paclitaxel and daily radiation following TURBT in the treatment of noncystectomy candidates with muscle-invasive bladder cancer. The protocol was completed with 70 patients accrued in 2013. Thirty-one percent of patients overexpressed Her-2. Among patients with evaluable data, overall complete response rate was 62% (trastuzumab group) versus 58%.[78] This response rate was higher than expected from historical controls.

Another RTOG study evaluated VEGF pathway biomarkers and outcomes following chemoradiation for patients managed with selective bladder preservation.[79] No correlations of ligands VEGF A-D or receptors VEGF R1-2 were found with response to induction chemoradiation or with local tumor recurrence. However, VEGF-B overexpression did predict for distant failure and worse OS. Therefore, VEGF-B might prove useful in identifying patients more likely to benefit from early cytotoxic therapy or anti-VEGF–targeted therapies.

Alterations in fibroblast growth factor receptor (FGFR) expression and signaling have emerged as recurring and potentially important events in bladder urothelial carcinoma. In bladder cancer, these alterations primarily occur in one of the following ways: (1) activating mutations in the extracellular ligand-binding domain of FGFR3 that lead to ligand-independent signaling, (2) overexpression of the receptor, or (3) fusions primarily with TACC3 or BAIAP2L1. In addition, FGFR3 gene copy number alterations occur but are rare.[79a-79e] Data suggests that the presence of mutations in fibroblast growth factor receptor 3 (FGFR3) identifies a subgroup of patients with nonmuscle-invasive disease who may have a favorable prognosis.[80] Further investigation into the potential diagnostic and therapeutic implications of such findings is warranted and may lead to the rational development of targeted therapies.

DNA Repair

Biomarkers involved in DNA repair may also be prognostic and even predictive following radiation-based therapy.

Excision repair cross-complementing 1 (ERCC1) is vital for nucleotide excision repair (NER) and may predict efficacy of chemoradiation. Cisplatin-DNA adducts can by removed by NER, thus high levels of ERCC1 expression have been correlated with cisplatin resistance. ERCC1 also may participate in double-stranded break (DSB) repair and cells deficient in ERCC1 are highly sensitive to ionizing RT. ERCC1 down-regulation in high-expressing cells results in sensitization to RT but not cisplatin. Expression levels of ERCC1 in human tumors correlate with treatment response and survival to platinum-based chemotherapy and chemoradiation. Clinical complete response (CR) rate for patients with negative ERCC1 was 86% (12 of 14), compared to 25% (2 of 8) for patients with positive ERCC1.[81] Five-year OS was 31.2% for those with positive ERCC1 and 69.2% for those with negative ERCC1. Therefore, ERCC1 expression levels may predict for patients unlikely to respond to a chemoradiotherapy-based approach. Another recent effort found that tumors with ERCC2 mutations were enriched among muscle invasive bladder tumors that responded well to cisplatin-based combination cytotoxic chemotherapy.[80a]

X-ray repair cross-complement group 1 (XRCC1) and human AP endonuclease 1 (APE1) are both proteins vital for base excision repair (BER) in DNA repair. Increased expression

A cooperative group trial tested the role of three cycles of combination MVAC chemotherapy in patients with negative nodes but mutated *p53* given that *p53* alteration was thought to be prognostic for relapse in patients with urothelial bladder cancer and predictive for benefit from combination MVAC adjuvant chemotherapy.[61] Accrual was halted on the basis of a futility analysis. Overall 5-year probability of relapse was 0.20 (95% CI, 0.16 to 0.24) with no difference on the basis of *p53* status. Although the study was underpowered, neither the prognostic value of *p53* nor the benefit of MVAC chemotherapy in patients with *p53*-positive tumors was confirmed. These data emphasize the importance of careful validation of any biomarker before proceeding on with Phase III analysis. Work from the Radiation Therapy Oncology Group (RTOG) on patients who were treated with chemotherapy and radiation have also not shown any clear association between either *pRb*, *p16*, or *p53* status and outcome.[62]

Other genes regulating apoptotic function or involved in the initiation of bladder carcinogenesis and its progression have been studied, such as *Bax*, *Bcl*-2, *p21*, survivin, and matrix metalloproteinases.[63-70] In examining a large database containing bladder cancer of different stage all treated by a variety of methods it did seem that those who had Bax or CD40L tumors lived longer. Bcl-2 positivity appeared to predict worse survival. The caveat, however, is that most of these were not prospective studies balanced for other prognostic variables.

The FDA has approved the use of ZD1839, an inhibitor of EGFR1, for patients with lung cancer and of trastuzumab, a monoclonal antibody against EGFR2 or Her-2, for appropriate patients with breast cancer. In breast cancer, overexpression of Her-2 is associated with poor prognosis, and the activity of trastuzumab unequivocally correlates with overexpression of Her-2.

of XRCC1 and APE1 were both associated with improved DSS, but only when both were present ($p = 0.0003$).[82]

Ionizing radiation creates DNA damage sensed by the MRE11/NBS1/RAD50 (MRN) complex, which initiates cell cycle checkpoints, activates apoptosis, and is involved in MRN-mediated DSB repair. MRE11 (meiotic recombination homolog) is a vital member of the MRN complex responsible for detecting DNA DSB. Along with Rad50 and NBS1/XRS2, MRE11 is responsible for activation of checkpoint kinases and induction of cell cycle arrest in response to DNA damage. It is vital for recruiting ATM and other mediators of DSB repair. A group in the United Kingdom has shown that reduced tumor MRE11 protein expression by immunohistochemistry is associated with and appears to be predictive of poorer cause-specific survival (CSS) following radical RT for bladder cancer.[83] High-MRE11 expression was associated with superior CSS in patients treated with radical RT with a 57% improvement in CSS at 3 years ($p = 0.012$). The effect of MRE11 expression on clinical outcomes was only evident in patients treated with RT and not those treated with cystectomy. When compared, similar patients with high-MRE11 expression had improved CSS when treated with RT compared to cystectomy, whereas the opposite was true for those with low-MRE11 expression. MRE11 expression levels may therefore identify a cohort of patients with improved survival when treated with RT compared to cystectomy.

Mechanistically, it was postulated that failure of cell cycle arrest/apoptosis responses may result in radioresistance and reduced local tumor control.

The MRE11 findings were validated by a Danish group, who showed that TIP60 (histone acetyltransferase involved in chromatin remodeling and DNA repair) was a predictive marker for DSS in a cystectomy cohort, and MRE11 in an RT cohort.[84] In that study, *p16* also correlated with DSS, but was not predictive. *Ki67*, *p53*, and *pATM* were not correlated with DSS in any of the cohorts.

Hypoxia

Hypoxia is well recognized to be strongly associated with both radiation and chemotherapy resistance. Indeed, the addition of carbogen and nicotinamide (CON) to RT improves OS in invasive bladder cancer. Hypoxia results in the upregulation of genes that facilitate anaerobic metabolism and promote tumor vascularization. One such hypoxia–inducible factor is carbonic anhydrase IX (CA IX). It appears to be useful as a surrogate marker of hypoxia within bladder tumors. Several studies have shown that the majority of bladder tumors express this marker though it appears, strangely, to be more strongly expressed in superficial than invasive tumors. Evidence on its role as a prognostic marker has been conflicting.[85,86] Necrosis seems to predict benefit from hypoxia modification in patients with high-risk bladder cancer.[87] The hypoxia marker hypoxia-inducible factor-1α (HIF-1α) may be used to predict benefit from CON in patients with bladder cancer but does not improve on use of necrosis.[88]

Future of Molecularly Targeted Therapy

To date, no molecularly targeted agents have been approved for treatment of bladder cancer. Large scale sequencing efforts are likely to change this and provide new insights into the molecular alterations in bladder cancer and targetable mutations.

The addition of rational molecular targeted therapy and personalized treatment selection based on biomarkers (e.g., DNA repair, apoptosis, proliferation, hypoxia, such as high MRE11, normal Her2, low ERCC1, high XRCC1/APE1) of response and outcome, continues to be investigated and needs further validation. Future focused correlative analyses using findings discussed in this section are likely to refine clinically useful biomarkers for patients undergoing selective bladder preservation.

CLINICAL PRESENTATION, PATIENT EVALUATION, AND STAGING

Clinical Presentation

Painless, gross, and episodic hematuria is the most frequent presenting manifestation of bladder cancer (80%), typically present through urination. It also may be associated with irritative symptoms (dysuria, frequency, urgency), which can occur in up to one third of patients and is suggestive of bladder carcinoma in situ (CIS). Ten percent to 20% of patients presenting with gross hematuria are diagnosed with bladder cancer.[89,90] Some asymptomatic patients proven to have bladder cancer are found to have microscopic hematuria or less frequently pyuria. Bladder tumors can cause strangury (pain on straining to urinate), urinary retention, ureteral obstruction, sepsis, and rarely life-threatening hematuria. Regional pelvic disease may cause flank pain because of nerve invasion, edema, and ureteral obstruction. The signs and symptoms of bone, liver, pulmonary, and central nervous system metastases may be present if disease has disseminated.

Workup of Hematuria or Suspected Bladder Tumor

Patient workup should include physical examination (including digital rectal and bimanual), voided urine analysis, urinary cytology, intravenous pyelogram or CT urogram (for upper tract evaluation), and cystoscopy with biopsy of suspicious lesions. If the disease is classified as T1 or greater, the work-up must include abdominopelvic CT scan or MRI and chest radiograph (or chest CT). For those with muscle-invading disease a bone scan is also necessary.

Endoscopy

The endoscopic evaluation forms the mainstay of diagnosis and staging. Initially, an outpatient cystoscopy with biopsy is performed, and urine is obtained for cytology. Cystoscopy provides direct visualization of the bladder and facilitates biopsy of the bladder. Number, size, shape, and location of tumors as well as appearance of the surrounding mucosa, urethra, and urethral orifice are documented. Size (<2 cm, >5 cm), shape (papillary or flat), and associated Tcis lesions are of predictive importance. Using an illustrative bladder map, the location, number, size, and characteristics (papillary versus sessile) of the bladder tumor as well as presence or absence of CIS should be noted. Fluorescence cystoscopy after intravesical instillation of a photoactive substance (a porphyrin such as 5-aminolevulinic acid [5-ALA]) that preferentially accumulates in neoplastic tissue may be more effective than white light cystoscopy. Randomized trials have shown that fluorescence endoscopy detects more tumors (particularly CIS) and this improved tumor identification may result in better patient management and reduced disease recurrence,[91-93] though not all clinical trials have shown a benefit.

If the findings are positive for bladder cancer, a subsequent cystoscopic TURBT, which is generally performed under epidural or general anesthesia, is scheduled.

TURBT and Bladder Biopsy

Cold cup biopsies of all suspicious areas, the mucosa surrounding the area, any exophytic lesions, and the prostatic

The Cancer Genome Atlas project recently reported an integrated analysis of 131 urothelial carcinomas to provide a comprehensive landscape of molecular alterations.[49] There were statistically significant recurrent high frequency mutations/alterations in 32 genes, including multiple genes involved in cell-cycle regulation, chromatin regulation, and kinase signaling pathways, as well as 9 genes not previously reported as significantly mutated in any cancer. RNA sequencing revealed four expression subtypes, two of which (papillary-like and basal/squamous-like) were also evident in microRNA sequencing and protein data. Whole-genome and RNA sequencing identified recurrent in-frame activating FGFR3-TACC3 fusions and expression or integration of several viruses (including HPV16) that are associated with gene inactivation. These analyses identified potential therapeutic targets in 69% of the tumors, including 42% with targets in the phosphatidylinositol-3-OH kinase/AKT/mTOR pathway and 45% with targets (including ERBB2) in the RTK/MAPK pathway. Chromatin regulatory genes were more frequently mutated in TCC than in any other common cancer studied so far, indicating the future possibility of targeted therapy for chromatin abnormalities.

urethra as well as random biopsies of all four quadrants are obtained. All material is collected. When diffuse CIS is present, the prostatic urethra contains neoplastic cells in up to 25% of cases. For evaluation of muscle invasion, sufficient resection to provide adequate staging has to be done. An attempt is usually made to resect the bladder tumor as completely as is safely possible (i.e., a maximal safe resection).

Bimanual Examination

Bimanual examination is performed before and after complete TUR, and the size and mobility of any palpable mass are evaluated. A residual palpable mass suggests muscle invasion. Most invasive bladder cancers are located near the trigone or posterior bladder wall and cannot be reliably palpated. This procedure alone leads to understaging in up to 50% of patients.

Urinary Cytology

Urine cytology should be used to complement the findings of cystoscopy. It is extremely valuable for the diagnosis of high-grade TCC, especially CIS that might be difficult for the endoscopist to visualize, and upper tract malignancies. The presence of high-grade TCC in the cytology specimen in patients with low-grade papillary TCC suggests either unrecognized CIS or less commonly high-grade disease in the upper urinary tracts.[94,95] For the diagnosis of low-grade papillary tumors, cytology is not sensitive because grade 1 TCC appears to be identical to normal urethral cells.[31]

Cytology has been regarded as the gold standard for noninvasive screening of urine for bladder cancer. It has a sensitivity of around 40% to 60% with specificity in excess of 98%.[31] Cytology is illustrative of the problems of noninvasive screening. Poorly differentiated tumors have a 20% false-negative detection rate whereas well-differentiated tumors have up to an 80% false-negative detection rate.

Multiple urine-based biomarkers have been developed because of the low sensitivity of cytology and perhaps benefit from the lack of subjectivity by the person reading the test.[96-101] These tests identify proteins in urine, detect cellular antigens by immunohisto- or cytochemistry, or use FISH microsatellite analysis of free DNA, and telomerase reverse transcriptase determination to identify genetic alterations associated with bladder cancer.

Imaging

Although fewer than 60% of bladder cancers are seen on intravenous urography, this imaging modality provides valuable information about the status of the upper urinary tract.[102] Ureteral obstruction or a nonfunctioning kidney predicts muscle-invasive disease in 90% of cases.[103] Concomitant or subsequent upper urinary tract tumors are found in 2% to 5% of patients. CT urography has replaced IVP as the procedure of choice, though IVP remains an appropriate alternative when CT is not available.

Evaluation of a patient with potential muscle-invading bladder cancer should include CT scan of the abdomen and pelvis (with and without contrast and with delayed images). Although it is not sensitive in reliably describing the depth of invasion or lymph node involvement, it can be helpful in determining extravesical extension and the planning for subsequent treatment. Notably, the detection of lymph node metastases with CT imaging is poor (high false-negative rate). About 20% to 30% of patients with node-negative disease by CT have positive nodes at time of cystectomy with lymphadenectomy.[104,105]

Gadolinium-enhanced MRI imaging may prove useful in distinguishing superficial from invasive disease and in distinguishing intra- from extravesical tumor.[106-110] Lymphangiography using iron nanoparticles and MRI might be particularly useful in detecting early nodal metastases.[110] Positron emission tomography (PET) has limited value. All bladder-specific imaging should be performed before TURBT, because of postsurgical edema.

Patients with Ta or low-grade T1 tumors do not require extensive metastatic workup. However, those with muscle-invading tumors have up to a 50% risk of occult metastatic disease and should have chest imaging and a bone scan.

Staging

Stage is the most important independent prognostic variable for progression-free survival and OS for invasive bladder cancer. The basis for the major staging systems is the classic clinicopathologic study by Jewett and Strong,[111] which correlates the probability of regional lymph node and distant metastases with the depth of invasion of the primary bladder tumor. The tumor, node, and metastasis (TNM) system of 2010 is shown in Table 54-1 and Figure 54-1.[46] Of note, CT and MRI are not used for staging of the primary in the TNM system. If lymphadenectomy is performed, sampling should include excision of an average of 12 or more lymph nodes.

In clinical practice, the correlation between depth of invasion, based on cystoscopic evaluation, and the final cystectomy specimen is only 50% to 60%. Significant rates of clinic-pathologic stage discrepancy and clinical (TURBT) understaging have been described. That is to say that 40% to 50% of patients undergo pathologic upstaging.[113,114] The accuracy of the determination of degree of muscle infiltration is, therefore, modest at best. The clinical staging system as

TABLE 54-1 AJCC 2010 TNM Bladder Cancer Staging

PRIMARY TUMOR(T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Noninvasive papillary tumor
Tis	Carcinoma in situ
T1	Tumor invades the lamina propria (subepithelial connective tissue), but not beyond
T2	Tumor invades the muscularis propria
pT2a	Tumor invades superficial muscle (inner half)
pT2b	Tumor invades deep muscle (outer half)
T3	Tumor invades perivesical tissue
pT3a	Microscopically
pT3b	Macroscopically (extravesical mass)
T4	Tumor invades any of the following: prostate, seminal vesicles, uterus, vagina, pelvic or abdominal wall
T4a	Tumors invade prostatic stroma, uterus, vagina
T4b	Tumor invades pelvic or abdominal wall
REGIONAL LYMPH NODES (N)	
NX	Regional lymph nodes cannot be assessed
NO	No regional lymph nodes metastasis
N1	Single regional lymph node metastasis in the true pelvis (hypogastric, obturator, external iliac, or presacral)
N2	Multiple regional lymph node metastases in the true pelvis (hypogastric, obturator, external iliac, or presacral)
N3	Lymph node metastasis to the common iliac region
DISTANT METASTASIS (M)	
MX	Distant metastasis cannot be assessed
MO	No distant metastasis
M1	Distant metastasis

Markers include nuclear matrix proteins (e.g., NMP22), fibrin/fibrinogen degradation products (FDP), cytokeratins,[6,16-18] hyaluronic acid, urinary bladder cancer antigen (BTA), basic fetoprotein, survivin, telomerase, microsatellite DNA, UroVysion, and chromosomal abnormalities (3, 7, 17, 9p21). These approaches have demonstrated a higher sensitivity than urine cytology, but lower specificity. However, none of these markers have sufficient sensitivity (especially for low-grade small tumors) and diagnostic reliability to replace cystoscopy and their clinical use has not been recommended by consensus panels. Additional trials are needed to evaluate these newer techniques and their clinical and cost-effectiveness as they are integrated into patient management.

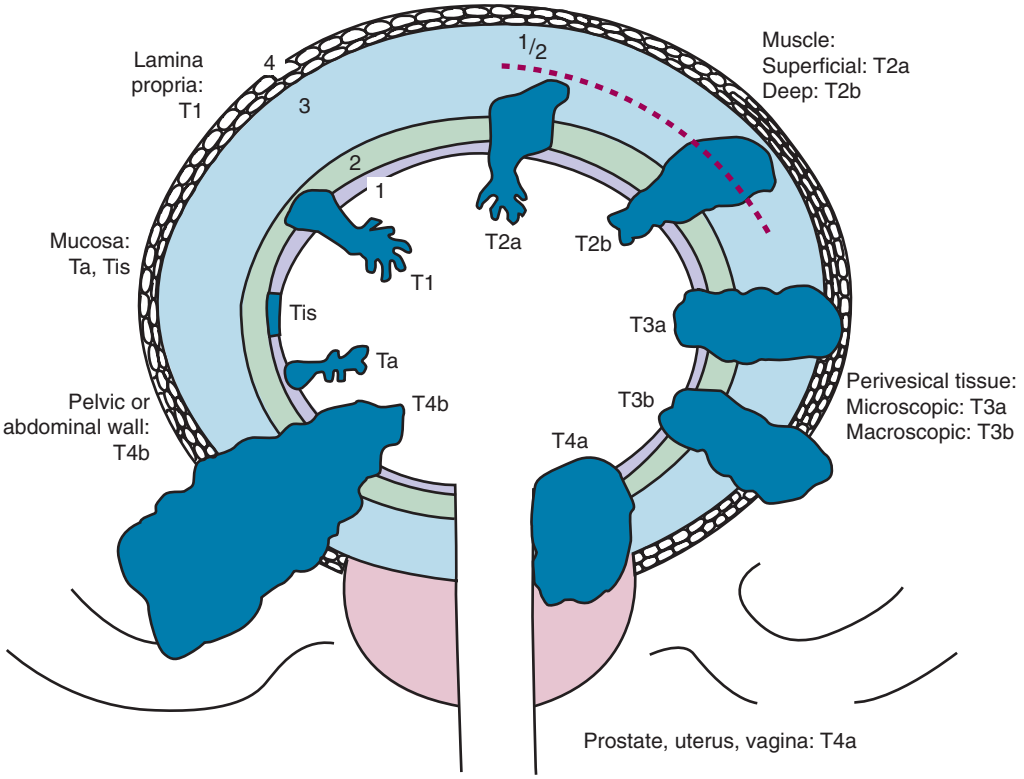

Figure 54-1 Staging of bladder tumors.

proposed by Union Internationale Contre Cancer was often more practical. Cancer without residual induration after TURBT was staged as T2 and cancer with palpable residual induration, T3. The most important determination of treatment outcome seems to be whether the tumor is organ confined (≤T2) or not organ confined (≥T3). When comparing outcome for different treatment modalities, it is important to consider whether the disease was staged clinically or whether a cystectomy specimen was available for a thorough pathologic staging.

PRIMARY THERAPY

The presence or absence of muscle invasion is the key factor in determining the appropriate treatment option for bladder cancer. In the absence of muscle invasion, endoscopic TUR with or without intravesical therapy is the therapy of choice.

The most appropriate treatment algorithm for muscle-invading disease remains controversial. Although radical cystectomy has long been the standard treatment in the United States, organ-preserving regimens using radiation with concurrent chemotherapy have emerged as viable alternatives in select patients (Figure 54-2).[115,116] These two approaches appear to have similar survival rates in uncontrolled comparisons, but strong physician and patient preferences have so far prevented completing a randomized, controlled trial comparing these treatment options.[117]

Noninvasive Bladder Cancer (Ta, T1, Tcis)

Transurethral Resection (TURBT)

Patients with superficial nonmuscle-invasive TCC (including Ta, T1, and Tis) account for approximately 70% of all newly diagnosed bladder cancer cases and are initially treated by TURBT. The appropriate treatment regimen may also include adjuvant intravesical therapy for a selected patient population. Decisions concerning the use of adjuvant therapy are based primarily on the probability of disease progression, not the probability of recurrence.

The majority (40% to 80%) of patients with superficial TCC will eventually experience recurrent disease after TURBT.[118] Progression to invasive disease after TURBT alone occurs in 10% to 25% of patients and is closely associated with tumor type, stage, and grade.[119,120] Other factors include multicentric disease, frequency of recurrence, tumor size, and presence or absence of concomitant CIS.

Although Ta, G1 tumors have recurrence rates higher than 50% at 5 years, they rarely (5% or less) invade or cause death. Consequently, TUR alone may be sufficient treatment for these tumors.

The risk of progression is substantially higher for tumors of higher grade or stage. Ta, G2-3 disease will progress to invasive TCC in 20% of cases at 5 years after treatment with TURBT alone. Nearly all patients (>70%) with T1 disease have high-grade tumors, and approximately 50% experience invasive disease at 5 years. In patients with T1 disease with CIS in the pathologic specimen, the rate of progression rises to 80% at 5 years.[121,122]

Intravesical Therapy

Bacillus Calmette-Guérin

Intravesical therapy involves the instillation of high local concentrations of a therapeutic agent into the bladder, potentially destroying viable tumors cells and preventing implantation. BCG, a live attenuated form of *Mycobacterium bovis*, is currently the most effective and most commonly used intravesical agent for treatment of nonmuscle-invasive TCC of the bladder. BCG is typically instilled into the bladder weekly for 6 weeks. The role of maintenance BCG for longer than 6 weeks remains

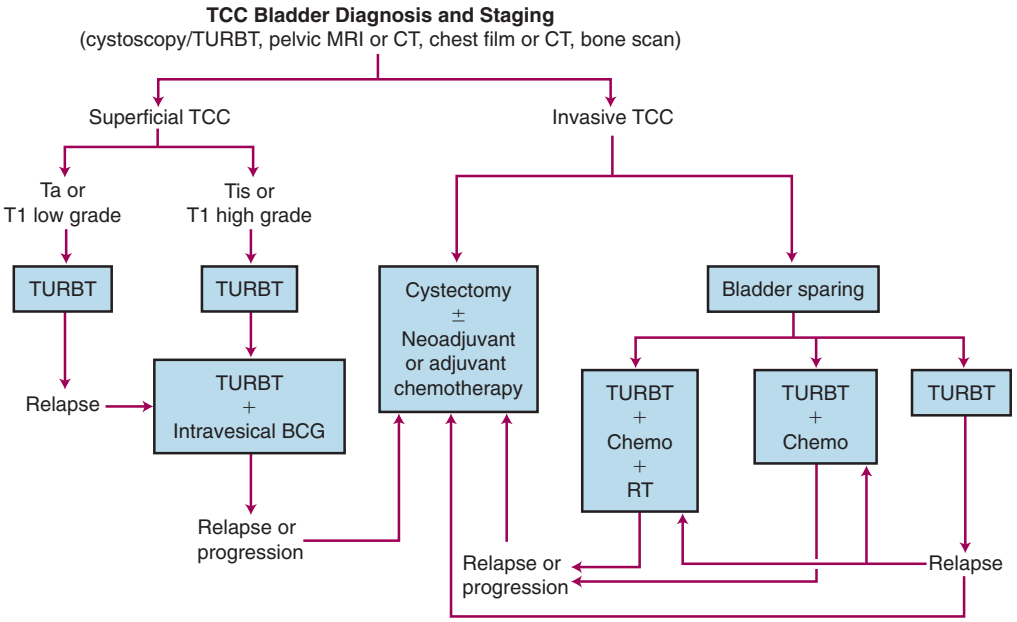

Figure 54-2 Diagnosis and treatment algorithm. *BCG*, Bacillus Calmette-Guérin; *Chemo*, chemotherapy; *CT*, computed tomography; *MRI*, magnetic resonance imaging; *RT*, radiation therapy; *TCC*, transitional cell carcinoma; *TURBT*, transurethral resection of the bladder tumor.

controversial. For a number of patients who respond to induction, maintenance BCG therapy may be used for up to 3 years, although patients frequently discontinue therapy early because of bladder toxicity.

Several randomized, controlled trials compared TURBT alone with TURBT plus BCG.[123-127] Those treated with BCG had significantly fewer recurrences at 12 months. For patients with Ta, G2-3, and T1 disease, adjuvant therapy with BCG reduces the rate of progression to 5% to 15% at 5 years. Nonetheless, 50% of patients with T1/CIS will experience muscle-invading cancer at 10 years. Progression rates to muscle invasion among patients who respond to BCG are 1% at 1 year, 5% at 3 years, and 15% at 5 years.

The positive impact on progression translates into a survival advantage.[128,129] With long-term follow-up, adjuvant intravesical BCG improved survival rates to 88%, compared to 63% with TURBT alone, and reduced the cystectomy rates from 42% to 20%.[128]

Besides reducing progression and improving survival, BCG treatment also delays tumor recurrence in approximately 50% of patients. In the published randomized, controlled trials in which TURBT plus BCG was compared with TURBT alone, recurrence rates ranged from 20% to 42% with intravesical therapy versus 42% to 100% without.

Intravesical therapy is the first-line treatment for diffuse CIS. The average complete response rate of CIS to BCG is greater than 70% for more than 1 year.[130] It prevents subsequent disease in 60% of cases for up to 5 years and in 40% of cases for up to 10 years. Particularly in CIS of the prostatic urethra, BCG has spared many patients cystectomy. TURBT is recommended to stage the disease and to open the bladder neck to allow BCG to bathe the prostatic urethra.

One consequence of controlling the bladder component of disease in a patient with a TCC of the bladder is an increase in the frequency of extravesical relapses,[131] hence careful follow-up is required. Relapses can develop anywhere transitional epithelium is found: renal pelvis, ureters, and urethra. The risk for upper tract tumor is 20% at 5 years, 25% at 10 years, and 33% at 15 years. Prostatic urethra and duct involvement at 5 years is 10% to 15% and at 10 years, 20%. If a complete resection of tumors of the urethra cannot be obtained, patients are managed with cystectomy. Patients with a positive cytology and no obvious bladder tumor need careful monitoring of the upper tracts. Urethroscopic resection and instillation of BCG through the renal pelvis is possible.

Careful follow-up surveillance is required after intravesical therapy. This includes repeat cystoscopy and urine cytology 3 months after therapy, at 3- to 6-month intervals for the first few years and then annually. Surveillance should include imaging of the upper tracts every 1 to 2 years, unless very low risk. For residual or recurrent disease, a repeat TURBT and course of intravesical therapy may be indicated. Cystectomy should be considered for persistent or recurrent tumor after one to two cycles of intravesical therapy.

Role of Irradiation in High-Risk Superficial Bladder Cancer

It is well recognized that TURBT may clinically understage tumors as noninvasive when they have already invaded into the muscle wall (approximately 20% to 30%). Radiation therefore has an advantage in that it can reach tumor deposits too deep for instillation therapy. There have been no randomized trials comparing RT to current intravesical treatment options. The Dutch South Eastern Bladder Cancer Group has presented data in 121 patients with T1G3 cancers.[135] External RT with 50 Gy was one treatment option and 17 patients received this. Though the numbers are limited it appeared to be as effective as intravesical BCG or mitomycin. Good results have also been achieved at the University of Rotterdam with interstitial implants.[136] In this selective but prospective series, patients with single T1-tumors of less than 5 cm in diameter underwent TURBT and subsequent local irradiation of the tumor area in the bladder wall by an interstitial radium implant. The definitive local control rate was 82% and the 10-year survival rate 76%. Another group in the Netherlands has published their results using a combination of transurethral resection, external beam radiotherapy (EBRT; 3.5 Gy × 3 to 4), and interstitial radiotherapy (mean implant dose of 55 Gy) in patients with solitary T1G3 and T2-tumors.[137] The local control rate was 70% in the whole patient population.

BCG triggers a variety of local immune responses and has been shown effective in reducing rates of disease progression, decreasing recurrence and the need for subsequent cystectomy, and improving survival. Toxicities of intravesical therapy include symptoms of bladder irritation (dysuria and frequency).[122a] To minimize risk of systemic infection, intravesical therapy should not be given to patients with traumatic catheterization, active cystitis, or persistent gross hematuria.

Several conditions other than those just outlined call for the use of intravesical therapy with BCG. These include CIS and frequent recurrence of low-grade disease. Urothelial dysplasia or severe atypia can be treated prophylactically with BCG. Persistent positive urine cytology without associated upper tract lesions, and disease involving more than 40% of the bladder surface are also indications for intravesical therapy.

Other Agents

Although BCG is the treatment of choice for intravesical therapy, a variety of other agents have been investigated, such as mitomycin C, doxorubicin, epirubicin, valrubicin, thiotepa, gemcitabine, interferon, and docetaxel. None has proved consistently superior to BCG,[130,132-134] especially in cases of high-risk disease features (high grade, T1, Tis), though they may have a role in BCG failures and as an immediate single postoperative dose for patients at low risk of recurrence following TURBT. Novel approaches to decrease recurrence following initial treatment for nonmuscle-invasive bladder cancer include photodynamic therapy.

The 5-year DSS was 80% for T1 tumors and 60% for T2a. One randomized trial of EBRT alone (60 Gy in 30 fractions) in the management of high-grade T1 TCC of the bladder did not seem to indicate a benefit over observation for patient with unifocal disease or over BCG for those with multifocal disease or CIS.[138]

A large series of 141 patients with high-risk T1 cancers treated with either TURBT plus EBRT with or without platinum-based chemotherapy comes from the University of Erlangen.[139,140] In this series, 88% of patients achieved a CR, about 15% progressed to muscle-invasive disease after 5 years and 30% at 10 years, which compares favorably to most studies of TURBT and instillation therapy. DSS at 5 years and 10 years was 82% and 73%, respectively. More than 80% of survivors preserved their bladder, and 70% were "delighted" or "pleased" with their urinary function. These results suggest that irradiation may have a role to play in patients with high-grade or recurrent T1 lesions and may be attempted ahead of cystectomy on protocol or in place of cystectomy in those who are medically inoperable.

Currently there is an open Phase II protocol in RTOG (protocol 0926) for patients with recurrent BCG refractory T1 bladder cancer evaluating selective organ preserving treatment by irradiation plus concurrent chemotherapy (either cisplatin or 5-fluorouracil [5-FU]/mitomycin C) following a thorough TURBT.

Muscle-Invading Bladder Cancer (T2-4)

Muscle-invading tumors comprise 20% to 25% of all newly diagnosed bladder cancers. The most appropriate treatment algorithm for muscle-invading disease remains controversial. Although radical cystectomy and urinary diversion has been the mainstay for treatment for decades, organ-preserving regimens using predominantly multiple-modality therapy, consisting of TURBT followed by irradiation with concurrent chemotherapy, have emerged as viable proven alternatives in select patients. Refining the treatment choice by maximizing quality of life without compromising survival is the ultimate goal.

Radical Cystectomy

Surgical Methods

Radical cystectomy entails the surgical removal of the bladder, adjacent organs, and regional lymph nodes. Although traditionally performed as an open procedure, laparoscopic and robotic radical cystectomy have been investigated as less-invasive alternatives. In male patients, the bladder, prostate, seminal vesicles, proximal vas deferens, and proximal urethra, with a margin of adipose tissue and peritoneum, are resected en bloc. In females, the procedure involves an anterior pelvic exenteration to remove the bladder, urethra, uterus, fallopian tubes, ovaries, anterior vaginal wall, and surrounding fascia en bloc. The extent of bilateral pelvic lymph node dissection is an important predictor of outcome and many centers have adopted an extended template dissection to include presacral and common iliac lymph nodes to the aortic bifurcation and often more proximal to the origin of the inferior mesenteric artery, in addition to pelvic lymph nodes distal to the common iliac bifurcation.[141] Before cystectomy, grossly abnormal lymph nodes are sampled. In case of metastases, cystectomy is aborted unless urinary diversion is required to relieve symptoms. Urinary diversion is usually accomplished through an ileal conduit opening onto the anterior abdominal wall through a urostoma though continent diversions including a neobladder reconstruction are growing in popularity.

Incontinent Urinary Tract Reconstruction. In the early 1950s, Bricker et al developed what was to become the most common type of diversion after cystectomy, the ileal conduit diversion. Urine drains directly from the ureters through a segment of ileum to the skin surface, where it is collected by an external collection appliance.

Continent Urinary Tract Reconstruction. Techniques for performing continent urinary diversions have been developed over the past 20 years. The two most important approaches are formation of a continent urinary reservoir made of bowel (small bowel alone or plus colon), which drains to a stoma that can be catheterized, and creation of an orthotopic neobladder, in which a newly formed urinary reservoir made out of bowel (ileum, ileo-colon, sigmoid colon) is anastomosed to the urethra.

Morbidity of Cystectomy

Operative mortality from cystectomy in modern series ranges from 1% to 3%, with postoperative complication rates ranging from 15% to 64% and a 26% readmission rate.[147-150] Complications include hemorrhage, rectal injury, deep venous thrombosis, pulmonary embolus, pelvic abscess, sepsis from urine or bowel leak, wound infection/dehiscence, and small-bowel obstruction. The frequency of complications appears to be related to surgeon experience, hospital volume, age, and presence of comorbidities.

The need for urinary diversion and loss of sexual function in patients undergoing radical cystectomy are the most serious side effects and may impair quality of life dramatically. In women, loss of sexual function occurs secondary to subtotal vaginectomy and in men secondary to prostatectomy with loss of vascular supply or nerves serving penile erection. Newer nerve-sparing techniques for men may allow for up to approximately 50% of selected patients to regain their erectile potency.[151]

When feasible, continent urinary diversions achieve 82% continence rates with early complication rates of 15% to 20% and mild hypochloremic acidosis in 50% of the patients. Intestinal obstruction, acute pyelonephritis, ureteral obstruction, hydronephrosis, stomal stenosis, intestinal fistula, and ureteroileal urinary leakage are also reported. Ten percent of patients experience ureteral-intestinal strictures, reservoir dysfunction requiring augmentation of the pouch, and dysfunction of the stoma. Overall, 10% to 15% of patients require reoperation. Decreased renal function is noted in most patients during long-term followup after radical cystectomy.[152] Choice of urinary diversion does not appear to be independently associated with decreased renal function.

Cancer Outcome after Cystectomy

Contemporary large series provide the best data on outcome after radical cystectomy.[153-157] The University of Southern California reported on 633 patients undergoing radical cystectomy with pathologic stages pT2-T4a with an actuarial OS rate at 5 years of 48% and at 10 years of 32%.[153] The series from the Memorial Sloan Kettering Cancer Center (MSKCC) showed that in 184 patients with tumors of pT2-4, the 5-year OS was 36%. The 5-year OS for all 269 patients with pathologic stages ranging from pT0 to pT4 was 45%.[154] Pathologic stage or T category is a significant independent predictor of survival and local control. By clinical stage, 5-year OS was 56% for T1, 50% for T2, and 23% for T3a-b. Five-year local relapse rates by pathologic stage ranged from 6% for pT2 disease to 51% for pT3b.

The presence or absence and extent of lymph node disease, and the lymph node density (ratio of number of positive lymph nodes to the number of lymph nodes removed) are also significant determinants of survival.[158] The estimated

a. Cutaneous Urinary Reservoir. The two main options are reservoirs made from colon and small bowel (Indiana pouch) or entirely from small bowel (Kock pouch).[142,143] The Indiana pouch consists of approximately 25 cm of right colon often including some distal ileum, which is brought to the abdominal wall. It relies on the ileocecal valve for continence. Patients catheterize the pouch on average four to six times per day.

The Kock pouch is a cutaneous continent urinary reservoir constructed from 60 cm of ileum, with an afferent antireflux nipple valve for the ureteral intestinal anastomosis and an efferent nipple valve for the catheterizable stoma. Major complication rates of around 20% are reported. Incontinence, difficulty with catheterization, loss of antireflux features of the nipple valve, and urinary leaks are the major problems with these diversions.

b. Orthotopic Diversion. A neobladder is constructed from ileum, ileo colon, or sigmoid colon and anastomosed to the native urethra as opposed to the abdominal wall. This permits the patient to void in a relatively normal fashion per urethra. The Mainz pouch (neobladder) consists of an ileocecal segment, which is detubularized and anastomosed to the urethra.[144] The Hautmann pouch consists of a W-shaped ileo-neobladder, in which 60 cm ileum is configured into a sphere.[145]

The choice of urinary diversion is based on patient and surgeon preferences and may be influenced by the extent of cancer. Orthotopic bladders are contraindicated when the tumor involves the urethra. Orthotopic neobladders are becoming increasingly common in patients undergoing cystectomy but have been predominantly used in men. They are less common in women because of the technical difficulties in maintaining continence and the risk of urethral recurrence given the shorter length of the female urethra.[146]

It remains true, however, that many patients still do not receive a continent reservoir because of intercurrent disease, impaired renal function, surgery time, dilated ureters, and bowel disease.

probability of 5-year OS of patients with nodal metastases is 29%; with one to five nodes positive 35%, and with six or more nodes positive 17%.[159] The incidence of positive lymph nodes varies according to pathologic tumor stage. In cystectomy series, it ranged from 0% to 6% for superficial disease, 18% to 22% for muscle-invasive disease (pT2, 6% to 20%; pT3a, 30% to 31%), 30% to 64% for disease invading the perivesical fat (pT3b), and 45% to 59% for disease invading adjacent organs (pT4).[160-162]

Other factors that may influence outcome include the quality of surgery, margin status, presence of lymphovascular invasion and marker status (*p53, p21, pRb, p16*). Nomograms that consider multiple prognostic factors such as stage, nodal status, tumor grade and histology, lymphovascular invasion, and age have been developed.[163]

Although the disease is locally controlled, many patients will ultimately develop distant metastases (5-year distant disease rate for T3-4, 40% to 50%; T2, 30%). Median time to diagnosis of distant metastases is approximately 18 months. The most common sites for distant metastases are bone, lung, and liver.

Radiation as an Adjunct to Cystectomy

Preoperative Radiation Therapy

The recognition that moderate-dose radiation (20 Gy to 50 Gy) may reduce the volume of gross disease and eradicate microscopic TCC led to its frequent use before cystectomy in the 1970s.[164,165] In nonrandomized studies, these doses were found to reduce the frequency of metastases in the lymphadenectomy specimens by approximately 50%.[166] By the 1980s, improvements in the technique of radical cystectomy, together with the introduction of more extensive therapeutic lymphadenectomies, made many question the need for radiation.[167] It has been argued that radiation delays the time to definitive surgery, increases its morbidity, and may compromise the surgeon's ability to perform continent urinary diversions. The question was addressed by an intergroup trial reported in 1997[168] in which 140 patients with invasive or recurrent superficial bladder cancers were randomized to receive cystectomy alone or plus preoperative radiation (20 Gy in five fractions). There was no significant survival advantage to either group at 5 years. The trial was small, the doses low, and the predominant pattern of failure distant, all factors that would make it practically impossible to detect any advantage to radiation. Parsons and Million[169] did, however, demonstrate an apparent survival advantage for patients with clinical T3 tumors who received preoperative radiation.

Cole et al reported on 133 patients with T3b disease treated at the M. D. Anderson Cancer Center (MDACC).[170] This retrospective review documented that when pelvic wall recurrence occurs following modern radical cystectomy, it is usually only in patients who had clinical stage T3b or T4 tumors. They report a 28% incidence of pelvic recurrence in patients with stage T3b disease treated by radical cystectomy, with or without multidrug chemotherapy. However, when patients with stage T3b disease were treated with preoperative EBRT (which this institution used extensively before 1980), the pelvic recurrence rate was only 10%. Before 1983, all patients underwent 50-Gy preoperative EBRT (25 to 28 fractions over 5 to 5.5 weeks), followed 4 weeks later by cystectomy. Actuarial 5-year pelvic control was 91%. After 1983, radiation was discontinued, and subsequent pelvic control rates fell to 73% despite improvements in surgical technique, staging, and the addition of systemic chemotherapy. A survival decrement (52% to 42%) was also seen. The extent to which patient-selection factors contributed to this observed difference is unknown. Others have reported lower rates of pelvic recurrence using cystectomy alone for this subset of patients, and it therefore remains uncertain whether these findings are widely applicable.[167]

The morbidity of preoperative RT is small. Whitmore reported comparable rates of wound healing and perioperative mortality for patients who received and those who did not receive irradiation before cystectomy.[166] There is limited experience in the creation of continent urinary diversions after preoperative RT, although Housset et al report that it is possible after the delivery of 44 Gy (24 Gy delivered in 8 fractions over 17 days according to a modified bifractionated split-course schedule [3 Gy fractions twice daily on days 1, 3, 15, 17] followed by a 20 Gy boost [2.5 Gy fractions twice daily on days 64, 66, 78, 80]).[171] TCC of the bladder have a high propensity to autotransplantation. Iatrogenic wound seeding after cystotomy was commonly reported by those who performed partial cystectomies or bladder brachytherapy. Low-dose preoperative radiation (8.5 Gy to 20 Gy) profoundly reduced the incidence of this problem.[172] Low-dose radiation is still occasionally given in the United States before a partial cystectomy. The partial cystectomy is, however, not commonly performed because it is limited to small, unifocal tumors of the dome, an unusual location.

Postoperative Radiation Therapy

When the cystectomy specimen shows extensive extravesical disease or positive surgical margins, the risk for pelvic recurrence is high. Postoperative RT has been evaluated in only one randomized study. The National Cancer Institute of Egypt reported on 236 patients with T3-4 tumors (68% squamous cell) who received either no adjuvant therapy or postoperative radiation (using three daily fractions of 1.25 Gy each, with 3 hours between fractions, up to a total dose of 37.5 Gy in 12 days [75 patients] or conventional fractionation for a total dose of 50 Gy over 5 weeks [78 patients]).[173] The 5-year rates of disease-free survival ([DFS] 44% to 49% versus 25%) and local control (87% to 93% versus 50%) were improved while the incidence of pelvic recurrence was significantly reduced in the groups receiving postoperative radiation. Whether this finding is as applicable to transitional as to squamous cell tumors remains an unanswered question. Today, patients with such extensive disease commonly receive adjuvant chemotherapy, although the ability of this modality to prevent local recurrence has been called into question by Cole et al.[170] RT rarely cures patients with pelvic wall recurrences following radical cystectomy.[174] Perhaps some could be cured if given adjuvant RT.

The morbidity of postoperative irradiation is high because of the large volumes of small bowel that occupy the pelvis after cystectomy if the urologist does not use pelvic reconstruction techniques to displace small bowel loops from the tumor bed (omental pedicle flap, mesh, other). Two series reported a greater than 30% incidence of small-bowel obstruction when 50 Gy was delivered using conventional fractionation.[175] So although adjuvant radiation therapy could reduce local failure it currently has no defined role because of a concern for morbidity. Modern techniques with improved normal tissue sparing have however rekindled interest in RT. Models of risk stratification based on pathologic stage of disease, margin status, and number of nodes removed have been developed that stratify patients into groups with significantly different local-regional failure risks.[176] Patterns of failure studies within the pelvis suggest that RT should target the iliac and obturator nodes and possibly the presacral nodes and cystectomy bed.[177] A cooperative group randomized trial GU001 recently opened in NRG Oncology to further evaluate the role of adjuvant RT in patients at higher risk for pelvic failure after cystectomy.

Salvage Radiation Therapy

Attempts to salvage patients with TCC of the bladder at the time of symptomatic or gross pelvic recurrence after radical cystectomy with RT or with combined chemotherapy and RT are usually unsuccessful. Some palliation can be achieved.[174] In some centers consideration is given to preoperative chemoradiation followed by attempted resection of the pelvic mass and intraoperative radiation. There is no large published experience looking at this approach.

Bladder Preservation

Conservative Surgery

Partial Cystectomy

Surgical resection by partial cystectomy requires careful patient selection, that is, the lesion should be solitary and located in a region of the bladder that allows for complete excision with a 2-cm tumor-free margin (e.g., the bladder dome). The portion of the bladder to be resected should be small enough to allow adequate bladder capacity. Contraindications include association with CIS in other sites of the bladder, prostatic urethral involvement, prior recurrent bladder or upper tract tumors, and bladder neck or trigone tumors in which ureteral reimplantation would be required to achieve an adequate margin. Given these constraints, only 6% to 19% of patients with primary, muscle-invading bladder cancer are potential candidates.[178] Even for this select group of patients, local recurrence rates range from 38% to 78%; one half of the recurrences appear in the first year and two thirds by 2 years.

Transurethral Resection of Bladder Tumor

Clinical complete response rates after TURBT alone (assessed cytoscopically with repeat biopsy 3 weeks after initial TURBT) for T2 and T3 cancers overall are in the 10% to 20% range.[179,180] Five-year OS in 85 patients with grades 1 and 2 T2 cancers was an unacceptable 27%.[181] Some studies have reported 10-year DSS as high as 76%,[182] but these results included only those patients who had no residual disease or no invasive disease on repeat biopsy and urine cytology. Although potentially effective in a small proportion of favorable T2 tumors, TURBT is usually not sufficient as monotherapy in muscle-invading bladder cancer.

Radical External Beam Irradiation

In the past, EBRT was widely used as a single modality for T2-4 bladder cancers, particularly in Europe. In the United States, however, the use of RT was frequently limited to patients whose tumor characteristics or medical comorbidities made them poor candidates for surgical monotherapy.

The total radiation dose used in these series (Table 54-2) varied from 55 Gy to 65 Gy, with 1.8 Gy to 2 Gy per fraction in North America, and from 50 Gy to 55 Gy at 2.5 Gy to 2.75 Gy per fraction in the United Kingdom.[183-196] Most patients were treated with one fraction per day five times a week. Patient response was evaluated by cystoscopic examination and biopsy 3 to 6 months after completion of RT. Patients with residual tumor and no known metastatic disease underwent salvage surgery (range of salvage cystectomy rate, 13% to 24%) if they were suitable surgical candidates. Those unfit received palliative measures.

The 5-year local control ranged from 31% to 50% for the entire patient population and from 49% to 79% for the subgroup of patients with complete response. Factors reported as having a significant favorable effect on local control[196] with RT included:

- Early clinical stage (T2 and T3a)
- Absence of ureteral obstruction

- Complete response
- Visibly complete TURBT
- Absence of coexisting CIS
- Small tumor size (<5 cm maximum diameter)
- Solitary tumors
- Tumor configuration (papillary versus sessile)
- Hemoglobin level (>10 mg/dL)

Tumor eradication ranged from as high as 66% for those with solitary T2 tumors to as low as 9% for those with multiple tumors and hydronephrosis. The 5-year OS in these reports ranged from 25% to 46%. Stage-specific 5-year OS ranged from 49% to 71% for T2 to 37% for T3b.

The success of any bladder conserving strategy rests on the ability to rapidly recognize local recurrence and treat promptly with salvage surgery. Salvage cystectomy can be undertaken safely without significantly increased morbidity after a complete course of RT or chemoradiation regimens.[197,198] After radiation, an ileal conduit, rather than a neobladder is the more likely method of urinary diversion. A Kock pouch urinary diversion may also be performed safely in patients who received prior RT to the pelvis.[199]

Interstitial Brachytherapy

This was developed as a technique in the early part of the 20th century but has progressively declined in popularity and is mainly performed in specialist centers in France, Belgium, and the Netherlands. The early technique involved the implantation of permanent radon seeds or temporary radium or cobalt needles.[200,201] Although effective there were substantial problems with radiation safety and significant morbidity from urinary leakage. Hospital stays were protracted. As alternative techniques employing EBRT became available and as the morbidity and mortality of the cystectomy declined, these became preferred approaches. Over the last three decades, however, afterloading techniques and computer planning mean that some centers are again looking at this as an option for selected patients. Brachytherapy has been combined with EBRT to

DFS, *Disease-free survival;* EBRT, *external beam radiation therapy;* OS, *overall survival;* yr, *year.*
All series employed combinations of EBRT and brachytherapy, usually preoperative EBRT does of <15 Gy to reduce the risk of tumor seeding. The series of Moonen and Pos gave 30 Gy in 15 fractions and those of Van der Steen and Wijnmaalen gave 40 Gy in 20 fractions to tumors of stage T2b or higher.

provide a radiation boost to the primary tumor as well. External-beam doses of 30 Gy are used in combination with an implant tumor dose of 40 Gy. Appropriate candidates for brachytherapy are those with a solitary TCC with a diameter of <5 cm, stage T1 (with high grade) to T3a (muscle invasion but no extension through wall).

Early experience made clear that TCC is a tumor that may be surgically seeded either into the wound or to the peritoneal cavity. Van der Werf-Messing demonstrated the value of small doses of preoperative radiation to prevent iatrogenic scar implantation.[172] In those centers using brachytherapy, low doses of EBRT are given preoperatively with fractionation schemes that fit the convenience and ideology of the center. These range from 1×8.5 Gy or 3×3.5 Gy to 15×2 Gy. Historically wound implants occurred in 10% to 20% and are now rarely seen.

Five-year local control rates for selected patients treated with brachytherapy in combination with EBRT do appear excellent varying between 70% and 90% with DSS of approximately 75% and correspondingly high rates of bladder preservation[202-209] (Table 54-3). In selected patients, survival appears similar to cystectomy.[210]

The most serious acute morbidity is fistula with wound leakage. This is most strongly predicted by tumor size, active length of radioactive sources, and use of a partial cystectomy. Serious late toxicity is rarely reported because the treated bladder volumes are relatively small. A study reported by Pos does however raise the possibility that there is more late morbidity using fractionated high-dose rate than continuous low-dose rate.[211]

Combined-Modality Therapy

Chemotherapy as monotherapy achieves a clinical complete response in only 25% to 37% of patients.[212-219] This is more frequently reported in lower stage disease, small tumors (<5 cm), and papillary tumors. Two-year OS with chemotherapy alone is approximately 30% (cT3-4). Even in responders, chemotherapy alone spares the bladder in only 15% to 20% of patients. Chemotherapy is therefore rarely used alone for localized disease and almost invariably in combination with other therapies.

Chemotherapy and Conservative Surgery

Chemotherapy has been used with TURBT in an attempt to spare the bladder. In a highly selected patient population, 5-year local control rates of up to 48% have been reported. CR rates after chemotherapy and TURBT range from 45% to 54%.[219-225] These findings suggest that the addition of TURBT to MVAC confers a considerable local control advantage over either alone. In a highly selected patient population, chemotherapy followed by partial cystectomy in conjunction with pelvic lymphadenectomy has been used in an attempt to spare the bladder.[226] Patients should meet the following criteria to be considered for such treatment:

- complete or major response to chemotherapy,
- solitary lesion in the dome or the anterior wall of the bladder,
- no history of prior invasive bladder cancer,
- no CIS, and
- a good bladder capacity.

Though 5-year survival is high at close to 50%, less than half of these patients preserve their bladders.

Chemotherapy and Radical Local Therapy

In attempts to eradicate micrometastatic disease and improve survival for patients with muscle-invasive bladder cancer, systemic chemotherapy, given either neoadjuvantly or adjuvantly, has been evaluated.

Neoadjuvant Chemotherapy before Definitive Local Therapy

Neoadjuvant chemotherapy offers the potential to assess the response of the primary lesion and for tumor downstaging, though it may lead to a discordance between clinical and pathologic staging and delayed definitive local therapy. Chemotherapy before definitive local therapy has been well tested in invasive bladder cancer. The results of the major randomized controlled trials are shown in Table 54-4.[227-238]

Many of the earlier trials comparing neoadjuvant chemotherapy and definitive local therapy alone used single-drug (cisplatin) chemotherapy regimens. None of these studies detected a survival difference. The survival rates among both treatment arms were almost identical. The Spanish trial using neoadjuvant cisplatin reported a significant prolongation of disease-free interval with chemotherapy (mean time to progression, 13 months versus 30 months, $p = 0.03$).[229] It is important to note that in these trials the definitive treatment of the primary bladder cancer was delayed for 3 months during the administration of chemotherapy, but ultimate survival was not reduced.

A number of more recent trials[228,231-236,238,239] used cisplatin-based multidrug chemotherapy regimens. These studies, unfortunately, do not provide a clear and consistent indication of the efficacy of neoadjuvant cisplatin-based chemotherapy. The Nordic 1 Cooperative Bladder Cancer Study Group

randomized patients with T1G3-T4a bladder cancer to two cycles of neoadjuvant cisplatin and doxorubicin or to no chemotherapy. Patients in both arms received preoperative irradiation (20 Gy in five fractions) and cystectomy as definitive local treatment. A significant survival advantage was seen in the chemotherapy arm for the subgroup of patients with cT3-4a disease (5-year OS 52% versus 37%, $p = 0.03$), but not for the entire patient population.[228] The subsequent Nordic 2 trial evaluated cisplatin plus methotrexate followed by cystectomy versus cystectomy alone in patients with T3 or T4a disease and did not show a statistically significant survival difference.[234]

The RTOG 89-03 trial evaluated two cycles of neoadjuvant MCV (methotrexate, cisplatin, and vinblastine) chemotherapy before concurrent cisplatin and definitive radiation. Neoadjuvant chemotherapy did not confer any detectable survival advantage. Rates of distant metastases, local metastases, and CR rates were similar in the two arms.[231]

The MRC-EORTC trial randomized 976 patients to three cycles of neoadjuvant MCV versus no chemotherapy.[232,239] Definitive local treatment was cystectomy, radical RT, or preoperative RT followed by immediate cystectomy as determined by physician or patient preference. With a median follow-up of 7.4 years, the trial reported a small but significant survival gain for neoadjuvant chemotherapy with the difference in 5-year survival between those who received chemotherapy (49%) and those who did not (43%) just reaching clinical significance ($p = 0.048$). At 8 years the survival for the chemotherapy patients was 43% compared with 37% in the control arm and the risk of bladder cancer death was reduced by 17%.

MVAC, the most aggressive regimen and most extensively evaluated, has been tested in several studies including an intergroup trial led by SWOG.[238] The SWOG trial, after slow accrual and long follow-up, achieved a trend toward significance with a 25% reduction in the risk of death through the addition of MVAC for three cycles (57% versus 43% at 5 years; $p = 0.06$) given before radical cystectomy, but the side effects were appreciable. One third of patients receiving neoadjuvant chemotherapy had a grade 3 or higher hematologic or gastrointestinal adverse effect, though there were no drug-related deaths nor did the chemotherapy adversely affect the performance of surgery. An almost identical study by the Italian GUONE group showed no significant difference.[236]

A meta-analysis that included data from 3005 patients enrolled in 11 randomized trials demonstrated a 5% absolute 5-year OS advantage (50% versus 45%; hazard ration [HR] = 0.86, 95% CI 0.77 to 0.95, $p = 0.003$) for neoadjuvant cisplatin-based combination chemotherapy compared to local therapy alone.[240,241] There was also a significant DSS benefit of 9% absolute improvement at 5 years (HR = 0.78, 95% CI 0.71 to 0.86, $p < 0.0001$).

Debate continues as to the relevance of all these conflicting findings especially when set against the morbidity of chemotherapy. Newer chemotherapeutic combinations that have activity in patients with metastatic disease, such as dose-dense or accelerated MVAC, and more favorable toxicity profiles, such as gemcitabine and cisplatin, are being investigated.

Although neoadjuvant chemotherapy seems to improve survival only marginally, it certainly has a significant impact in terms of tumor down-staging. Major responses (defined as transition from invasive disease to T0, CIS, Ta, or T1) occurs in approximately 40% of patients. Complete clinical response, as evaluated by repeat cystoscopy and biopsy after chemotherapy, ranges from 25% to 57%.

Response to neoadjuvant therapy certainly seems to predict survival. Survival rates at 5 years range from 62% to 75% among responders versus 20% to 26% among nonresponders in several of the trials.

In the 2015 National Comprehensive Cancer Network *Clinical Practice Guidelines in Oncology: Bladder Cancer*, neoadjuvant chemotherapy is a category 1 recommendation for localized stage T2-T4a disease. However, only a minority of patients in the United States undergo any perioperative chemotherapy with most still being given in the adjuvant setting. Gene profiling may in the future identify those most likely to respond to chemotherapy.[80a]

Adjuvant Chemotherapy after Definitive Local Therapy

Adjuvant chemotherapy allows for pathologic staging and avoids delay in potentially curative local therapy. No randomized trials have compared neoadjuvant to adjuvant chemotherapy in patients undergoing definitive local therapy. Although some trials have suggested a survival advantage

for neoadjuvant chemotherapy, there have been no contemporary studies supporting such a benefit with adjuvant chemotherapy.

A study from MDACC attempted to address the optimal timing of perioperative chemotherapy by comparing neoadjuvant plus adjuvant chemotherapy to postoperative chemotherapy alone and did not show any difference.[242] Several randomized, controlled trials provide information on the value of adjuvant chemotherapy after radical primary therapy (Table 54-5).[243-250] All of these studies used three to four cycles of platinum-based multiagent chemotherapy. As with neoadjuvant therapy the results have been conflicting and most of these studies suffered from underpowering and poor accrual.

In three studies, a significant progression-free survival (PFS) benefit at 3 years and 5 years was observed when patients were randomized to adjuvant chemotherapy compared with observation. However, OS was not significantly different. Patients in the observation group were treated with chemotherapy at relapse except in the study reported by Stöckle et al.[244-246] The failure to provide salvage chemotherapy in this study may explain the low survival rates in the observation arm (5-year crude survival, 17%). The PFS benefit does not translate into an OS benefit if patients receive salvage chemotherapy. In other words, observation with salvage chemotherapy might be just as effective as adjuvant chemotherapy in terms of survival. A meta-analysis including 491 patients from six trials suggested a 25% relative reduction in the risk of death (HR 0.75, 95% CI 0.60 to 0.96, $p = 0.019$) for patients receiving cisplatin-based combination adjuvant chemotherapy; however, the power of this meta-analysis was clearly limited and the authors concluded that there was insufficient evidence on which to base reliable treatment decisions.[252]

More recent studies have used different adjuvant chemotherapy regimens or molecular stratification.[61] A randomized Phase III trial from the Spanish Oncology Genitourinary Group (SOGUG 99/01) comparing four cycles of adjuvant paclitaxel/gemcitabine/cisplatin to observation in patients with resected high-risk (pT3-4 or pN+) bladder cancer was prematurely closed because of poor accrual; however, preliminary results suggest improved 5-year OS (60 versus 31%, $p = 0.0009$).[249]

Bladder Preservation with Limited Resection, Chemotherapy, and Irradiation

The rationale for combining chemotherapy with RT is twofold:

1. Certain cytotoxic agents, in particular cisplatin and 5-FU, are capable of sensitizing tumor tissue to radiation, thus increasing cell kill in a synergistic fashion.
2. Patients with muscle-invading TCC harbor occult metastases in approximately 50% of cases, which makes a case for the addition of systemic chemotherapy in an attempt to control occult distant disease.

Trimodality therapy consisting of TURBT with concurrent chemoradiation may, therefore, increase the efficacy of bladder-sparing protocols. The evolution of this approach over the last three decades is shown in Figure 54-3.

Many Phase II trials have combined chemotherapy and RT in different sequences in patients with invasive bladder cancer. Although a variety of different drugs and radiation doses have been used, it is apparent that the highest clinical CR rate (T0) was achieved in patients who received concurrent chemotherapy and RT compared with sequential regimens.[139,171,237,253-256] Table 54-6 shows results from several modern series of multimodality bladder preservation therapy.[139,171,231,256-265]

The recently reported Phase III randomized Bladder Cancer 2001 (BC2001) trial of 360 patients from the United Kingdom demonstrated that concurrent chemoradiation using 5-FU and mitomycin C is well tolerated and significantly improved locoregional DSS compared to radiation alone (67% versus 54% at 2 years; HR 0.68, $p = 0.03$ with median follow-up of 70 months). Survival at 5 years was higher with chemoradiation (48% versus 35%) but did not reach statistical significance (HR 0.82; $p = 0.16$). Bladder function was good, and no increase in late toxicity was found.[256]

Single-Institutional Experiences

One of the clearest indications of the potential of multimodality therapy for bladder preservation can be found in a study from the University of Paris.[171] In this study, TURBT followed by concomitant cisplatin, 5-FU, and accelerated RT was initially used as a precystectomy regimen. The first 18 patients who had no residual tumor on cystoscopy and repeat biopsy (clinical CR) underwent radical cystectomy as planned. None of these patients had any evidence of malignancy in the cystectomy specimens—a 100% pathologic CR rate. Previous studies using TURBT and chemotherapy found residual tumor in as many as 50% of the cystectomy specimens in clinical complete responders.

After this striking evidence of tumor eradication, the University of Paris investigators changed their protocol to one of selective bladder preservation. In 1988, they converted to induction chemoradiation, restaging with cystoscopy, and repeat biopsy of the tumor site 4 to 6 weeks after completion of the chemoradiation. Subsequent consolidation chemoradiation was only selectively given to patients who did not have any evidence of disease at restaging (CR). In cases of persistent

A randomized trial performed in Italy randomized patients after cystectomy either to four courses of gemcitabine plus cisplatin or to the same treatment at time of relapse. There was no difference in the 5-year OS across treatment arms. However, because of poor accrual the study was insufficiently powered to detect a survival difference.[251] Ongoing clinical trials will hopefully provide additional insight into the role of adjuvant chemotherapy.

disease, patients underwent immediate cystectomy. The 5-year OS for all patients who entered the protocol was 63%.

At the University of Erlangen in Germany, a prospective bladder preservation study was started in 1982. The first 106 consecutive patients, however, were treated only with TURBT followed by EBRT to 50 Gy to 56 Gy at 2 Gy daily. A multimodality approach was initiated in 1985 when chemotherapy (cisplatin or carboplatin) was added concurrently with the radiation regimen in subsequent patients.[139,259] This protocol differed in two aspects from the University of Paris study. All recruited patients underwent the entire course of chemoradiation. Restaging TURBT was performed at 6 to 8 weeks, only after completion of the entire protocol. In addition, only patients with invasive persistent disease or poorly differentiated residual superficial tumors underwent cystectomy. Patients with well-differentiated superficial disease (Ta, CIS) were treated further conservatively with TURBT and intravesical chemo- or immunotherapy. CR was achieved in 72%. Ten-year DSS was 42%, and more than 80% of survivors preserved their bladder. Thirty-five percent developed distant metastases at 10 years. Concomitant chemotherapy was more effective than EBRT alone in terms of CR and survival. The subgroup of patients who either had persistent invasive tumor (nonresponders) at first restaging or needed a cystectomy for early invasive recurrences within 9 months after completion of the treatment had dismal survival rates (5-year OS, 16%) because of early systemic spread. Patients who needed salvage cystectomy later than 9 months after completion of the treatment achieved a 5-year OS comparable to that of the entire group.

In June 1986, investigators from the Massachusetts General Hospital (MGH) implemented a selective bladder preservation protocol for operable patients with muscle-invading bladder cancer. Initially to improve on previous results in terms of both local and distant control, two cycles of neoadjuvant MCV chemotherapy were added before the chemoradiation regimen.[260] MCV was chosen because three- or four-drug (e.g., MVAC) chemotherapy had been shown to be more effective than single-agent cisplatin in metastatic bladder cancer. Five-year OS was 48% (68% for those with T2 disease).

Long-term follow-up of 348 patients with T2-4aNXM0 bladder cancer treated successively at the MGH with combined-modality therapy using concurrent cisplatin-based chemotherapy and RT after maximal TURBT with or without neoadjuvant/adjuvant chemotherapy is available.[258] With a median follow-up for all surviving patients of 7.7 years, the results demonstrate that a visibly complete TURBT was achieved in approximately two thirds of patients and a CR rate to induction chemoradiation (~40 Gy in 1.8-Gy 2-Gy fractions) in 72% (78% in patients with stage T2 disease). Patients with a CR rate and those medically unfit for cystectomy received boost chemoradiation to 64 Gy to 65 Gy. Five- and 10-year OS were 52% and 35%, respectively (61% and 43% for T2 tumors), and 5- and 10-year DSS were 64% and 59% (74% and 67% for T2 tumors). Clinical stage and achieving a CR were significantly associated with both OS and DSS. A nomogram predicting response has been

developed from this data.[261] Ultimately 102 patients (29%) underwent radical cystectomy, 17% for less than a CR and 12% for recurrent invasive tumors. The 10-year DSS for the patients undergoing cystectomy was 44%, illustrating the important contribution of prompt salvage cystectomy. No patient required cystectomy because of treatment-related toxicity. Therefore, combined-modality therapy achieved a CR and preserved the native bladder in ~70% of patients, while offering long-term survival rates comparable to contemporary radical cystectomy series. Use of neoadjuvant chemotherapy did not improve survival or incidence of metastases, though this may warrant further investigation in the modern era.

Cooperative Group Experience: The RTOG

In North America, most cooperative group combined-modality therapy for bladder cancer has occurred within the RTOG. RTOG 85-12 treated 42 patients who were candidates for cystectomy with induction once-daily radiation therapy (40 Gy in 2-Gy daily fractions) and concurrent cisplatin, with prompt cystectomy reserved for patients who responded incompletely.[262] Complete responders received consolidation therapy, with an additional 24 Gy (in 2-Gy daily fractions) delivered with concurrent cisplatin. The approach was feasible and well-tolerated, and yielded a complete response rate of 66%, a 5-year OS of 52%, and a 5-year survival with an intact bladder of 42%.

The subsequent protocol, RTOG 88-02, looked at the role of neoadjuvant MCV given immediately following TURBT. It entered 91 patients and reported a 75% response rate and 51% 5-year OS.[263] This was followed between 1989 through 1994 by RTOG 89-03, which was a Phase III trial that directly tested the contribution of two cycles of neoadjuvant MCV chemotherapy before concurrent cisplatin and once-daily radiation.[231] This study fell short of its accrual goal and was prematurely closed because of an unexpectedly high rate of severe leukopenia in the MCV arm, which resulted in a 67% protocol completion rate (compared to 81% in the non-MCV arm) and three treatment-related deaths. Analysis of 123 patients showed no significant differences between the MCV arm and the non-MCV arm in CR after induction (61% and 55%, respectively), 5-year OS (48% and 49%), 5-year survival with an intact functioning bladder (36% and 40%), or distant metastasis (33% and 39%). Treatment-related morbidity and mortality, however, were significantly higher in the neoadjuvant chemotherapy arm. In summary, this trial suggested that two cycles of neoadjuvant MCV were not a necessary component of a bladder-preservation strategy. Therefore, future studies abandoned neoadjuvant chemotherapy, though they continued to evaluate patient tolerance for newer chemotherapeutic agents and started to explore adjuvant regimens.

In 1995, the RTOG began Phase I-II protocols to evaluate accelerated radiation fractionation schemes in combination with concurrent chemotherapy. RTOG 95-06 evaluated the regimen piloted by the University of Paris, using 5-FU plus cisplatin concurrent with accelerated but hypofractionated radiation therapy delivered over 17 days.[264] Patients with tumor-associated hydronephrosis were excluded, based on findings that these patients had a significantly lower CR rate and a higher cystectomy rate. Among 34 evaluable patients, 67% had a CR on induction and an encouraging 3-year OS of 83%. However, 7 patients (21%) had grade-3 to grade-4 hematologic toxicity on this regimen, though no deaths resulted and no patients required cystectomy for radiation toxicity.

In 1997, the RTOG began to study the role of adjuvant chemotherapy after treatment with either bladder preservation or cystectomy and turned to twice-daily hyperfractionation. In RTOG 97-06, induction and consolidation chemoradiation included twice-daily radiation and outpatient cisplatin (30 mg/m^2) as a radiation sensitizer given on the first 3 days of each week.[265] Radiation doses of 1.8 Gy to the pelvis and 1.6 Gy to the bladder tumor were given daily for 12 days with a 4- to 6-hour interval between fractions during induction treatment. In the consolidation phase, 1.5-Gy fractions were given to both, twice-daily for 8 days (total dose 45.6 Gy to pelvis and bladder, 64.8 Gy to bladder tumor). After consolidation chemoradiation or cystectomy (depending on response), patients received three cycles of adjuvant MCV chemotherapy. The rationale for this protocol was to reduce the duration of the induction treatment to 12 days, thereby decreasing the delay between onset of consolidation chemoradiation or cystectomy for those patients in whom induction therapy failed. The CR rate was 74% and only 11% of patients experienced grade-3 to grade-4 toxicity during induction and consolidation phases. However, only 45% of patients went on to receive a full three cycles of MCV, and of those who did 41% developed grade-3 toxicity. The potential benefit of adjuvant chemotherapy in delaying or preventing metastasis exists because the 2-year actuarial incidence of developing metastasis in this trial was only 18% (compared to about 30% in trials without adjuvant systemic therapy).

RTOG 99-06 added paclitaxel as a radiation-sensitizing agent during the induction and consolidation schedules along with twice-daily radiation.[266] The protocol also used the adjuvant chemotherapy regimen of cisplatin (70 mg/m^2 on day 1) and gemcitabine (1000 mg/m^2 on days 1, 8, and 15). There was a 70% protocol completion rate and an impressive 81% CR rate. Five-year OS and DSS were 56% and 71%, respectively.

More recent RTOG trials have continued to address the question of the optimal concurrent chemotherapy regimen by evaluating different induction regimens in an effort to further enhance the radiation response and improve local control. RTOG 02-33 was a Phase II study that finished accrual of 97 patients in 2008.[267] In this trial, patients were randomized to twice-daily radiation with either concurrent paclitaxel and cisplatin or concurrent 5-FU and cisplatin during the induction and consolidation phases. Adjuvantly, patients received a triplet regimen of gemcitabine (1000 mg/m^2 on days 1 and 8), paclitaxel (50 mg/m^2 on days 1 and 8), and cisplatin (35 mg/m^2 on days 1 and 8). This is similar to the triplet regimen piloted by Bellmunt et al[268] and as tested in a Phase III trial led by the European Organization for Research and Treatment of Cancer (EORTC) and the Southwest Oncology Group (SWOG). RTOG 07-12 is a recently closed Phase II trial randomizing patients to twice-daily irradiation plus concurrent 5-FU and cisplatin or to daily irradiation plus gemcitabine (based on a regimen from the University of Michigan and the United Kingdom) followed by selective bladder preservation and gemcitabine/cisplatin adjuvant chemotherapy. A long-term pooled analysis of a number of RTOG protocols (8802, 8903, 9506, 9706, 9906, 0233) demonstrate an overall CR rate of 69%; 5- and 10-year OS rates of 57% and 36%, respectively; and 5- and 10-year DSS rates of 71% and 65%, respectively. The 5- and 10-year estimates of muscle-invasive LF, nonmuscle-invasive LF, and DM were 13% and 14%, 31% and 36%, and 31% and 35%, respectively.[268a]

Other Experiences

Another original way to combine chemotherapy and radiation has been employed by Eapen et al. This group has combined conventionally fractionated EBRT plus intraarterial cisplatin. Their durable CR rates (83%) are as high as any in the literature. The principal problem they have faced is a high level of sacral neuropathy which, in recent years, they have reduced through reducing the dose of infused cisplatin.[269]

Another novel combination of therapy in locally advanced bladder cancer was undertaken by Hoskin et al who reported a Phase III trial randomizing 333 patients to radiation alone versus radiation plus radiosensitizing carbogen and nicotinamide.[270] A schedule of either 55 Gy in 20 fractions in 4 weeks or 64 Gy in 32 fractions in 6.5 weeks was used. Three-year estimates of OS were 59% and 46% (p = 0.04) and 3-year estimates of relapse-free survival were 54% and 43% (p = .06) for RT + CON compared with RT alone. In multivariate comparison, RT + CON significantly reduced the risk of relapse (p = 0.05) and death (p = 0.03). Risk of death was 14% lower with RT + CON (p = 0.04). There was no indication of an increase in radiation-induced late urinary or gastrointestinal morbidity.

Survival Outcomes Compared to Cystectomy

The primary goal of bladder-preserving therapy, as with any therapy for muscle-invading TCC of the bladder, is optimizing patient survival. Bladder preservation in the interest of quality of life can only be considered a secondary objective. The long-term outcome data presented previously from single-institution and cooperative group experiences suggest that modern combined-modality therapy results in CR rates of 60% to 80%, 5-year OS of 45% to 60%, and 5-year survival rates with an intact bladder of 40% to 45%. Although no completed randomized comparisons of cystectomy with combined-modality therapy exist, these long-term OS rates are encouraging and comparable to those reported in contemporary radical cystectomy series (Table 54-7). Similarly, a retrospective review of a nonrandomized cohort of 458 patients undergoing radical RT or cystectomy in Yorkshire, United Kingdom, showed no significant difference in 10-year OS.[271]

Selection bias makes a nonrandomized comparison difficult. Surgical patients are generally younger with a better performance status. Surgery allows for a more accurate pathologic staging and identification of only surgically identifiable metastatic disease, which leads to a discontinuation of approximately 15% of cystectomies (if node-positive, tumor-unresectable, distant disease), and thus these series do not necessarily report by intention to treat. Furthermore, most cystectomy studies do not provide data on the initial clinical staging and only report outcomes by pathologic stage and rates of clinicopathologic stage discrepancy and clinical understaging are high.[114] The optimum way to compare outcomes of selective bladder-conserving strategies is to compare the outcomes of prospective protocols in which eligibility is based on clinical staging, all patients are cystectomy candidates, and all entered patients are reported for outcome whether or not they completed treatment. Comparison of survival outcomes from contemporary cystectomy and bladder-sparing therapy protocols in patients with muscle-invasive cancer of similar clinical stage, all of whom were potential candidates for cystectomy, are similar, with OS ranging from 45% to 54%.[231,238,256,258,272,273] Martinez-Pineiro et al also reported their cystectomy series by clinical stage.[229] The 5-year OS was 41% (48% for clinical T2); this is similar to that of the bladder-preservation strategy (5-year OS from 45% to 60%), in which all patients who initiated their therapy are reported, not only those whose tumor response was satisfactory to complete the organ-preservation program. It is important to remember that the appropriate strategy for bladder-preservation therapy includes prompt salvage cystectomy for nonresponders. Any comparison of cystectomy protocols with bladder-preservation protocols must include these nonresponders to avoid being biased by patient selection.

Prognostic Factors in Chemoradiation

Complete Response. Clinical CR (or T0 response), evaluated by cystoscopy with tumor site biopsy with or without cytology 2 weeks to 8 weeks after completion of the induction chemoradiation, ranged from 70% to 80%. The CR rate was significantly higher in patients in whom a macroscopically visibly complete TURBT could be achieved compared with patients with residual macroscopic disease after TURBT (80% to 90% versus 60%, $p < 0.001$).[171,257,258] Patients with clinical stage T2-3a achieved significantly more frequent CRs than those with T3b-4 disease (University of Paris, 83% versus 58%, $p < .001$; MGH, T2 vs. T3-4, 81 vs 64%). Patients who presented with *hydronephrosis* achieved a 66% complete response versus 83% in patients who had no hydronephrosis at presentation (University of Paris, $p < 0.05$; MGH, 52% versus 77%). The Erlangen group have shown that those with Tcis disease in the bladder in addition to the invasive tumor are less likely to have a durable response and more likely to require cystectomy.

Chemoradiation added significant improvement to the clinical CR rates compared with the "early" CR after induction chemotherapy alone. After two cycles of MCV, the CR rate for patients with T2 disease was 62% and with T3 or T4 disease, 41%. After adding a course of concurrent chemoradiation, the CR rate increased to 81% and 64%, respectively.[257] Factors predicting for a CR also predict local control and ultimately bladder preservation. For example, among patients who underwent a visibly complete TURBT, only 22% required cystectomy (versus 42% of patients who underwent an incomplete TURBT, $p < 0.001$).[258]

TABLE 54-7 Muscle-Invasive Bladder Cancer: Survival Outcomes Following Curative Therapy in Contemporary Series

		Overall Survival		
Series	**Stages**	**Number**	**5-Year**	**10-Year**
CYSTECTOMY				
USC 2001[153]	pT2-pT4a	633	48%	32%
MSKCC 2001[154]	pT2-pT4a	181	36%	27%
SWOG/ECOG/CALGB*† 2002[238]	cT2-cT4a	317	49%	34%
SELECTIVE BLADDER PRESERVATION				
U. Erlangen* 2002[139,259]	cT2-cT4a	326	45%	29%
MGH* 2012[258]	cT2-cT4a	348	52%	35%
RTOG* 1998[231]	cT2-cT4a	123	49%	—
RTOG 2014 ([268a])	cT2-cT4a	468	57%	36%
BC2001* 2012[256]	cT2-cT4a	*182*	*48%*	—

**These series included all patients by their intention to treat.*

†50% of patients were randomly assigned to receive three cycles of neoadjuvant M-VAC.

Survival. Clinical complete responders generally have significantly higher survival rates than nonresponders. The amount of residual tumor after TURBT is also a prognostic factor for survival as for local control. The same is true for those with T2 clinical category compared with T3-4 and those presenting without hydronephrosis. In multivariate analyses, clinical T category and CR to induction therapy remained significantly associated with improved DSS and OS.[257,258]

The 5-year distant metastasis rate for all patients entered in the protocols ranged from 34% to 40%. In the MGH series, the 5-year distant metastasis rate in the T0 responder group was only 20%.[257,258] Patients who did not respond rapidly (T > 0) and underwent immediate cystectomy had a 50% distant metastasis rate at 5 years. However, it was similar to the 5-year rate of initial T0 responders who subsequently underwent salvage cystectomy for local failure (5-year distant metastasis rate, 54%). Delayed cystectomy for recurrent invasive disease did not confer worse outcomes when compared to immediate cystectomy for a noncomplete response.

Follow-Up after Chemoradiation. All patients with bladder cancer (either superficial or invasive) treated with bladder-preserving therapies must be willing to return for regular, thorough clinical examinations, cystoscopy, biopsy of the tumor site, and urine cytology follow-up so that transurethral surgery, intravesical therapy, or salvage cystectomy can be implemented at the earliest opportunity if necessary. The optimal timing of cystoscopy after RT is unclear but is usually first done at 3 months.[187] At the MGH our protocol mandates cystoscopy and urine cytology every 3 months for the first 2 years, then every 6 months until 5 years and annually thereafter. In patients with a series of negative followup evaluations, the biopsy and examination under anesthesia may be omitted in favor of office cystoscopic evaluation if no worrisome office endoscopic findings are present.

Managing Recurrent Disease in the Bladder. Of patients who have complete response, 84% of patients remained free from invasive recurrence in the bladder at 10 years, and approximately 60% remained free from any noninvasive or invasive occurrence.[257,258] Of patients whose invasive recurrence was cured, 17% to 30% may subsequently experience superficial noninvasive (≤T1) TCC[258,274,275] Eighty-four percent of patients who experienced superficial recurrences (Ta or CIS) at MGH have been maintained in remission by TURBT and intravesical drug therapy.[274] For these individuals the OS and DSS was comparable to those who had no failure. However, significantly fewer patients with a superficial relapse survive with their native bladder and up to one quarter of these patients may ultimately require a salvage cystectomy.

Although superficial tumors may be managed by TURBT and intravesical therapy,[274-276] invasive recurrences are generally managed with salvage cystectomy. In selected series, salvage cystectomy results in a 40% to 50% survival rate at 5 years and good locoregional control rates.[198,258]

Conclusions Regarding Combined Chemoradiation and TURBT. The *ideal* candidate for bladder preservation meets the following criteria:

1. Primary T2-3a tumors that are unifocal
2. TCC (urothelial) histology
3. Tumor size less than 5 cm in maximum diameter
4. Tumor not associated with extensive CIS
5. No presence of ureteral obstruction or tumor-associated hydronephrosis
6. Good capacity of the bladder and good bladder function (i.e., a bladder worth sparing)
7. Visibly complete TURBT
8. Adequate renal function to allow cisplatin concurrent with radiation (though good alternative chemotherapy regimens such as 5-FU/MMC can be considered in patients with lower glomerular filtration rate [GFR][256]).

Notably age is not a contraindication to successful bladder sparing therapy, and indeed results are favorable in patients age 75 or older.[258] This is an important consideration given that the elderly generally appear to be undertreated for invasive bladder cancer in the United States.[277] Bladder-sparing chemoradiation remains a good option for those patients who are not cystectomy candidates and often such patients would be treated with daily radiation and appropriate concurrent chemotherapy without a break.

Quality-of-Life Studies

Radical cystectomy causes changes in many areas of quality of life, including urinary, sexual, and social function; daily living activities; and satisfaction with body image.[278-282] Sexual function has been particularly emphasized because of the high prevalence of erectile dysfunction. Researchers have, over the last decade, concentrated on the relative merits of continent and noncontinent diversions. Available data have been mixed with some groups, surprisingly, reporting few differences between the quality of life of those with an ileal conduit and those with continent diversions.[283] Until recently, little comparative data have been available on those who have neobladders. Hart et al have compared outcome in cystectomy patients who have ileal conduits, cutaneous Koch pouches, or urethral Koch pouches.[282] Of 1074 patients undergoing cystectomy for bladder cancer at the University of Southern California, 368 were eligible for study because they were alive, spoke English, and had no major health issues that would affect global quality of life. Of these, 61% completed self-reporting questionnaires. Regardless of the type of urinary diversion, the majority of patients reported good overall quality of life, little emotional distress, and few problems with social, physical, or functional activities. Problems with their diversions (in approximately 60% of patients) and with sexual function were the most commonly reported. After controlling for age, no significant differences were seen among urinary diversion subgroups in any quality-of-life area. It might be anticipated that those receiving the urethral Koch diversions would be the most satisfied and the explanation why this is not so is unclear. It may be that the subgroups were too small to detect differences, but perhaps it is more likely that each group adapts in time to the specific difficulties presented by that type of diversion.

Zietman et al have performed a study on patients receiving TURBT, chemotherapy, and RT in the treatment of their bladder cancer at the MGH.[284] Of 221 patients with clinical T2-4a cancer of the bladder treated at the MGH from 1986 to 2000, 71 were alive with their native bladders and disease free in 2001. These patients were asked to undergo a urodynamic study (UDS) and to complete a quality-of-life questionnaire. Sixty-nine percent participated in some component of this study with a median time from trimodality therapy of 6.3 years. This long follow-up is sufficient to capture the majority of late radiation effects. Seventy-five percent of patients had normally functioning bladders by UDS. Reduced bladder compliance, a recognized complication of radiation, was seen in 22%, but in only one third of these was it reflected in distressing symptoms. Two of 12 women showed bladder hypersensitivity, involuntary detrusor contractions, and incontinence. The questionnaire showed that bladder symptoms were uncommon, especially among men, with the exception of control problems. These were reported by 19% with 11% wearing pads (all women). Distress from urinary symptoms was half as common as their prevalence. Bowel symptoms (e.g., rectal urgency) occurred in 22% with 14% recording any level of distress. The majority of men retained sexual function.

Global health–related quality of life was high. The great majority of patients treated by trimodality therapy therefore retained good bladder function. It was concluded that there is a small but detectable level of lasting bowel dysfunction and distress and that this might be judged the additional price that these patients have had to pay to retain their bladders.

A prospective Phase II multicenter study from France has recently been reported.[285] It tracked voiding symptoms and quality of life in 53 patients from before their trimodality treatment. Sixty-seven percent retained their bladders and these were interviewed 6, 12, and 24 months later. Levels of urinary symptoms were high but only 5% reported any EORTC grade-3 symptoms. It was also notable that most patients experienced improvement of symptoms over the 2 years after treatment presumably because of the eradication of a symptomatic primary tumor.

Two cross-sectional questionnaire studies, one from Sweden and one from Italy, have compared the outcome following radiation with the outcome following cystectomy.[286,287] The questionnaire results for urinary function following radiation were similar to those recorded in the MGH study. More than 74% of patients reported good urinary function. Both studies compared bowel function in irradiated patients with that seen in patients undergoing cystectomy. In both, the bowel symptoms were greater for those receiving radiation than for those receiving cystectomy (10% versus 3% and 32% versus 24%, respectively) but in neither was this statistically significant.

In the assessment of sexual function, most women in the MGH study preferred not to answer the questions and no data were therefore available for them. Almost all men, however, did. In contrast to patients who have been irradiated for prostate cancer, the majority of male bladder-sparing patients reported adequate erectile function (full or sufficient for intercourse), and only 8% reported dissatisfaction with their sex lives.[284] These are in line with those obtained in the Swedish and Italian series in which 38% and 25% of men retained useful erections as compared with 13% and 8% of cystectomized controls. The MGH series allowed the use of sildenafil probably contributing to the better outcome. Another study reported that 71% of women who underwent bladder-preservation therapy showed no decline in their subsequent satisfaction with sexual intercourse.[288]

An analysis of four prospective RTOG bladder-sparing protocols (89-03, 95-06, 97-06, 99-06) suggested that rates of significant late pelvic toxicity for patients completing combined-modality therapy for invasive bladder cancer and retaining their native bladder is low.[289] Only 7% of patients experienced a late grade-3 pelvic toxicity (5.7% genitourinary and 1.9% gastrointestinal) and in only one patient did the toxicity persist. Notably, there were no late grade-4 toxicities reported and no treatment-related deaths.

LOCALLY ADVANCED DISEASE AND PALLIATION

When bladder cancer has invaded adjacent organs or spread to the pelvic lymph nodes cure is rare, as the primary tumors are typically bulky and distant metastases usually present, even if subclinical. In this situation if the voiding symptoms are not too severe and the renal function allows, it is common to give combination chemotherapy and reassess after several cycles. If the patient has had a good response they may receive consolidation chemoradiation delivered with "curative" intent. If renal function is poor, patients may be given nonplatinum–based regimens such as 5-FU/MMC or taxol either before or with the radiation. If voiding symptoms are severe or there is bilateral hydronephrosis, they may be better served by percutaneous urinary drainage and then cystectomy with urinary diversion. For patients with locally advanced T4 primary tumors or locally recurrent cancer, there is a rationale for combining resection with intraoperative radiation therapy (IORT) but experience is limited. Resection and IORT would preferably be preceded by several cycles of multiagent chemotherapy, then pelvic radiation (45 Gy to 50.4 Gy in 1.8-Gy fractions) plus concurrent weekly cisplatin (see previous section). Trials have been published from our colleagues in Lyon, France, and Pamplona, Spain, demonstrating the potential value of pursuing such approaches in other centers with IORT capabilities.[290-292]

If the patient is unfit for cystectomy then radiation may be given to the bladder for palliation. Duchesne et al reported an MRC trial in the United Kingdom in which 500 patients were randomized to two palliative fractionation schedules: 35 Gy in 10 fractions and 21 Gy in 3 fractions (given weekly). When assessed at 3 months 68% had had some symptomatic improvement but there was no difference between the arms.[293] There was no evidence for a difference in toxicity justifying the use of this ultrahypofractionated regimen for the palliation of patients at the end of their lives.

Metastatic bladder cancer is responsive to platinum-based chemotherapy. MVAC or MCV (often given in dose-dense fashion) have been the usual choices as first-line drugs but gemcitabine and cisplatin (and the addition of taxol) are emerging as reasonable alternatives and may be better tolerated.[294] It is remarkable that, unlike most other solid tumors, CRs are not unusual and durable responses do occur. Recently, immunotherapy with checkpoint inhibitors has shown promise in clinical trials for metastatic bladder cancer.[294a]

Radiation is often used in the palliation of bone and brain metastases. Palliative radiation may also relieve the inferior vena cava or lymphatic obstruction that can occur when there is heavy involvement of the paraaortic nodes.

IRRADIATION TECHNIQUES AND TOLERANCE

External Beam Irradiation

Historically all work on bladder cancer that has been published used RT that was delivered by conventional two-dimensional RT. More recently, three-dimensional (3D) techniques became standard in RTOG protocols employing appropriate margins for an organ as mobile as the bladder. Now, IMRT has emerged as an option given the availability of advanced daily image guidance such as cone-beam CT and even real time tracking of the bladder and the possibility of more conformal treatment to spare central lying low hanging bowel.

At the MGH the following 3D technique has been used on and off-protocol regularly, though IMRT planning has been adopted more consistently in recent years. The standard protocol for radical EBRT as well as combined-modality therapy uses a four-field isocentric technique, which consists of shaped anterior, posterior, right, and left lateral fields for the initial or induction treatment field (Figure 54-4). This is followed by a boost or consolidation field (Figure 54-5).

Simulation

All simulations begin after the patient has voided (i.e., empty bladder). Treatments are also given with the bladder empty as this makes bladder position and tumor localization more reproducible and predictable. The patient is then immobilized in a supine position and a CT simulation is performed.

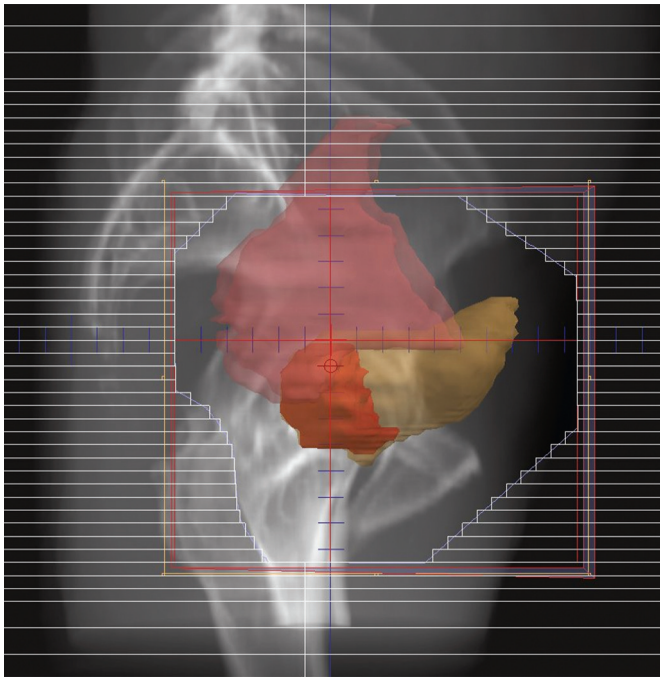

Figure 54-4 Sagittal digitally reconstructed radiograph (DRR) image showing a lateral view of a small pelvis field.

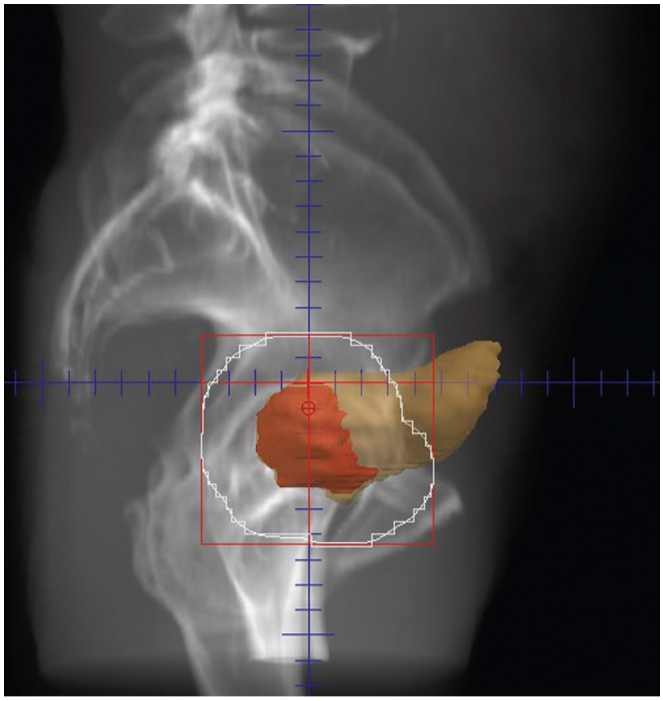

Figure 54-5 Sagittal digitally reconstructed radiograph (DRR) image showing how a lateral boost may be given to a tumor to spare the anterior bladder.

Target Volumes

During the first phase of treatment the bladder is treated along with a margin of 2 cm. In men, the entire prostate is also covered in this first phase because there may be occult stromal invasion or extension into the prostatic urethra. In women, the proximal 2 cm of urethra are also considered target. Care must be taken to avoid the inferior border of the field glancing the vulva because this may limit tolerance. The internal and external iliac lymph nodes of the pelvis are also covered for this phase of therapy. The top border of the field usually lies around the midsacroiliac joint and only at the level of the bifurcation of the common iliac vessels and does not include the entire pelvis. This is because a significant number of irradiated patients may subsequently require salvage cystectomy with urinary diversion. It is therefore prudent to limit the amount of radiation to bowel that may subsequently be needed for this purpose. Another good reason to limit the bowel volume is that quality-of-life studies have shown that the most troublesome consequences of irradiation for bladder cancer relate to the small bowel irradiation rather than the bladder irradiation.[284,287]

During the boost phase of treatment, MGH investigators boost the entire bladder excluding nodes and then further boost the tumor alone with a 2 cm margin (an alternative is to just boost the tumor alone). Defining the tumor may be difficult, but we employ a combination of an operative report and bladder map drawn by the urologist at the time of cystoscopy/TURBT, and CT and MR information from the initial (pre-TURBT) staging work-up. CT scan after TURBT may overestimate the tumor residuum because of edema in the bladder wall. Using these sources of information it is usually possible to exclude at least one third of the bladder from the boost volume (Figures 54-5 and 54-6). Although this may not seem like much, it does mean that less than the entire volume is treated to full dose, a factor that may contribute to the good functional results seen after use of this technique. Fiducial markers may be inserted either cytoscopically or through the anterior abdominal wall into the edges of the resection bed to aid boost visualization (Figure 54-7). Such fiducial markers around the tumor site placed at time of TURBT can help tailor field design and can be used with daily imaging (such as cone-beam CT) for localization to further guide treatment during the tumor boost phase. It is possible that treating with a full bladder during the tumor boost phase could further limit bladder and bowel dose.

Fields

The first phase treats the pelvic lymph nodes, prostate, and bladder (if using a four-field arrangement, roughly mid-SI joint superiorly, bottom of the obturator foramen inferiorly, and 1.5-cm margin on the pelvic brim laterally). The second phase boosts the bladder alone and the third phase the tumor alone. As most tumors are on the bladder trigone or on the postero-lateral walls, it is easiest to boost with opposed lateral fields when not using IMRT. If this is anticipated the 4-field box used in the first phase has to be weighted more heavily toward the antero-posterior (AP) and posterior-anterior (PA) to save femoral head tolerance and allow the lateral boost.

Patients are encouraged to empty their bladders before treatment to achieve a more reproducible target and to minimize volume irradiated. Many patients with bladder cancer have significant postvoid residual volume so artificial emptying of the bladder by catheterization may give a false impression of the shape and size of the target volume at simulation.

IMRT planning has been adopted at the MGH more recently (Figure 54-6). Planning target volume (PTV) expansions of 2 cm around bladder and bladder tumor have been employed, with 0.8-cm margins for prostate (0.5-cm posterior) and pelvic nodes. PTV margins may be decreased a little when targets abut large amounts of low hanging small bowel. A seven-field beam arrangement is typically used for small pelvis, and either a five- or seven-field beam arrangement for bladder only and tumor boost. We start with beams equally spaced and modify the angles as anatomy requires.

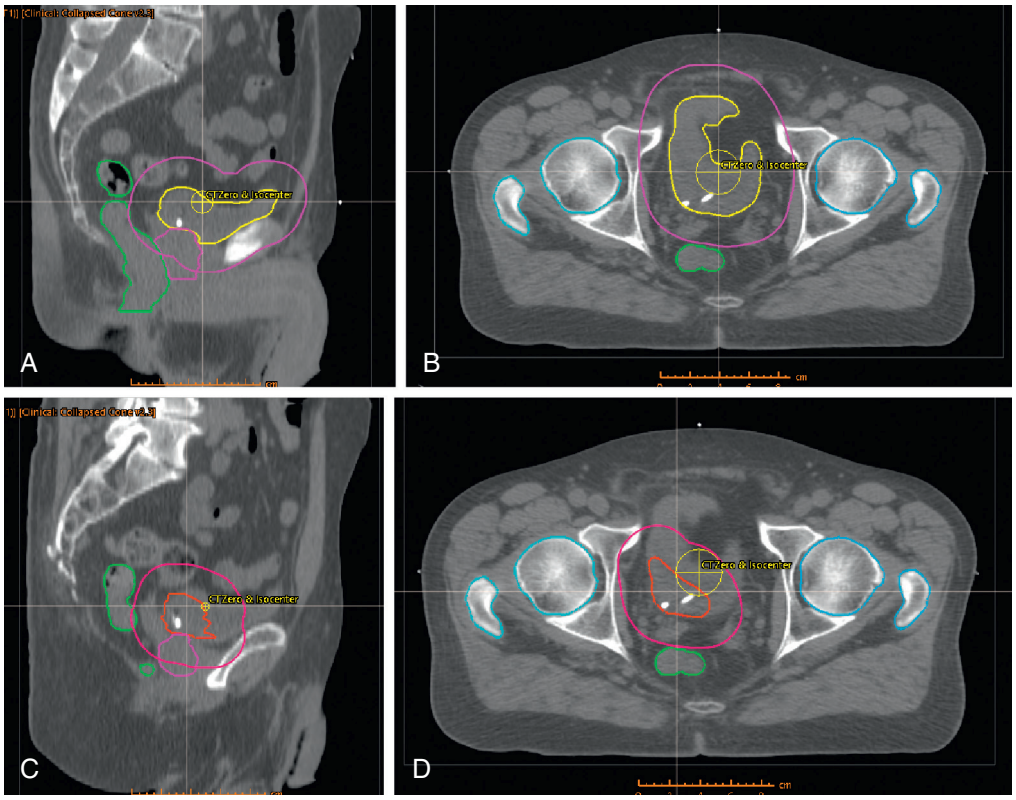

Figure 54-6 **A** and **B,** Planning target volume (PTV) expansions around bladder, tumor, prostate in sagittal and axial CT cuts for small pelvic fields; Panels **C** and **D,** PTV expansions for bladder tumor boost fields.

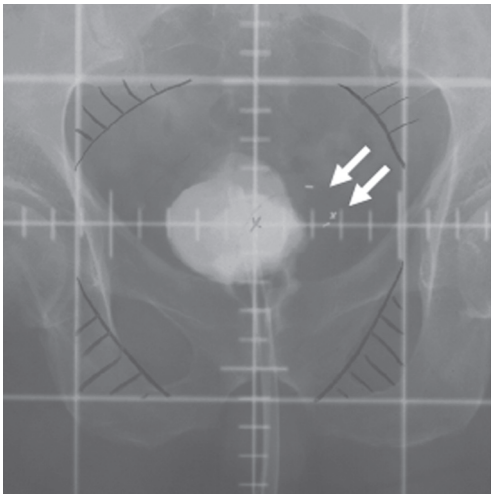

Figure 54-7 Fiducial markers placed adjacent to a bladder tumor at the time of transurethral resection.

Total Dose

At the MGH, investigators have traditionally given total doses on the order of 65 Gy delivered in once daily (1.8-Gy to 2-Gy fractions, 5 days per week) or twice daily (please refer to RTOG 0712) fashion, together with concurrent chemotherapy (cisplatin alone, cis/5-FU or 5-FU/MMC when not on protocol) and a maximal TURBT. Typically, 40 Gy to 45 Gy is delivered in the first phase to the larger small pelvic field covering the entire bladder, prostate, and the low pelvic lymph nodes. The whole bladder receives an additional 10 Gy 14 Gy, and the tumor is boosted to full dose with an additional 10 Gy. If not employing a bladder-alone boost, then the tumor is boosted to the full dose after the small pelvic phase. An invasive local recurrence is limited to only 15% to 18% of all complete responders, implying that this is an adequate dose for durable local control in the vast majority of those who respond to radiation. Investigations into adaptive planning and dose escalation are ongoing.

Treatment Break to Evaluate Response

At the MGH, investigators have routinely built in a 3-week break as an early treatment assessment response following the delivery of 39 Gy to 42 Gy. This is quickly followed by repeat cystoscopy/biopsy of the tumor site (Figure 54-8). Patients are selected to continue and complete radiation (the consolidation phase) on the basis of their response at this point. Those who have had a CR (anticipated to be 80% of patients) or in whom the tumor residuum is less than T1 by stage (Ta or Tis) continue. The others are recommended to undergo an immediate cystectomy. This can thus be performed before the patient has had full-dose radiation, an easier proposition for the surgeon (both in time to cystectomy and in dose to the pelvis). It also means that a patient responding poorly can be identified early and recommended surgery promptly rather than waiting for an entire course of radiation to be completed by which time progression may have occurred that could threaten the efficacy of salvage therapy. Concerns have been expressed on radiobiological grounds that split-course treatment compromises efficacy.[295,296] There is also the worry that those who have not been complete responders after 40 Gy might yet become complete responders after 65 Gy, and thus, some may be recommended an unnecessary

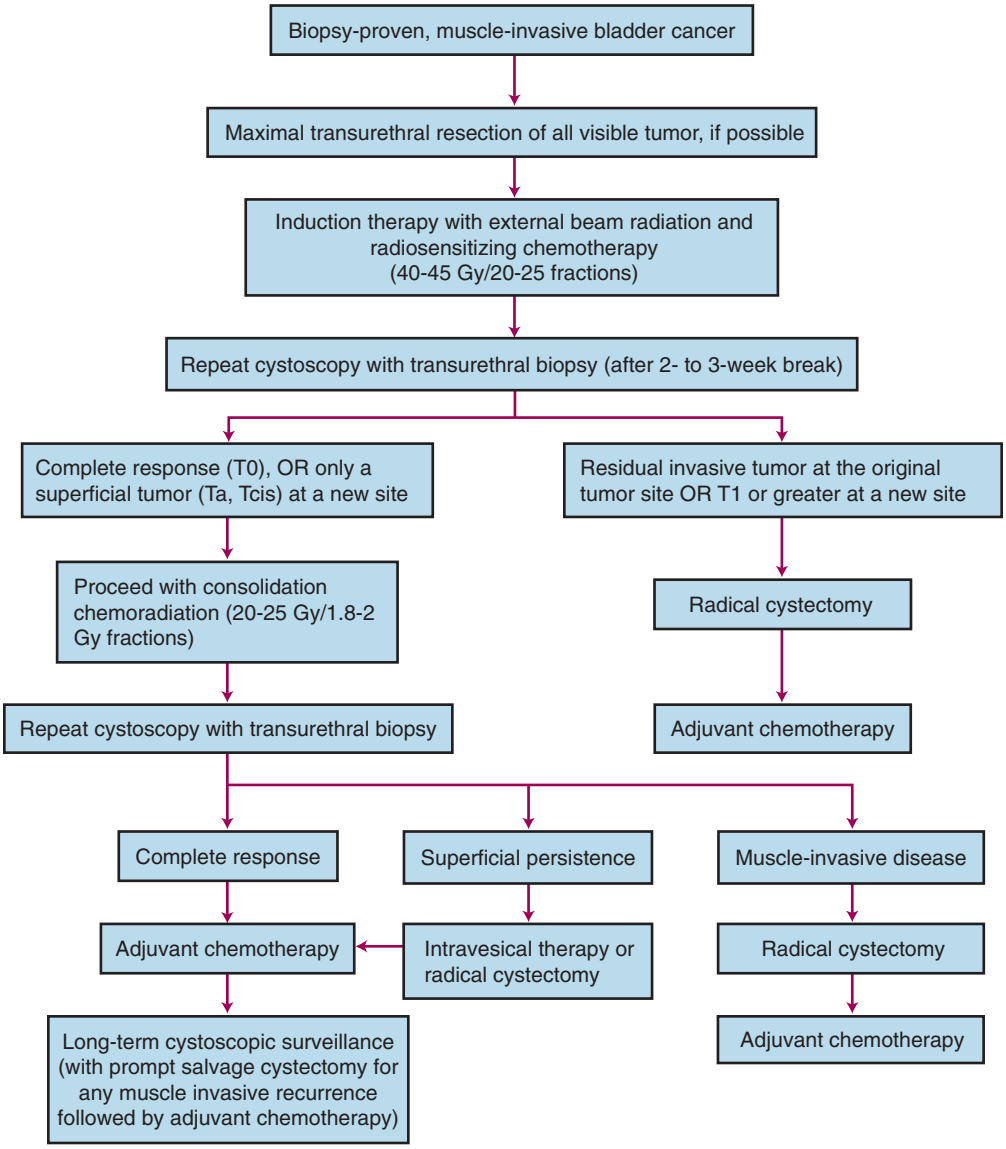

Figure 54-8 **Current algorithm for the trimodality management of invasive bladder cancer.**

cystectomy. This concern, however, probably affects only a minority of patients.

Controversial Issues in EBRT Technique

Nodal Treatment

Lymph node involvement is common in this disease and is seen in approximately 25% of patients coming to a radical cystectomy.[153] The number of lymph nodes involved is well established as a prognostic indicator that surgeons use to determine the extent of their lymph node dissection and the need for adjuvant chemotherapy.[158] This information is, however, unavailable to radiation oncologists. More interesting for them is the knowledge that some patients with positive lymph nodes may be cured by a lymphadenectomy, a situation akin to breast or head and neck cancers. The thoroughness of a lymph node dissection (>10 nodes removed) also correlates with outcome independent of nodal status.[297] Thus, radiation to the pelvis might confer a survival advantage though it comes at the price of additional morbidity. Centers that do irradiate the bladder alone (typical in UK practice) do not report either an increased pelvic failure rate or reduced survival although direct comparisons are difficult and randomized data is not available.[298] It may be that either chemotherapy does the job of the nodal irradiation or that nodal disease extends beyond the confines of the current pelvic template. Surgeons have started to perform extended lymphadenectomies to the level of the inferior mesenteric artery.[141,299]

Partial Bladder Treatment

Estimates of bladder tolerance have been made which suggest that up to 80 Gy could be given if one third of the bladder is spared, whereas 65 Gy is the limit for whole-bladder treatment.[300-302] In addition, the low rate of development of new invasive tumors elsewhere in the bladder after brachytherapy (5% to 7%) suggests that localized partial bladder radiation is a reasonable strategy.[202] Careful selection is, however, necessary with such approaches being limited to smaller tumors (<5 cm), unifocal tumors, and those without extensive Tis tumor elsewhere in the bladder. A randomized trial in the United Kingdom has shown that partial bladder irradiation does allow for the delivery of a higher dose to the

tumor than whole-bladder radiation without an increase in morbidity.[303] It did not, however, show either improvement in local control or survival. One hundred forty-nine patients were randomized to receive whole-bladder conformal RT to 52.5 Gy in 20 fractions or partial bladder conformal radiation to either 57.5 Gy in 20 fractions or 55 Gy in 16 fractions. The 5-year local control rates for these three regimens were 58%, 59%, and 34%, respectively, without any significant differences between arms ($p = 0.18$). The recently reported BC2001 Phase III trial also randomized patients to standard whole-bladder EBRT or reduced high-dose volume EBRT that aimed to deliver full radiation dose to the tumor and 80% of maximum dose to the uninvolved bladder.[304] There were no statistically significant differences between groups in terms of late toxicity and noninferiority of locoregional control could not be concluded formally. Overall low rates of clinically significant toxicity combined with low rates of invasive bladder cancer relapse help to confirm that chemoradiation therapy is a valid option for the treatment of muscle-invasive bladder cancer.

Treatment Margins

At the MGH in expanding the clinical target volume (CTV) to the PTV we have adopted isotropic 2-cm margins around either the bladder (first phase of treatment) or tumor (boost) in all three dimensions. This is to account for set-up errors and organ motion. Several studies employing serial CT scans have shown that margins less than this may be inadequate. Turner et al demonstrated that bladder wall movement of >1.5 cm occurs at least once during a course of treatment in more than 60% of patients.[305] Several others have reported that the gross target volume (GTV) moves outside the PTV on at least one occasion in at least 20%.[306,307] Our own analysis showed that these variations are highly patient dependent and occurred even when strict instructions were given regarding bladder and rectal filling.[308] The greatest degree of bladder wall positional change occurred in the cranial direction with the least variation in the antero-inferior direction, limited by the pubic symphysis. In light of this information it is clear that organ motion is the dominant source of error and that the magnitude of the error depends on the region of the bladder. The solutions are clear though difficult to achieve. Graham et al have recommended anisotropic margin widths of 1.6 cm anterior and posterior, 1.4 cm laterally, 3 cm superior, and 1.4 cm inferior.[309] The problem is that these margins incorporate much normal tissue. Daily image-guided therapy is the only way to reduce these margins significantly. Daily cone-beam CT that can delineate the bladder is one option. There is also interest in the use of fiducial markers that could be placed by the urologist at the time of TURBT in the bladder wall around the tumor crater (Figure 54-6 and Figure 54-7). Roof et al have shown that if the daily treatment is centered on the bladder centroid, rather than referenced to bony anatomy, margins of <1.5 cm could be feasible.[308] None of these studies account for the fact that the bladder not only changes in size but also in shape, it is deformable. This will likely set a limit on our ability to shrink margins significantly anytime soon.

Radiation Dose

There is evidence for a dose-response curve in bladder cancer with most studies showing that doses of <62 Gy (at 1.8 Gy to 2 Gy per fraction) predict poor outcome.[310-312] Most of these studies have, however, employed radiation alone and the curve is likely to be greatly modified by effective debulking of the tumor or by radiation sensitization with concurrent chemotherapy. Increasing dose may result in increased CR rates but may add to the morbidity and may also be limited by the rapid proliferative index and short doubling time of these tumors.[313] Interest recently has therefore concentrated on dose intensification using accelerated regimes rather than an increase in total dose. Acceleration may be achieved through hypofractionation, but this may be better limited to the palliative setting or through the use of conventional 2-Gy fractionation given twice a day.[314] The Royal Marsden Hospital has reported on 85 patients with twice-daily fractions of 1.8 Gy to 2.0 Gy 5 days a week to doses between 57.6 Gy and 64 Gy in 32 fractions over 26 days. Of 70 patients who had cystoscopic reevaluation 3 months to 6 months after RT, 80% were found to be complete responders (i.e., cystoscopy and biopsy negative for tumor 3 months to 6 months later).[315] Plataniotis et al reported a total response rate of 67% when a twice-daily fractionation was used during the last week (fifth week) of RT.[316]

Unfortunately, acceleration with fraction sizes of 2 Gy seems to increase acute toxicity. The RTOG has therefore explored acceleration with hyperfractionation and recent protocols have employed fraction sizes of 1.2 Gy to 1.8 Gy with a concomitant boost technique. No comparative studies have yet been performed but morbidity appears low.[265] The recently closed RTOG protocol 0712 did compare a twice daily to once daily regimen, though results are pending.

Hyperfractionation has also been used to increase the total tumor dose. A randomized trial of 168 patients with T2-4 tumors, unsuited for cystectomy, compared hyperfractionated EBRT (1 Gy three times a day to a total dose of 84 Gy) with conventional fractionation (2.0 Gy every day to 64 Gy).[317,318] Hyperfractionation achieved superior results with respect to 5-year OS (27% versus 18%), local control (12% versus 7%), and clinical CR rates (59% versus 36%) with an increase in late toxicity. Both study arms were treated by a split-course of RT with a 2-week gap after the first 3 weeks, the effect of which is unknown. The benefit of the hyperfractionated schedule persisted over a 10-year follow-up period, both for local control and survival. It should be noted, however, that patients in the conventional fractionation arm did poorly compared with those receiving similar treatment in other studies largely because patients unfit for cystectomy were entered in this study.

Future improvements in the CR rate may also come without any need to escalate radiation dose: better selection of patients, better radiation sensitization (including novel targeted therapy and immunotherapy), and more aggressive TURBT. Others have argued that doses of 65 Gy at 1.8 Gy to 2 Gy per fraction may actually be more than is needed especially for those who have had visibly complete transurethral resections. The Erlangen group has delivered doses tailored to the estimated residuum following resection. These doses are in the range of 50 Gy to 59 Gy (1.8 Gy to 2 Gy per fraction) depending on whether disease to be treated is microscopic or gross in volume.[319]

Brachytherapy

Shortly after completion of the preoperative radiation (<2 weeks), a suprapubic cystotomy is performed to ascertain the true dimensions of the tumor and to confirm that it is indeed unifocal. There are regional differences in the type of surgery performed on the primary tumor. In France, a partial cystectomy is preferred. In the Netherlands, citing concerns about the risk of fistula, this is only performed for lesions on the dome or in a diverticulum. The target area is determined by the surgery and is either the bladder scar after partial cystectomy or the macroscopic tumor plus a 1.5-cm to 2.0-cm margin. It may be marked by fiducials at this point. Narrow afterloading tubes are then inserted into the target area parallel and halfway through the bladder wall. In the case of a partial cystectomy, two tubes one on either side of the scar are sufficient. If a partial cystectomy is not performed, then three to

five tubes in a single plane will encompass most lesions. The tubes are then brought out to the anterior abdominal wall and a suprapubic catheter inserted for drainage. The tubes are removed without anesthesia after the completion of radiation; the urinary catheter is removed 2 weeks later.

Radiation planning may be performed using stereo-shifted radiographs, but it is now preferable to use CT. Doses given vary greatly in the literature according to the additional external beam given and whether or not high- or low-dose rate brachytherapy is planned. If less than 10 Gy to 15 Gy is given preoperatively, then 30 Gy to 60 Gy are given using low-dose rate. The lower doses are given to those who have had partial cystectomies or complete resections. In the Netherlands 30-Gy EBRT is either supplemented with 40 Gy low-dose rate or 10 × 3.2 Gy high-dose rate (two fractions per day with a 6-hour interval).

TREATMENT ALGORITHM, CHALLENGES, AND FUTURE POSSIBILITIES

Selective bladder preservation is based on the response of the tumor to induction combined-modality therapy, which includes a TUR of as much of the primary bladder tumor as is judged safely possible combined with concurrent chemotherapy and EBRT; early salvage cystectomy is recommended for patients whose tumors are not responding to combined-modality therapy or for an invasive recurrence to maximize the possibility of cure (Figure 54-8). In appropriately selected muscle-invasive patients, bladder-preserving treatment with chemo-radiation offers a chance for long-term cure and survival comparable to radical cystectomy, while affording a 70% to 80% chance of maintaining their native bladder (Tables 54-6 and 54-7). Quality-of-life studies have demonstrated that the retained native bladder functions well and long-term toxicity of chemoradiation to pelvic organs is low. These results support the acceptance of modern bladder-sparing trimodality therapy for selected patients as a proven alternative to cystectomy (and for patients who are not good surgical candidates). This approach is not suitable for patients with tumors obstructing a ureter. Twenty percent to 30% of patients cured of muscle-invading bladder cancer will subsequently acquire a new superficial tumor, but these superficial tumors have generally responded well to the usual TURBT and intravesical drug therapy. These patients require close urologic surveillance, as do any patients with superficial bladder cancer treated conservatively. Bladder-preserving treatment usually results in a normally functioning bladder for patients with T2 and T3a disease; however, patients with T3b-4 disease experience local control less frequently using these techniques. No data exist, however, to suggest that patients with more advanced disease are in any way disadvantaged by preoperative chemoradiation as an attempt at bladder conservation. Radiation-based strategies are also being explored in the recurrent T1 BCG refractory and locally advanced postcystectomy settings. Further clinical practice guidelines are available through the updated National Comprehensive Cancer Network[320] and other guidelines.[115]

Although many urologists have found merit in a selective bladder-sparing approach to muscle-invading transitional cell bladder cancer, many more will need to become convinced if there is to be a significant change in treatment practices for bladder cancer across the country. As studies addressing the possibility of organ preservation continue to demonstrate positive results, it is hoped that more patients will become informed about and be offered selective bladder-sparing approaches as an alternative to radical cystectomy. The contribution of selective bladder-sparing therapy to the quality-of-life of patients so treated represents a unique opportunity for urologic surgeons, radiation oncologists, and medical oncologists to work hand in hand in a truly multidisciplinary effort.

The immediate therapeutic challenges for radiation oncologists include:

- More effective radiographic tumor definition and tracking during radiation therapy. This may allow tighter margins, more accurate and higher dose delivery, and higher rates of bladder preservation.
- More effective radiation sensitization. The optimal regimen of combined chemoradiation continues to be investigated. Current standards are cisplatin-based (such as cis/5-FU) or 5-FU/MMC. Gemcitabine has been under evaluation at several centers and by the RTOG.
- More effective evaluation of pelvic lymph nodes using, perhaps, iron nano-particle MR lymphangiography, and more effective treatment of pelvic lymph nodes with either extended lymphadenectomy or radiation delivered using intensity-modulated irradiation (IMRT).
- Further defining a role for radiation-based strategies in the recurrent T1 BCG refractory and locally advanced postcystectomy settings.
- Integrating rational molecularly targeted biologic and immune-based strategies into primary therapy.
- Further defining clinical factors and molecular biomarkers predictive of response and outcome to therapy.

CHAPTER

55 Testicular Cancer

Peter W.M. Chung, Phillipe Bedard, and Padraig R. Warde

INCIDENCE

In men 15 to 35 years of age, testicular cancer represents the most frequently diagnosed malignancy but overall only 1% of all malignant tumors. In 2008, 52,000 new cases and 9000 deaths were estimated worldwide from this disease

BIOLOGIC CHARACTERISTICS

Isochromosome 12p is present in more than 80% of cases.

STAGING EVALUATION

After a history and physical examination is undertaken, serum tumor markers, including alpha-fetoprotein (AFP), β-human chorionic gonadotropin (β-HCG), and lactate dehydrogenase (LDH) is important for further assessment.

Imaging should include chest radiography and computed tomography (CT) scan of the abdomen and pelvis. CT scan of the thorax may be omitted in patients with seminoma with normal abdominopelvic CT but is otherwise usually included. Other imaging modalities such as magnetic resonance (MR) and positron emission tomography (PET) scans are not routinely included for staging patients.

PRIMARY AND ADJUVANT THERAPY

Radical inguinal orchiectomy allows pathological subtyping, enables appropriate management, and is also the initial treatment for testicular cancer.

Seminoma

Stage I seminoma has overall survival (OS) rate of almost 100%. There are three main management options with resultant differing relapse rates. Surveillance is the preferred option, with a 15% relapse rate, whereas adjuvant therapy, with either retroperitoneal irradiation or carboplatin chemotherapy, has a 5% relapse rate. Similarly, stage II seminoma has a 5-year OS of 97%. Radiation therapy (RT) for stage IIA or IIB disease, with a 10% relapse rate, and cisplatin-based chemotherapy for stage IIC disease, with a <5% relapse rate are commonly employed as treatment options. For stage III seminoma, the 5-year OS is approximately 85% and cisplatin-based chemotherapy is the preferred treatment option.

Non-Seminoma

Stage I non-seminoma has a 99% 5-year OS. The main treatment options include surveillance with a 30% relapse rate, retroperitoneal lymph node dissection (RPLND) with a 10% relapse rate, and adjuvant chemotherapy (most often given only for high-risk patients) with a 1% relapse rate.

For stage II non-seminoma, the 5-year OS is ~98%. Stage IIA disease is managed with cisplatin-based chemotherapy alone or RPLND plus chemotherapy (both <5% relapse rate), and stage IIB or IIC disease is managed with cisplatin-based chemotherapy, with a 5% relapse rate. Stage III disease is managed with chemotherapy.

Patients with metastatic germ-cell tumors have been divided into good-prognosis, intermediate-prognosis, and poor-prognosis groups based on anatomic spread and elevated level of serum tumor markers. The *good-prognosis group* (60% of cases) has an approximately 86% OS. These patients have a primary tumor of the testis or retroperitoneum, no visceral metastases (except for pulmonary metastases), and low tumor marker levels (AFP, <1000; β-HCG, <5000; and LDH, <1.5 ULN). The *intermediate-prognosis group* (26% of cases) has an approximately 80% OS. These patients have a primary tumor of the testis or retroperitoneum, no visceral metastases (except pulmonary metastases), and AFP levels of 1000 to 10,000, or β-HCG levels of 5000 to 50,000, or LDH levels of 1.5 to 10 ULN. In the *poor-prognosis group* (14% of cases), the OS is around 50%. A primary tumor of the mediastinum is present, or nonpulmonary visceral metastases are found, or tumor marker levels are high (AFP >10,000; β-HCG >50,000; LDH >10 ULN).

Testicular cancers are uncommon in the general population but are one of the most common and important malignant tumors in young men. Worldwide, 52,000 new cases and 9000 deaths were estimated for this disease in 2008.[1] More than 95% of testicular cancers are primary germ cell tumors (GCTs); the others include lymphomas and sarcomas. The incidence of GCTs has doubled in the past 30 years. Although the majority (70% to 80%) present with early-stage and at the same time highly curable disease, the continued rise in incidence of these tumors presents a challenge in these relatively young men most of whom are in the prime of their lives. As with most cancers, specific management is based in part on histologic subtype but more importantly on disease extent. Advances in chemotherapy, imaging, and adoption of multidisciplinary care have led to continued improvements from a potentially deadly disease to the paradigm of the curable cancer over the past three decades. In this chapter, we will discuss the management principles for patients with primary GCTs of the testis, malignant extragonadal GCTs, and other rare testicular tumors.

ETIOLOGY AND EPIDEMIOLOGY

Testicular cancer accounts for only 1% to 2 % of all cancers in men in most populations across the world.[2] Germ cell testicular tumors are the most common solid malignant tumors in men between 20 and 35 years of age, projections for the United States for 2015 were that 8430 new cases would occur with 380 deaths.[3] The cumulative lifetime risk of developing a GCT for a white man in the United States is 0.2%.[4] Although the disease

is rare, the observed rising incidence is a concern. Between 1973 and 2003 the incidence of GCTs rose by 61% in the United States, with the major rise occurring in seminomas rather than non-seminomas.[5]

The age distribution of testicular cancer is similar in all populations of European origin. There is a small peak in early childhood at around 2 years of age, with rates then remaining low until 15 years of age. There is a second peak in young adults at around 25 to 40 years of age, and the rate then declines, with a small peak again between 65 and 75 years of age. Testicular cancers occurring in childhood and in the young adult years are usually GCTs, whereas those occurring after age 65 years are principally nongerm cell malignant tumors, mainly lymphomas. Nonseminomatous tumors are more common in childhood and in young men between 15 and 30 years of age, whereas seminomas present on average 1 decade later (at 25 to 40 years of age).

Risk factors for testicular germ cell cancer (TGCC) include a family history of cancer, the presence of an undescended testis or gonadal dysgenesis, subfertility, and testicular microlithiasis. Men with a history of cryptorchidism have an approximately sixfold increased chance of developing testicular cancer.[6] Orchiopexy before puberty appears to lower the risk of developing a subsequent tumor and may help preserve Leydig cell function and enhance fertility.[7,8] Although most testicular cancers in men with a history of maldescent occur on the ipsilateral side, approximately 5% to 20% develop in the contralateral testicle.[6] The mechanism by which cryptorchidism increases the risk of developing GCTs is unknown, but the effects of maldescent on the testis (e.g., increased temperature or increased risk of trauma if the testis is in the inguinal region) have been suggested as possible factors. The increase in the incidence of tumors in the contralateral testicle, however, suggests that maldescent and testicular cancer may result from the same prenatal etiologic process. Other genitourinary abnormalities associated with testicular cancers include hydrocele and hypospadias.[9]

There is considerable geographic and ethnic variation in the incidence of testicular tumors, with the highest incidence being reported from Denmark (8.4 per 100,000 men per year) and Switzerland (6.2 to 8.8 per 100,000 men per year).[2] The incidence of testicular cancer is lower in non-Europeans as compared with Europeans. In the United States, white men (6.36 per 100,000 per year) are five to six times more likely to develop testicular cancers than black men (1.30 per 100,000 per year); low incidence rates are seen in other ethnic groups, such as Americans of Chinese and Japanese descent.[5] A high incidence of testicular cancer is seen in some nonwhite populations such as the Maoris in New Zealand and Native Americans.[10]

Prior testicular cancer is a major risk factor for the development of a contralateral malignant tumor. In a large population-based follow-up study of 29,515 patients with unilateral testicular cancer, the cumulative risk (at 15 years after diagnosis of the primary tumor) of developing a contralateral malignant tumor was 1.9%.[11]

Heritability of Testicular Germ Cell Cancer

The racial disparities in persons who develop GCTs and the association with other urogenital abnormalities strongly suggest a genetic susceptibility to this disease. In support of this hypothesis, GCTs are among the most heritable of all cancers. Several studies estimate the risk to brothers and fathers of patients with TGCC to be 4 to 6 times increased and 8 to 10 times increased, respectively. This is far greater than the twofold elevated risk of first-degree relatives in other cancers, such as cancers of the breast or colon or melanoma. The relative risk is much greater in monozygotic and dizygotic twins. In addition, brothers and fathers of patients with bilateral tumors have a risk 3.9 and 4.7 times greater, respectively, than relatives of patients with monozygotic tumors.

Given the strong familial association of TGCC, extended pedigrees with this disease are curiously rare. Most families with TGCC have two affected members, most commonly sibling pairs. The International Testicular Germ Cell Linkage Consortium has carried out two large-scale genome scans, neither of which provided convincing or replicable evidence for susceptibility gene(s).[12] Candidate association studies have demonstrated that rare gr/gr deletions of the Y chromosome predispose to TGCC, but such deletions cannot explain more than a fraction of heritable cases of this disease.

More recently, two groups carried out association studies, based on genome-wide, single-nucleotide polymorphisms (SNPs), of patients with TGCC and controls.[13,14] Both research groups identified strong evidence for two susceptibility loci for seminoma and non-seminoma; one locus is on chromosome 12p22, within the *KITLG* gene, encoding the ligand for the receptor tyrosine kinase KIT, and the second locus is on chromosome 5q31.3 near the *SPRY4* gene, encoding sprouty 4, an inhibitor of the MAP kinase pathway. A third locus on chromosome 6 was identified by only one of the research groups and is not associated with a known gene. The relative risk was approximately 3 for the *KITLG* locus and about 1.4 for the other two loci. Both the *KITLG* gene and the *SPTY4* gene are biologically feasible candidates because their products lie in the same signal transduction pathway. Moreover, activating mutations of the *KIT* gene have been identified in a subset of seminomas, while paradoxically, deletions of the *KIT* gene predispose to germ cell cancer in the SV/129 mouse strain. Of note, cases in the association studies included patients with and patients without a family history of TGCC, but none of these loci were enriched in the familial cases and neither were they associated with other abnormalities such as an undescended testis.

As mentioned previously, the SV/129 mouse strain is particularly susceptible to the development of germ cell cancer, and this system has been exploited by Nadeau et al[15] to map several genes predisposing to the disease. Curiously, none of the corresponding loci in humans appear to have any role in TGCC development.

In summary, TGCC is a highly heritable disease, and at least two loci may contribute to its risk in the general population. Despite almost two decades of studies, however, no gene has yet been identified in families with this disease, suggesting that the genetic underpinnings of TGCC may be highly heterogeneous or novel, or both.

Environmental Factors and Testicular Germ Cell Cancer

Other factors linked to the development of TGCCs include a history of testicular trauma, an increased body mass index, immunosuppression following organ transplantation, and human immunodeficiency virus (HIV) infection.[2,16-18] There is no evidence to suggest a causal relationship between testicular trauma and the development of a tumor, and the likely explanation is that testicular trauma leads to examination of the testes. Because of the age distribution of testicular cancer, exposure must occur early in life if there is an environmental contribution to the etiology of these tumors. Prenatal factors linked to the later development of testicular cancers include threatened miscarriage, excessive maternal nausea, and birth by caesarean delivery.[2] To explain these associations it has been suggested that exposure of the germinal epithelium in utero to an elevated level of free unbound maternal estrogen

could give rise to subsequent cryptorchidism and an elevated risk of developing a testicular tumor; the prenatal estrogen theory remains unproven, however.[2]

PREVENTION AND EARLY DETECTION

The identification of carcinoma in situ (CIS) or testicular intraepithelial neoplasia (TIN) as a precursor of testicular GCTs has raised the possibility that the development of invasive testicular cancer could be prevented by treating CIS. In adults, CIS is found adjacent to GCTs in virtually 100% of cases, and it is thought that, with the exception of spermatocytic seminoma, CIS precedes the development of all invasive tumors.[19] The natural history of testicular CIS is unknown, but the Danish experience suggests that all cases of adult CIS will ultimately progress to invasive cancer.[19]

The diagnosis of testicular CIS can only be made by testicular biopsy. Because the incidence of CIS in the general population is low (at most, 0.7%), screening biopsies are currently not recommended. They should be considered in high-risk patients, however, including those with presumed extragonadal germ cell cancer, intersex individuals, and select patients with contralateral GCT (age <40 years and testicular volumes of <12 mL).[20]

The management of patients with testicular CIS is controversial. Orchiectomy has been suggested for unilateral disease, and in cases diagnosed after orchiectomy for GCT, three options can be considered and discussed with the patient: orchiectomy, low-dose RT, or surveillance.[20] Although both orchiectomy and RT offer definitive treatment for testicular CIS, they both destroy any residual fertility. Surveillance, with careful follow-up of the affected testis, is a reasonable option, especially given the excellent prognosis for metachronous testicular cancers.[21]

Testicular self-examination has been advocated for the early detection of invasive tumors, but its usefulness is unproven. There is no evidence to indicate that a population-based screening program would be of benefit; however, there is a need for education about the early signs and symptoms of testicular cancer to reduce delay at diagnosis. The optimal follow-up schedule for patients with unilateral testicular GCTs and those with cryptorchidism, both of whom have a risk of approximately 2% to 5% of developing a future testicular cancer, is unclear, but a yearly testicular ultrasound examination from age 15 years would seem reasonable.

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

GCTs have a distinctive capacity for totipotential differentiation as demonstrated by the frequent finding of combinations of choriocarcinoma, embryonal carcinoma, and seminoma in a single tumor. They also can retain their ability to differentiate as displayed by the not infrequent identification of mature teratoma in residual posttreatment retroperitoneal masses. Cytogenetic analysis of GCTs has shown that chromosome numbers are more homogenous in seminomas than in non-seminomas.[22-24] Triploid and tetraploid chromosomal patterns are common in seminomas, and hyperdiploid to hypertriploid counts are common in non-seminomas. A characteristic chromosome anomaly in GCTs of all histologic types is the presence of an isochromosome of the short arm of chromosome 12.[25] This isochromosome, first reported by Atkin and Baker in 1982,[22] consists essentially of two chromosome 12 short arms. It is present in more than 80% of cases, and GCTs without a 12p isochromosome have extra copies of 12p segments incorporated into other chromosomes. The 12p isochromosome is also found in testicular CIS.[25] Isochromosome copies tend to be more numerous in non-seminomas than in seminomas.

The study of the genetics and molecular biology of GCTs has enhanced our understanding of these tumors.[23,26,27] To date, however, cytogenetics has had little impact in the clinic, with the possible exception of the use of various markers for the identification of non-TGCCs located elsewhere in the body.[28-30]

PATHOLOGY AND PATHWAYS OF SPREAD

Pathology

Testicular cancers can arise from intratesticular and paratesticular cells (Box 55-1). The vast majority is of germ cell origin, and three major classification schemes have been in use worldwide[31-33] (Table 55-1). The Dixon and Moore classification as modified by Mostofi has been adopted by the World Health Organization (WHO) and is the classification scheme most widely used in North America.[34]

For clinical purposes, GCTs are classified into two major groups: seminomas and non-seminomas (NSGCTs). It should be noted that patients with pure seminoma may have relapse with pure NSGCT, and vice versa. Approximately 60% of GCTs are pure seminomas, 30% are NSGCTs, and 10% are mixed tumors (both seminomatous and NSGCT elements are present).[35] Patients with mixed tumors are clinically considered to have NSGCT, the only exception being tumors with syncytiotrophoblastic cells in cases of seminoma.

Carcinoma in Situ

Intratubular germ cell neoplasia, or CIS, is felt to precede the development of all cases of seminoma and NSGCT in adults (with the exception of spermatocytic seminoma).[36] On light microscopy, CIS cells closely resemble seminoma cells and in most cases are found within the seminiferous tubules. Cytologically, there is no difference between the CIS cells that develop into seminomas and those that develop into NSGCTs. In the general population, the incidence of CIS is low (0.2%),

BOX 55-1 Histologic Classification of Testicular Neoplasms

Germ cell tumors (demonstrating one or more of the following components)
- Seminoma
- Embryonal carcinoma
- Teratoma
- Choriocarcinoma
- Yolk sac tumor (endodermal sinus tumor: embryonal adenocarcinoma of the prepubertal testis)

Sex cord stromal tumors (gonadal stromal tumors)
- Leydig cell tumor
- Sertoli cell tumor
- Granulosa cell tumor (adult and juvenile types)

Tumor with both germ cell and gonadal stromal elements
- Gonadoblastoma

Adnexal and paratesticular tumors
- Mesothelioma
- Tumors of soft tissue origin (e.g., sarcomas)
- Adnexal tumor (e.g., adenocarcinoma) of the rete testis

Miscellaneous neoplasms
- Carcinoid
- Lymphoma
- Cyst

Metastatic neoplasms

It is not known how these chromosomal changes contribute to the development of the neoplastic phenotype. The frequent finding of the 12p isochromosome in both CIS and invasive tumors, however, indicates that this chromosome plays an important role in the biology of these tumors. The possibility of amplification of normal or modified genes, such as the *DDX1* gene on the 12p isochromosome, is currently being investigated.[26] Proto-oncogenes present on the short arm of chromosome 12 could be activated by point mutations, deletions, or translocations to become oncogenes, which could then act in a dominant manner.[27] The *KRAS* gene is located on the short arm of chromosome 12, and amplification or enhanced expression of this gene has been reported to occur in testicular tumors and derived cell lines. Other candidate genes being studied include the *c*-KIT oncogene and its ligand KITGL or SCF, the *c*-MOS oncogene, and the *CCND2* gene. In addition to chromosome 12, 17q is overrepresented in 50% of cases of GCT; this area contains a number of genes of interest, including the *GRB7* gene and the plakoglobin gene.[23]

TABLE 55-1 Three Classifications of Germ Cell Tumors

Dixon and Moore, 1953[30]	WHO Classification[33]	Pugh, 1976[32]
Group I	Seminoma	Seminoma
Seminoma	Spermatocytic seminoma	Spermatocytic seminoma
Spermatocytic seminoma	Embryonal carcinoma, adult-type	Malignant teratoma, undifferentiated
Group II	Teratoma	Teratoma, differentiated
Embryonal carcinoma	Mature	Malignant teratoma, intermediate
Group III	Immature	Yolk sac tumor; orchioblastoma
Teratoma, pure	Teratoma with malignant areas other than seminoma, embryonal carcinoma, or choriocarcinoma	
Group IV	Embryonal carcinoma and teratoma (teratocarcinoma)	
Teratoma with carcinoma or sarcoma	Infantile embryonal carcinoma	
Group V	Polyembryoma	
Teratoma with embryonal carcinoma or choriocarcinoma		

but it is somewhat higher in men with impaired fertility (0.5%) and in those with cryptorchid testes (2% to 4%).[19]

Seminomas

Seminoma, the most common type of testicular GCT, is most often seen in the fourth decade of life. On gross examination, the tumors are usually well demarcated from the residual testicular tissue and rarely have foci of necrosis or hemorrhage. On microscopic examination, the classical or typical seminoma type is made up of large cells with abundant cytoplasm divided by connective tissue septae into sheets or cords.[37] These cells typically have round, hyperchromatic or vesicular nuclei with prominent nucleoli. Frequently, there is a lymphocytic infiltrate, and macrophages, plasma cells, and multinucleated giant cells are often present. Syncytiotrophoblasts are present in 15% to 20% of cases, and their presence does not appear to alter the prognosis.

On immunohistochemical testing, virtually all seminomas express placental leukocyte alkaline phosphatase (PLAP) and do not express low-molecular-weight keratins, blood group antigens, or vimentin. Several histologic variants of seminoma have been identified, including anaplastic seminoma and spermatocytic seminoma. Anaplastic seminoma is diagnosed when there are three or more mitoses seen per high-power field.[37] Spermatocytic seminoma is a rare subtype mainly seen in older men and is not associated with CIS or bilateral disease.[36] Also, these tumors do not stain for PLAP on immunohistochemical testing and rarely, if ever, metastasize. An atypical variant of seminoma with some features similar to those of NSGCT on immunohistochemical examination has been reported, although its morphologic appearance is similar to that of classical seminoma.[38] Usually, there is little or no lymphocytic infiltrate and the tumor cells have less cytoplasm than classical seminoma cells. In terms of prognosis, this atypical variant appears to have the same prognosis as classical seminoma.

Nonseminomatous Germ Cell Tumors

Nonseminomatous tumors make up 40% of TGCCs and occur most commonly in the third decade of life. In the WHO classification system, NSGCTs include embryonal carcinoma, teratoma (mature, immature, or with malignant differentiation), choriocarcinoma, yolk sac tumor, and mixed GCTs. Most tumors are mixed, with two or more cell types present. Although some tumors have a component of seminoma, the association of seminoma within a histologically confirmed NSGCT has no major impact on the clinical outcome.[39]

Patients with combined tumors present at an age (median, 33 years) intermediate between those with seminoma (median, 36 years) and those with non-seminoma (median, 27 years).[39]

On gross examination, there is usually a soft irregular mass poorly demarcated from the surrounding testicular tissue, and a considerable amount of necrosis and hemorrhage is often present. Immunohistochemical studies usually demonstrate cytoplasmic expression of low-molecular-weight keratins in embryonal carcinomas, and yolk sac elements, low-molecular-weight keratin, or vimentin expression in mature teratomas.

Pathways of Spread

Direct extension of tumor into the epididymis, through the tunica vaginalis, into the spermatic cord (T3), and rarely into the scrotum (T4) may occur. Locally extensive tumors are rare, however.

Lymphatic spread is the most common route of metastatic spread. The lymphatic drainage of the testis is directly to the paraaortic lymph nodes. There are differences in the distribution of metastases from left or right testicular tumors. The left testicular vein drains to the left renal vein, and the lymphatic drainage is primarily to the lymph nodes in the paraaortic area, directly below the left renal hilum. On the right side, the testicular vein drains directly to the inferior vena cava below the level of the renal vein, and, therefore, paracaval and interaortocaval nodes are the first ones to be involved in right-sided tumors. Figure 55-1, *A* and *B*, shows the distribution of retroperitoneal lymph node metastases in NSGCT and seminoma.[40,41] Contralateral nodal involvement occurs in approximately 15% of cases and is rarely found in the absence of ipsilateral involvement. Supradiaphragmatic spread can occur through the thoracic duct, and although left supraclavicular nodal disease is infrequent at presentation, it is often seen at the time of relapse.

Pelvic and inguinal lymph node involvement is rare (<3%). Factors predisposing to inguinal lymph node involvement include prior scrotal or inguinal surgery, scrotal orchiectomy with incision of the tunica albuginea, tumor invasion of the tunica vaginalis or lower third of the epididymis, and cryptorchid testis.[42,43] Disruption of lymphatic vessels in the spermatic cord during inguinal surgery has been shown to induce anastomoses between the testicular lymphatic vessels and the regional lymphatics destined for inguinal or pelvic lymph nodes. In an occasional patient, a connection with the contralateral inguinal lymph nodes may be established, but this is uncommon. In a small proportion of patients with inguinal relapse, no predisposing factors may be apparent.[42]

In patients with NSGCTs, hematogenous spread occurs early in the course of the disease. The lung parenchyma is the commonest site of hematogenous spread, but liver, bone, brain, kidney, and gastrointestinal metastases are also seen. In a review of over 5000 patients with metastatic GCT,

Teratomas are tumors composed of cells derived from two or more of the germ cell layers (ectoderm, mesoderm, or endoderm). When one of the component tissues in any of the types of teratoma exhibits the histologic appearance of another malignant tumor, such as sarcoma or carcinoma, the term *teratoma with malignant transformation* is used.

Choriocarcinomas are tumors composed of both multinucleated syncytiotrophoblasts and mononuclear cytotrophoblast cells. Pure choriocarcinoma is rare and is usually associated with widespread metastases, high levels of β-HCG, and a poor prognosis. Elements of choriocarcinoma are found in up to 10% of NSGCTs and do not appear to affect the prognosis.

Yolk sac tumor, also known as endodermal sinus tumor, is composed of cells that usually produce AFP and resemble those seen in the yolk sac in an embryo. Pure yolk sac tumors are rare but are the most common variant of childhood GCT. Elements of yolk sac tumor are found in up to 50% of NSGCTs.

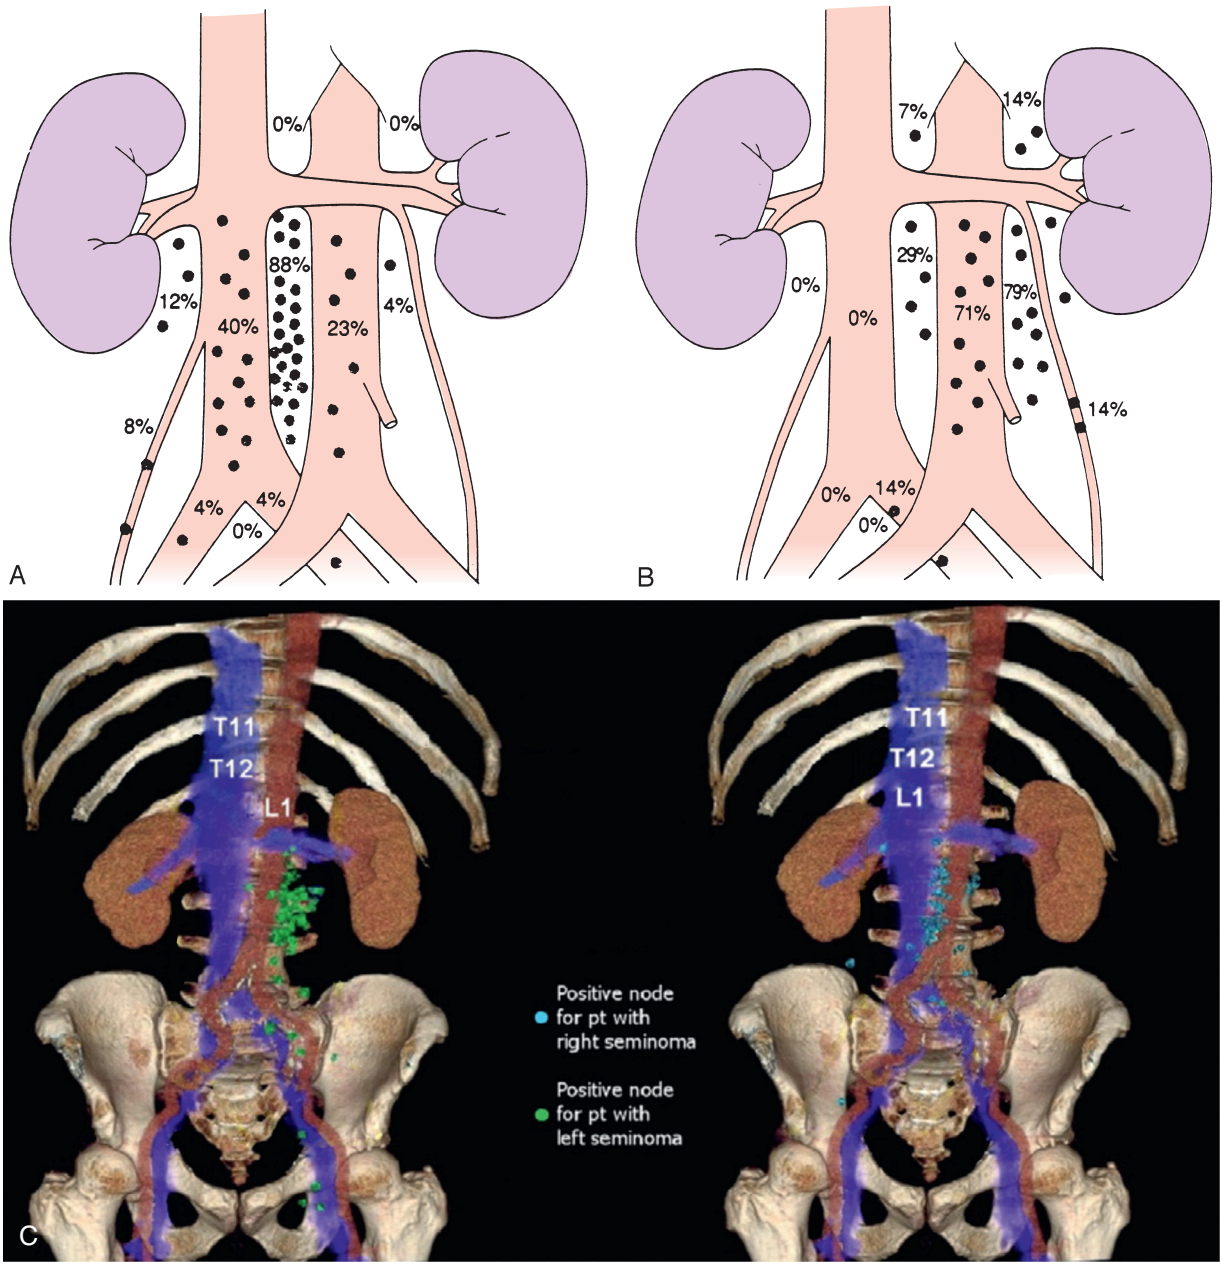

Figure 55-1 Distribution of retroperitoneal lymph node metastases in early-stage testicular non-seminoma germ cell tumor. **A,** Right testis primary tumor. **B,** Left testis primary tumor. **C,** Distribution of retroperitoneal lymph node metastases in early-stage testicular seminoma germ cell tumor. *From Paly J, Efstathoiu J, Hedgire S, et al: Mapping patterns of nodal metastases in seminoma: Rethinking radiotherapy fields. Radiother Oncol 106:64–68, 2013. Copyright © Elsevier.*

pulmonary metastases were present in 44% of cases and liver metastases in 6% of cases, with all other areas of hematogenous spread present in 1% or less of cases.[44] Mediastinal and neck node involvement was present in 11% to 12% of cases.

CLINICAL PRESENTATION, PATIENT EVALUATION, AND STAGING

Clinical Presentation

Testicular cancer most commonly present with a painless mass but up to 45% of patients may have testicular pain, where up to 25% have signs and symptoms suggestive of acute epididymitis. Symptoms and signs suggestive of metastatic disease such as back pain, dyspnea, and gynecomastia (from malignant tumors that produce HCG) is a much less common presentation. Patients with high HCG levels (up to 3.5% of patients) may have hyperthyroidism as a result of stimulation of the thyroid by the alpha subunit of HCG, which behaves identically to thyroid-stimulating hormone (TSH).[45] Various benign conditions including torsion, hydrocele, varicocele, spermatocele, and epididymitis should be considered in the differential diagnosis of a testicular mass (in addition to tumor). Transillumination of the testis on examination does not rule out a diagnosis of malignancy as a small percentage of tumors are associated with a hydrocele.

Patient Evaluation

A solid mass is detected on physical examination or by ultrasonography should prompt a diagnostic and therapeutic radical orchiectomy when there is no obvious evidence of metastasis. Preoperative measurement of serum tumor markers, including AFP, β-HCG, and LDH should be done to allow monitoring of decay with treatment. Staging investigations are usually performed after the histologic diagnosis is confirmed, except for some patients who present with life-threatening advanced metastatic disease where systemic therapy may be instituted based on a clinical diagnosis and unequivocal abnormality of AFP and β-HCG levels. In such cases, pathology may be obtained via needle biopsy or held until orchiectomy, after chemotherapy has been completed.

Staging investigations include chest x-ray, CT scans of the chest, abdomen, and pelvis, and tumor markers. For patients with seminoma and absence of retroperitoneal lymph node involvement, thoracic CT scans add little value. Bipedal lymphography for staging is of historical interest only; however, magnetic resonance imaging (MRI) with lymphotrophic nanoparticles has shown some promise but further data is required to be able to evaluate its role in routine clinical practice.[46] In stage II and III seminomas, especially in patients with bulky retroperitoneal disease, a bone scan may be performed. Abnormal serum marker levels should be monitored to document postorchiectomy decay according to their respective half-lives. Patients with extensive metastatic disease, nonpulmonary visceral metastases (NPVMs), or high tumor marker levels (especially HCG) are at risk for brain metastases, and CT or MRI (preferably) of the brain should be performed.[47] Baseline pulmonary and renal functions are assessed in patients who require chemotherapy.

Tumor Markers

Measurements of AFP, β-HCG, and LDH are essential in the diagnosis and management of patients with GCTs.[48] HCG is a glycoprotein with a molecular weight of 45,000 daltons, composed of two subunits, of which the α-subunit is identical to that of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and thyroid-stimulating hormone (TSH), and a distinct β-subunit. HCG is normally produced by the placenta. About 15% of patients with seminoma have elevated β-HCG levels. Low levels of β-HCG may be found in other neoplasms, including prostate, bladder, and renal tumors. The use of marijuana derivatives also may lead to elevated levels. Because of the possible cross-reactivity with LH, and in cases where an elevated HCG level is thought to be the result of this cross-reactivity, consideration should be given to having levels remeasured after treatment with testosterone.[49] The half-life of β-HCG in blood is approximately 22 hours. In the subset of patients with GCT with elevated HCG, the level of HCG reaches a plateau after the fourth cycle of chemotherapy and is considerably greater than normal. Such persistent HCG levels may not be an indication for salvage therapy because of the possibility of tissue binding of HCG, which slows the decay of serum levels.[47]

AFP is the major serum protein of fetal life. It is a glycoprotein of molecular weight 70,000 daltons. In addition to being elevated in nonseminomatous GCTs, it is elevated in hepatocellular carcinoma, cirrhosis, and hepatitis and during pregnancy. The half-life of AFP is approximately 5 days. AFP is not found in pure seminoma; its elevation in this setting implies the presence of nonseminomatous tumor elements and in those patients is considered to have non-seminoma regardless of the pathologic subtyping seen in the tissue. Liver disease should be considered in the differential diagnosis in patients whose disease appears to be responding and in whom the AFP level fails to fall appropriately or is found to be increasing.

One or both of these markers are elevated in 85% of patients with nonseminomatous GCTs. However, normal markers do not exclude the presence of clinically occult disease.[50]

LDH is another important marker in patients with GCTs. It is elevated in up to 60% of patients with non-seminomas and also in a high proportion of patients with advanced seminomas, but it is the least specific of the three recognized tumor markers in GCTs.[44,51]

Both AFP and β-HCG levels are useful in the diagnosis of malignancy when measured before orchiectomy with the rate of decline (after orchiectomy) indicating the likelihood of residual tumor. Tumor marker levels may be used to assess response to treatment, to predict the likelihood of achieving complete remission, and in regular follow-up to indicate relapse, this is often in the absence of symptoms, physical findings, or abnormal imaging studies.

PLAP is an isoenzyme of alkaline phosphatase and is normally expressed by placental syncytiotrophoblasts. It is also expressed by testicular tissue and has been investigated as a tumor marker in seminoma. Although PLAP levels are often elevated in patients with seminoma, this factor has proven to be of little practical value.[52]

Staging

The 2009 American Joint Committee on Cancer/International Union Against Cancer (AJCC/UICC) TNM classification (Table 55-2) is the recommended staging system. In stage I disease, one of the most important determinants of outcome is the presence of vascular invasion in the primary tumor (particularly in non-seminoma), and this differentiates a pT1 tumor from a pT2 tumor.[53] Tumors with invasion of the spermatic cord are staged as pT3 cancers, and the rare tumors with scrotal invasion are classified as pT4 lesions.

In stage II disease, the extent of retroperitoneal adenopathy and serum tumor marker level determines treatment and outcome. Patients with retroperitoneal lymph nodes less than 5 cm in diameter (N1/N2 disease) are often successfully treated with regional therapy, either RPLND in NSGCTs or external beam radiation therapy (EBRT) in seminomas; however, those with nodal disease greater than 5 cm in diameter have a high risk of distant failure following regional therapy and are usually treated with systemic chemotherapy.

With the current use of cisplatin-based chemotherapy, the survival rate of patients with metastatic testicular tumors is excellent, although a minority of patients still die of testicular cancer despite treatment.

The International Germ Cell Cancer Collaborative Group (IGCCCG) analyzed data from 5168 patients with advanced disease.[44] Independent prognostic variables identified by the IGCCCG were included: histologic type (non-seminoma versus seminoma), site of the primary tumor (testis, retroperitoneal site, or other), presence or absence of nonpulmonary visceral metastases (NPVMs), for example, brain, bone, or liver, and degree of marker elevation (AFP, β-HCG, and LDH). Based on the results of multivariate analysis, the IGCCCG recommended prognostic groupings for patients with metastatic disease. For nonseminomatous cancers, the 5-year OS for the good-prognosis group was 92%, for the intermediate-prognosis group, 80%, and for the poor-prognosis group, 48%. For seminoma, a good-prognosis group without NPVMs had a 5-year OS of 86% and an intermediate-prognosis group with NPVMs with a 5-year OS of 72%. This classification system has been validated by van Dijk et al[51] using Cox regression analysis and recursive partitioning in a cohort of 3048 patients with NSGCT.

TABLE 55-2 Staging of Testis Tumors by the American Joint Committee on Cancer (AJCC)

Primary Tumor	
(The extent of primary tumor is classified after radical orchiectomy)	
pTX	Primary tumor cannot be assessed. (If no radical orchiectomy has been performed, TX is used.)
pT0	No evidence of primary tumor (e.g., histologic scar in testis)
pTis	Intratubular germ cell neoplasia (carcinoma in situ)
pT1	Tumor limited to the testis and epididymis without vascular/lymphatic invasion. Tumor may invade into the tunica albuginea but not the tunica vaginalis
pT2	Tumor limited to the testis and epididymis with vascular/lymphatic invasion, or tumor extending through the tunica albuginea with involvement of the tunica vaginalis
pT3	Tumor invades the spermatic cord with or without vascular/lymphatic invasion
pT4	Tumor invades the scrotum with or without vascular/lymphatic invasion
Regional Lymph Nodes (N) Clinical	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis with a lymph node mass 2 cm or less in greatest dimension; or multiple lymph nodes, none more than 2 cm in greatest dimension
N2	Metastasis with a lymph node mass, more than 2 cm but not more than 5 cm in greatest dimension; or multiple lymph nodes, any one mass greater than 2 cm but not more than 5 cm in greatest dimension
N3	Metastasis with a lymph node mass more than 5 cm in greatest dimension
Pathologic Lymph Nodes (pN)	
pNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	Metastasis with a lymph node mass 2 cm or less in greatest dimension and five or fewer nodes positive, none more than 2 cm in greatest dimension
pN2	Metastasis with a lymph node mass more than 2 cm but not more than 5 cm in greatest dimension; or more than five nodes positive, none more than 5 cm; or evidence of extranodal extension of tumor
pN3	Metastasis with a lymph node mass more than 5 cm in greatest dimension

Distant Metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
M1a	Nonregional nodal or pulmonary metastasis
M1b	Nonpulmonary visceral metastasis
Serum Tumor Markers (S)	
SX	Marker studies not available or not performed
S0	Marker study levels within normal limits
S1	LDH <1.5 × N *and* HCG (mIU/mL) <5000 *and* AFP (ng/mL) <1000
S2	LDH 1.5-10 × N *or* HCG (mIU/mL) 5000-50,000 *or* AFP (ng/mL) 1000-10,000
S3	LDH >10 × N *or* HCG (mIU/mL) >50,000 *or* AFP (ng/mL) >10,000
	N indicates the upper limit of normal for the LDH assay

Stage Grouping				
Stage 0	pTis	N0	M0	S0
Stage I	pT1-4	N0	M0	SX
Stage IA	pT1	N0	M0	S0
Stage IB	pT2	N0	M0	S0
	pT3	N0	M0	S0
	pT4	N0	M0	S0

PRIMARY THERAPY

The initial management involves a radical inguinal orchiectomy in almost all cases except for the uncommon life-threatening presentation in which systemic treatment is urgently needed. Postorchiectomy management is based on the histologic type and extent of disease. The management policies for both seminomatous and nonseminomatous tumors have evolved separately but mirror each other quite closely, with the exception of the use of EBRT in early-stage seminoma and RPLND in non-seminoma. Sperm testing and banking should be considered before treatment with chemotherapy, RPLND, and EBRT because of potential effects on fertility.

Surgery

Surgery involves a radical inguinal orchiectomy to allow high division of the spermatic cord. Orchiectomy offers cure in a high proportion (60% to 90%) of patients with stage I disease.[20,54] Although not recommended, a transscrotal approach does not appear to compromise the outcome, provided that the scrotal cavity has not been grossly contaminated by tumor during surgery. In patients with life-threatening metastatic disease and a clear-cut diagnosis of germ cell malignancy, initial management is with chemotherapy and surgery is postponed until completion of systemic treatment.[20,54] The role of partial orchiectomy in patients with metachronous or synchronous bilateral tumors will be discussed later.

Seminoma

Most patients present with stage I disease (70% to 80%); stage II disease is found in 15% to 20%; and stage III disease in 5% of cases. Of the predicted 4700 cases of seminoma in the United States in 2013, 3700 were expected to present as stage I disease.

In stage I seminoma, historically, adjuvant retroperitoneal RT was the most widely applied treatment in postorchiectomy management. RT provided excellent long-term results, with local control in the abdomen and pelvis in virtually all patients. However, it is now known that more than 85% of patients are cured with orchiectomy alone and RT has been associated with an increased risk of late gonadal toxicity, development of secondary malignant tumors, and perhaps an increased risk of cardiovascular disease.[55-60] With this knowledge and also the excellent salvage rates with cisplatin-based chemotherapy, the use of adjuvant RT became questionable. Attempts at minimizing RT-associated morbidity included a reduction in radiation dose and treatment volume, surveillance (avoidance of adjuvant therapy and treating only on evidence of relapse), and adjuvant chemotherapy.[61-65] Of these options, surveillance is now the standard approach, minimizing the burden of treatment while maintaining the cure rate at 100%.[66-68]

For stage II disease, retroperitoneal irradiation is effective and is recommended for patients with nonbulky tumor (stage IIA to IIB), whereas chemotherapy is the treatment of choice for patients with more advanced disease. RPLND is usually reserved for rare situations where neither of the other treatments is possible.

In stage III disease, chemotherapy is the treatment of choice.[20,54]

Management of Stage I Seminoma

Surveillance

Mature series of patients managed with surveillance have reported relapse rates of 15% to 24% (Table 55-3) (also see references 62, 67, 68, 71-73). A large experience of surveillance spanning a period of 24 years (1984 to 2007) was from Denmark using cancer registry linked data with median follow up of 15.4 years, the crude relapse rate was 19.5% (355 of 1822 patients).[69] Similarly, in the Princess Margaret Hospital (PMH), Toronto, series of 484 patients, median follow-up was 6.6 years, crude relapse rate was 15%.[68] The other studies with adequate follow-up (>36 months) have reported similar relapse rates. The predominant site of relapse in all studies was the paraaortic lymph nodes (82% in the Danish Testicular Cancer Study Group [DATECA] study and 89% in the PMH series.[67,68] The median time to relapse ranged from 12 to 18 months, but late relapses (>2 years, 4% and >5 years, 1.4%) have been reported.[69,70]

A number of single institution studies reported prognostic factors for relapse, such as age, primary tumor size, and small vessel invasion were predictive of relapse for surveillance patients. Based on these studies an attempt to further refine a prognostic model based on these factors was undertaken by a pooled analysis of four large surveillance data sets.[74] Tumor size and rete testis invasion predicted for relapse on multivariable analysis in 638 patients managed by surveillance. The effect of tumor size on the relapse rate is shown in Figure 55-2, and the hazard ratio for relapse with a tumor size of more than 4 cm was 2 (95% CI, 1.3 to 3.2) relative to baseline (tumor size <4 cm and no rete testis invasion). The high-risk group had up to 35% risk of relapse. The model was not fully validated in an independent dataset analysis of 685 patients, but similar to

the previous study; larger primary tumors were associated with an increased risk of relapse, whereas median tumor size (>3 cm) was associated with a hazard ratio of 1.87.[75] The more recent analysis of national data from Denmark also confirmed the prognostic value of tumor size but small vessel invasion and HCG elevation >200 IU were also found to be predictive for relapse.[69]

Management options at relapse include irradiation and cisplatin-based chemotherapy. Most patients who relapse while on surveillance are initially treated with retroperitoneal RT and have an associated 10% incidence of second relapse after RT.[76] The likelihood of detecting early progression in the retroperitoneal lymph nodes (nodes <5 cm) and, therefore, suitability of the patient for RT depends on the frequency of follow-up CT scans of the abdomen and pelvis.

The current PMH follow-up policy is shown in Table 55-4. Reducing the frequency of imaging such as chest radiographs and eliminating routine measurement of serum tumor markers has simplified the protocol. There appears to be limited value to routinely including these tests in surveillance protocols because chest radiographs most often were negative in the absence of retroperitoneal nodal relapse and serum tumor markers heralded few relapses in advance of detectable macroscopic disease.[77,78]

One of the concerns regarding the routine use of surveillance was the potential for an increased burden of treatment because of the need for more patients requiring subsequent chemotherapy particularly if first treated with RT in the relapse setting. There seems little to base these fears on as a similar proportion of patients managed with surveillance (4.3%) and adjuvant RT (3.6%) required subsequent chemotherapy as part of their management.[68]

Surveillance does lead to an increased number of imaging studies (most commonly CT scans) during follow up and there are concerns that this might increase the rate of radiation-associated cancers. There is no concrete data available that quantitates the risk of radiation-induced cancer from CT scanning. Estimation of these risks has been derived from long-term follow-up data from survivors of the atomic bombings of Hiroshima and Nagasaki who received low-dose radiation akin to that for medical imaging.[79] The methodologic issues related to these estimations mean that there is doubt as to the accuracy of the data. However, in the pediatric setting there does appear to be some epidemiologic evidence supporting a small increase in the risk of leukemia and brain tumors related to diagnostic radiation.[80] Another epidemiologic study that attempted to estimate radiation-induced cancers in patients with stage I testicular cancer surveillance found no excess cancers in the time period studied but the relatively short follow up in the adult setting may have lead to an underestimation of the risk.[81] The seminoma surveillance population may conceivably be at some risk of radiation-induced cancer, given the young age of many patients and the use of repeated CT scans of the abdomen. Thus, attempts to decrease the frequency of imaging, the use of low-dose CT in surveillance protocols and nonionizing imaging such as MRI to decrease overall exposure is currently under way.[82,83] Currently MRI is not routinely recommended until results of studies become available, although it should be noted that some centers, mainly in Scandinavia, have already adopted this as their standard approach.

Radiation Therapy

OS ranges between 92% and 99% at 5 to 10 years, with the cause-specific survival (CSS) approaching 100%. Although most deaths are the result of intercurrent illness, some premature deaths may be as a result of radiation-induced cancers or possibly cardiac disease.[55,59] Relapse rate after RT has varied from 0.5% to 5%[84-88] (Table 55-5). Wherever local recurrence in-field in suspected, because of its rarity, a biopsy to rule out a nonseminomatous tumor or another malignant tumor is generally recommended. The commonest sites of relapse following adjuvant RT are the mediastinum, lungs, and left supraclavicular fossa. A small proportion of patients, many with predisposing factors, develop relapse in the inguinal nodes. Uncommon sites of isolated metastases such as the brain and tonsils have been noted but are unpredictable.[89,90] For supradiaphragmatic relapse, chemotherapy results in virtually 100% cure rate. Isolated inguinal relapse may be treated successfully with RT alone.[88]

Relapse after adjuvant RT most frequently occurs within the first 2 to 3 years with the occasional relapse beyond this time frame. In the PMH series of 282 patients treated between 1981 and 1999, the median time to relapse was 18 months, with the latest relapse occurring at 6 years. Thus, follow-up policy is concentrated in this early time period and frequency of clinic visits is similar to efforts for patients during surveillance, with the exception that CT of the abdomen and pelvis does not need to be performed because of the exceedingly low risk of local recurrence in the retroperitoneum after adjuvant RT.

Prognostic features that may predict relapse in this group are difficult to ascertain primarily because of the low event rate. The presence of anaplastic seminoma was thought be one possible factor associated with an increased relapse risk,[88] but the WHO criteria for this diagnosis (three or more mitoses per high-power field) are not uniformly used, and contradictory data exist that suggests no difference in relapse between anaplastic and classical histologies.[92] Other features associated with a higher risk of relapse may include tumor invasion of

The more frequent follow up within the first 3 years allows earlier detection of disease relapse in about 90% of those who are destined to relapse. Thereafter only a small proportion of patients will relapse and the frequency of follow up is reduced accordingly. CT thorax is not routinely recommended given the rare instance of chest only relapse but is done to determine extent of disease whenever abdominal relapse occurs.

the tunica albuginea, lymphovascular invasion, invasion of the epididymis, raised preoperative HCG levels, and spermatic cord involvement.[84,88]

Adjuvant Chemotherapy

Seminoma is highly chemosensitive and cures are routinely achieved even in advanced disease settings, thus adjuvant carboplatin has been investigated as an alternative strategy to RT or surveillance in stage I disease. The use of single agent carboplatin after orchiectomy was initially pioneered by Oliver et al[93] in 78 patients, of whom 53 patients had two courses and 25 had one course. Only one patient relapsed with median follow up of 44 months. Relapse rates of 0% to 8.6% have been reported in other Phase II studies with some of the variability in results explained by the method of calculation of the dose of chemotherapy delivered.[94]

In a Phase III noninferiority study design, the United Kingdom Medical Research Council (MRC UK) compared adjuvant RT and a single course of carboplatin (dose calculated with area-under-the-curve [AUC] method) in 1477 patients.[95] The relapse free rates at 5 years were similar, 96% for RT and 94.7% for carboplatin.[96] Relapses in the carboplatin arm occurred largely in the retroperitoneal lymph nodes and similar to adjuvant RT, relapses beyond 3 years was uncommon.[97] A possible benefit of adjuvant carboplatin that was noted was the lower incidence of second primary testicular germ cell tumors, although it is not clear whether the occurrence is eliminated or just delayed.[65] Overall relapse risk may be reduced by higher doses of carboplatin (using the AUC formula) as such patients had lower relapse rates.[98]

Data from other single-institution series indicate that if adjuvant carboplatin is given in this setting, then two courses of treatment may lower the relapse risk further and is consistent with the previous dose-related data.[61,99] Unfortunately, despite the increased dose, small but significant percentage of patients develop relapse in the retroperitoneum, and the usefulness of this approach is uncertain.[61,99] The concept of giving single course, minimally toxic chemotherapy leading to a virtually zero relapse rate allowing patients to be discharged from follow-up with no risk of relapse has not materialized. In addition, the relapse pattern dictates continued surveillance of the retroperitoneal lymph nodes (similar to a surveillance policy albeit with reduced frequency), and although a relative reduction in relapse rates of two thirds is impressive, the absolute reduction of 10% (15% with surveillance and 5% with adjuvant chemotherapy) and small numbers of patients that this affects is less so. Regardless in an adjuvant setting, 85% of patients receive treatment that has no direct benefit, and any long-term toxicity is as yet not fully characterized.[65]

Retroperitoneal Lymph Node Dissection

There is minimal literature about the routine use of RPLND in seminoma. It is a seldom used approach but may be appropriate for patients unwilling to comply with surveillance or unable or unwilling to be treated with RT or carboplatin (e.g., inflammatory bowel disease). RPLND may also be appropriate in patients with a concurrent or previous malignant tumor for whom histologic examination of the lymph nodes is essential to plan treatment.

Overview of Management of Stage I Seminoma

Stage I seminoma is almost universally curable regardless of the approach after orchiectomy. The main advantage of surveillance is the ability to limit further treatment to those who will require it without compromise in survival. The disadvantage is that surveillance requires a commitment to more intense and potentially prolonged follow-up from both patients and clinicians compared to an adjuvant treatment approach. Studies into long-term effects of RT have now documented that patients with seminoma treated with irradiation have an increased risk of second malignant tumors and also the possible risk of developing cardiac disease, and such factors should be considered in management decision making.[55,57,58,100,101]

Patients' role in directing their particular management should likely take precedence and surveillance should be offered as a first choice.[102,103] These preferences may be based on many socioeconomic factors as well as the toxicity associated with adjuvant therapy. Also, the identification of prognostic and molecular factors for occult disease may allow patients and clinicians to adopt a more individualized approach based on a more accurate assessment of risk of relapse.[103,104]

Management of Stage II Seminoma

Stage II disease is usually classified as involvement of paraaortic (and much less frequently pelvic) nodes. These abnormalities are most frequently detected radiologically, and stage II patients are approximately 15% to 20% of patients presenting with seminoma. Patients historically have most often been divided into three groups depending on the transverse diameter of the largest retroperitoneal lymph node mass (≤2 cm, stage IIA; 2.1 cm to 5 cm, stage IIB; and >5 cm, stage IIC), but currently the categories are based on the largest measurement regardless of dimension. Thus, it is possible that over time some of the differences in reported outcomes (i.e., relapse rates), particularly for patients treated with primary RT may have occurred. Approximately 70% of stage II patients have small-bulk retroperitoneal disease at presentation with lymph nodes that are 5 cm or less. Because of the relatively small number of patients in this group, randomized controlled trials have been extremely difficult to accomplish and management has been largely directed by data published from single institutions.

The most important prognostic factor in stage II seminoma (treated with RT) is the bulk of retroperitoneal disease, this as previously mentioned in historic series was often defined by the transverse diameter of the largest lymph node mass visible on CT scanning. It was the only prognostic factor for relapse in a consecutive series of 95 patients with stage II seminoma treated with RT at the PMH between 1981 and 1999.[105] The 5-year relapse-free rate in 79 patients with stage IIA or IIB disease was 91%, compared with 44% in 16 patients with stage IIC disease. Relapse occurred most commonly in mediastinal or supraclavicular lymph nodes, lung, or bone. These results are similar to other series in the literature (Table 55-6) of primary RT in patients with stage IIA or IIB. In a more recent cohort of patients treated at PMH (1995 to 2010), relapse rates have remained at about 10% for patients treated with primary RT.[76] Of 106 patients treated, 49 had stage IIA/B and 57 had retroperitoneal nodal relapse under 5 cm size and the majority (n = 87) were treated with RT with a resultant 5-year relapse rate of 9%. These data support the continued use of RT in this setting.

In stage IIC disease, chemotherapy is recommended. In more recent years, there has been a tendency for larger number of patients even with lower bulk retroperitoneal disease to be treated with chemotherapy.[100,109]

Management decisions, however, should not be based solely on substage of disease; overall tumor bulk, location of disease relative to normal tissue, and anatomic variants must also be considered. Patients with cranial caudal extent of disease in multiple single nodes each smaller than 5 cm may be classified as stage IIB disease, but such a patient should be treated with chemotherapy because of the overall bulk of disease and the possibly higher risk of distant relapse if RT was used. The necessity of irradiating a large volume of

adjacent renal or hepatic tissue when nodal disease is lateralized or has extensive transverse diameter and other anatomic situations such as a horseshoe, or pelvic kidney usually lead to unacceptable risk of irreversible long-term toxicity. Such circumstances are where chemotherapy would better serve these patients. It should be noted that cisplatin-based chemotherapy may also be associated with toxicity and, in some rare instances, mortality because of unforeseen toxicities such as cardiovascular deaths and not necessarily directly related to the usual expected toxicities of chemotherapy.[110-112] In the unusual situation where the patient has contraindication to both RT and chemotherapy, RPLND may be considered.

The commonest sites of relapse following RT in patients with stage II disease are mediastinal or supraclavicular nodes, lung, and bone. Most relapsing patients are cured with chemotherapy, which emphasizes the importance of regular follow-up with clinical examination and chest x-ray after RT. CT imaging of the abdomen and pelvis is not necessary after complete resolution of abdominal disease.

Carboplatin with RT in stage IIA or IIB seminoma has been used at the Royal Marsden Hospital in 51 patients (of whom 8 had stage I seminoma relapse on surveillance) treated with one course of carboplatin 3 to 6 weeks before RT.[113] The median follow up was 55 months and there had been no relapses, the 95% confidence interval for relapse free survival was 93% to 100%. This approach is interesting and currently under investigation in a Swiss Phase II multiinstitutional study with a smaller volume of RT compared to the Marsden experience.[114]

The technique of irradiation in stage II seminoma is similar to that used in stage I disease and is discussed later in this chapter.

Residual Retroperitoneal Mass

Following treatment, imaging of the abdomen in done until complete resolution of disease is observed. Persistent masses that are stable usually contain fibrotic or necrotic tissue, but occasionally even with pure seminoma primary tumors, a non-seminomatous component within the metastatic disease needs to be considered. However, surgical resection in this setting, often routinely undertaken for non-seminoma, is fraught with technical challenges and also associated morbidity.[115]

Observation of residual masses is an option, particularly if regressing; if disease is suspected, surgical resection may be undertaken or RT may be used to control active disease. PET imaging to help with decision making is controversial in this setting because of false-positive results that may occur, and the decision to treat the residual mass should not be based on a positive PET image alone.[116-118]

There is limited experience of surgical excision in this setting as it occurs with less frequency than residual mass in non-seminoma. Even large experiences may be gathered over a number of years such as that published by the Memorial Sloan Kettering Cancer Center (MSKCC) group where 55 of 104 patients had residual mass following chemotherapy.[119] A substantial minority, 23 (42%), had only intraoperative biopsy because their disease was not resectable; the remaining 32 (58%) did undergo RPLND. Of 27 patients with mass more than 3 cm, 8 (30%) had viable disease (of whom 2 actually had teratoma pathology), whereas no patients with mass smaller than 3 cm had viable tumor. Six of the 8 patients with viable disease remained relapse-free at 47 months of follow-up, the other 2 patients had poorly defined masses on CT scans, died of disease. MSKCC investigators concluded that resection or at least biopsy of masses of 3 cm or larger should be performed. Culine and Droz from the Centre Léon-Bérard in France[120] have recommended an alternative strategy of continued observation as long as the retroperitoneal mass continues to decrease in size after treatment.

Consolidation of treatment with RT localized to the mass was historically used in the postchemotherapy setting. This notion was challenged by Horwich et al[121] who found that the relapse rate was similar whether RT or observation was performed. In addition, the MRC Testicular Tumor Working Party published a retrospective pooled analysis that examined the role of RT for postchemotherapy residual masses among men with seminoma.[122] Of 123 patients with a residual abdominal mass, 56% received consolidative RT. The outcomes reported from this study showed no significant difference regardless of the use of RT, which suggests that routinely applying RT for a postchemotherapy mass should be avoided. Clearly RT in this setting would not be useful for a mass that contains no active tumor or in the setting of distant microscopic disease.

Generally, patients with a residual mass of 3 cm or less may be observed. For those with larger masses, surgery should be a consideration in addition to observation, but should be tailored to the individual situation.

Management of Stage III Seminoma

This uncommon presentation seen in less than 5% of patients with seminoma is usually managed with cisplatin-based regimens (see the section on non-seminoma) and results in high cure rates. Patients with stage III seminoma should be classified according to the IGCCCG system into either the good prognostic group or intermediate prognostic group based on the presence or absence of NPVMs.[44] For patients in the good-prognosis group, three courses of 5-day bleomycin, etoposide, cisplatin (BEP) chemotherapy is considered the standard of care.[100,123] In patients at risk for bleomycin toxicity, four courses of etoposide-cisplatin (EP) is given. For patients with intermediate-prognosis disease, four courses of 5-day BEP is standard.

Non-Seminoma

Since the 1970s, when cisplatin, bleomycin, etoposide, and vinblastine were introduced, non-seminoma has become one of the most curable adult cancers. Before these drugs were available, nonseminomatous tumors were treated with a wide

range of chemotherapeutic agents and there were occasional reports of long-term remissions with the use of single-agent mithramycin and actinomycin D.[124] The modern era in treating advanced disease began at the M. D. Anderson Cancer Center (MDACC) with the use of continuous infusions of bleomycin and vinblastine; at MSKCC with the vincristine plus actinomycin D plus bleomycin (VAB) regimens; and, later, at Indiana University, with the cisplatin plus vinblastine plus bleomycin (PVB) regimen.[125-127] With these regimens, complete responses to treatment became frequent and cures were seen in patients with metastatic disease. The current BEP protocol emerged in the 1990s and is now the standard for first-line chemotherapeutic treatment of metastatic seminoma and non-seminoma.

Management of Stage I Non-Seminoma

The risk of relapse following orchidectomy for Stage I non-seminoma is 25% to 30%. Current treatment options include surveillance with a 30% relapse rate, RPLND with a 10% relapse rate, and adjuvant chemotherapy (most often given only for high-risk patients) with a 1% relapse rate.

The optimal follow-up protocol for nonseminoma surveillance has not been defined. The current National Comprehensive Cancer Network (NCCN) guidelines recommend history and physical examination, tumor marker measurements, and chest x-ray every 2 months, with abdominal and pelvis CT scan every 4 months during year 1 and 4 to 6 months during year 2 for stage IB patients, with less frequent assessments thereafter (see references 53, 62, 125, 126, 129, 131-136).[140] Patients with stage IA disease are also followed on a less intense schedule. It has been suggested that the number of CT scans could be reduced to two, at 3 and 12 months after diagnosis, but this approach has not been widely accepted.[141] There is growing consensus that the optimal CT evaluation schedule may include three to five assessments within the first 2 years of orchiectomy. Given the concern that CT scanning may increase the risk of second malignant tumors, this approach should be explored further. Low-dose CT scanning[83,142] and MRI of the abdomen and pelvis at high-volume imaging centers may be alternatives to reduce cumulative radiation exposure with surveillance imaging.

The OS rate in stage I non-seminoma approaches 100% in most series irrespective of the treatment strategy used.[112] A risk-adapted approach with surveillance for low-risk disease and treatment (either adjuvant chemotherapy or RPLND for patients at a moderate to high risk of occult metastatic disease) has been advocated by some.[147] A surveillance policy, however, is associated with excellent outcomes, and overall, 75% of patients avoid any treatment after orchidectomy.[112,126,148,149] International consensus statements have concluded that all three approaches should be discussed with the patient,[20,54,123] although there is growing support for a universal policy of active surveillance as the preferred approach to reduce the burden of overtreatment.[146] Patients with persistently elevated or rising tumor markers with no radiographic evidence of metastatic disease (Stage IS) are considered IGCCCG good risk and receive treatment with primary chemotherapy with excellent long-term survival.

Management of Clinical Stage II Non-Seminoma

The cure rate for stage II non-seminoma is approximately 98%. Stage IIA disease is managed with cisplatin-based chemotherapy alone or RPLND plus chemotherapy (both <5% relapse rate), and stage IIB or IIC disease is managed with cisplatin-based chemotherapy, with a 5% relapse rate.

For patients with pathologic stage IIA or IIB disease, the risk of relapse with no adjuvant treatment after surgery is 30% to 50%.[123,150] Relapses occur almost exclusively outside the retroperitoneum. Adjuvant chemotherapy with two cycles of BEP in all patients with pathologic stage IIA or IIB disease after RPLND reduces this risk of relapse to 0% to 7%.[151] However, adjuvant chemotherapy represents overtreatment in 50% to 70% of patients with pathologic stage IIA or IIB disease, with resulting treatment-related toxicity and possible late sequelae.

Management of Stage III Disease

Patients with advanced GCTs should always be considered potentially curable. Survival outcomes appear to be better in specialized centers, and this may be related to experience, case selection, volume, or organization of multidisciplinary care. Referral of all patients with advanced GCTs for consultation to a specialized center is strongly recommended

Chemotherapy with or without Retroperitoneal Node Dissection

The standard first-line chemotherapy for all patients is three to four cycles of BEP using a 5-day schedule.[54,123] Modifications in BEP, such as substitution of cisplatin with carboplatin to reduce toxicity or improve convenience, should be avoided because they may reduce efficacy; however, if there is a contraindication to bleomycin, four cycles of EP can be given.

Postchemotherapy radiologic restaging should be performed in all patients 4 to 6 weeks following the final cycle of chemotherapy. If tumor marker decline is seen, as expected, all residual masses should be managed appropriately (see the following section). Only in the case of unequivocal tumor marker rise should salvage chemotherapy be initiated.

Residual Retroperitoneal Mass

In many patients who complete chemotherapy and have normalized tumor markers, residual masses (>1 cm) are seen on imaging. If technically feasible, these masses should be resected 4 to 6 weeks after chemotherapy. On histologic testing, approximately 50% will show necrosis, 35% mature teratoma, and 15% malignant disease.[54] In some centers, RPLND is performed in all cases, even in patients with no residual retroperitoneal disease on imaging. However, there is increasing evidence that observation in patients with complete response after chemotherapy, reserving surgery for those who relapse, gives excellent results and spares many patients unnecessary surgery.[159,160]

Treatment-Related Side Effects

Radiation Therapy Toxicity

RT is generally well tolerated in patients with seminoma partly because of the low doses used in this disease.[111] Nausea and vomiting may occur, but only some patients require regular antiemetics and have fatigue that interferes with activities of daily living. Diarrhea may also occur but usually this is a minority of patients. Severe late radiation complications are unusual but may occur in the patient with underlying medical issues.

Gonadal Toxicity

As the testicular germinal tissue is extremely sensitive to ionizing radiation, it is not surprising that even a small amount of scatter radiation may cause, at minimum, temporary arrest of spermatogenesis. In a series of 451 consecutive patients treated for testicular cancer, RT had a significantly greater deleterious effect on fertility than chemotherapy.[161] Doses between 20 cGy and 50 cGy may produce temporary aspermia, and doses greater than 50 cGy may preclude recovery of spermatogenesis.[162] Scrotal shielding may not eliminate all scatter radiation and thus protection of spermatogenesis is not

The presence of vascular invasion or pure embryonal carcinoma in the primary tumor are associated with a high risk of occult nodal disease. [105,109-111,127-131] Vascular invasion is the most important factor predicting relapse, and the presence or absence of this factor has been used to divide patients into those with high-risk disease (a third of cases), who have an approximately 50% risk of relapse, and those with low-risk disease, who have an approximately 15% to 20% risk of relapse.[53]

In a recent pooled analysis of 1168 patients with clinical stage I non-seminoma managed with active surveillance from six institutions with a median follow-up of 63 months, the overall relapse rate was 22% (256 relapses) with 5-year CSS >99% (six deaths from testicular cancer or treatment).[132] The median time to relapse was 6 months and relapses beyond 2 years from orchidectomy were rarely observed (<5%). Of all relapses, 90% were IGCCCG good risk. At the time of progression, the vast majority of patients were treated with chemotherapy, although RPLND was successfully used in selected cases with small retroperitoneal nodes and negative or low level serum tumor marker elevations. Relapses were more frequently observed in patients who are LVI positive (48% or 117 of 244) compared with patients who are LVI negative (14% or 129 of 903). Relapses occurred earlier (median 5 months versus 8 months) and were more often detected with serum tumor marker elevation ($p < 0.05$) in patients who were LVI positive versus those who were LVI negative. A summary of institutional series of active surveillance for Stage I non-seminoma is provided in eTable 55-1.

RPLND is a recognized alternative to surveillance in clinical stage I disease. A modified unilateral infrahilar RPLND is performed, with nerve-sparing techniques to preserve ejaculation. For right-sided tumors, the interaortocaval nodes and paracaval nodes are removed, with preservation of the left sympathetic chain, and for left-sided tumors, the paraaortic and interaortocaval nodes are removed and the right autonomic chain is preserved. If significant lymphadenopathy is revealed at surgery, a more extensive surgical resection is performed. The relapse rate following surgery is approximately 10% for patients with pathologic stage I disease.[143] Most patients who relapse after RPLND are cured with subsequent chemotherapy.[144]

In some centers, patients with clinical stage I NSGCT at high risk of relapse on surveillance are offered adjuvant chemotherapy with two cycles of BEP or EP chemotherapy.[124] In a recent meta-analysis of one randomized and seven nonrandomized studies of adjuvant chemotherapy, with a total of 873 evaluable patients, 23 relapses (2.6%) were observed.[112] To reduce treatment-related toxicity, a number of studies have tested a single cycle of adjuvant BEP.[145] A recent randomized trial of one versus two cycles of adjuvant BEP chemotherapy for stage I non-seminoma was closed prematurely because of poor accrual.[146] It should be noted that adjuvant chemotherapy does not completely eliminate the need for ongoing clinical and radiological follow-up, although it does reduce the frequency of assessments.

Patients with stage IIA disease with marker elevations (AFP, β-HCG, or LDH) or stage IIB or stage IIC disease regardless of marker status should be treated with chemotherapy according to the algorithms for patients with advanced disease.[54,123] Patients with stage IIA disease with normal or minimally elevated markers have several options. The enlarged nodes may be benign or they may contain teratoma, pure embryonal carcinoma, or mixed tumor elements. In the event of uncertainty about the clinical significant of minimally enlarged nodes, short-term follow-up imaging and tumor marker evaluation to see if the nodes regress without accompanying tumor marker elevation is reasonable. Patients with enlarging nodes or rising markers should receive chemotherapy based on the IGCCG risk classification described in this chapter. Primary RPLND may be considered if there are pathologically enlarged small volume lymph nodes and normal or minimally elevated tumor markers. After RPLND, surveillance or adjuvant chemotherapy may be employed if there are viable germ cell elements.

In patients with IGCCCG good-prognosis disease, three cycles of BEP should be given. If there is a contraindication to bleomycin, four cycles of EP can be given; however, four cycles of EP, however, has been associated with a nonstatistically significant but higher death rate in one randomized clinical trial.[152] Three cycles of BEP with a higher total dose of bleomycin (270 units) and greater dose intensity of etoposide (500 mg/m^2 per cycle) was shown to be superior and less toxic that four cycles of BEP with a lower total dose of bleomycin (120 units) and reduced dose intensity of etoposide (360 mg/m^2 per cycle).[153]

In patients with IGCCCG intermediate- or poor-prognosis disease, four cycles of BEP should be considered the standard therapy.[54,123] The VIP regimen (etoposide, ifosfamide, and cisplatin) has been compared with BEP in this patient population and shows similar outcomes but with more acute toxicity. The VIP regimen represents an alternative to BEP for patients with a contraindication to bleomycin or who develop pulmonary compromise while receiving BEP.[154] The addition of paclitaxel to BEP chemotherapy failed to improved progression-free survival in a randomized clinical trial involving patients with intermediate-risk disease.[155] For patients with intermediate- or poor-prognosis, there is no evidence to date that the use of high-dose chemotherapy with autologous stem cell transplantation is superior to the standard four cycles of BEP.[156,157] A prospective randomized clinical trial has demonstrated that poor-risk patients with unfavorable serum tumor marker decline after 1 cycle of BEP treatment benefitted from dose-intensification of subsequent cycles of treatment compared with standard BEP. However, there was no difference in OS and dose intensification for poor-risk disease is not widely accepted as a standard of care.[158]

Chemotherapy should be given, preferably without dose reductions, even in the setting of a critically ill patient, at 21-day intervals with no delays between cycles. In patients with life-threatening disease, orchiectomy should not delay the initiation of curative therapy and can be performed at the end of therapy. If possible, these patients should be treated in centers with expertise in the management of germ cell tumors. During chemotherapy, assessment of tumor markers before each treatment cycle is essential. As long as tumor markers are declining, a full course of chemotherapy should be completed. If metastases can be seen growing on radiologic examination as tumor marker levels are declining, a diagnosis of growing teratoma syndrome should be considered. In most cases, the full course of chemotherapy should be completed and resection of the residual masses should be done following chemotherapy.

Reduction in fertility appears to have a strong association with testicular cancer as many men who develop testicular cancer may already have a history of subfertility or infertility. However, even with men who have "normal fertility," it is advisable to undertake sperm banking before treatment because there may be a deleterious effect due to therapy and recovery from this may be slow and incomplete. However despite these risks, the majority of men who desired to father children after treatment did so.

universal when using this technique. There has been no evidence to suggest that the incidence of genetic abnormalities in offspring of men previously treated with RT is increased.[163] Although increasing the distance of the testis from the treated volume is expected to reduce scatter dose, this also does not eliminate all dose. However it does appear to have an effect on the length of time to recover normal sperm counts as demonstrated in the MRC randomized trial of paraaortic RT alone versus paraaortic and pelvic RT, where the median time to a normal posttreatment sperm count was 13 months in patients treated to the paraaortic lymph nodes compared to 20 months for patients treated to the paraaortic and pelvic lymph nodes.[63] However, at 3 years, there was no significant difference in sperm counts between the two groups. Testicular shielding is recommended for all patients who wish to retain fertility after treatment.[164]

Cardiovascular Toxicity

Since mediastinal RT has been abandoned, the risk of cardiovascular disease in long-term survivors has decreased. Institutional data from the MDACC and the Royal Marsden Hospital, and population-based data from Norway, however, suggest that long-term survivors of testicular seminoma treated with infradiaphragmatic RT following orchiectomy are at significant excess risk of death as a result of cardiac disease.[55,59,165] Although more recently this notion has been challenged by SEER data that demonstrated no obvious increase in rates in patients treated with RT, the bulk of the published data supports the notion that infradiaphragmatic RT is associated with an increased risk of cardiac mortality.[60] The etiology of the cardiovascular toxicity is currently unclear, but it seems reasonable for patients to be made aware of the data when deciding on whether to undergo adjuvant RT.[166]

Second Malignant Tumor

Second malignant tumors may be induced by RT and a number of studies have been published on this topic. The increased risk is usually expressed more than 10 to 15 years following RT, is often not apparent in series with shorter follow-up times.[167] The largest study of second cancers in long-term survivors of testicular cancer was conducted by Travis et al.[57] This report combined 14 population-based registries including 10,534 patients with seminoma treated with RT. The overall relative risk of a second nontesticular malignant tumor was 2 (95% CI, 1.8 to 2.2). For a 35-year-old man with seminoma, the cumulative 40-year risk of a second malignant tumor was 36%, compared with 23% in the normal population. The increased risk of second malignant tumors after treatment with RT was also shown in a Dutch population-based study of more than 2700 long-term survivors where the risk of a second malignant tumor with subdiaphragmatic RT was 2.6-fold increased as compared with surgery alone.[58] The increased risk associated with irradiation was similar to the increased cancer risk seen with smoking. A recent study from the United Kingdom has confirmed these findings.[101] Limitation of the RT field likely results in a lower risk of second malignant tumors than more extensive fields.

Psychological Toxicity

The issue of psychological morbidity associated with the diagnosis of cancer in young men may result in survivors with a higher level of anxiety and a higher prevalence of anxiety disorders than the normal population, and screening using a simple tool such as the Hospital Anxiety and Depression Scale (HADS) should be part of routine follow-up care.[111,168] Appropriate social support should be offered to patients with testicular tumors. Although highly curable, testicular cancer is still a life-threatening condition in young patients with a concomitant threat of infertility and impaired sexual function as a result of the disease or its treatment.[169]

Chemotherapy Complications

The complications of chemotherapy in testicular GCTs are related to the drugs employed.[111] Nausea and vomiting occur with all the drugs used but are controlled effectively in most patients with 5-hydroxytryptamine receptor-3 (5-HT3) antagonists, steroids, and neurokinin receptor 1 (NK1) antagonists. Myelosuppression is frequent. Febrile neutropenia is seen in about 10% to 15% of patients receiving BEP, and prophylactic hematopoietic growth factors may be considered in some patients at increased risk. Nephrotoxicity, primarily a reduction in the glomerular filtration rate, occurs with the use of cisplatin and ifosfamide. Renal tubule function is normal in most patients, but hypomagnesemia is seen in patients after repeated use of cisplatin. Raynaud phenomenon has been reported in 23% to 49% of patients, although resolution of symptoms is common.[170] Chronic peripheral neuropathy (often asymptomatic) is well recognized after treatment with cisplatin, vinblastine, and etoposide. This symptom may require up to 12 months to 18 months to resolve or may be permanent. Cisplatin-induced hearing loss, particularly at higher frequencies, may occur particular with >400 mg/m^2 of cumulative cisplatin doses. Pulmonary toxicity is seen with the use of bleomycin and can be fatal in a small number of cases.[171] Impaired fertility, which may precede the use of chemotherapy, may also continue after its use. Although chemotherapy also produces infertility, recovery of sperm counts at least to levels compatible with fertility has been observed in the majority of patients.[172] Approximately 75% of patients who attempt paternity after chemotherapy are successful with a strong association with treatment intensity.[173] Hypogonadism is observed is 11% to 35% of long-term survivors (often subclinical), related to the duration of follow-up and the cumulative dose of cisplatin.[109] There is an increased risk of late onset atherosclerotic cardiovascular disease, possibly related to early development of metabolic syndrome (obesity, hyperlipidemia, and hypertension) following cisplatin-based chemotherapy.[174]

Nongerm Cell Testicular Tumors

Leydig Cell Tumors

Leydig cell, or interstitial cell tumors account for less than 2% of testicular tumors.[175] Twenty-five percent occur in children and can present with signs of prepubertal virilization. Seventy-five percent are in patients presenting between the age of 20 and 50 years, usually with a painless testicular mass. Most Leydig cell tumors are benign, and there are no definite histologic criteria for malignancy.[175] The regional lymph nodes are the commonest site of metastatic disease, but lung, bone, and liver metastases have also been reported. The initial management is similar to that for GCTs, with a radical inguinal orchiectomy followed by staging assessment with a chest radiograph and CT scanning of the abdomen and pelvis.[176] Testis-sparing surgery can be considered in experienced hands. Urinary and serum steroids should also be assessed. RPLND can be considered in selected cases.[177] There is no role for adjunctive or definitive irradiation or chemotherapy.

Sertoli Cell Tumors

Sertoli cell tumors account for less than 1% of all testicular tumors.[175] They have been classified into three subtypes: classic, large cell calcifying, and sclerosing.[178] Most present with a painless testicular mass, and initial management is with a radical inguinal orchiectomy. Both precocious puberty and feminization have been reported to be associated with Sertoli

cell tumors in children. Most Sertoli cell tumors are benign, and orchiectomy is nearly always curative.

Extragonadal Germ Cell Tumors

Extragonadal germ cell tumors (EGCTs) have histologic findings similar to those of testicular GCTs but are found in other parts of the body, in the absence of a testicular mass. They account for 1% to 5% of all GCTs and like testicular GCTs tend to occur in young men, although the median age of presentation is 5 to 10 years older than with testicular GCTs.[179] In infants, EGCTs are more common than testicular primary tumors (usually, sacrococcygeal teratomas).[179]

Overall, patients with EGCTs (especially NSGCTs) have a worse prognosis than patients with testicular primary tumors.[180] An increased incidence of EGCTs is seen in Klinefelter syndrome. A number of patients present with poorly differentiated carcinomas (predominantly in midline locations), with a cytogenetic pattern similar to those with typical EGCTs, and do respond to cisplatin-based chemotherapy regimens.[29]

EGCTs most commonly arise in three midline sites in the mediastinum, the pineal and suprasellar regions, and the sacrococcyx (usually in infants). There have been rare case reports of tumors arising in the orbit, prostate, vagina, and liver. Tumors arising in the retroperitoneum are usually thought to be associated with an occult testicular primary lesion. Mediastinal GCTs usually occur in the anterior superior region of the mediastinum adjacent to the thymus. Patients may present with cough, dyspnea, and chest pain, and tumor marker levels are frequently abnormal. Local invasion or metastatic disease to the lungs, liver, or bone is common. Biopsy should always be performed because treatment is dependent on the histologic subtype. For mature teratomatous tumors surgery is advised, whereas for NSGCTs or seminomas the preferred approach is cisplatin-based chemotherapy, omitting bleomycin as many patients require extensive thoracic resection after primary chemotherapy.[181] Surgical resection is recommended for residual mass after chemotherapy. However, the precise role of locoregional therapy after primary chemotherapy is unclear.

The results of an international analysis of 635 consecutive patients with EGCT treated in 11 European and U.S. centers have shown that patients with pure seminomatous histologic typing had a long-term cure rate of 89%, irrespective of the primary site (retroperitoneum or mediastinum).[180] In patients with nonseminomatous tumors, however, a mediastinal primary site was an adverse feature, with only 45% of these patients alive at 5 years as compared with 63% of patients with retroperitoneal presentations. Prognostic variables for response and outcome have been identified, and four prognostic risk groups have been identified based on histologic findings, the presence of liver, lung, or central nervous system (CNS) metastases, elevation of β-HCG levels, and number of metastatic sites involved with disease.[182] The best prognostic group has an 89% 5-year OS and encompasses all patients with seminoma. The other groups all have nonseminomatous histologic findings and 5-year OS of 69%, 55%, and 17%, respectively.

The excellent treatment results with chemotherapy alone of mediastinal seminomatous tumors would suggest that there is no routine role for RT in their management. Platinum-based chemotherapy regimens are recommended. Although a 5-year OS of 73% has been reported with the use of cisplatin, vincristine, methotrexate, bleomycin, actinomycin D, cyclophosphamide, and etoposide (POMB/ACE), there is no evidence that this regimen is superior to BEP.[183] POMB/ACE is considerably more toxic, and its routine use cannot be recommended.

Special Treatment Situations

Germ Cell Tumors in Patients with Horseshoe Kidney

Horseshoe kidney (pelvic kidney) occurs in approximately 1 in 400 persons in the general population.[184] There are two main problems in the management of GCTs associated with horseshoe kidney. The first is related to the technical problem of delivery of RT in patients with seminoma. In a number of cases of horseshoe kidney, a large part of the renal parenchyma directly overlies the regional lymph nodes and lies within the standard radiation volume. The delivery of a standard radiation dose would be associated with an unacceptable risk of radiation nephritis. The second problem is related to the possible abnormalities in lymphatic drainage of the testis, and therefore, the possibility of relapse when the standard radiation fields are used. Unusual patterns of relapse have been observed in patients managed by surveillance, confirming concerns regarding abnormal lymphatic pathways.[185] For these reasons, in patients with seminoma and NSGCTs, postorchiectomy surveillance in stage I and chemotherapy in stage II have usually been recommended. RPLND is another option for patients unwilling to follow the surveillance program, but it has to be assumed that the issue of abnormal lymphatic drainage may also result in technical challenges for the surgeon. However, reports in the literature suggest that RPLND was both safe and effective in the selected cases where it was performed.[185]

Testicular Tumors Developing in Patients Who Are Immunosuppressed

It is well established that the risks of developing Kaposi's sarcoma and non-Hodgkin lymphoma are markedly increased in patients with human immunodeficiency virus (HIV) infection.[186] Initial data suggested that men who are infected with HIV have an increased incidence of testicular cancer, but more recent studies have indicated that this may not be true.[18,186] Organ transplant patients may also have an increased incidence of testicular tumors.[187] The clinical course of patients who are immunosuppressed with testicular tumors is similar to that of patients who are immunocompetent, and these patients should be offered standard oncologic therapy. Both chemotherapy and RT reduce the CD4 count even when antiretroviral therapy is used; therefore, wherever possible, surveillance should be used in patients with stage I disease.[18] Caution must be exercised because benign retroperitoneal adenopathy related to acquired immunodeficiency syndrome (AIDS) may be mistaken for metastasis from a testicular primary tumor. For those receiving chemotherapy, consideration should be given to concomitant prophylaxis for opportunistic infection. Most patients can be cured of their tumors, and the outcome of patients with HIV-related GCTs is similar to that of patients who do not have HIV.

Bilateral Testicular Germ Cell Tumors or Tumors Arising in a Single Testicle

Men who have had cancer in one testicle are at increased risk of developing contralateral disease with reported rates of metachronous or synchronous development of 1% to 5%.[187] Bilateral orchiectomy is recommended as standard management, with resulting infertility, lifelong dependence on androgen replacement, and psychological morbidity because of castration at a young age.[188]

To preserve endogenous hormonal function, organ-sparing surgery followed by low-dose RT (16 Gy to 20 Gy in 2-Gy daily fractions using a direct field with electrons) to the remnant testis to eradicate residual CIS and prevent future invasive disease is an option with a high likelihood of cure in selected patients.[20,189] Close observation after surgery may be

undertaken and adjuvant radiation may be postponed if there is a fertility concern for the patient and he is willing to risk the onset of invasive disease during that period.[189] Patients with large tumors (>30% of the testis volume) or clinical evidence of metastatic disease are not suitable for this approach. Because this is an area that requires expertise, organ-sparing approaches should be concentrated in centers with such experience.[20]

Central Nervous System Metastases

Up to 40% of patients who die of progressive disease have brain metastases at autopsy. Thankfully, presentation with brain metastases is uncommon with approximately 2% to 3 % of patients overall. Such patients are potentially curable, with approximately 50% 5-year CSS, but this requires aggressive treatment.[54] The optimal sequence of chemotherapy, RT, and surgery is unknown, although systemic chemotherapy is required in all cases, only in one study did the addition of cranial RT improve overall survival.[190] Whether the addition of RT when a complete response is obtained with chemotherapy is needed is uncertain, as is the need for RT if surgery removes gross disease. When RT is given, a dose of 40 Gy to 45 Gy should be considered for gross disease if using conventional fractionation. It is unclear if the entire brain should be irradiated but when this is done, the intended dose should not exceed 40 Gy because of the risk of neurotoxicity. A stereotactic approach is now being used more frequently and has the advantage of tumoricidal doses and relatively low risk of toxicity to the surrounding brain. Patients presenting with late relapse with CNS metastases should be treated aggressively because long-term disease-free survival times are possible.[191] Patients who develop brain metastases during chemotherapy have a poor prognosis.[191]

Spermatocytic Seminoma

Spermatocytic seminoma is a rare testicular tumor accounting for only 1% to 2% of all seminomas.[192] It usually occurs at age 50 to 60 years but is seen in younger patients.[192] It is distinct in its histologic characteristics, usually having three different cell sizes, spherical nuclei, a lack of cytoplasmic glycogen, and sparse or absent lymphocytic infiltrate when compared with classical seminoma.[193] Unlike classical seminoma, it does not appear to arise from CIS, occurs solely in the testis and has no ovarian equivalent. All patients present with stage I disease, and subsequent metastatic disease is extremely rare. In the past, the treatment approach was similar to seminoma with adjuvant RT. Current recommendations call for surveillance in all patients and the frequency of investigations may also be reduced given the seemingly minimal metastatic risk this histology poses.[194]

IRRADIATION TECHNIQUES AND DOSE

With the advent of successful salvage chemotherapy in metastatic disease, various strategies have been investigated to reduce the long-term complications of RT and in particular adjuvant RT (the standard of care after orchiectomy in stage I disease). This has included the reduction of the volume of tissue irradiated together with a dose reduction strategy. Alternative to RT including adjuvant chemotherapy and surveillance also have become popular, as has the increasing use of cisplatin-based chemotherapy in stage II disease. All of these strategies have been designed to lessen the potential adverse impact of RT.

Radiation Target Volume

The intended clinical target volume for both stage I and stage II seminoma has included the paraaortic lymph nodes and ipsilateral pelvic lymph nodes. In the case of left-sided tumors, the left renal hilum is included to allow for nodes that cluster around the left gonadal vessels. The most frequently used field arrangement is parallel opposed anteroposterior fields, and patients are treated with 10-MV to 18-MV linear accelerator photons. Although almost identical on both sides of the Atlantic, this classical plan was called the "hockey-stick" field in North America and the "dogleg" field in the United Kingdom and Europe. The superior extent is usually at the T10/T11 interspace and the inferior at the inguinal ligament. The penis is moved out of the field and the contralateral testis is placed in a scrotal shield to protect fertility and to a lesser extent future hormone production. In general, scrotal irradiation is avoided except in patients with extensive local disease, incomplete surgery, and gross scrotal contamination before surgery. Of note is that in the case of transscrotal orchiectomy, scrotal irradiation is still not recommended. Mediastinal irradiation is now of historical interest only.

More conformal radiation techniques such as intensity-modulated radiation therapy (IMRT) have not been pursued in part because the necessity of exposing more normal tissue to the low-dose radiation that is typical for the multiangle beam arrangements used in IMRT, resulting in an increase in the integral dose.[195] Another concern is the possibility that this integral dose may risk an increase in second malignancy rates in this younger population. With the increase in the availability of proton facilities, there has been some interest in exploring the possibility of using proton beams to improve dose conformality as well as minimize the risk of second malignancy.[196]

Reduction in Radiation Treatment Volume

Stage I Seminoma

Recognition of the low risk of pelvic nodal involvement in stage I disease led to the investigation of eliminating pelvic nodal irradiation. Advantages of such an approach would include lower scatter dose to the testes and reduced irradiated volume of normal tissue which in theory might reduce risk of second malignancy. The literature shows excellent results with few pelvic failures.[92,197] This was confirmed in the MRC Testicular Study Group randomized study of 478 patients comparing paraaortic plus pelvic RT and paraaortic RT alone, relapse rates were similar, 4% with paraaortic irradiation and 3.4% relapse rate with paraaortic and pelvic irradiation.[63] The sites of relapse were different, whereas all patients who received paraaortic and pelvic RT relapsed in supradiaphragmatic sites, four patients (1.6%) treated to the para-aortic lymph nodes alone had pelvic relapse. This highlighted the potential need for regular imaging with CT to detect pelvic relapse in these patients. When no imaging of the pelvis is carried out, patients fail with bulky disease (median, 5 cm).[92] It may be reasonable to confine such imaging to the first 3 years after RT as supported by data from the German Testicular Cancer Study Group.[198] Although there are advantages to paraaortic RT alone, its true value in stage I disease remains unclear especially when surveillance is an attractive alternative.

A compromise between traditional irradiation fields and paraaortic irradiation alone is to treat the paraaortic and ipsilateral common iliac lymph nodes by positioning the inferior border of the radiation fields at midpelvis[199] (Figure 55-3). This encompasses the lymph nodes that are typically removed at lymphadenectomy in patients with nonseminomatous tumors and also covers the vast majority of pelvic nodal relapses in patients treated with paraaortic irradiation alone.[197] This treatment volume is also partly supported by the data for stage II disease discussed in this chapter. Similarly a multiinstitutional study that examined nodal relapse sites in 90 patients with

stage I seminoma relapsed surveillance and de novo stage IIA/B found no sites of disease cranial to the L1 vertebral body.[41] This data may therefore support a reduction of the cranial aspect of the traditional RT field to the superior aspect of T12 vertebral body and may allow lower amount of radiation exposure to the heart and upper abdominal structures with the ultimate goal of the minimizing radiation toxicity without sacrificing rates of disease control.[200]

Stage II Seminoma

The RT technique in stage II seminoma is similar to that used in stage I disease. The treatment volume includes the gross tumor as well as the paraaortic and ipsilateral common and external iliac lymph nodes (Figure 55-4, *A*). Previously the dog-leg field was used but data from the German Testicular Cancer Group, although not a randomized study, provide some support for the placement of the inferior extent of the field at the acetabulum.[106] In this study of 87 assessable patients at median follow up of 70 months, only 4 patients relapsed with none distal to the inferior extent of the volume; although this study was small and not designed to test the question of volume reduction it is somewhat reassuring with the low rate of relapse seen. The contralateral iliac lymph nodes may also be treated in cases where lymphadenopathy in the low paraaortic area is deemed to increase the risk of these nodes being involved by tumor. However, such patients often have bulky retroperitoneal lymphadenopathy and are better treated with primary chemotherapy. Adjuvant RT of the supraclavicular lymph nodes in patients with stage II disease has been suggested by some, although it is not justified on a routine basis in view of the low risk of isolated supraclavicular relapse (2 of 79 patients with stage IIA or IIB disease in the PMH series).[108,201]

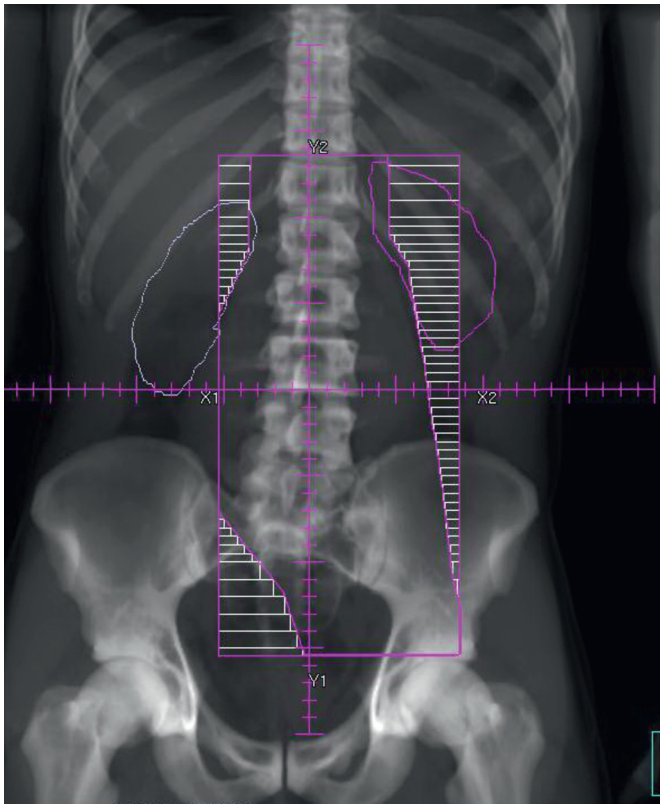

Figure 55-3 Radiation fields, stage I.

Radiation Dose

Stage I Seminoma

Doses of 20 Gy and 25 Gy are more than adequate to eradicate microscopic seminoma. No in-field recurrences have been observed in the series from PMH (Toronto) where 25 Gy is delivered over 20 daily fractions with total duration of 4 weeks.[68] A Phase III study of dose reduction comparing 30 Gy in 15 fractions over 3 weeks and 20 Gy in 10 fractions over 2 weeks in 625 patients was undertaken in the MRC TE18 trial.[64] A total of 10 and 11 relapses, occurred in the 30-Gy and 20-Gy groups (hazard ratio [HR], 1.11; 90% CI, 0.54 to 2.28), respectively, at median follow up of 61 months. The resulting 5-year relapse rates were 3% and 3.6% for the 30-Gy and 20-Gy groups, respectively. Longer follow up data published subsequently have confirmed these findings.[97]

Stage II Seminoma

The radiation dose is typically 25 Gy in 20 daily fractions plus a boost of a further 10 Gy to the gross lymphadenopathy (see Figure 55-4, *B*). At PMH, this boost is given concurrently with the large-field treatment. Some authorities suggest that 30 Gy for small bulk (IIA) gross disease is adequate but no trials have

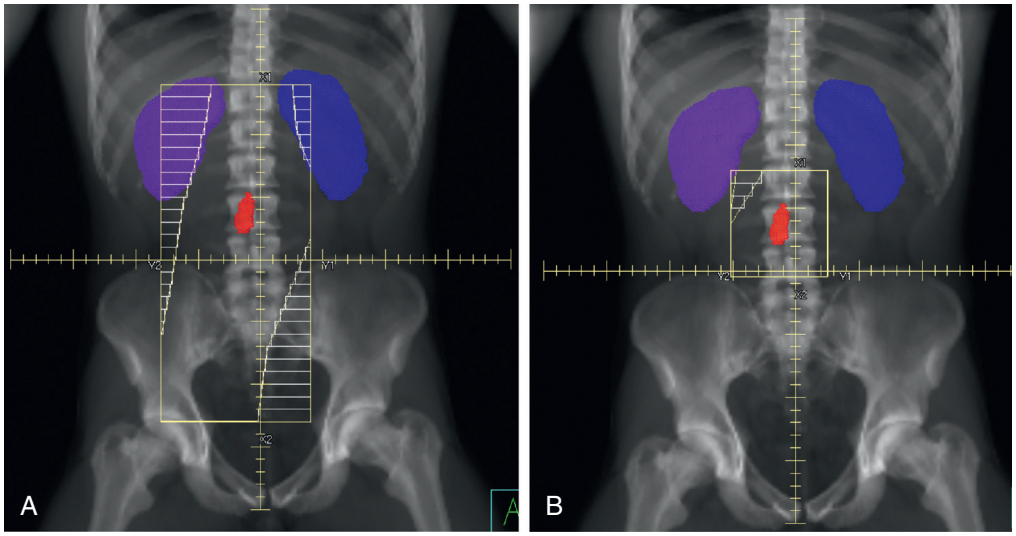

Figure 55-4 Radiation fields, stage II. **A,** Extended field. **B,** Boost field.

been done in this area.[106] One possible mechanism to reduce dose in this setting is the addition of carboplatin in a sequential fashion perhaps allowing even bulky disease to be safely eradicated with lower doses.

TREATMENT ALGORITHMS, CONCLUSIONS, AND FUTURE POSSIBILITIES

The recommended treatment algorithms for seminomas and non-seminomas based on disease extent are outlined in Figures 55-5 and 55-6. Although the overall results are excellent, there are ongoing controversies regarding the optimal management of GCTs.

In seminoma, the major area of controversy involves the management of stage I disease. The mature data from surveillance and adjuvant therapy series suggest that almost 100% of patients with stage I testicular seminoma are cured no matter which approach is chosen as postorchiectomy management. Surveillance should be considered the management option of choice, although the patient should be fully involved in the decision making.[146] Change is adopted slowly and a considerable proportion of urologists and oncologists do not discuss all the options with their patients.[202]

The optimal RT target volume for patients with stage I seminoma is under investigation, and limiting treatment to the paraaortic lymph nodes is now popular. However, if pelvic irradiation is omitted, it does not eliminate the need for ongoing follow up and surveillance of the pelvic lymph nodes; patients thus managed will experience both the morbidity of RT and the ongoing inconvenience of surveillance. Thus, a modified treatment volume to include the common iliac nodes may reduce the need for ongoing surveillance of the pelvis.

The management for patients with NSGCT needs to be further refined and improvements in outcome still remain elusive particularly for patients with the highest risk of death related to disease. In stage I disease, individualized management perhaps based on prognostic factors and patient participation in the decision making should now be routine. For good and intermediate-risk metastatic disease, identification of subgroups that may be adequately treated with reduced toxicity may be a priority area for further research, which may come in the form of less chemotherapy, omission of bleomycin, or even new agents with similar efficacy and less toxicity. In advanced or poor-risk disease, clinical trials are needed to further evaluate high-dose regimens with stem cell support, identify subgroups of patients most likely to benefit from this

aggressive approach and identify alternative regimens that reduce toxicity. Finally, new drugs with similar clinical efficacy but less toxicity would be a welcome addition in the treatment of these neoplasms.

CHAPTER

56 Kidney and Ureteral Carcinoma

William W. Wong, Jennifer L. Peterson, Winston W. Tan, Michael G. Haddock, Alexander S. Parker, Michael J. Wehle, and Ryan C. Hutchinson

INCIDENCE

In 2015, an estimated 61,560 new cases of cancers arising from the renal pelvis and kidney proper were expected in the United States and approximately 14,080 deaths. It represents the sixth most common cancer in men and the eighth most common cancer in women. The vast majority (>90%) of these cancers of the kidney are classified as renal cell carcinoma (RCC). By comparison, the projection for ureteral and other upper urinary tract cancers is 2710 new cases and 900 deaths in 2013.

BIOLOGIC CHARACTERISTICS

Factors known to be associated with risk of relapse and death from RCC following surgery include tumor stage, nuclear and Fuhrman grade, tumor size, extension through the renal capsule, nodal involvement, renal vein involvement, histologic pattern, and presence of necrosis. Presence of a sarcomatoid component is also associated with a poor prognosis. The presence of lymphovascular invasion (LVI) is an independent predictor of RCC relapse. To date, there are no molecular markers (either tumor based or otherwise) that are routinely used in the clinic to predict outcome following surgery for localized RCC.

For upper urinary tract cancer (UUTCA) the most important prognostic factors for survival are stage and histologic grade of tumor. The presence of LVI also is predictive of worse outcome.

STAGING EVALUATION

Evaluation of a patient with RCC includes a history and physical examination, complete blood cell count, serum chemistries, urinalysis, chest radiography (CXR), and computed tomography (CT) or magnetic resonance imaging (MRI) of the abdomen and pelvis. Magnetic resonance angiography may be used in some cases for preoperative mapping of vasculature.

Evaluation of patients with renal pelvis and ureteral cancers includes a history and physical examination, complete blood cell count, blood chemistries, urinalysis, urine cytology, CXR, and CT of the abdomen and pelvis. Selective urine cytology of the upper urinary tract (UUT) is more sensitive than routine urine cytology. CT or MR urography is performed to evaluate the UUT bilaterally. Cystoscopy and ureteroscopy are performed to obtain tissue diagnosis and rule out synchronous lesions in the remainder of the urothelial tract.

PRIMARY THERAPY

Surgical resection (partial or radical nephrectomy) is the primary treatment of RCC. The 5-year survival is about 90% for those patients whose tumor is confined to the kidney, about 60% if it has extended to nearby tissues, and about 9% if it has spread to distant sites.

Nephroureterectomy, via either an open or minimally invasive approach, with resection of a bladder cuff at the ureterovesical junction is the standard therapy for resectable UUTCA. When preoperative evaluation or clinical suspicion is high for nodal involvement, lymphadenectomy is also recommended. Five-year survival is 80% or more for minimally invasive disease not having invaded through the wall of the collecting system (T1 and T2 lesions), 30% to 50% for deeply invasive disease without nodal involvement, and 10% to 15% for cases involving lymph nodes or distant metastases. Conservative nephron-sparing surgery is an option for selected patients with distal ureteral tumors and marginal renal function. Endoscopic resection is an option for low-grade and low-stage tumors in patients with marginal renal function.

ADJUVANT THERAPY

Adjuvant therapy for RCC is indicated in selected patients on the basis of failure patterns and survival results with surgery alone. Patients who undergo a gross total resection of tumor have a low risk of local failure and a moderate risk of distant metastases. There is no proven role for routine use of adjuvant radiation, chemotherapy, immunotherapy, or molecularly targeted therapy as part of the primary management for patients with localized RCC. Postoperative radiation therapy can be considered in patients with positive margins or positive lymph nodes.

Patients with UUTCA that are high grade or locally advanced, or with lymph node involvement, are at significant risk for developing both distant and locoregional relapses. Adjuvant radiation decreases local failure rates and may be combined with concomitant chemotherapy. Some studies suggest that adjuvant chemotherapy may benefit patients with high-risk disease.

LOCALLY ADVANCED DISEASE

For RCC, a combined treatment approach consisting of preoperative external beam radiation external beam irradiation (EBRT) and cytoreductive surgical resection with or without intraoperative irradiation has the greatest potential for local control of disease.

For UUTCA, irradiation with or without chemotherapy may occasionally achieve long-term disease control in patients with gross residual or locally recurrent disease after surgery. For patients with unresectable disease, combined EBRT and chemotherapy or EBRT alone may achieve downstaging of disease to allow surgical resection.

PALLIATION

Nephrectomy may alleviate local symptoms of RCC or enhance the effects of systemic therapy. Radiation therapy is effective in palliating painful bone metastases and in alleviating symptoms from brain metastases. Several molecularly targeted and immunotherapeutic drugs have been approved for metastatic RCC.

For metastatic UUTCA, cisplatin-based chemotherapy regimens can achieve a response rate of 50% to 70% and should be considered in patients with good performance status. Radiation therapy provides palliation of local symptoms such as pain or hematuria and improves the quality of life in some patients.

RCC, historically referred to as hypernephroma or Grawitz's tumor, was first reported by Konig in 1826. In 1894, Birch-Hirschfel used the term *hypernephroid* to describe these tumors.

In addition to the classic triad of symptoms (hematuria, abdominal pain, and a flank mass), RCC often presents with numerous other clinical manifestations. Complete surgical resection is the primary treatment of localized tumors. Nephron-sparing surgery is now commonly performed in lieu of radical nephrectomy for patients with small to medium-size tumors. RCC appears to be more resistant to radiation therapy and chemotherapy than most epithelial tumors. Immunomodulation and molecularly targeted treatment have a role in the systemic treatment of patients with metastatic disease.

Primary cancers of the renal pelvis and ureter are uncommon. About 5% of urothelial carcinomas occur in the kidneys and ureters.[1] Radical nephroureterectomy (RNU), with removal of the bladder cuff, is the main means of treatment. In recent years, laparoscopic and robot-assisted surgeries have become available as alternatives to an open approach. The use of more conservative surgery should be limited to well-selected patients who have low-grade and low-stage disease, small unifocal lesions, solitary kidney, or significant medical comorbidity. Patients with high-grade tumors or advanced-stage disease are at significant risk of local as well as distant relapse. Adjuvant chemotherapy or radiation therapy may improve the treatment outcome in patients with locally advanced disease.

ETIOLOGY AND EPIDEMIOLOGY

Kidney

Epidemiology

In the United States, kidney and renal pelvis cancer comprises approximately 4% of new cancer cases and 3% of cancer deaths each year.[2] In 2015, an estimated 61,560 new cases of kidney and renal pelvis cancer diagnosed in the United States and approximately 14,080 deaths. More than 90% of kidney cancers are classified as RCC, and of these the vast majority (>80%) are clear cell RCC.[3]

RCC is most commonly diagnosed in the seventh decade of life, with a median age at diagnosis of 65 years; however, it has been observed in children as young as 6 months old. According to data from the Surveillance, Epidemiology and End Results (SEER) program, the overall incidence of RCC in the United States has increased at a rate of 2% to 3% per year since the early 1970s.[4,5] The greatest increase in RCC incidence has been among localized tumors, many of which are detected incidentally during abdominal imaging performed for unrelated reasons.[4] However, early detection of subclinical tumors cannot fully explain the rising incidence of RCC.

There is a strong gender preponderance, with incidence rates in men approximately twice that of women.[2] The incidence of RCC also varies among racial and ethnic groups. The highest rates occur in whites and African Americans, whereas the lowest rates are reported for Asian Americans. Between 1999 and 2008, incidence rates among African Americans males increased by 3.1% compared with only 2.3% in white males and 2.0% in Hispanic and Latino males. Globally, the incidence rate of RCC is the highest in North America and Scandinavia and the lowest in Asia and South America.[6]

Etiology

Cigarette smoking and obesity are two well-established risk factors for RCC. Large meta-analyses of studies suggest that each of these exposures increases the risk of RCC roughly twofold.[7-9] Hypertension has emerged as a third consistent risk factor for RCC, with several studies suggesting an 80% increase in risk of RCC for individuals with a history of hypertension.[10,11] These three factors (smoking, obesity, and hypertension) may account for approximately 50% of all RCCs diagnosed in the United States.[12]

A number of studies, including a pooled analysis of several large population-based cohort studies support an inverse association between alcohol consumption and risk of RCC.[13-15] Some data also support an inverse association with physical activity, as well as a positive association with a history of urinary tract infections.[16-20]

There are few consistent associations of RCC and dietary factors.[21-23] Consumption of vegetables may be associated with reduced risk, whereas red meat consumption may slightly increase the risk of RCC. However, a recent meta-analysis did not support an independent association of red meat consumption and RCC.[24] Finally, occupational exposures to asbestos, gasoline, lead, and cadmium; use of Thorotrast; and treatment with phenacetin, as well as a history of end-stage renal disease or acquired cystic kidney disease, have been associated with increased risk of RCC.[25-30]

A positive family history increases the risk of RCC as much as twofold.[31] Although genes that are associated with inherited forms of RCC have been identified (e.g., VHL, Met1), it is less clear whether individuals carrying single nucleotide polymorphisms in specific genes may be at increased risk of sporadic (i.e., non-familial) RCC.[32-38]

Renal Pelvis and Ureter

Epidemiology

Although urothelial carcinoma is a common malignancy, most of the cases occur in the urinary bladder. Only about 5% of all urothelial neoplasms occur in the UUT.[1] The age-adjusted annual incidence of renal pelvic and ureteral cancers is 0.73 per 100,000 person-years.[39] There is a strong male predominance, with a male-to-female ratio of 3:1. The peak age at diagnosis is in the sixth and seventh decades of life. The incidence of UUTCA has been increasing.[39,40] Disease-specific annual mortality is greater in black than in white individuals and in women than in men. Primary tumors of the ureter occur only half as frequently as those of the renal pelvis. Patients with UUTCA have a 36% to 50% risk of developing a second bladder cancer.[41,42] The risk of developing UUTCA after treatment of bladder cancer is 0.75% to 6.4%.[43] The median time to the development of secondary UUTCA after bladder cancer diagnosis is 48 months.[44] Contralateral metachronous UUTCA is relatively uncommon, occurring in 3% to 6% of patients.[45,46]

Etiology

Risk factors and environmental agents that cause bladder cancer are considered to play similar roles in the development of UUTCA.[39,40,45,47] However, more recent data suggest that there are genetic and environmental factors that are specific for the promotion of UUTCA and not bladder cancer.

Cigarette smokers have a 2.6- to 7.2-fold increased risk of UUTCA.[48-50] The relative risk of developing UUTCA is 4.8 for smoking more than 40 cigarettes daily. Occupational exposure to organic chemicals is associated with a higher risk of UUTCA for workers in the chemical, petrochemical, or plastic industries.[48] Chronic use of phenacetin as an analgesic causes papillary necrosis, which promotes carcinogenesis and increases the risk of UUTCA.[50-52]

Balkan endemic nephropathy (BEN) in some Balkan countries is associated with a 57- to 100-fold increase in risk of UUTCA.[53,54] The disease is characterized by an interstitial nephritis. These patients often present with higher-grade disease and more solid growth pattern compared with those from nonendemic regions.[55] Recent studies demonstrate that consumption of bread made from grain contaminated by aristolochic acid (AA) is a significant risk factor for BEN and the

development of UUTCA. DNA adducts derived from AA are present in patients with BEN and are also detected in their UUTCA, These tumors have a distinct p53 mutation spectrum involving A:T→T:A transversion.[56-58] The incidence of UUTCA in Taiwan is among the highest in the world and is associated with the widespread use of Aristolochia herbal remedies.[59] These patients develop a nephropathy characterized by progressive renal fibrosis and increased risk of urothelial cancer.[60,61] The p53 mutation in UUTCA of these patients is dominated by A:T→T:A transversion, identical to that seen in UUTCA associated with BEN.[59]

Patients with a history of kidney or ureteral stones have a 2.5-fold increase in risk of renal and ureteral cancers, suggesting that chronic irritation and infection may play a role.[62]

There are reports of kindred with familial UUTCA.[63-65] UUTCA ranks as the third-most common malignancy (5%) in patients with hereditary nonpolyposis colorectal cancer (HPNCC) syndrome (Lynch syndrome), after colon (63%) and endometrial cancers (9%).[66] The risk is 22-fold compared with the general population and the median age of onset is 56 years, which is 10 years to 15 years earlier than usual.[67] There is an inherited mutation in mismatched pair genes, resulting in microsatellite instability and DNA replication fidelity.[68]

PREVENTION AND EARLY DETECTION

Kidney

Cessation of cigarette smoking is the most effective method of preventing RCC. A large case-control study in Iowa reported that the risk of RCC development decreases steadily from the time of smoking cessation.[69] After 15 years of cessation the risk of developing RCC returns to that of nonsmokers. It is unclear whether reduction in weight would decrease the risk for RCC. Some data suggest that daily moderate alcohol consumption and physical activity reduce the risk of RCC; however, more investigations are needed to confirm their benefits.[14,17]

Early diagnosis of RCC is challenging. Twenty-five percent to 40% of patients are asymptomatic at the time of diagnosis.[70] The increased use of imaging modalities including CT, MRI, and ultrasonography for other medical conditions often detect RCC at earlier stages as an incidental finding.[71] Over the past 3 decades, less than 10% of patients present with the classic triad of flank pain, hematuria, and a palpable mass at diagnosis.

Renal Pelvis and Ureter

The risk of UUTCA in smokers is reduced by 60% to 70% after 10 years of smoking cessation.[49] Diet with frequent intake of both green and yellow vegetables may also reduce the risk of urothelial cancers.[72] The value of urine cytology as a screening test for urothelial cancer is not defined and has not been used routinely, even in populations at increased risk of developing these diseases (e.g., occupational exposure to organic chemicals or diagnosis of BEN). For patients with a prior history of bladder cancer under surveillance after treatment, the use of pyelography in any form (i.e., computed tomography [CT], magnetic resonance imaging [MRI], intravenous pyelography [IVP]) as a routine follow-up examination remains controversial.[73]

PATHOLOGY AND PATHWAYS OF SPREAD

Kidney

Pathology

In 1997, an international consensus conference on RCC sponsored by the Union Internationale Contre le Cancer (UICC) and the American Joint Committee on Cancer (AJCC) outlined recommendations for the classification of RCC.[74] The classification system originally proposed at the Heidelberg conference in 1996 was adopted.[75] RCC is categorized as clear cell, papillary, chromophobe, or collecting duct subtypes. RCC that does not fall into one of these four groups is classified as "renal cell carcinoma, not otherwise specified." Granular cell RCC was excluded from the classification because it encompassed oncocytoma (benign kidney tumor) as well as chromophobe and clear cell RCC and was not specific to a single subtype. This classification system recognizes that RCC consists of several histologic subtypes with distinct morphologic and genetic characteristics. Previous reports have demonstrated significant differences in patient outcome based on histologic subtypes.[76-78] Patients with clear cell RCC have a worse prognosis compared with patients with papillary and chromophobe RCC. There is no statistically significant difference in outcome between patients with papillary RCC and those with chromophobe RCC.[79]

Furthermore, features predictive of a poorer prognosis, including histologic tumor necrosis and sarcomatoid differentiation, have been shown to differ by subtype.[77-80] Histologic tumor necrosis is noted in 20% to 45% of patients with RCC, whereas sarcomatoid differentiation occurs in 5% to 15% of patients.

Fuhrman et al developed a nuclear grading system based on the size and appearance of nuclei and nucleoli.[81] The Fuhrman nuclear grade is predictive of outcome in patients with RCC. A large cohort study in Germany reported that presence of LVI is an independent marker of RCC recurrence more than 5 years following nephrectomy.[82]

Algorithms have been developed to predict outcomes for patients with RCC. Using retrospective data from 1801 patients with clear cell RCC, investigators from the Mayo Clinic developed a predictive model using a SSIGN scoring system that incorporated stage, tumor size, nuclear grade, and histologic tumor necrosis.[83] Ten-year cancer-specific survival can be estimated based on a patient's SSIGN score. Kattan et al developed a nomogram to predict 5-year probability of treatment failure using presenting symptoms, histology, tumor size, and stage.[84] Zisman et al developed a clinical outcome algorithm based on 814 patients, using stage, Fuhrman grade, and Eastern Cooperative Oncology Group (ECOG) performance status.[85] This algorithm has been validated by two international multicenter studies.[86,87] Similar algorithms have also been developed and validated for predicting time to death for patients with metastatic RCC.[88,89] Overall, these robust prognostic tools based on multivariate models have become widely accepted in the clinic given the high degree of accuracy for forecasting RCC patient outcome.

Pathways of Spread

RCC may spread by local extension through the renal capsule into the perinephric fat or the adrenal gland, or by direct extension through the renal vein to the inferior vena cava (occasionally reaching the right atrium). Regional lymphatic drainage includes renal hilar, paracaval, aortic, and retroperitoneal lymph nodes. RCC may also spread by blood-borne metastases to the lung, soft tissue, bone, and brain, or by retrograde venous drainage to the ovary or testis.[90]

Renal Pelvis and Ureter

Pathology

Transitional cell carcinoma (TCC) accounts for the majority of renal pelvis and ureter neoplasms.[91] High-grade UUTCA of the renal pelvis may present with a broad spectrum of morphologic variants, including micropapillary, clear cell,

sarcomatoid, lymphoepithelial, and plasmacytoid features.[92] Nonurothelial histology is uncommon in UUTCA. Squamous cell carcinoma (SCC) accounts for about 4% of all cases.[93] Although patients with SCC tend to present with more advanced-stage diseases and worse prognosis, stage for stage, there is no significant difference in prognosis between TCC and SCC. Other rare cell types include adenocarcinoma, neuroendocrine carcinoma, and sarcoma.

Both stage and tumor grade are important prognostic factors for survival.[94-99] Lymph node metastasis and lymphovascular space invasion are associated with stage and grade and predict for worse outcome.[100,101]

Gross tumor architecture (sessile versus papillary growth pattern) is an independent predictor of tumor relapse and cancer-specific mortality.[102] Sessile growth pattern is associated with higher tumor grade, more advanced stage, and nodal metastasis. A history of prior bladder cancer has also been associated with worse disease-specific survival (DSS).[103]

Pathway of Spread

Involvement of multiple areas of the urothelial epithelium by TCC, either synchronously or metachronously, is common in patients with renal pelvis and ureteral cancers. As the tumor progresses, it invades the surrounding tissues with direct extension through the ureteral wall into periureteral tissues or to adjacent renal parenchyma as well as extrarenal tissues. Lymph node metastasis is the most common site of metastasis in UUTCA. In a multiinstitutional series of 1363 patients, lymph node metastasis was shown to increase with advancing pathologic stage: less than 1% for T0/Ta/Tis, 2% for T1, 8% for T2, 17% for T3, and 46% for T4.[104] High-grade tumors were more likely to have nodal involvement (15% for high grade, 2% for low grade).

Kondo et al outline the distribution of nodal metastatic sites.[105] For tumors of the right renal pelvis, the primary metastatic sites are the right renal hilar, paracaval, and retrocaval nodes. Tumors of the upper two thirds of the right ureter primarily metastasize to the retrocaval and interaortocaval nodes. Tumors of the left renal pelvis metastasize to the left renal hilar and paraaortic nodes. Tumors of the upper two thirds of the left ureter primarily metastasize to the paraaortic nodes. Tumors of the lower ureter primarily metastasize inferiorly to the aortic bifurcation. The finding of lymph vessel invasion in the tumor is predictive of regional lymph node metastasis.[106] Nodal metastasis is a predictor for distant metastasis and is associated with worse survival.[101,104]

Patients with high-grade or advanced-stage disease are at significant risk of developing distant metastasis.[94,107] Common sites of distant failure include lung, liver, and bone.[97]

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

Kidney

RCC occurs in both familial as well as sporadic forms. There are several hereditary syndromes associated with the development of RCC, including the von Hippel-Lindau syndrome, tuberous sclerosis, hereditary papillary renal carcinoma, Birt-Hogg-Dubé (BHD) syndrome, and hereditary renal carcinoma.[108] The von Hippel-Lindau syndrome, an autosomal dominant disorder affecting 1 in 40,000 individuals, is caused by a mutation of the *VHL* tumor suppressor gene located on chromosome 3p. Silencing of the *VHL* gene by either somatic mutation or hypermethylation is believed to play a role in 50% to 60% of sporadic cases of clear cell RCC.[109] Tuberous sclerosis is an autosomal dominant disorder affecting 1 in 10,000 individuals and results from mutations of either the *TSC1* gene on chromosome 9q or the *TSC2* gene on chromosome 6p.[110] Hereditary papillary renal carcinoma is also an autosomal dominant disorder in which patients develop bilateral, multifocal lesions with associated germline mutations of the *MET* proto-oncogene located on chromosome 7q.[111] BHD syndrome is a dominantly inherited predisposition to benign fibrofolliculomas and other skin and soft-tissue tumors, including RCC. The gene for BHD syndrome has been mapped to chromosome 17p12-q11.2.[112]

There are currently no molecular markers (either tumor based or otherwise) that are routinely used to predict outcome following surgery for localized RCC. Historically, the focus in this field has been on analyzing single candidate biomarkers within RCC tumor tissue for their association with risk of death from RCC following nephrectomy. From these studies, candidate biomarkers such as B7H1, survivin, ki-67, CAIX, IMP, BAP1, PBRM1, SETD2, and IMP3 have emerged as examples of molecular alterations that are independently associated with RCC aggressiveness and risk of cancer-specific death.[113-121] Unfortunately, the associations reported in these studies are not sensitive or specific enough for them to be used routinely in guiding the postoperative surveillance of patients with RCC for recurrence. Some investigators have combined individual biomarkers into multimarker panels that provide more robust forecasting for patients with RCC; however, the accuracy of these panels is still not at the level to warrant routine clinical use.[122,123] More recently, investigators have harnessed next-generation sequencing technology to broaden the scope of our understanding of the genomic landscape of kidney cancer, primarily RCC.[124,125] These genome wide studies will hopefully provide the benchmark for the next iteration of biomarker discovery in RCC and enhance the future development of prognostic tools for the postoperative management of patients with RCC.

Renal Pelvis and Ureter

The karyotypic profile of UUTCA has been shown to be similar to that of bladder cancers.[126] Loss of the entire chromosome or partial loss of the short arm of chromosome 9 is a common finding, suggesting that it may be an early important event in tumorigenesis. Gains of DNA sequences are frequently observed in chromosome regions 1q21, 2p23, and 8q21.[127] Overexpression of *TP53,* cyclin A, and cyclin E is seen in 24% to 30% of UUTCA and is associated with advanced stage and grade, as well as worse prognosis.[128-130] E-cadherin is a transmembranous cell-cell adhesion receptor responsible for the maintenance of tissue architecture. Loss of E-cadherin expression promotes invasion and metastases, and is associated with an increased risk of recurrence.[131] In a study using immunohistochemical staining of tumor tissues, expression of p21, p27, p53, cyclin E, and ki-67 were altered in 19%, 49%, 45%, 11% and 89% of the specimens, respectively.[132] There was a significant association between the number of altered markers and clinicopathologic findings that predicted worse outcome (e.g., nonorgan-confined disease, sessile architecture). Patients with two or fewer marker alterations had much better survival.

The expression of survivin, an inhibitor of apoptosis, and the apoptotic index are associated with shorter disease-specific survival. Ki-67 is a protein that is involved in cell proliferation. It is overexpressed in 24% of cases and is an independent predictor of progression and cancer-specific survival.[133] Nuclear factor-kB, a transcription factor involved in antiapoptosis, invasion, and angiogenesis, plays a role in the carcinogenesis of UUTCA and is a predictor of disease-specific survival.[134] In UUTCA associated with HNPCC, as well as 25% of sporadic UUTCA, mismatch pair gene mutations and microsatellite instability are present.[68]

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Kidney

Clinical Manifestations

RCC may present as an incidental finding on imaging studies. It may also present with multiple signs and symptoms if there is local extension or metastatic disease. Because of these multiple symptoms, RCC has been called the "internist's tumor." Symptoms resulting from local tumor extension include hematuria, abdominal pain, and a flank mass. However, this "classic triad" of symptoms occurs in only about 10% of cases.[90] Symptoms caused by metastatic disease include fever, weight loss, and night sweats. Two percent of male patients present with a varicocele, usually left sided, as a result of impaired drainage of the testicular vein.[135]

Paraneoplastic syndromes occur in about 30% of patients with RCC. Symptoms include hypertension, hypercalcemia, pyrexia, and hepatic dysfunction.[136,137]

Patient Evaluation

The widespread use of CT, MRI, and ultrasonography to evaluate the upper abdomen has significantly increased the detection of asymptomatic renal masses, accounting for 25% to 40% of diagnoses of RCC.[138,139] These tumors are usually smaller, and therefore, are more likely to be surgically resectable.[140,141]

The diagnosis of RCC is usually based on clinical and radiologic findings and pathologically confirmed at the time of nephrectomy. The staging evaluation includes a history and physical examination, complete blood cell count, serum chemistries, lactate dehydrogenase level, urinalysis, CXR or chest CT, and CT or MRI of the abdomen and pelvis (Box 56-1). If clinically indicated, bone scan and brain MRI may be considered. CT can predict tumor extent preoperatively in 90% of cases.[142] MRI is superior to CT in determining inferior vena cava tumor extent.[143] MR angiography can be used to evaluate vasculature preoperatively, especially when nephron-sparing surgery is being considered for patients with bilateral cancers.

Staging

Two staging systems are used to define disease extent in RCC. Historically, Robson's modification of the Flocks and Kadesky system was used.[144] More recently, the AJCC Staging and End Results Reporting Classification has been used (Table 56-1).[145] This system appears to be superior to the Robson system because it delineates more clearly local tumor extent and quantifies lymph node involvement.[71]

BOX 56-1 Diagnostic Evaluation/Algorithm for Kidney Carcinoma

Complete history and physical examination
Laboratory tests
- Complete blood cell count
- Serum chemistries
- Lactate dehydrogenase
- Urinalysis

Radiologic studies
- Chest radiography or chest computed tomography
- Computed tomography of the abdomen and pelvis or magnetic resonance imaging with intravenous gadolinium of the abdomen
- Bone scintigraphy, if clinically indicated
- Brain magnetic resonance imaging, if clinically indicated

Selected additional studies
- Ultrasonography
- Magnetic resonance angiography

Renal Pelvis and Ureter

Clinical Manifestations

The most common presenting symptom is gross or microscopic hematuria (75% to 80%). Flank pain is present in 27% to 35%.[95,146] Urinary symptoms such as frequency and dysuria are reported in 25% to 50% of patients. A palpable mass may be found in up to 10% of patients and is usually a hydronephrotic kidney. Constitutional symptoms such as malaise and weight loss are frequently seen in patients with extensive disease or metastases.

Patient Evaluation

Patients are evaluated with urine cytology, CT urography (CTU), and ureteroscopy. Radiologic findings of UUTCA include a radiolucent filling defect or obstructive hydronephrosis. The sensitivity and specificity of CTU in detecting lesions of 5 mm to 10 mm is 96% and 99%, respectively, but the sensitivity decreases to 40% for lesions <3 mm.[147] Gadolinium-enhanced MR urography has a sensitivity, specificity and accuracy of 74%, 97%, and 94%, respectively, in the detection of UUTCA.[148] Cytology of voided urine detects 35% to 59% of UUTCA and is more useful in higher-grade cancers.[95] Urine specimens obtained by ureteral catheterization, or by washings of the upper tract, improve the positive yield of the study. Upper tract urine cytology is positive in up to 70% of patients.[149] Fluorescence in situ hybridization (FISH) assay to detect specific abnormalities in chromosomes 3, 7, 17, and specific 9p21 deletions has been used as an adjunct to urine cytology.[150] FISH has a lower sensitivity for detecting low-grade than high-grade disease. Ureteroscopy or percutaneous nephroscopy is performed if exfoliative cytology or radiologic studies show suspicious findings. Ureteroscopic biopsy provides the tissue diagnosis in up to 89% of cases.[151]

Additional studies include complete blood cell count and chemistries. CXR or chest CT is performed routinely. Although CT of the abdomen and pelvis is useful to assess the local extent of disease and intraabdominal metastasis, it is not a sensitive or specific test for nodal staging.[152] If there is any concern about the function of the contralateral kidney, a renal scan should be performed before nephroureterectomy.

Staging

The current TNM staging system is listed in Table 56-1. Tumor grade and nodal status are strongly associated with disease stage, and they are important prognostic factors for survival. Table 56-2 illustrates the impact of stage, grade, and nodal status on long-term outcome.[99,104,133,153-155]

PRIMARY THERAPY

Kidney

Surgery

The only possible curative treatment for RCC is complete surgical resection. A radical nephrectomy typically includes removal of the ipsilateral kidney with perinephric tissues including Gerota's fascia and the ipsilateral adrenal gland. Survival results for treatment with standard open radical nephrectomy are delineated in Table 56-3.[144,156-161] In a report of 643 patients, the 5-year disease-specific survival (DSS) was 91% for those with stage I disease, 74% for stage II disease, 67% for stage III disease, and 32% for stage IV disease based on the 1997 TMN staging criteria.[161] In a Mayo Clinic series of 1547 patients, the 10-year cause-specific survival (CSS) was

TABLE 56-1 American Joint Committee on Cancer Staging Classification System for Kidney and Ureteral Carcinoma, 7th Edition (2010)

PRIMARY TUMOR (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Kidney	
T1	Tumor 7 cm or less in greatest dimension, limited to the kidney
T1a	Tumor 4 cm or less in greatest dimension, limited to the kidney
T1b	Tumor more than 4 cm but not more than 7 cm in greatest dimension, limited to the kidney
T2	Tumor more than 7 cm in greatest dimension, limited to the kidney
T2a	Tumor more than 7 cm but less than or equal to 10 cm in greatest dimension, limited to the kidney
T2b	Tumor more than 10 cm, limited to the kidney
T3	Tumor extends into major veins or perinephric tissues but not into the ipsilateral adrenal gland and not beyond Gerota's fascia
T3a	Tumor grossly extends into the renal vein or its segmental (muscle containing) branches, or tumor invades perirenal and/or renal sinus fat but not beyond Gerota's fascia
T3b	Tumor grossly extends into the vena cava below the diaphragm
T3c	Tumor grossly extends into the vena cava above the diaphragm or invades the wall of the vena cava
T4	Tumor invades beyond Gerota's fascia (including contiguous extension into the ipsilateral adrenal gland)
Ureteral/Renal Pelvis	
Ta	Papillary noninvasive carcinoma
Tis	Carcinoma in situ
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades muscularis
T3	(Renal pelvis only) Tumor invades beyond muscularis into peripelvic fat or renal parenchyma
T3	(Ureter only) Tumor invades beyond muscularis into periureteric fat
T4	Tumor invades adjacent organs or through kidney into perinephric fat

REGIONAL LYMPH NODE (N)*	
Kidney	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in regional lymph node(s)
Ureteral/Renal Pelvis	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single regional lymph node, 2 cm or less in greatest dimension
N2	Metastasis in a single lymph node, more than 2 cm but not more than 5 cm in greatest dimension; or multiple lymph nodes, none more than 5 cm in greatest dimension
N3	Metastasis in a lymph node more than 5 cm in greatest dimension
DISTANT METASTASIS (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

91% for T1, 70% for T2, 53% for T3a, 42% for T3b, and 43% for T3c tumors.[162]

Removal of the adrenal gland is not required for RCC involving the middle or lower poles. Upper pole cancers may necessitate adrenal gland removal with nephrectomy depending on the size, pathologic type, and extent of invasion of the renal tumor. Preoperative CT has demonstrated 99.6% specificity and a 94.4% negative predictive value in predicting adrenal gland involvement.[163,164] In a review of 511 radical nephrectomies with adrenal gland removal, the incidence of renal cancer involvement with the adrenal gland was 5.7% and T1-2 tumors had an incidence of adrenal involvement of 0.6%.[163]

A radical nephrectomy can include resection of hilar lymph nodes and occasionally includes regional lymph node dissection. Although regional lymph node dissection (LND) provides additional prognostic information, it has not been proven to prolong survival.[71] The European Organization for Research and Treatment of Cancer (EORTC) conducted a Phase III trial evaluating the role of LND.[165] Seven hundred seventy-two patients were randomized to a radical nephrectomy with or without a complete lymphadenectomy. All patients were clinically node negative based on preoperative CT. The incidence of positive lymph nodes was 4%. After a median follow-up of 12.6 years, there were no differences in OS, progression-free survival (PFS), or complications. One criticism of this trial is that 70% of patients were T1 or T2 category, suggesting a low risk of lymph node involvement. For patients with locally advanced tumors, the benefit of LND is not clearly defined. In a study from Mayo Clinic, LND was performed as part of a radical nephrectomy in 955 patients.[166] High-grade tumor, presence of sarcomatoid features, tumor size ≥10 cm, T3 category, and histologic tissue necrosis were significant predictors of lymph node-positive disease. The presence of these high-risk factors can help to determine which patients may benefit from an extensive LND. Pantuck et al retrospectively analyzed 900 patients with RCC and concluded that a LND offered no survival advantage in patients who were clinically node-negative but was associated with improved survival and improved response to immunotherapy in patients who were node-positive.[167]

Nephron-sparing surgery or partial nephrectomy is an option for selected patients. The initial indications for this surgery were presence of bilateral tumors or a cancer involving an anatomic or functional solitary kidney. Local recurrence was low (<6%). The procedure has subsequently been performed in patients with small tumors (<4 cm), achieving a local relapse rate of ≤3%.[168] Recent data suggest larger tumors (>7 cm) can also be considered for nephron-sparing surgery.[169] Patients undergoing nephron-sparing surgery have a decreased cumulative incidence of chronic renal insufficiency compared with patients who undergo radical nephrectomy.[170,171]

Laparoscopic radical nephrectomy and laparoscopic partial nephrectomy have become a commonly used surgical option for patients with RCC. Both pure and hand-assisted laparoscopic techniques for radical nephrectomy and nephron-sparing surgery achieve oncologic outcomes comparable to the standard open approach.[172-175] Laparoscopic approaches have demonstrated advantages regarding blood loss, length of hospital stay, pain medication usage, cosmetics, and patient recovery compared with the standard open approach.[172,173]

Ablation through radiofrequency heating and cryosurgical freezing are two frequently used techniques to obliterate suspicious small renal lesions.[176] These procedures can be performed through an open, laparoscopic, or percutaneous approach.[176-178] In a review, the local relapse rate with laparoscopic approach was 0% to 15% at a follow-up of 5 years.[179] The percutaneous approach demonstrated similar recurrence rates, but follow-up was only 2 years. Major morbidity was infrequent.

In summary, radical nephrectomy continues to be the first line of therapy for localized renal carcinoma. Less invasive techniques, such as laparoscopic radical nephrectomy, are becoming more popular. Nephron-sparing surgery is increasingly performed for patients with normal contralateral kidneys and for small to medium-sized tumors.

Primary Irradiation

Primary irradiation is rarely used for RCC because of its relative radioresistance. The previous experience with improvement in local control for patients treated with stereotactic radiosurgery for renal cell brain metastases have led to growing interests in the treatment of primary RCC with stereotactic body radiotherapy (SBRT) using high-dose per fraction. Beitler et al reported on nine patients with nonmetastatic primary RCC who refused a nephrectomy.[180] The majority of patients received 40 Gy in 5 fractions over 15 days. With a median follow-up of 26.7 months, four of nine patients survived. Only one patient had a local failure, which consisted of a new primary tumor in the unirradiated portion of the kidney. All surviving patients had an initial tumor size <3.4 cm and no clinical evidence of nodal disease, renal vein, or inferior vena caval extension or penetration of Gerota's fascia. Wersall et al treated eight patients with an inoperable primary or local inoperable recurrence. The median follow-up surpassed 58 months and there was only one local failure.[181]

In a Phase II trial by Svedman et al, 30 patients with inoperable primary or metastatic RCC received SBRT to 82 lesions.[182]

The dose fractionations were 32 Gy to 40 Gy in four or five fractions of 8 Gy, 30 Gy to 40 Gy in three or four fractions of 10 Gy, and 30 Gy to 45 Gy in two or three fractions of 15 Gy. With a median follow-up time of 52 months for living patients and 22 months for deceased patients, local control was 98%. Sixteen of 28 patients experienced side effects, 96% of which were grade I or II.

In a meta-analysis of SBRT for primary RCC, 126 patients from 10 trials were included.[183] Dose and fractionation varied, with 40 Gy in five fractions being the most common. Median and mean follow up ranged from 9 to 57.5 months. The weighted local control rate was 93.1% (range 84% to 100%). Toxicity was acceptable with a weighted rate of grade 3 or higher toxicity of 3.8% (range 0% to 19%).

In summary, early results of SBRT for primary RCC suggest good local control rates in patients unable to undergo a nephrectomy. However, additional studies are needed to confirm the role of SBRT in the management of RCC.

Adjuvant Irradiation

Although the use of postoperative irradiation has been evaluated both retrospectively and prospectively, its role remains controversial (Table 56-4).[184-189] In a nonrandomized comparison of surgery with or without postoperative irradiation, Rafla found a 5-year OS advantage for 94 patients undergoing postoperative irradiation versus 96 patients treated by nephrectomy alone (56% versus 37%).[184] This data was confirmed in an expanded updated analysis.[190] The 5-year OS was 38% (40 of 105) for patients who received postoperative irradiation versus 18% (24 of 135) for those undergoing nephrectomy alone.

In a pseudo-randomized trial of 100 patients (randomization by odd versus even date of birth), Finney found that incidence of distant metastases, local recurrence, and survival were not affected by the addition of postoperative radiation therapy (RT, 55 Gy in 25 fractions in 5 weeks).[185] These results are difficult to interpret because randomization was not blinded or stratified by risk factors. In addition, the mortality of treated patients was high, partly because of liver failure from treatment of patients with right-sided tumors.

A small prospective, randomized study of postoperative RT was conducted by the Copenhagen Renal Cancer Study Group.[186] Patients were randomized to nephrectomy alone (33 patients) versus nephrectomy and postoperative RT (32 patients, 50 Gy in 20 fractions). The 5-year OS was 62% for nephrectomy alone compared with 38% for nephrectomy and postoperative RT. Forty-four percent of the patients treated with RT had significant complications involving the stomach, duodenum, or liver that contributed to the death of 19% of these patients.

The role of postoperative RT using multiple treatment fields and CT-based planning in patients at high risk for local recurrence for RCC was evaluated in several retrospective studies. Stein et al evaluated 147 patients with localized RCC who underwent a nephrectomy.[187] Fifty-six patients received postoperative RT with a median dose of 46 Gy. With a median follow-up of 19 months, there was no difference in OS. However, there were more local recurrences in nonirradiated T3 patients (37% in patients who were nonirradiated versus 11% in patients who were irradiated). In a follow-up descriptive study of patients treated with RT after a nephrectomy, Gez et al reported no benefit of postoperative RT, even for T3 patients.[191]

Kao et al described 12 patients treated with nephrectomy alone and 12 patients treated with nephrectomy and postoperative RT, with a median dose of 45 Gy.[188] After a median follow-up of 5 years, no difference in disease-free survival (DFS) was noted. However, the local failure rate was 30% for the nephrectomy patients and 0% for those who had postoperative RT. In another retrospective study, Ulutin et al found no difference in OS but a significant difference in DFS in favor of radiation therapy for 26 patients treated with postoperative RT compared with 14 patients treated with nephrectomy alone.[189]

Rabinovitch et al performed a patterns-of-failure analysis by CT on patients with localized RCC who underwent a radical or partial nephrectomy alone.[192] The risk of local failure after a gross resection was approximately 5%. Positive surgical margins and positive lymph nodes had an adverse impact on local failure, increasing the rate of local failure to 21%. The risk of distant metastasis after gross resection was 26%. Lymph node involvement and renal vein involvement were significant prognosticators of distant metastases. Approximately half of patients who experienced a local relapse also experienced distant relapse concurrently. Therefore, the risk of micrometastatic disease at the time of surgery must be weighed against the potential benefit of local irradiation.

Tunio et al performed a meta-analysis of seven trials, including 735 patients, to evaluate the effects of postoperative RT.[193] There was a significant reduction in locoregional failure with the use of adjuvant irradiation, with an odds ratio of 0.47. Patient selection for postoperative RT varied among the

studies but included the common high-risk factors of positive margins, lymph node involvement, inferior vena cava or renal vein invasion, and sarcomatoid features. No significant difference in DFS or OS was noted.

In conclusion, the role of routine postoperative irradiation in the management of RCC is not established in patients with localized disease after gross total resection. However, the risk of local failure is higher in patients with positive margins and lymph node involvement, and postoperative irradiation may be considered.

Adjuvant Chemotherapy, Immunotherapy, and Molecularly Targeted Treatment

Adjuvant therapy is given to patients with high risk of systemic disease relapse after curative surgery. Three separate clinical trials evaluating adjuvant interferon-alfa after nephrectomy failed to demonstrate a survival benefit.[194-196] The Cytokine Working Group had conducted a high-dose intravenous bolus interleukin-2 (IL-2) trial versus observation in patients after nephrectomy, and it did not show any survival benefit.[197] A different approach was studied by Jocham et al using autologous tumor cell vaccine.[198] Five hundred and fifty-eight patients with resected pT2-3b, pN0-3, M0 RCC were randomly assigned to vaccine compared with observation. At 4.5 years, PFS was 77% with the vaccine and 68% with observation; however, its effect on OS would require longer follow-up. Phase III studies are being conducted on numerous drugs that have been approved in the metastatic setting for their use in the adjuvant setting, including everolimus, sorafenib, sunitinib, and pazopanib, and the results are pending. At present, there is no indication to support the use of adjuvant systemic therapy for renal cell carcinoma following resection of the kidney for curative intent.

Renal Pelvis and Ureter

Surgery

RNU with removal of the bladder cuff is the standard treatment for patients with UUTCA. The removal of the bladder cuff is recommended because ureteral stump recurrence is seen in 11% to 55% of patients if the stump is left in place.[199,200] Significant factors associated with disease relapse and survival include tumor stage, pathologic grade, nodal metastasis, LVI.[104] Locoregional relapses occur in 9% to 15% of patients with low-grade, low-stage disease and in 30% to 50% of those with high-grade, high-stage disease. The probability of nodal metastasis increases with T category. Although there is controversy about the benefit of lymphadenectomy on the survival of patients, nodal status is a significant prognostic factor and may be used to guide the decision for adjuvant treatment.[101,201,202] Patients with T2-4 disease should have lymphadenectomy. Roscigno et al suggested that at least eight lymph nodes should be removed to achieve a 75% probability of finding ≥1 positive nodes.[203] For selected patients with distal ureteral cancers, distal ureterectomy and lymphadenectomy with reimplantation of ureter may be an option. Jeldes et al developed a nomogram that predicted 5-year CSS based on the age, pT and pN stages, and tumor grade.[204] The nomogram was 75% accurate in predicting 5-year CSS in external validation.

Minimally invasive surgery is now available as an alternative to open nephroureterectomy. The oncologic outcomes of laparoscopic nephroureterectomy (LNU) are similar to open RNU, while achieving a shorter recovery time and hospital stay, as well as fewer blood transfusions.[205-208] In a report of 115 patients, port-site metastasis occurred in one patient (0.9%).[209] In the only prospective randomized trial comparing open RNU with LNU, 80 patients were enrolled.[210] No difference in CSS and metastasis-free survival was found between the two treatment groups except in patients with pT3 and high-grade tumors, for whom open RNU achieved better CSS than LNU. The small number of patients in the study limits the validity of the conclusion. More recently, robot-assisted nephroureterectomy is performed in selected patients.[211-214] It appears to be safe and feasible in some patients, but the long-term oncologic effectiveness of this procedure needs to be confirmed.

More conservative nephron-sparing surgery would be an option for selected patients. These procedures include segmental ureterectomy, or endoscopic surgery with ureteroscopic ablation. The selection criteria usually include low-grade and low-stage disease, superficial disease, small lesion size (<1.0 cm to 1.5 cm), absence of multifocal disease, solitary kidney, bilateral disease, or major medical comorbidities. There are conflicting reports about the efficacy of these nephron-sparing surgery or partial ureterectomy.[212-214] One study reported relapse rate of 68%.[212] Proper patient selection for these procedures is necessary to minimize the risk of local recurrence. These patients would need to be followed closely so that salvage nephroureterectomy can be offered if recurrence is detected.

Primary Irradiation

Primary irradiation is rarely used as initial treatment. The few published reports using primary irradiation are mostly case reports or small series. Some patients with gross residual disease after nephroureterectomy or who have recurrent disease are treated with EBRT. In a series with 19 patients with unresectable disease, the median survival was 11 months for the 11 patients treated with RT versus 4 months for those who did not receive radiation.[199] Two patients were disease free after receiving 45 Gy and 50.4 Gy, respectively, for gross residual disease after surgery. Using doses ranging from 10 Gy to 60 Gy, Batata et al reported one of eight patients had long-term disease control by the use of RT for gross residual disease after surgery.[215]

Combined chemotherapy and radiotherapy has been used successfully as primary treatment for bladder cancer and would seem to be a reasonable treatment for patients with UUTCA who are not surgical candidates. However, there are little data for such an approach. Many patients have medical comorbidities that make them ineligible for surgery as well as poor candidates for cisplatin-based chemotherapy. Prospective studies evaluating the use of combined chemotherapy and radiation are urgently needed.

Adjuvant Irradiation

The risk of local relapse correlates with the stage of disease and tumor grade and can be up to 45% despite radical surgery. In a study by Cozad et al, the 5-year local control rate was 90% for grades 1 and 2 tumors and 41% for grades 3 and 4 tumors, respectively.[199] For stage I and II disease, the 5-year local control rate was 83%, compared with 52% for stage III disease. About half of the local relapses presented initially as isolated site of relapse. Distant metastasis occurred in 19% of patients with stages I and II disease and in 53% with stage III disease. Distant metastasis was the predominant site of initial relapse for stage III disease. The risk of lymph node metastasis also increases with disease stage and tumor grade.[104] The pattern of failure demonstrates that patients with high-stage or high-grade disease have significant risks of both distant and local relapse

Few studies have been published to evaluate the role of adjuvant irradiation in the management of UUTCA. Table 56-5 summarizes several published studies on the outcome of adjuvant irradiation for UUTCA. In a study by Cozad et al, 9 of 26 patients with T3 or T4 N0/+ disease received adjuvant

TABLE 56-5 Adjuvant Irradiation for Renal Pelvic and Ureteral Carcinoma

Study	Stage	Treatment	N	RT Dose	Local Failure	Survival

irradiation to a median dose of 50 Gy.[216] Local failure occurred in 9 of 17 without and 1 of 9 with adjuvant irradiation. The benefit of adjuvant irradiation was seen only in high-grade tumors. Five-year OS was 44% with, and 24% without, adjuvant irradiation ($p = 0.23$). In a study by Brookland and Richter, adjuvant irradiation was given to 11 of 23 patients who had tumor grade 3 or 4, or pathologic stage ≥T3.[217] The median dose was 50 Gy to the ureteropelvic bed, with or without inclusion of the paraaortic nodes. For the nonirradiated group, the median survival was 26 months and the local relapse rate was 45%, compared with 35 months and 11%, respectively, for those who received adjuvant irradiation. In a study by Chen et al, 67 of 133 patients received 50 Gy of adjuvant irradiation after surgery.[218] The clinical target volume included the ipsilateral ureteropelvic bed, the bladder, and the paracaval/paraaortic lymph nodes. Although there was no difference in the median survival of the radiation and no radiation group, there was a significant improvement in OS for patients with T3 or T4 tumors with adjuvant irradiation (29.9 months versus 11.4 months).

Czito et al reported a series of 31 patients with T3/4 or N+ disease that was treated with adjuvant irradiation to a median dose of 46.9 Gy.[219] Adjuvant MVAC (methotrexate, vinblastine, doxorubicin, cisplatin) chemotherapy and concurrent cisplatin with radiation was given to 9 patients. Five-year OS, DSS, locoregional control, and metastasis-free survival rates were 39%, 52%, 67%, and 48%, respectively. Compared with irradiation alone, the use of concurrent cisplatin improved the OS (67% versus 27%) and DSS (76% versus 41%). This study suggests that the addition of concurrent cisplatin to adjuvant radiotherapy improves the survival of patients with locally advanced disease.

Other studies have questioned the benefits of adjuvant irradiation. In a series of 138 patients, 45 received postoperative RT with a median dose of 50 Gy.[94] The 5-year OS was 21% for those who received postoperative RT, compared with 33% for those who did not. The 5-year locoregional failure rate was 67% for the patients who received postoperative RT, and 62% for those who had surgery only. However, patients who received postoperative RT had significantly higher T category and tumor grade. Moreover, 33% of the patients who had postoperative RT had either microscopic or macroscopic positive surgical margins, compared with 22% of those who had surgery alone. Maulard-Durdux et al treated 26 patients with 45 Gy of adjuvant RT and concluded that local control and OS were similar to those of other surgical series.[107]

Adjuvant Chemotherapy

Urothelial cancers of the bladder are sensitive to chemotherapy. However, there are few studies evaluating the use of adjuvant chemotherapy for UUTCA. Kwak et al reported a series in which 32 patients received more than four cycles of cisplatin-based adjuvant chemotherapy, whereas 11 did not.[220] Most of these patients had T3 cancer. Disease relapses occurred in 38% of those who had adjuvant chemotherapy, compared with 64% for those who did not. The 3-year OS was 81% versus 36%, respectively. In another small series of 46 patients, most of whom had pT3N0 disease, 24 were given adjuvant MVAC chemotherapy while 22 were observed.[221] There was a significant improvement in 5-year intravesical recurrence-free survival in the chemotherapy group compared with the nonchemotherapy group (84% versus 39%). However, there was no difference in OS. In a report that included 93 patients with pT3 disease, Kawashima et al reported an improvement in 5-year CSS from 64% to 81% by the use of adjuvant chemotherapy with MVAC or gemcitabine-cisplatin (GC).[222]

In an international collaborative database that included 542 high-risk patients, among which 121 received adjuvant chemotherapy, there was no difference in median OS and DSS between the chemotherapy and nonchemotherapy group.[223] However, the percentage of patients with high-grade and high-stage disease in the chemotherapy group was significantly more than in the nonchemotherapy group. Another international retrospective collaborative database also failed to demonstrate a survival benefit of adjuvant chemotherapy.[224] In summary, the role of adjuvant chemotherapy for UUTCA remains undefined and prospective studies are needed before its routine use can be recommended.

Neoadjuvant chemotherapy has been shown to improve survival in invasive bladder cancer. It would also be expected to provide benefits for patients with UUTCA because of the similarity in pathology between these two diseases. In a

TABLE 56-6 Preoperative Irradiation for Renal Cell Carcinoma

retrospective study comparing the outcomes of 43 patients with high-risk UUTCA and were given neoadjuvant chemotherapy, using mainly MVAC or GC, to 107 patients treated with surgery only, there was a significant downstaging of disease by neoadjuvant chemotherapy, with a pathologic CR in 14% of patients.[225] Youssef et al reported the result of neoadjuvant chemotherapy with MVAC or GC in 18 patients with node-positive UUTCA and compared the result to 120 patients treated with RNU alone.[226] The 5-year DFS were 49% and 30%, whereas the CSS were 44% and 36%, respectively. After neoadjuvant chemotherapy, 9 patients were pN0, 6 patients were pT0, and 5 patients were pT0N0. Available data suggest that neoadjuvant chemotherapy is likely to be beneficial to patients with node-positive or high-grade, high T category disease. Additional studies are needed to define the efficacy of neoadjuvant chemotherapy for UUTCA.

Adjuvant Topical Therapy

Intravesical therapy with Bacillus Calmette-Guerin (BCG) or other agents like mitomycin C has been studied in both noninvasive and invasive UUTCA. In a prospective randomized trial of 284 patients, a single dose of adjuvant intravesical mitomycin C resulted in an absolute reduction in risk of bladder tumor of 11% within the first year following RNU, compared to no treatment (16% versus 27%).[227] In a Phase II randomized trial by Ito et al, a single intravesical instillation of pirarubicin reduced the 2-year risk of bladder recurrence from 42% to 17%.[228] Topical treatment may have a role in the management of carcinoma-in-situ (CIS) of UUT and spare the patients from RNU. Shapiro et al reported the use of 6 weeks induction course of BCG/interferon α2B via an open-ended ureteral catheter for patients with biopsy proven isolated UUT-CIS. If there was a complete response (CR) (no visualized disease and negative cytology), patients would receive maintenance therapy for 2 years.[229] Eight of 11 patients achieved an initial CR after induction treatment. At a median follow-up of 13.5 months, the kidney preservation rate was 91%. In another study of 55 patients, antegrade perfusion with BCG resulted in recurrence-free survival of 53% after a median follow-up of 42 months.[230]

LOCALLY ADVANCED DISEASE

Kidney

RCCs rarely invade adjacent organs at presentation. Large tumors tend to displace and compress adjacent tissue. However, if tumor directly invades contiguous tissues such as the liver, duodenum, large intestine, and perinephric muscle, surgical resection may not be feasible. Preoperative irradiation can downsize the tumor and cause fibrosis, with thickening of the tumor capsule and sclerosis of small blood vessels, increasing the likelihood of an adequate surgical resection.[231] In a retrospective review, Riches et al reported survival advantages of patients treated with preoperative irradiation versus surgery alone (5-year OS: 49% versus 30%).[232]

Two prospective clinical trials evaluating the role of neoadjuvant irradiation have been conducted (Table 56-6).[233,234] Van der Werf-Messing reported a series of 126 patients from 1965 to 1972 randomized to nephrectomy alone versus low-dose preoperative RT (30 Gy in 15 fractions for 3 weeks) followed by nephrectomy.[233] Complete resection was more frequent for patients with tumors infiltrating intrarenal or extrarenal veins or lymph vessels. Survival was considerably better at 18 months with the use of preoperative irradiation. However, there was no difference in 5-year OS. Juusela et al conducted a prospective, randomized study of preoperative irradiation followed by nephrectomy (38 patients) versus nephrectomy alone (44 patients).[234] Patients treated with preoperative RT received 2.2 Gy per day to a total dose of 33 Gy and had a 47% 5-year OS, compared with 63% for patients treated with nephrectomy alone.

Intraoperative Irradiation Containing Approaches

In addition to neoadjuvant EBRT, an intraoperative irradiation supplement with electrons (IOERT) or high-dose-rate brachytherapy (HDR-IORT) may be used as an additive component of treatment in patients with locally advanced primary or recurrent disease.

IOERT has been used at the Mayo Clinic since 1983 as a component of therapy in selected patients with locally advanced genitourinary malignancies. In a recent update of the Mayo Clinic series, IOERT was used as a supplement to EBRT and resection in 25 patients with locally advanced recurrent (19 patients) or primary (3 patients) renal cell carcinoma.[235] Twenty-one patients (95%) received perioperative EBRT to a median dose of 45 Gy (range, 41.4 Gy to 55 Gy). Surgical resection was R0 in 5 patients (23%) and R1 in the remaining 17 (77%). The median IOERT dose was 12.5 Gy (range, 10 Gy to 20 Gy). With a median follow-up of 9.9 years in surviving patients, 5-year and 10-year survival was observed in 40% and 35%, respectively, and 5-year and 10-year DFS was 31%. Central relapse within the IOERT field was observed in 9%, local relapse in the EBRT field in 27%, and distant relapse in 64% of patients. Five patients (23%) experienced grade-3 or greater toxicity.

The University Gregorio Marañón in Madrid used IOERT as a component of treatment for 25 patients with locally advanced primary (15 patients) or locally recurrent (10 patients) lesions.[236] Patients received IOERT after maximal surgical resection, and 15 of the 25 received perioperative EBRT (median 44 Gy). Six patients had R0 resection and the remaining 19 had microscopic residual disease (R1). The IOERT dose ranged from 9 Gy to 15 Gy (median 14 Gy). Five-year and 10- year OS was 38% and 18%, respectively, and 5-year and 10-year DFS was 19% and 14%, respectively. Local control was achieved in 80% of patients, whereas 5-year distant metastasis

free survival was 22%. Six patients (24%) experienced grade-3 or greater toxicity.

Eble et al reported a University of Heidelberg series of 11 patients with renal cancer in whom IOERT was given as a component of treatment (primary, 3 patients; locally recurrent, 8 patients).[237] Patients had maximal resection, IOERT (15 Gy to 20 Gy), and postoperative EBRT (40 Gy in 2-Gy fractions, 5 days per week). Only 1 patient had R0 resection and the remainder had microscopic or gross residual disease. With mean follow-up of 24 months, no local relapse occurred. Distant metastases, however, occurred in 7 of 11 patients, or 64%. At 4 years, OS and DFS were 47% and 34%, respectively.

At UCSF, 10 of 14 patients who underwent resection of recurrent renal cancer received IOERT.[238] Nine patients died of progressive metastatic disease at a mean of 17 months. Five patients were alive (mean 66 months; range 14 months to 86 months) and OS was 40% at 2 years and 30% at 5 years. Local re-recurrence was observed in 2 patients.

More recently, a multiinstitutional study was published including patients treated at nine centers for locally advanced or recurrent renal cell carcinoma.[239] Of the 98 patients, 28% were treated for locally advanced disease, with a 5-year OS and DFS of 37% and 39%, respectively. In patients with locally recurrent disease, the 5-year OS was 55% and DFS was 52%. Initial nodal involvement, presence of sarcomatoid features, and higher IORT dose were associated with a decrement in OS. For patients with locally recurrent disease, the presence of a positive margin was associated with decrease in OS.

Renal Pelvis and Ureter

The prognosis for patients with locally advanced or unresectable UUTCA is poor. Long-term disease control has been reported in some patients who have gross residual or locally recurrent disease with the use of radiation therapy, with or without chemotherapy.[199,215] In a report by Cozad et al, postoperative irradiation was given to 11 of 19 patients with gross residual disease after surgery.[199] The median survival was 11 months for the irradiated group versus 4 months for those without radiation. Two patients who were treated with 45 Gy and 50.4 Gy of irradiation were disease-free at 21 months and 28 months. One of these 2 also had concurrent MVAC chemotherapy. In selected patients with locally advanced UUTCA, preoperative irradiation with or without chemotherapy may downstage the disease to allow surgical resection.

IOERT is an appealing adjunct in the management of locally advanced UUTCA. After preoperative EBRT with or without chemotherapy to downsize the tumor, patients may proceed to surgery. A boost may be given to areas of close or positive margins with IOERT while sparing the surrounding normal organs. Zhang et al treated 17 patients with locally advanced ureteral cancer with RNU and IOERT, followed by adjuvant EBRT.[240] Five patients had microscopic or grossly positive margins. The median IOERT dose was 14 Gy, and the median EBRT dose was 42 Gy. Adjuvant MVAC was given to 10 patients. The 5-year OS and local control rates were 46% and 51%, respectively. Two patients developed late grade-3 gastrointestinal toxicities. Dose escalation using IOERT appears to be an option for patients with locally advanced UUTCA.

PALLIATION AND METASTATIC DISEASE

Kidney

In patients with demonstrated widespread metastatic disease at initial diagnosis, nephrectomy is not justified if the intent is to induce a spontaneous regression; the incidence of such a regression is less than 1% and the morbidity outweighs the benefit. A palliative nephrectomy can be considered in patients suffering from repeated hemorrhages, tumor pain, or significant paraneoplastic syndromes.[71]

The role of nephrectomy has been evaluated in patients who present with solitary metastatic disease. Among 158 patients who presented to the Mayo Clinic between 1970 and 1980 with metastatic disease and no prior treatment at diagnosis, 56 patients (35%) had a solitary metastasis.[241] Nephrectomy was performed on 67.6% of patients who presented with multiple metastases and 83.9% of patients with solitary metastasis. The OS at 2 and 3 years for patients with solitary metastasis was 29.1% and 19%, compared with 6.8% and 4.3%, respectively, for patients with multiple lesions. Nephrectomy had a significant impact on survival only in patients with solitary metastasis, low-grade primary tumor, and weight loss of less than 10%.

Two clinical trials have shown that debulking nephrectomy may enhance the effect of immunotherapy. The Southwest Oncology Group (SWOG) randomized 241 patients with an ECOG performance status of 0 to 1 to initial nephrectomy followed by interferon versus interferon alone.[242] The median survival of the nephrectomy group was significantly improved by 3 months (11.1 versus 8.1 months). The EORTC also conducted a trial similar to the SWOG trial in 83 patients with metastatic RCC and an ECOG performance status of 0 to 1.[243] Patients undergoing nephrectomy experienced a 10-month median survival benefit (17 versus 7 months) and improved time to progression (5 versus 3 months). These debulking nephrectomy trials show that patients with a good performance status who subsequently receive interferon immunotherapy experience an improved survival. There are no prospective trials evaluating debulking nephrectomy followed by molecularly targeted therapy.

Motzer and associates evaluated prognostic factors for 670 patients with metastatic or recurrent RCC to develop a predictive model for survival.[244] The absence of a nephrectomy was a predictor for lower survival.

Solitary Metastases

Treatment of a solitary metastatic site has been evaluated in patients with both synchronous and metachronous solitary metastasis. Kavolius et al retrospectively evaluated 278 patients who developed recurrent or metastatic RCC after nephrectomy.[245] The 5-year OS for 141 patients treated with a curative metastasectomy for their first relapse was 44% as compared with 14% for patients who underwent noncurative surgery and 11% for patients treated nonsurgically. Factors associated with improved OS included a solitary site of first relapse, curative resection of first metastasis, and a long disease-free interval.

Leibovich et al developed a scoring algorithm to predict CSS based on 727 patients with metastatic RCC.[246] Two hundred eighty-five patients (39%) had metastatic disease at presentation and 87% of patients had a solitary metastasis. One hundred ninety-two patients (26.4%) underwent a complete resection, defined as no evidence of disease after nephrectomy and metastasectomy. Complete resection was associated with an improvement CSS on multivariate analysis. The presence of constitutional symptoms at presentation, bone metastases, liver metastases, tumor thrombus, multiple metastases, less than 2 years from nephrectomy to metastases, high nuclear grade, and coagulative tumor necrosis were associated with an increased risk of death.

Similarly, Naito et al studied 1463 patients with metastatic RCC, of whom 146 patients (20.8%) had undergone a metastasectomy.[247] The median OS in patients undergoing a

metastasectomy was 44.3 months compared with 16.4 months in patients who did not undergo a metastasectomy.

In summary, patients presenting with a synchronous or a metachronous solitary metastasis after a long disease-free interval may experience a prolonged survival compared to patients with extensive metastases and may warrant more aggressive treatment to the initial metastatic site.

Bone and Soft-Tissue Metastases

Metastases to the bone (solitary or multiple) may occur in 25% to 50% of all patients with RCC. Althausen et al evaluated 38 patients with osseous metastases secondary to RCC. Patients were treated with resection with or without allograft implantation, RT alone, or a combination of treatments.[248] The survival for the entire group was 90% at 6 months, 84% at 1 year, 55% at 5 years, and 39% at 10 years. Presentation without metastasis, long disease-free interval between nephrectomy and first metastases, appendicular skeletal location, and solitary metastasis were associated with longer survival. The authors concluded that patients who have an appendicular (preferably solitary) metastasis and who have a long duration from diagnosis of disease to metastasis should be treated with complex orthopedic surgical procedures if necessary. Postoperative irradiation should be considered in selected cases.

Palliative RT is an effective treatment for bone pain. Halperin and Harisiadis evaluated the results of 36 sites irradiated for bone pain.[249] The pain decreased in 77% of the treated sites, and the majority of the sites received a time-dose fractionation (TDF) equivalent dose ranging from 45 to 85. No relation was observed between the TDF equivalent dose and the probability of response. Twenty-four of the 28 sites (86%) were partially or completely free of pain for the remainder of the patients' lives. Wilson et al reported partial and symptomatic response rates to palliative irradiation, with pain reduction of 67% and 73%, respectively.[250] A dose response based on the biologic effective dose could not be established. In a prospective Phase II trial, Lee et al evaluated the effect of radiation therapy on symptoms in 31 patients with bone or soft-tissue RCC metastases.[251] With a median follow-up of 4.3 months, 83% of patients experienced site-specific pain relief with a median duration of response of 3 months.

Stereotactic body radiotherapy (SBRT) has been used for treatment of metastatic RCC to the spine and other extracranial sites. Zelefsky et al treated 105 metastatic lesions, primarily bone, with single fraction SBRT (59 lesions) at a median dose of 24 Gy (range 18 Gy to 24 Gy) or hypofractionated SBRT in three to five fractions to a dose of 24 Gy to 30 Gy (46 lesions).[252] The 3-year local PFS was significantly better for patients receiving 24 Gy in a single fraction (88%) compared to patients receiving lower dose single fraction treatment of <24 Gy (21%) or a hypofractionated course (17%). Gerszten et al treated 60 spinal lesions in 48 patients with a single fraction of radiation at median dose of 20 Gy.[253] Eighty-nine percent of patients experienced improvement in pain. Six patients eventually required surgical intervention because of disease progression. Nguyen et al reviewed 48 patients who underwent SBRT to 55 spinal lesions.[254] Doses included 24 Gy in one fraction, 27 Gy in three fractions, and 30 Gy in five fractions. Fifty-two percent of patients were pain free at 12 months. No grade-3 or grade-4 neurologic toxicity occurred.

Brain Metastases

Brain metastases are diagnosed in approximately 10% of patients with metastatic RCC.[255] In a retrospective study of 119 patients treated at M. D. Anderson Cancer Center, the median radiation dose was 30 Gy (range, 18 Gy to 56 Gy).[255] The median OS from the time of diagnosis of the brain metastases was 4.4 months. The cause of death was neurologic in 90 of the 119 patients (76%), suggesting poor central nervous system (CNS) control with conventional whole-brain irradiation (WBRT) alone. A retrospective comparison of WBRT dose comparing 30 Gy in 10 fractions to higher doses (40 Gy in 20 fractions or 45 Gy in 15 fractions) showed an improvement in both OS and local control with higher doses.[256] The median OS was 4 months versus 12 months and local control at 12 months was 7% versus 35%, respectively.

In view of the poor outcome of patients after WBRT, more aggressive treatments have been evaluated in selected patients with favorable prognostic features. Patients who could undergo surgical resection of brain metastases from RCC had a 12-month median survival.[257] Several retrospective studies, shown in Table 56-7, have reported local tumor control rates of 81% to 100% and median OS of 5 months to 12 months in patients treated with radiosurgery alone, or in combination with WBRT.[258-266] Although the local control rates were impressive, the follow-up interval in most series was short. For patients who have good performance status and systemic disease that is reasonably controlled, radiosurgery is an appealing option for management of brain metastasis.

Chemotherapy, Immunotherapy, and Molecularly Targeted Treatment

There is a plethora of molecularly targeted and immunotherapeutic agents for the therapy of metastatic kidney cancer, specifically clear cell RCC. These include sorafenib, sunitinib, temsirolimus, bevacizumab, interferon alpha (IFN), interleukin-2, pazopanib, and axitinib. The most common criteria used for therapy decisions are the Motzer criteria, which classify patients into different risk categories (favorable,

intermediate, and poor risk.).[244] Shorter survival is associated with low Karnofsky performance status (<80%), high corrected serum calcium (>10 mg/dL), low hemoglobin (<12 g/dL), high LDH (>1.5 times the upper limit of normal), and relapse of renal cancer within a year after nephrectomy. Several therapies, including sunitinib, pazopanib, and bevacizumab/interferon, have been approved for favorable and intermediate risk clear cell RCC in the first line setting.

Sunitinib is an oral tyrosine kinase inhibitor (TKI) that inhibits signaling by vascular endothelial growth factor receptor (VEGFR), platelet-derived growth factor receptor (PDGFR), and FLT-3. A Phase III study compared sunitinib and IFN-α in 750 patients who were treatment naive.[267] The median PFS was 11 months for sunitinib and 5 months for IFN ($p < 0.001$). Median OS was 26.4 months versus 21.8 months for sunitinib and IFN, respectively ($p = 0.051$). Common side effects include hypertension, fatigue, hand-foot syndrome, diarrhea, myelosuppression, and thyroid dysfunction.

Pazopanib is an oral multikinase TKI that inhibits signaling for VEGFR, PDGFR, and c-kit. A Phase III study in treatment naïve and cytokine pretreated patients compared pazopanib with placebo.[268] This study showed an improvement in PFS of 9.2 versus 4.2 months ($p < 0.000$). The median duration of response was longer than one year and the response rate was 30% as compared to 3% in the placebo arm. This drug has similar side effect profile as sunitinib. In a Phase III study comparing the tolerability of sunitinib and pazopanib, pazopanib caused fewer side effects and resulted in better quality of life.[269]

Bevacizumab is a monoclonal antibody to VEGFR. Two Phase III studies, including the AVOREN and CALGB 90206, showed improvement of PFS with the combination of bevacizumab and IFN compared to IFN alone. In the AVOREN study, PFS was 10.2 months with bevacizumab and IFN compared to 5.4 months with IFN alone ($p = 0.0001$).[270] In the CALGB study, patients receiving the combination of bevacizumab and IFN had a PFS of 8.5 months as compared to 5.2 months with IFN alone ($p < 0.0001$). Common side effects include hypertension, proteinuria, bleeding, thromboembolism, and poor wound healing.[271]

Temsirolimus is the only drug approved for the treatment of poor risk patients in the first-line setting. Temsirolimus is an intravenous M-TOR inhibitor. A Phase III study comparing interferon alpha, IFN with temsirolimus and temsirolimus alone showed survival benefit of 3 months with single-agent temsirolimus when compared to IFN alone or the combination of drugs in patients who were poor risk based on the Motzer criteria (temsirolimus 10.9 months, IFN 7.3 months, temsirolimus + IFN 8.4 months).[272] Common side effects include myelosuppression, dyslipidemia, hyperglycemia, fatigue, diarrhea, nausea, rash, stomatitis, and pneumonitis.

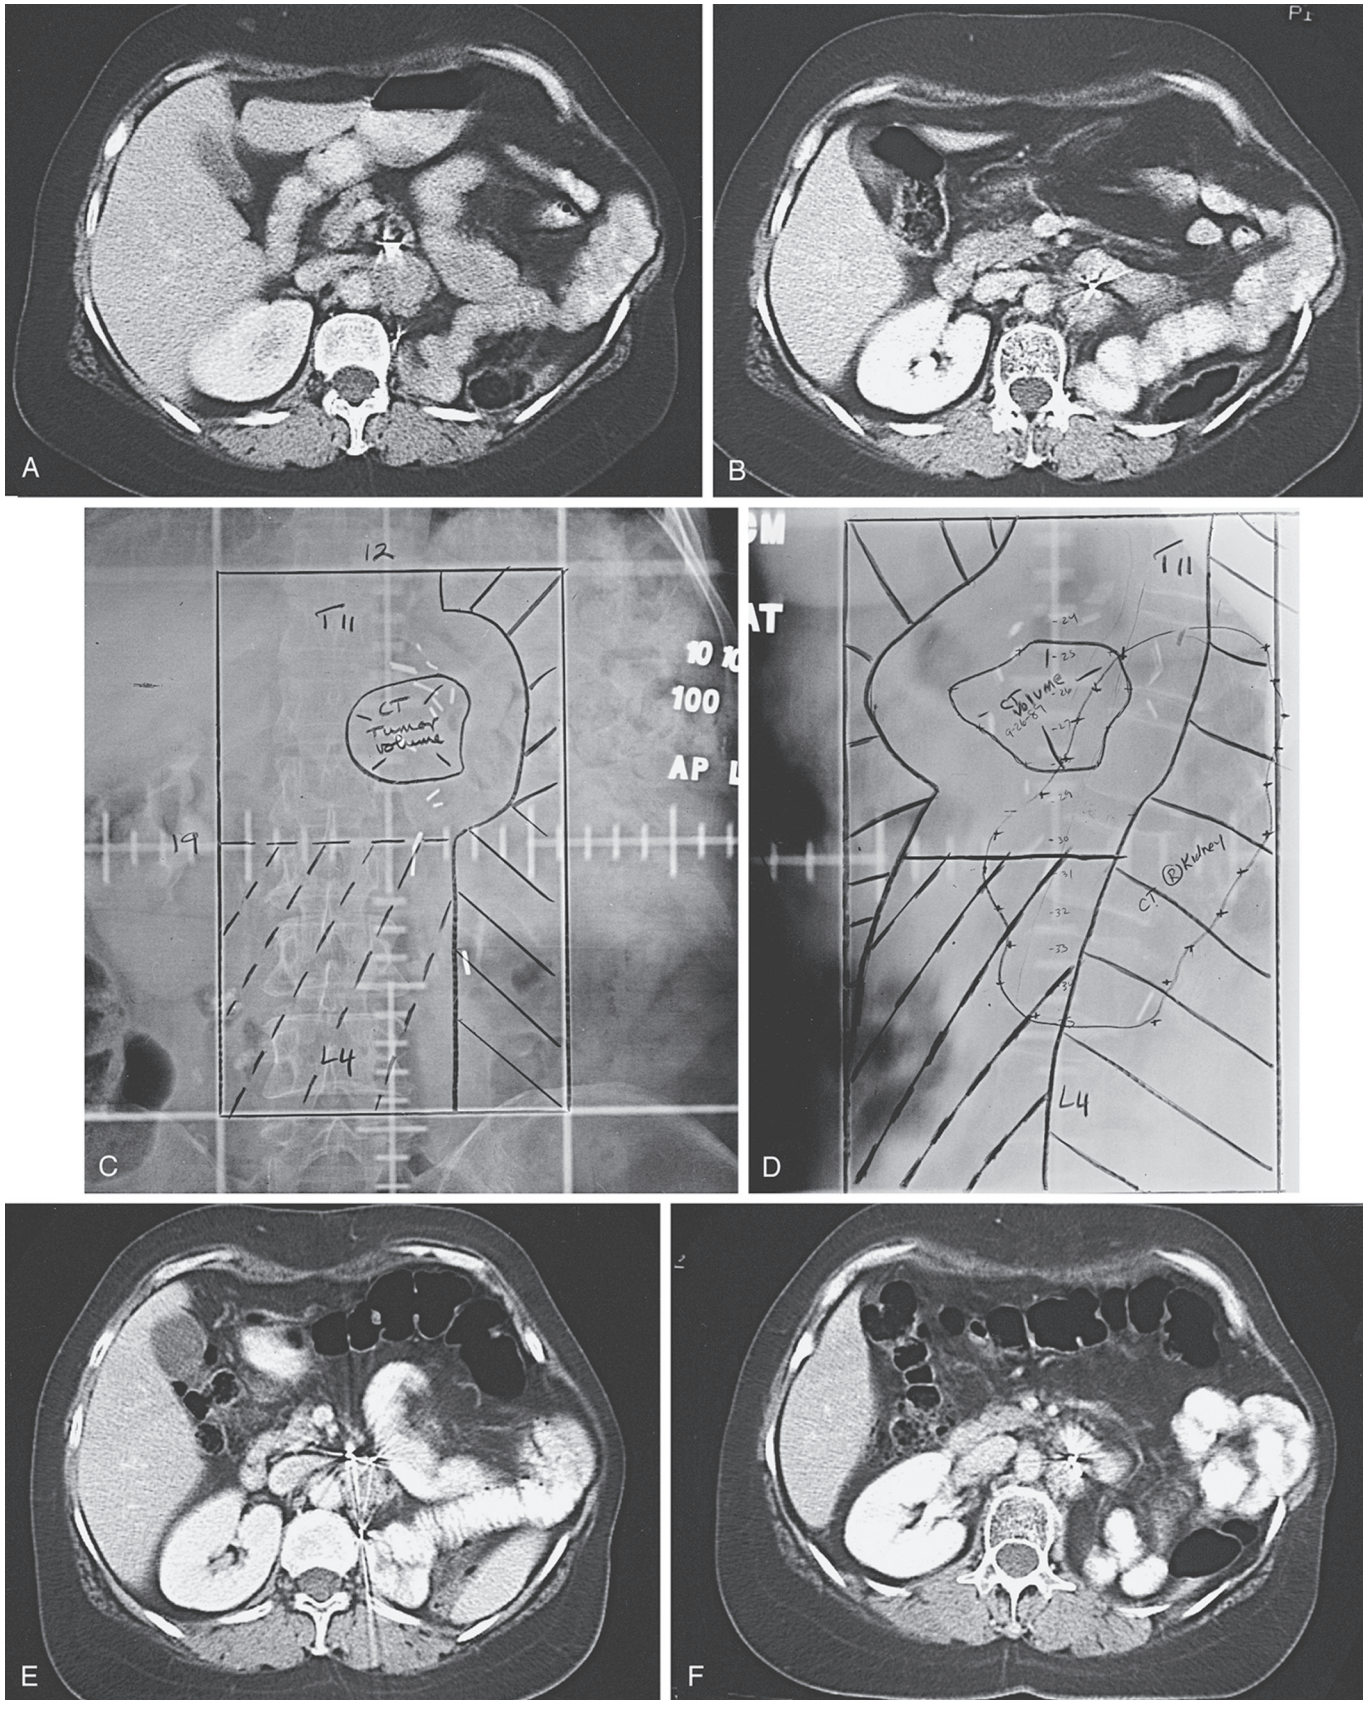
Sorafenib, pazopanib, everolimus, and axitinib are approved for treatment of metastatic RCC as second-line therapy. Sorafenib is an oral kinase inhibitor that inhibits targets such as VEGFR and PDGFR. A Phase III study by Escudier et al showed a PFS of 5.6 months with sorafenib compared to 5.7 months with IFN.[273] However, patients receiving sorafenib had a better quality of life and more reduction in their tumor burden. Sorafenib was the first targeted drug to be approved for RCC after cytokine therapy tumor progression. Common side effects include hypertension, fatigue, diarrhea, and hand-foot syndrome.

Everolimus is an oral M-TOR inhibitor. It was approved in advanced RCC for use after sunitinib or sorafenib disease progression. A Phase III trial comparing everolimus and placebo showed a median PFS of 4 months with everolimus compared to 1.9 months with placebo.[274] However, OS was 10.8 months with everolimus and 14.4 months with placebo. Cross-over was allowed in the study, which could account for the similar survival. Common side effects include myelosuppression, dyslipidemia, hyperglycemia, fatigue, diarrhea, nausea, rash, stomatitis, and pneumonitis.

Axitinib is another multikinase inhibitor of VEGFR 1, 2, and 3. In a Phase III study comparing axitinib and sorafenib in the second-line setting, axitinib had a longer PFS of 6.7 months versus 4.7 months and an improved response rate of 19% compared to 9.4%.[275] Toxicities are similar to other VEGFR inhibitors.

Renal Pelvis and Ureter

For patients with metastatic disease and good performance status, cisplatin-based chemotherapy can be considered. The response rates range from 54% to 70%.[276-278] At present, no molecularly targeted treatment is available for advanced UUTCA. EBRT can be used palliatively for local symptoms such as pain from bony metastasis.



IRRADIATION TECHNIQUES AND TOLERANCE

Kidney

Postoperative radiation should be considered for patients at high risk for local recurrence after surgery. Pathologic features predictive of local recurrence include positive lymph nodes and positive surgical margins. The clinical target volume should include the tumor bed, surgical clips, regional lymph nodes (hilar and paraaortic lymph nodes), and vascular extent of tumor (Figure 56-1). If feasible, the scar should be included in the target volume because scar recurrences have been reported.[187] Total radiation doses of 45 Gy to 50.4 Gy should be delivered with 1.8-Gy to 2-Gy fractions using multiple-field techniques. In addition, small-volume fields can be used to boost areas of residual disease to a total of 55 Gy to 60 Gy. Delivery of the boost can be facilitated by surgical reconstruction to displace small intestine or stomach, placement of surgical clips at the site of residual disease, prone positioning, and false tabletop techniques. Intensity-modulated radiation therapy (IMRT) can be used to treat the target volume and minimize the dose to the normal tissues (liver, small bowel, stomach, opposite kidney, and spinal cord) (Figures 56-2 and 56-3; see also Figure 56-1).

Preoperative irradiation treatment volumes for patients with locally advanced disease should encompass the primary tumor, renal hilar lymph nodes, paraaortic lymph nodes, and vascular extent of tumor. To spare dose-limiting organs, three-dimensional conformal field (3DCRT) combinations of anterior-posterior/posterior-anterior (AP/PA), laterals, or obliques are recommended. IMRT can also be used to minimize the dose to normal tissues (see Figure 56-3). Total doses of 45 Gy to 50.4 Gy in 1.8-Gy to 2.0-Gy fractions should be given preoperatively, followed by surgery in 4 to 6 weeks. If possible, an IORT supplement should be considered if residual disease or narrow margins exist after maximal surgical resection. At the Mayo Clinic, doses of 10 Gy to 20 Gy are usually delivered with IOERT; the dose is dependent on margin status and amount of EBRT delivered preoperatively or planned postoperatively.[235]

Patients in whom a local recurrence has developed in the tumor bed or regional nodes after radical nephrectomy should be considered for aggressive salvage treatment. This treatment includes preoperative RT or chemoradiation with 3DCRT or IMRT to the recurrent tumor volume, postoperative tumor bed, and renal hilar and paraaortic lymph nodes. A traditional field is shown in eFigure 56-1 on the Expert Consult website.

eFigure 56-1 Imaging studies and irradiation fields for a patient with locally recurrent renal cell carcinoma who received preoperative external beam irradiation before resection and intraoperative electron irradiation (IOERT) at the Mayo Clinic. **A** and **B,** Pre-irradiation CT scan demonstrates bulky paraaortic adenopathy and lack of fat plane adjacent to the aorta. **C** and **D,** Irradiation fields encompass the recurrent tumor and paraaortic lymph nodes using a multifield technique of anterior-posterior/posterior-anterior (AP/PA) **(C)** plus paired laterals **(D)** to deliver 45 Gy in 25 fractions to large fields from T-11 through L-4 *(solid lines).* The right kidney was excluded from the AP/PA fields **(C)** except for the upper medial components (>75% excluded). Because approximately 50% of the right kidney was within the lateral fields **(D)**, the lateral dose contribution was limited to less than 18 Gy. Spinal cord was excluded from the lateral fields. After 45 Gy, the field was altered to block from isocenter inferiorly *(interrupted lines).* **E** and **F,** Posttreatment CT scan of abdomen 4 weeks after 50.4 Gy/28 fractions/5 weeks and 2.5 months after pretreatment scan; note shrinkage of mass with the improved fat planes relative to aorta. An IOERT dose of 12.5 Gy was given after a marginal gross total resection.

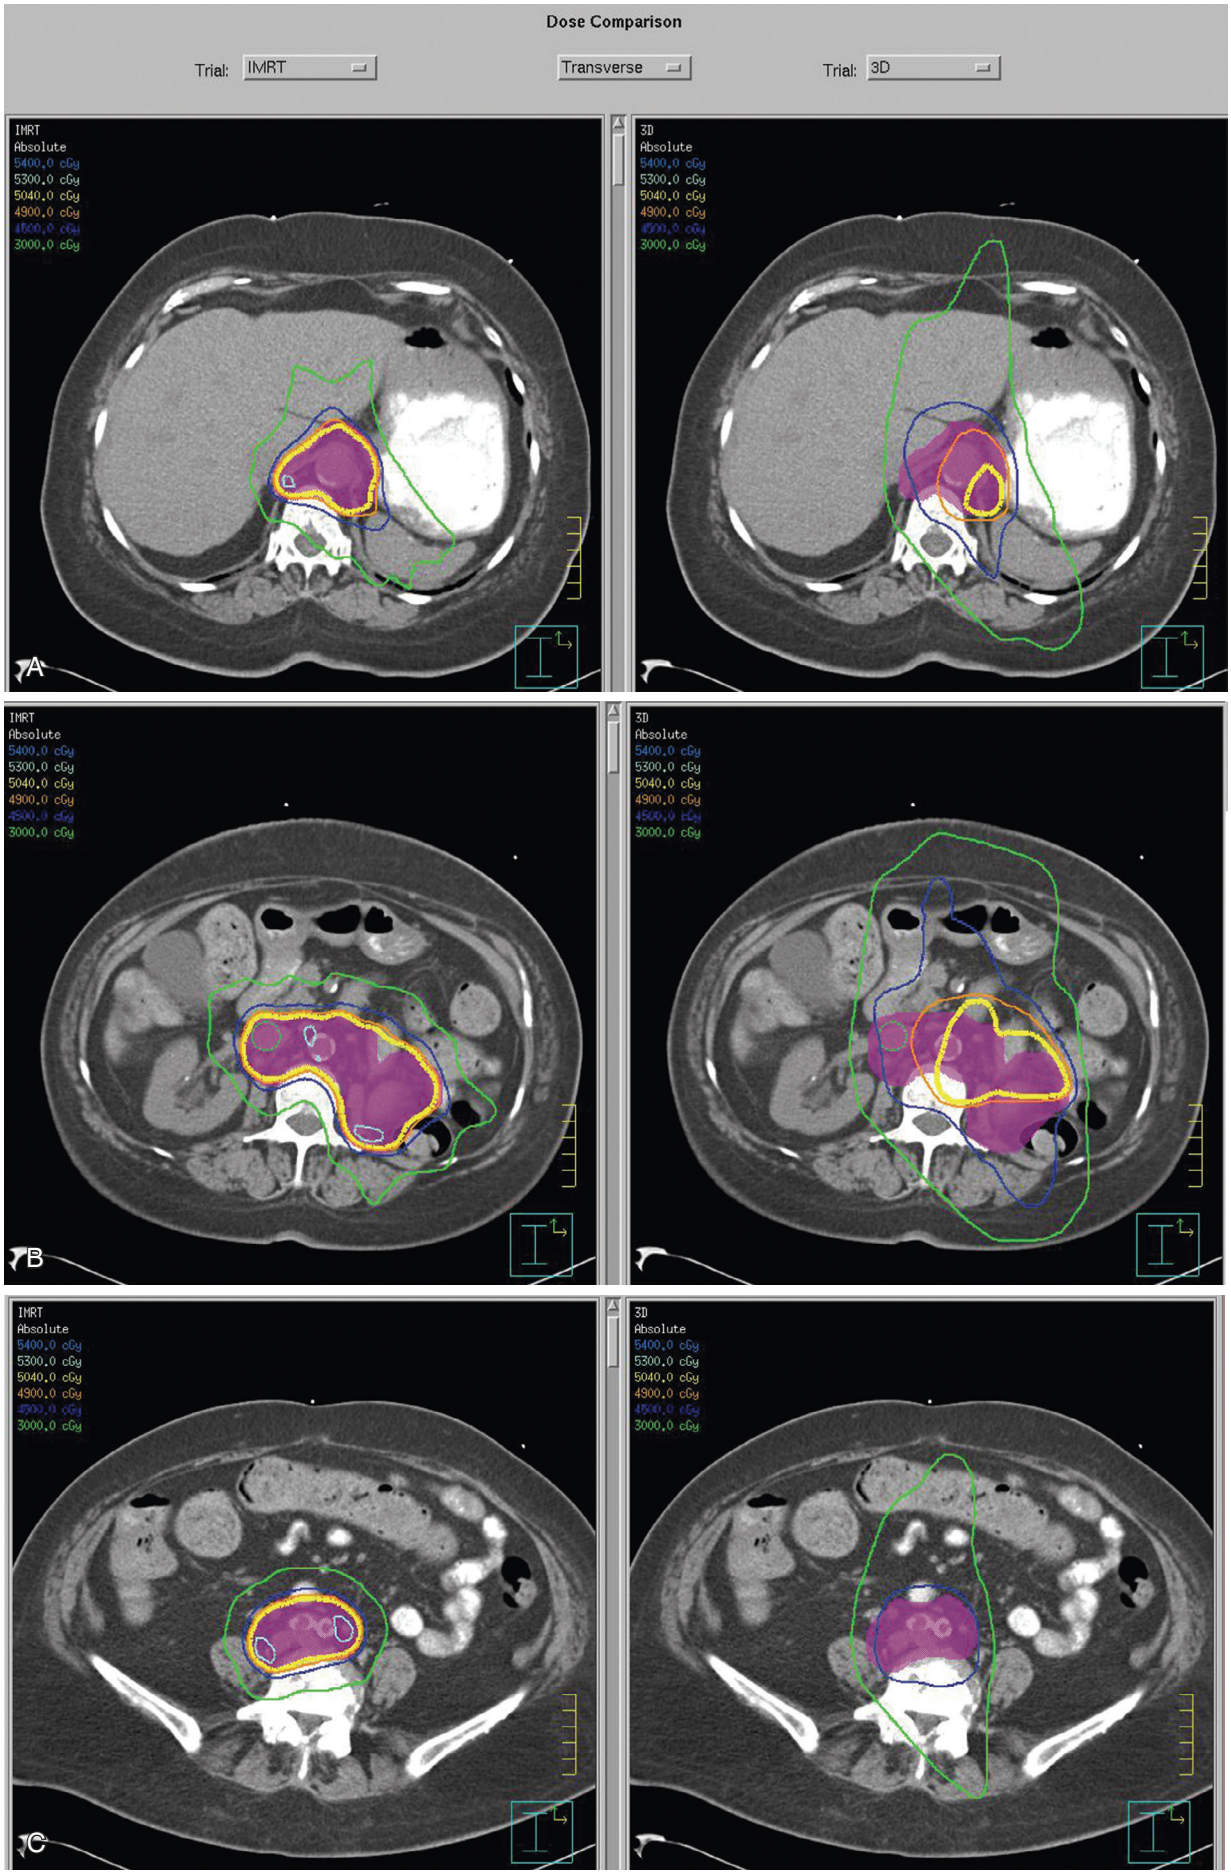

Figure 56-2 Comparison of an IMRT and three-dimensional (3D) conformal plan for a patient undergoing postoperative radiation therapy for a positive margin status after left radical nephrectomy for a T1bN0 renal cell carcinoma. **A** to **C,** Comparison of images taken from an IMRT and 3D conformal plan suggest improved sparing of normal structures, including the liver, right kidney, spinal cord, bowel, and stomach. With IMRT, a dose of 50.4 Gy was prescribed to the tumor bed and regional lymphatics. However, to respect the tolerance of normal tissues, the dose was decreased to 45 Gy with the 3D conformal plan to achieve appropriate sparing of normal structures.

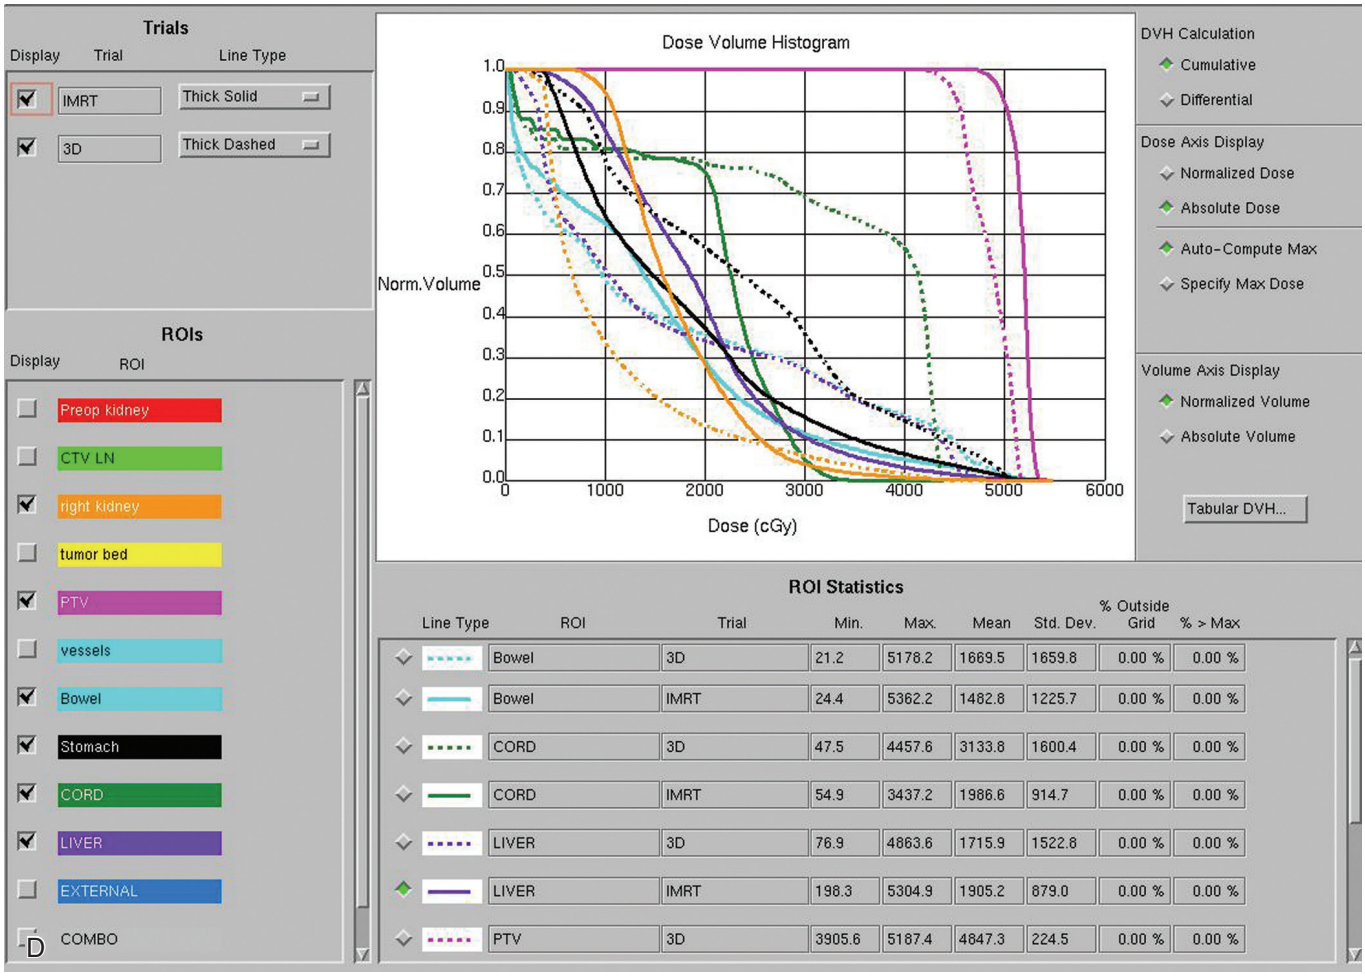

Figure 56-2,cont'd D, The dose-volume histogram demonstrates the ability of the IMRT plan to spare normal structures, most notably the spinal cord, as compared with the 3D plan. Despite lowering of the dose with the 3D plan, only 85% of the PTV is covered by the prescription dose compared with more than 90% for the IMRT plan.

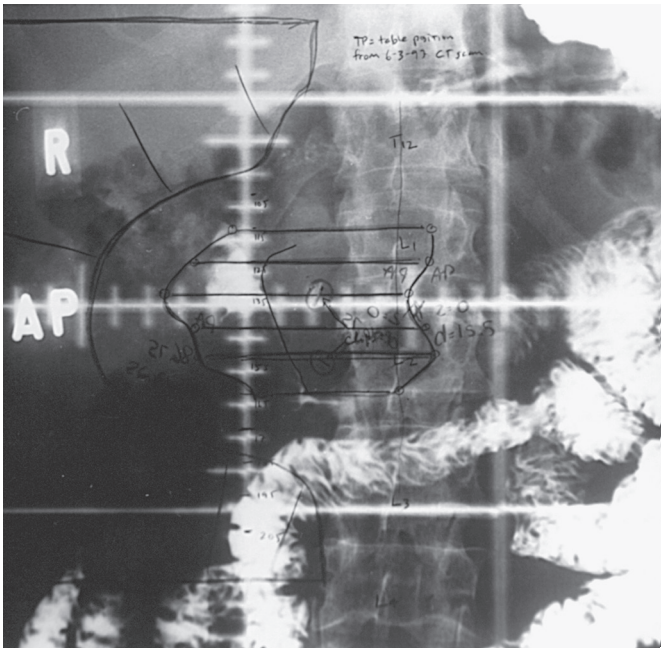

A total dose of 45 Gy to 50.4 Gy in 1.8-Gy to 2.0-Gy fractions should be delivered using multiple treatment fields. Maximal surgical debulking with consideration of IORT should occur within 4 to 6 weeks of completion of EBRT.

Treatment-Related Toxicity

CT-aided radiation therapy treatment planning (3DCRT or IMRT) is essential to reduce the risk of treatment-related toxicity. The Copenhagen Renal Study Group randomized 32 patients to receive postoperative irradiation after surgery.[186] Twenty-seven of the 32 patients randomized completed the course of postoperative RT to a dose of 50 Gy in 20 fractions. Significant complications to the stomach, duodenum, or liver occurred in 12 of the 27 patients and contributed to the death of 5 patients (19%). The increased fraction size of 2.5 Gy may have partially contributed to the high complication rate. In studies using modern CT-based planning, the risk of late complications was less than 5%.[187,188]

Renal Pelvis and Ureter

The radiation treatment field should include the primary tumor bed down to the bladder wall at the ipsilateral trigone with an adequate margin, plus the regional lymph nodes adjacent to the primary tumor bed. The pattern of lymphatic metastasis based on the location of the primary lesion is summarized earlier in the section on pathway of spread.[105] For renal pelvis and upper ureteral lesions, nodal metastasis most commonly occurs near or superior to the primary tumor site, involving the periaortic/pericaval lymph nodes and the renal hilar nodes. The initial treatment field, encompassing the renal pelvis and ureter and the regional nodes, should be treated to 45 Gy to 50.4 Gy with 1.8-Gy per fraction. Areas of gross disease may be boosted to 54 Gy to 60 Gy. CT-based 3DCRT or IMRT is used to reduce the volume of normal organs such as small bowel, liver, and contralateral kidneys in the high-dose region. The dose to the contralateral functioning kidney should not exceed 18 Gy. The volume of irradiated liver (for patients with left-sided lesions) and stomach (for patients with right-sided lesion) can be reduced with AP/PA fields. Lateral fields may be used to deliver part of the treatment to keep the dose to the spinal cord within tolerance. Representative fields for a local recurrence of renal pelvis cancer using 3DCRT are shown in eFigure 56-2 on the Expert Consult website. For lower ureteral lesions, pelvic lymph nodes should be included in the treatment field. The posterior location of the ureter allows the use of a four-field or three-field (PA and opposed laterals) technique. The use of a prone treatment position and small bowel contrast is helpful to minimize the amount of small bowel in the treatment field. A representative radiation treatment field for a lower ureter cancer is shown in Figure 56-4.

eFigure 56-2 Irradiation fields for a locally recurrent renal pelvis transitional cell carcinoma. Original location of the primary tumor is identified by clips. Current size of the gross, unresectable (by virtue of inferior vena cava and other vascular structure invasion) tumor is identified by CT scan–based reconstruction. Periaortic lymph nodes are included within the anterior-posterior/posterior-anterior field.

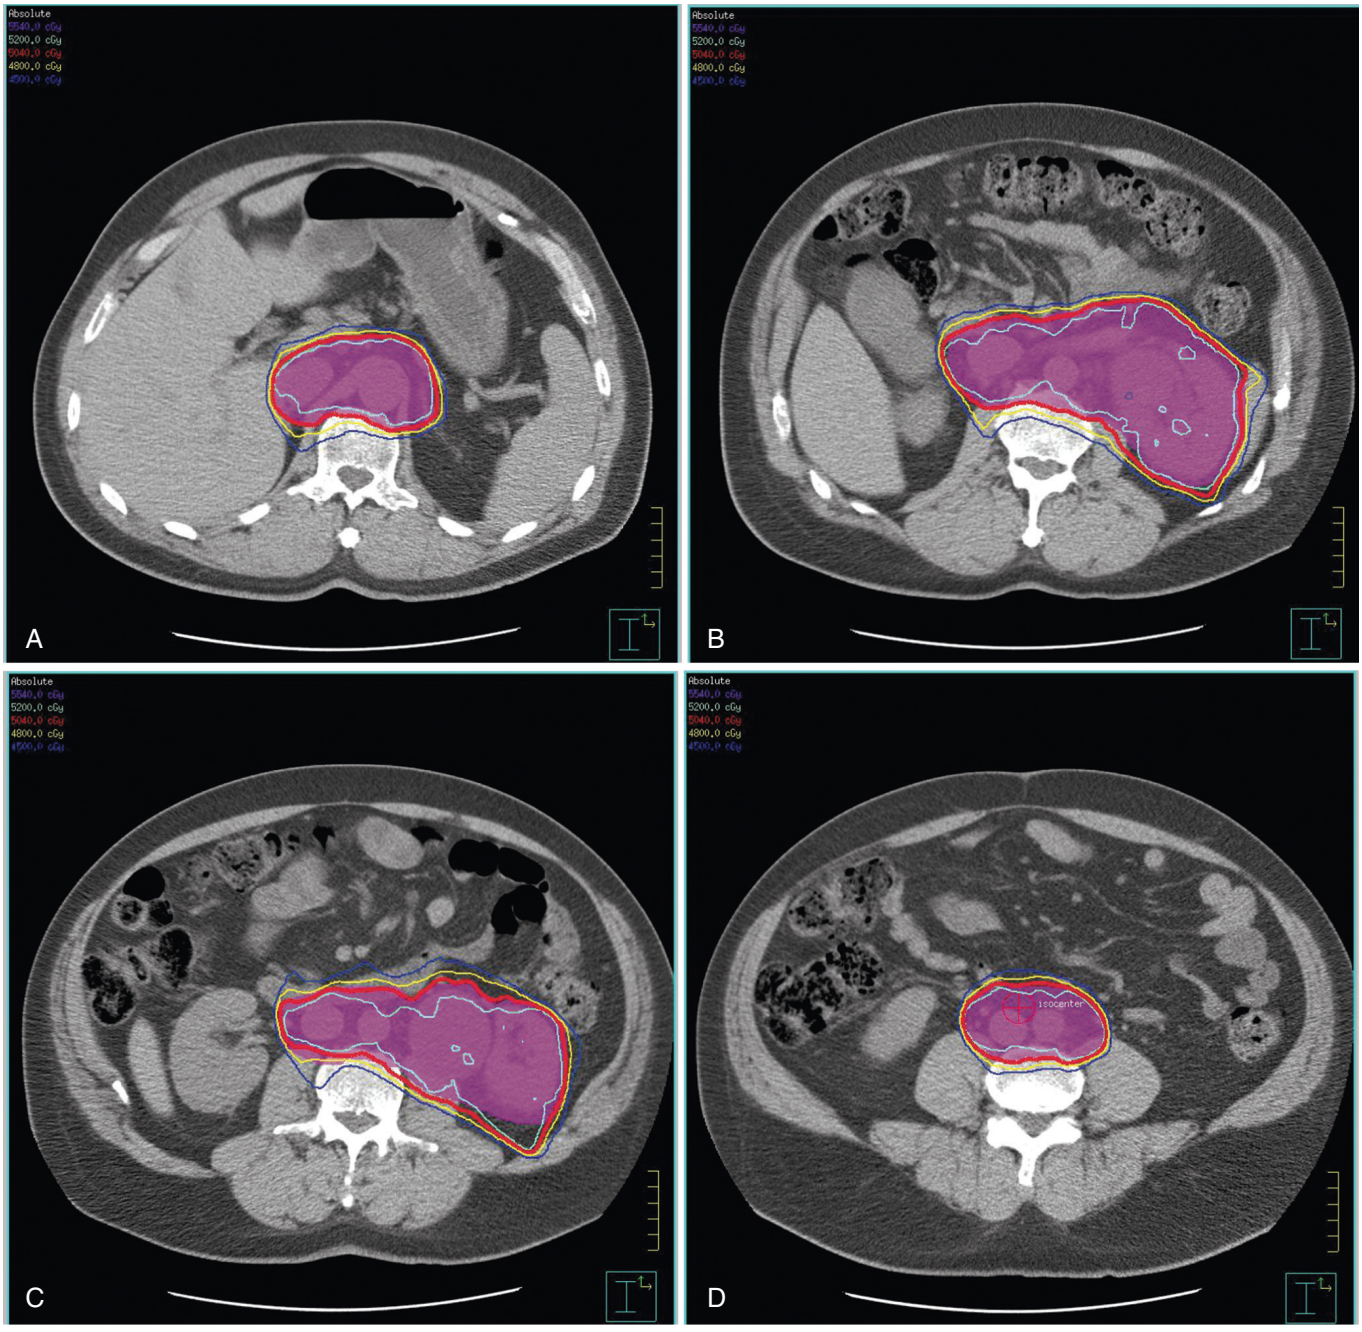

Figure 56-3 **A** to **D,** Illustration of a preoperative treatment plan for a locally advanced renal cell carcinoma with invasion of the psoas muscle. The tumor, involved kidney, and regional lymphatics were treated to 50.4 Gy using an IMRT plan to spare normal structures, primarily the contralateral kidney, liver, and spinal cord (see dose volume histogram in eFigure 56-3).

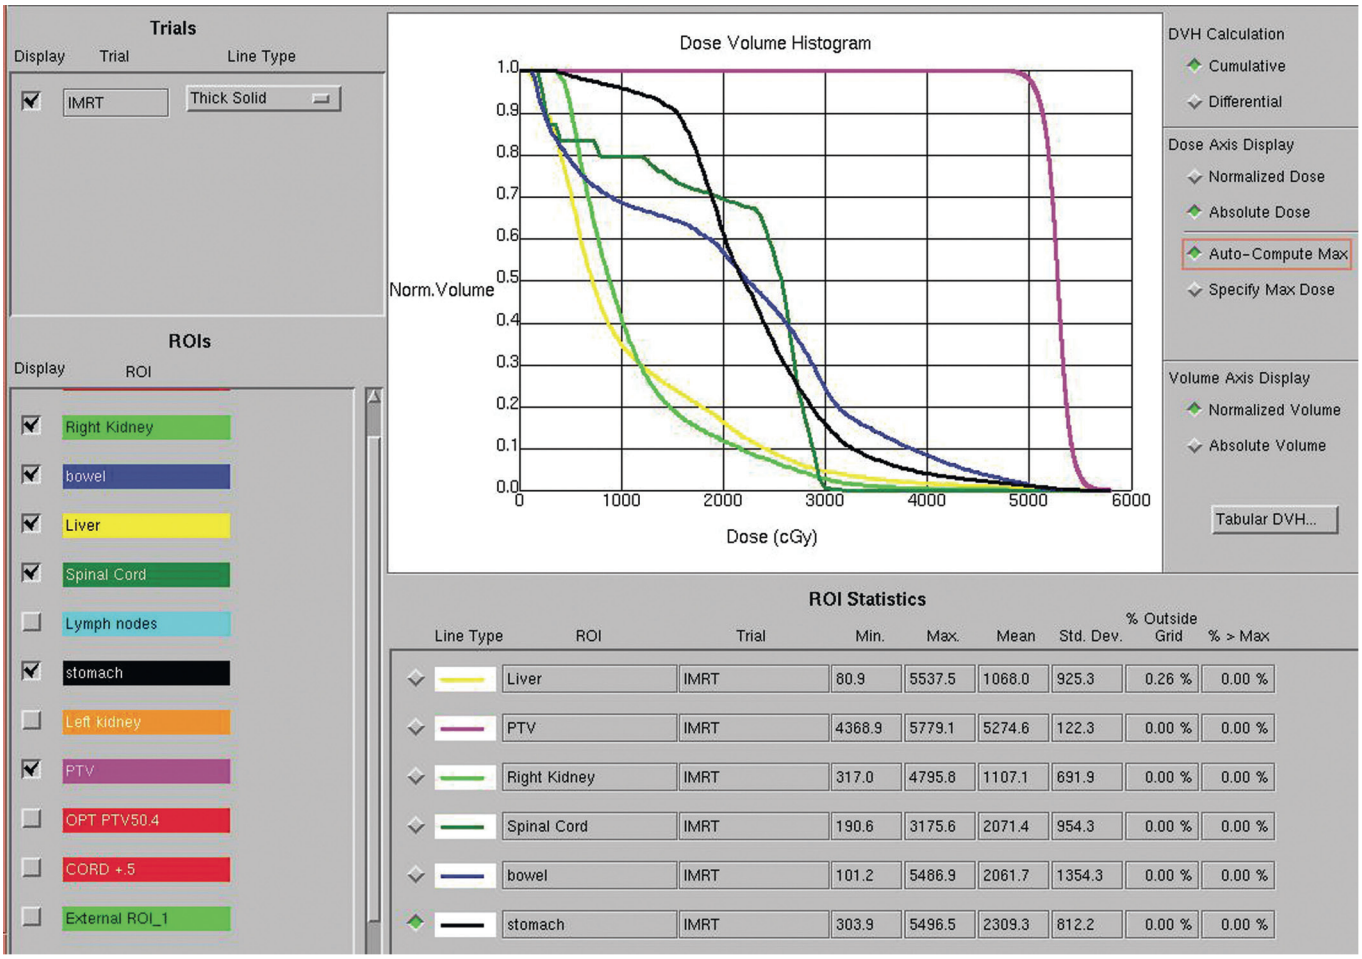

Figure 56-5 shows the dose distribution of an IMRT treatment plan for an 88-year-old patient who had TCC in the midureter and positive cytology from the renal pelvis. He was medically unfit for surgery because of heart disease.

TREATMENT ALGORITHM, CONCLUSIONS, AND FUTURE POSSIBILITIES

Kidney

Some progress has been made in understanding the environmental, occupational, hormonal, cellular, and genetic factors associated with disease development. With better understanding of the molecular pathways of pathogenesis, new systemic molecularly targeted agents have been developed. Future investigations should be directed to prevent local and distant recurrence after surgical resection and to control locally advanced and metastatic disease.

Figure 56-6 presents an algorithm for the current Mayo Clinic philosophy on diagnosis and treatment of RCC. Patients with a tumor 4 cm or smaller, a solitary kidney, bilateral RCCs, or impaired renal function may be candidates for a partial nephrectomy. Patients with tumors larger than 4 cm and a normal-functioning opposite kidney should be treated with radical nephrectomy. If gross total resection with negative margins is accomplished, the patient should be observed. If

eFigure 56-3 Dose-volume histogram for patient with locally advanced left renal carcinoma receiving preoperative treatment (case illustrated in Figure 56-3) using IMRT treatment plan to spare the normal right kidney, liver, spinal cord, and stomach.

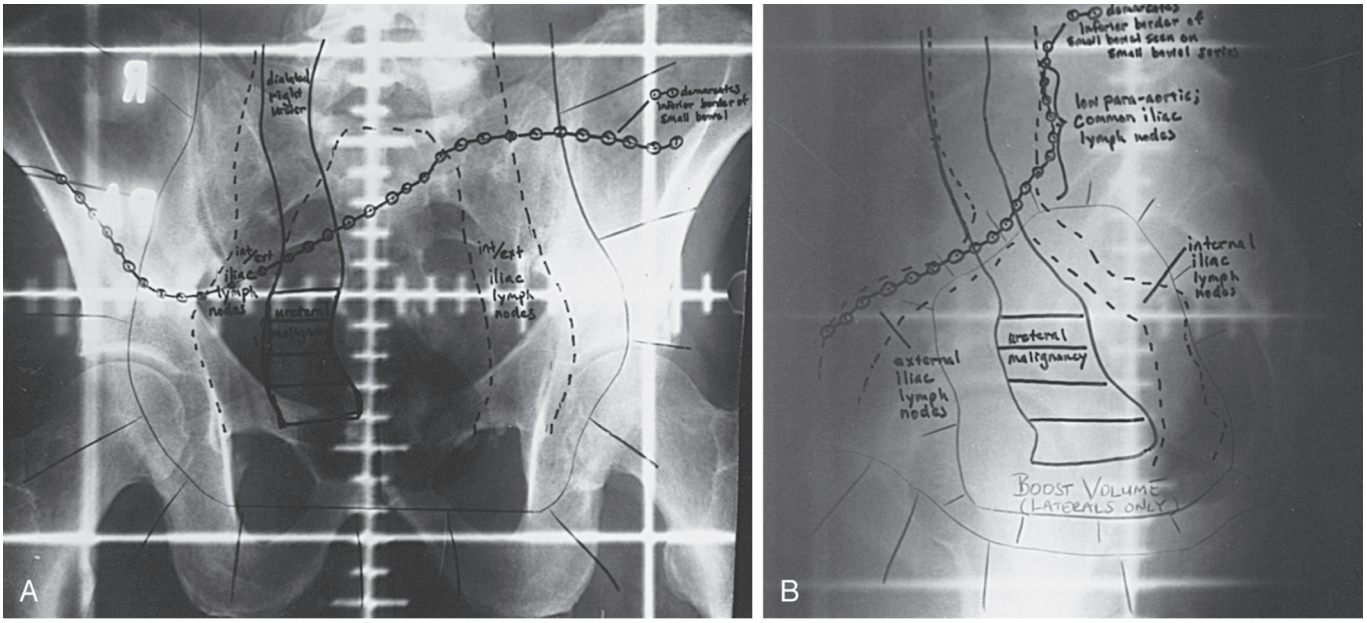

Figure 56-4 **A** and **B,** Radiation therapy fields for a low transitional cell carcinoma being managed by primary radiation therapy because of severe medical comorbidity preventing surgery. Beam's eye-view reconstruction of the lower ureteral tumor, bladder, and draining pelvic lymph nodes is superimposed on the simulation films. Initial blocking for the tumor nodal fields is shown with final boost volumes to the primary lesion plus several centimeters of margin based on location of small bowel identified by small bowel series.

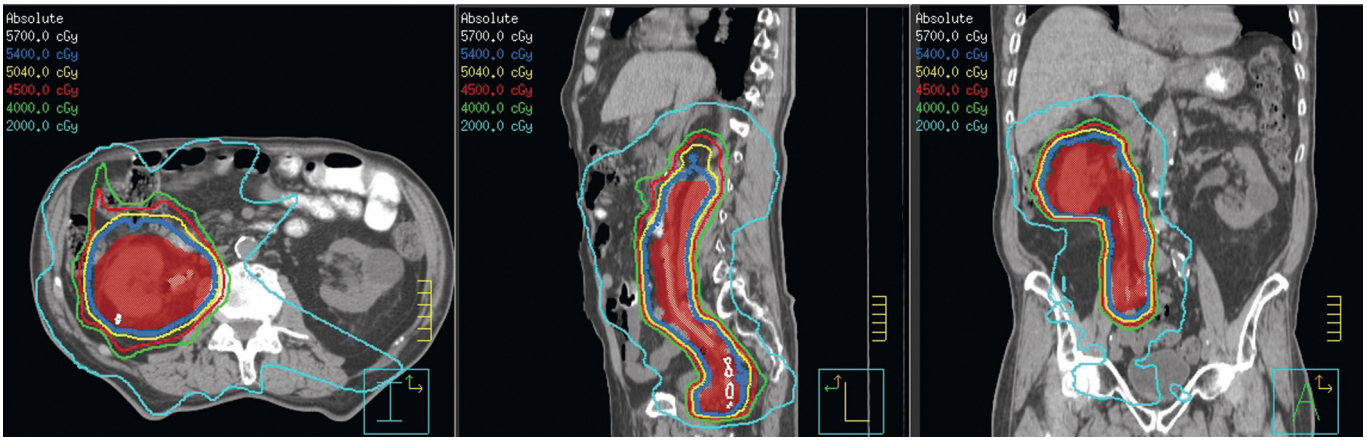

Figure 56-5 Isodose plan for an 88-year-old man with transitional cell carcinoma in the midureter and positive urine cytology from the renal pelvis. The patient had significant heart disease and was deemed medically unfit for nephroureterectomy. He also declined to have surgery. IMRT was used to deliver 54 Gy to the kidney, ureter, and part of the bladder but sparing the bowel and spine. The regional and periaortic lymph nodes were not included as clinical target volume to minimize toxicity. He also was given cisplatin concurrently for two cycles.

positive surgical margins or lymph node involvement is present at radical nephrectomy, consideration should be given to postoperative EBRT.

If locally advanced or locally recurrent disease is present, preoperative EBRT to the tumor, regional lymph nodes, and vascular extent of tumor may downsize the disease to facilitate surgery. Maximal resection, preferably combined with IORT to areas of narrow or positive margins, should be planned at 4 to 6 weeks after completion of EBRT. SBRT can be considered for patients who are medically inoperable or unwilling to undergo nephrectomy, although more studies are needed to evaluate the efficacy of this approach.

Patients who present with metastatic disease are candidates for molecularly targeted treatment. Palliative nephrectomy can be considered to palliate symptoms, to enhance the effects of systemic therapy, or in patients with favorable prognostic factors such as solitary metastasis.

Potential Clinical Trials

Future clinical trials should evaluate both local and systemic treatment modalities. Patients who have positive surgical margins or positive lymph nodes are at increased risk for local failure. A prospective randomized trial comparing observation versus postoperative irradiation (with or without concomitant systemic therapy) would help to define the benefits of postoperative irradiation.

Patients who have positive lymph nodes and renal vein involvement are at increased risk for distant metastases. Future trials should evaluate the use of adjuvant systemic treatment including molecularly targeted therapy for these patients.

Patients with locally advanced disease appear to benefit from aggressive treatment, including preoperative radiation therapy, surgical debulking, and IORT. Future trials can

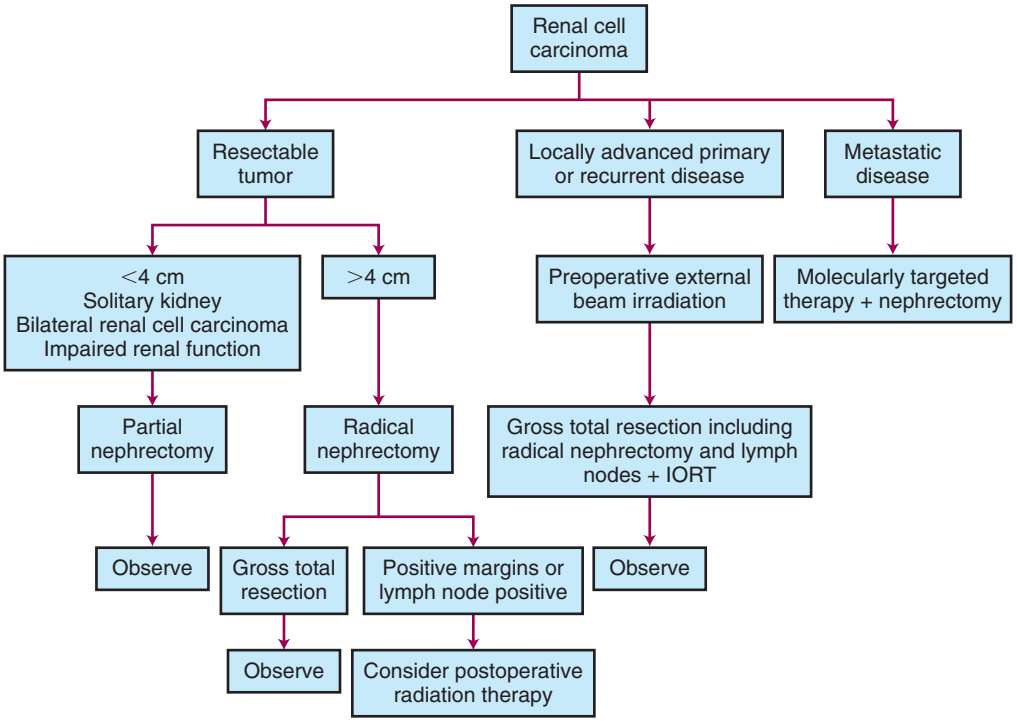

Figure 56-6 Diagnostic and treatment algorithms for renal cell carcinoma. *IORT*, Intraoperative irradiation.

evaluate the combination of systemic agents with local treatment modalities to improve local control and reduce distant spread of disease. For patients with metastatic disease, future clinical investigation should continue to focus on improving survival and quality of life with molecularly targeted therapy while minimizing the toxicity of treatment.

Renal Pelvis and Ureter

The primary management of UUTCA is surgical if the disease is resectable. The standard surgery is radical nephroureterectomy. Laparoscopic nephroureterectomy has been shown to reduce the recovery time from surgery while achieving outcomes comparable to the open approach. More conservative surgery with ureteroscopic nephron-sparing surgery or partial ureterectomy should be limited to patients with solitary kidney or medical comorbidities, as well as selected patients with low-grade, early-stage, and small cancers. Despite radical surgery, patients with locally advanced diseases are at significant risks of locoregional and distant failures. Emerging data suggest that adjuvant chemotherapy and neoadjuvant chemotherapy may improve treatment outcome in patients with high-risk disease and should be studied prospectively. The role of combined chemoradiation, either as adjuvant treatment or as primary therapy, needs to be better defined. There is an urgent need to identify molecular targets and pathways so that new therapeutic agents can be developed that are more specific for this disease.

CHAPTER

57 Penile Cancer

Juanita M. Crook and Jean-Jacques Mazeron

INCIDENCE

Penile cancer occurs in approximately 1 in 100,000 North American and European men (accounting for 0.4% to 0.6% of all male cancers), but it represents as much as 10% of male malignancies in parts of Asia, Africa, and South America.

BIOLOGIC CHARACTERISTICS

Human papillomavirus (HPV) types 16 and 18 are detected in 40% to 45% of penile cancers. Moderate or poor differentiation, invasion of the corpora, and the presence of tumor emboli in lymphovascular channels predict regional spread.

STAGING EVALUATION

Circumcision is recommended for full evaluation of the primary tumor. Magnetic resonance imaging (MRI) may supplement palpation in the determination of invasion of the corpora. Computed tomography (CT) for staging lacks sufficient sensitivity for evaluation of lymph nodes. For adverse pathology (grade, invasion of corpora, or lymphovascular spaces), surgical staging of lymph nodes is recommended and can be done by either bilateral superficial inguinal lymph node dissection or sentinel lymph node biopsy.

PRIMARY THERAPY

Penile conservation is recommended for Tis, Ta to T1, and G1 to G2 lesions and can be considered for those with G3 T1 or T2 category lesions (tumor < 4 cm) and for selected T3 tumors. Laser surgery for Tis and T1 tumors yields satisfactory local control and cosmesis.

Interstitial brachytherapy for T1 to T2 category tumors allows penile preservation in 70% to 85% of patients. The most common sequelae of treatment are meatal stenosis (12% to 45%) and soft-tissue ulceration (8% to 25%).

For external beam radiation therapy (EBRT), penile preservation rates are 50% to 65%.

ADJUVANT THERAPY

Adjuvant EBRT is recommended after lymph node dissection for patients with multiple positive groin nodes or extracapsular disease.

LOCALLY ADVANCED DISEASE

Locally advanced penile cancer is a highly lethal malignancy that requires a multimodality approach. This may begin with total or partial penectomy and lymph node dissection for cases that are surgically resectable. For unresectable presentations, combined chemoradiotherapy can be used as either a preoperative approach or continued to a definitive dose. Neoadjuvant chemotherapy may render the disease operable (response rate 50%).

PALLIATION

Unresectable nodes are rarely controlled by radiation therapy (RT), but palliation may be possible. A combined approach with systemic chemotherapy is warranted if the patient's general condition permits.

The penis is divided into three portions: the root, the body (or shaft), and the glans. The root is embedded in the superficial perineum. The shaft consists of the erectile bodies composed of the corpora cavernosa, the corpus spongiosum, and the overlying skin. The glans comprises the distal part of the corpus spongiosum and is covered by a skinfold known as the prepuce. The coronal sulcus delimits the glans from the shaft.

Early-stage, well-differentiated cancers of the penis can be effectively managed with local therapy, and attention should be paid to preservation of penile function and morphology. Traditional primary surgical management is effective but is associated with considerable psychosexual morbidity. Even partial penectomy can have a profound effect on sexual health and self-image.[1] Suicide or attempted suicide after partial penectomy has been reported.[2,3] In recent years, emphasis is increasingly in favor of penile-sparing approaches and surgical options have been developed in this regard, including procedures such as glans-sparing penectomy. EBRT and interstitial RT are also organ-sparing alternatives that preserve penile morphology and function without compromising disease control or survival in selected patients. Referral is encouraged to centers specialized in management of this rare cancer. Quality of life and sexual health after treatment requires more study. Sexuality and expectations should be discussed with the patient and partner when deciding on primary management. Advanced or poorly differentiated tumors require a multimodality approach. A recent study of 12 European Cancer registries and the Surveillance, Epidemiology, and End Results (SEER) program in the United States showed no improvement in 5-year survival for penile cancer patients since 1990.[4]

ETIOLOGY AND EPIDEMIOLOGY

Carcinoma of the penis is rare, with an estimated incidence of 1 case per 100,000 men in North America and Europe, where it accounts for 0.4% to 0.6% of cancers. Higher incidences are seen in parts of Asia, Africa, and South America, where it represents up to 10% of malignancies in male patients.[5] The peak incidence is in the sixth decade in developed countries but earlier where the incidence is higher.

Case-control studies have identified important risk factors (odds ratio [OR] > 10) to be phimosis, chronic inflammatory conditions such as lichen sclerosis, treatment with psoralens and ultraviolet A photochemotherapy (PUVA), tobacco products (dose-dependent association), and a history of genital

condylomata (threefold to fivefold increase in risk). Neonatal circumcision is associated with a threefold decrease in risk of penile carcinoma. However, circumcised men with a history of HPV infection remain at increased risk.[6] Oncogenic HPV, especially type 16, has been identified in about 50% of invasive penile cancers.[7] Penile trauma may be another risk factor for penile cancer. There is a threefold increase in development of carcinoma in the scarred penile shaft after penile tears or injury.[8]

PREVENTION AND EARLY DETECTION

Infant circumcision is highly effective in prevention of this disease, but it is not recommended on these grounds alone. The emphasis is instead on education, promotion of good hygiene for the normally retractile foreskin, and surgical correction of phimosis. Men should be aware of the association between certain HPV subtypes, venereal warts,[6] and cancer, as well as the premalignant nature of conditions such as lichen sclerosis, which may precede the diagnosis of cancer by many years. In a recent report from Scandinavia, patients delay an average of 6 months before seeking medical attention.[9]

Genital condyloma or warts and genital HPV infection refer to a sexually transmitted disease caused by HPV. Although not reportable, the number of new infections is estimated at 500,000 to 1 million annually. The prevalence of HPV in U.S. males is more than 50%, being 60% in uncircumcised and 50% in circumcised men, with higher rates of infection with increasing numbers of sexual partners, lack of condom use, and smoking.[10] Some 60 genotypes of HPV virus have been identified that involve the genital tract.[11] Virus types 6, 11, and 42 to 44 are associated with gross condylomata and low-grade dysplasia. Types 16, 18, 31, 33, 35, and 39 have a higher association with malignant disease. Immunocompromised men with human immunodeficiency virus (HIV) infection are more susceptible to development of penile lesions and squamous carcinoma with high-risk HPV types.[12]

An increased incidence of penile intraepithelial neoplasia has been found in the male partners of women with cervical intraepithelial neoplasia. A recently available quadrivalent vaccine (Gardasil, Food and Drug Administration, June 2006) protects against HPV types 5, 11, 16, and 18 and is recommended in females aged 9 to 26 years. Although approved for use in young males, vaccination rates in Australia and North America are far below those for females. Vaccine use in males still targets high-risk populations such as organ transplant recipients and homosexual men.[13] Successful HPV vaccination programs are necessary to combat the rising incidence of HPV-related neoplasms for which effective screening programs are lacking, including squamous carcinomas of the penis, anus, and oropharynx.[14,15]

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

The overall incidence of HPV in penile carcinoma is 40% to 45%, as detected by polymerase chain reaction (PCR) amplification of DNA. HPVs 16 and 18 are the most frequent subtypes detected.[16,17] The frequency of HPV detection depends on histopathologic subtype; HPV association is seen in 80% to 100% of basaloid and warty penile cancers but in only approximately 35% of verrucous or squamous cell carcinomas. The difference in prevalence of HPV in these two groups suggests different pathogenesis. Penile lesions can be classified into HPV-induced (HPV 16 in 76%, followed by HPVs 33, 31, 45, and 18) and HPV-independent, often in the background of chronic inflammation (lichen sclerosis, bowenoid papulosis). HPV presence in a tumor may confer a better prognosis.

The presence of p53 is found in 41% to 75% of invasive penile cancers.[18,19] Nuclear expression of p53 is seen in tumor cells and basal keratinocytes of p-16(ink4a) negative non-HPV induced lesions.[7] In multivariate analysis, p53 positivity and lymphatic embolization are predictive of lymph node metastases.[18,20]

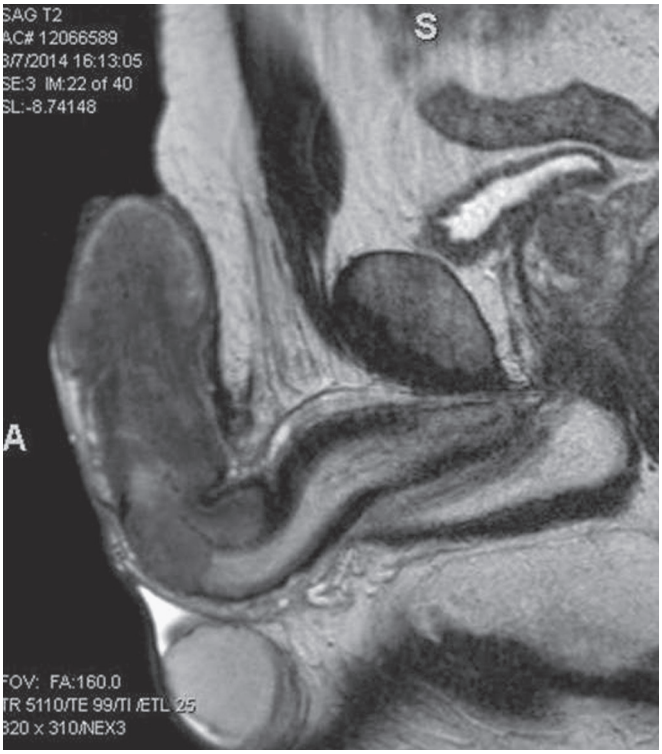
PATHOLOGY AND PATHWAYS OF SPREAD

Premalignant lesions are associated with invasive cancers in 20% to 30% of cases. Intraepithelial neoplasia such as bowenoid papulosis, Bowen disease, and erythroplasia of Queryat[21] are precursor lesions of warty and basaloid penile cancers. Lichen sclerosis (balanitis xerotica obliterans) is associated with non-HPV variants of penile carcinoma.[22,23] Condylomata, Buschke-Löwenstein disease, Kaposi's sarcoma, and leukoplakia are also associated with penile cancer.

The primary tumor most frequently occurs on the glans (48%) or prepuce (25%), with the glans and prepuce involved in 9%, the coronal sulcus in 6%, and the shaft in only 2%. Squamous cell carcinomas represent 95% of invasive cancers of the penis. Other histopathologic primary tumor types are malignant melanoma, transitional cell carcinoma, basal cell carcinoma, and sarcoma.

The lymphatics of the prepuce and the skin of the shaft drain into the superficial inguinal nodes located above the fascia lata. The glans and the deep penile structure drain into the superficial or deep inguinal nodes from which they spread along the femoral vessels to the external iliac, common iliac, and paraaortic regions. The sentinel nodes are located above and medial to the junction of the inferior epigastric and saphenous veins.

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING



General Approach

Because of the rarity of carcinoma of the penis, reported series often span several decades. Four different staging systems are encountered in a review of the literature of the past three decades[24-27] (Table 57-1).

As clinical staging of carcinoma of the penis is subjective, it may be difficult to distinguish T1 (i.e., invasion of subepithelial connective tissue) from T2 (i.e., invasion of corpus spongiosum or cavernosum). For this reason, techniques that treat less than the full thickness of the penis must be restricted to carefully selected cases. High-resolution MRI is the gold standard for evaluating the primary tumor and local extension.[28,29] Although small-volume lesions on the glans can be adequately staged by palpation in most cases, MRI especially with artificial erection by intracorporal injection of prostaglandin E1 improves staging of the primary tumor where invasion of the corpus cavernosum is suspected (eFigure 57-1).[30,31] Any patient who presents with phimosis and chronic discharge, bleeding, balanitis, or swelling in the region of the coronal sulcus or glans under an unretractable foreskin should have a dorsal slit of the foreskin to allow inspection of the glans, followed preferably by a full circumcision. Any suspicious lesions should be sampled. Figure 57-1 shows the diagnostic algorithm for a patient with clinically node-negative disease.

Lymph Node Assessment: The N0 Patient

Management of the patient with clinically negative groins has been considerably clarified in the past decade. Although many RT series have advocated a "wait-and-see" policy, with no systematic staging investigations such as CT or fine-needle

eFigure 57-1 MRI of the penis. The erectile bodies are normally bright white on MRI. This image shows dark tumor invasion of the shaft.
MRI, Magnetic resonance imaging.

TABLE 57-1 Staging Systems for Carcinoma of the Penis

Stage	Description
JACKSON STAGING SYSTEM*	
1	Tumor limited to the glans or prepuce
2	Tumor extending into the shaft or corpora but without node involvement
3	Tumor confined to the shaft but with malignant but operable lymph nodes
4	Invasion beyond the shaft with inoperable lymph nodes or distant metastases
TNM (UICC, 1978)†	
Tis	Carcinoma in situ
T1	Tumor ≤ 2 cm
T2	Tumor > 2 cm and ≤ 5 cm
T3	Tumor > 5 cm or deep invasion including urethra
T4	Tumor invades adjacent structures
N1	Metastases in unilateral inguinal lymph nodes
N2	Metastases in bilateral inguinal lymph nodes
N3	Fixed inguinal lymph nodes
TNM (UICC, 1987-2002)‡	
T1	Tumor in subepithelial connective tissue
T2	Tumor in corpus spongiosum or cavernosum
T3	Tumor in urethra or prostate
T4	Tumor in other adjacent structures
N1	Tumor in one superficial inguinal lymph node
N2	Tumor in multiple or bilateral superficial inguinal lymph nodes
N3	Tumor in deep inguinal or pelvic lymph nodes
TNM UICC 7TH EDITION 2009§	
Tis	Carcinoma in situ
Ta	Non invasive verrucous carcinoma
T1	Tumor invades subepithelial connective tissue T1a: without lymphovascular invasion; not poorly differentiated or undifferentiated T1b: with lymphovascular invasion or poor differentiation
T2	Tumor invades corpus spongiosum or cavernosum
T3	Tumor invades urethra
T4	Tumor invades other adjacent structures
N1	Palpable mobile unilateral inguinal lymph node
N2	Palpable mobile multiple or bilateral inguinal lymph nodes
N3	Fixed inguinal nodal mass or pelvic lymphadenopathy unilateral or bilateral

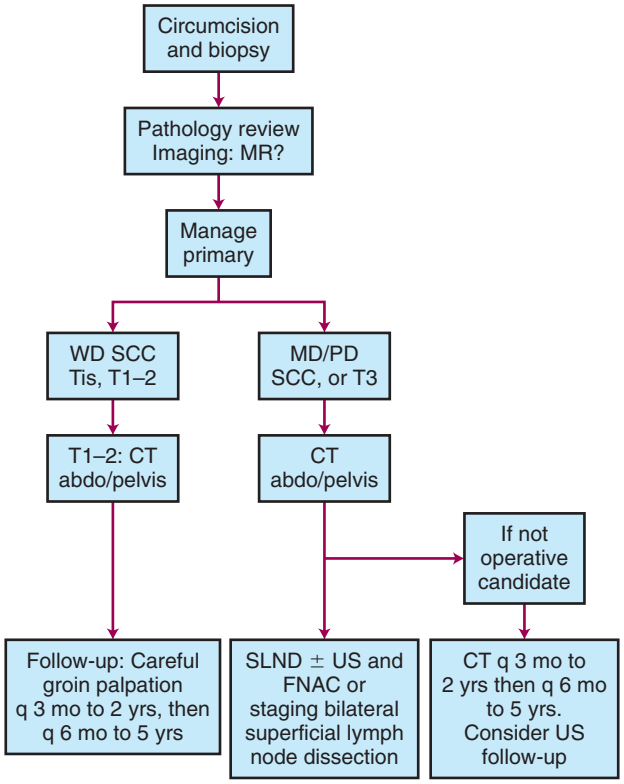

Figure 57-1 Diagnostic algorithm for penile cancer: A patient with clinically node-negative cancer. *CT,* Computed tomography; *FNAC,* fine-needle aspiration cytology; *MR,* magnetic resonance; *MD,* moderately differentiated; *mo,* month; *q,* every; *SCC,* squamous cell carcinoma; *SLND,* sentinel lymph node dissection; *US,* ultrasound; *WD,* well differentiated; *yrs,* year.

aspiration cytology (FNAC),[3,32-35] the predictive factors for lymph node involvement have been established and allow the practitioner to selectively offer surgical staging. Overall, only about 20% of clinically negative nodes have micrometastases, so staging lymph node dissection is not warranted for all patients; traditional inguinal node dissection may be complicated in one third of cases by infection, skin flap necrosis, deep vein thrombosis, or severe leg edema.[36-38] Nodal status is, however, the strongest predictive factor for overall survival (OS) and lymph node dissection may be curative for men with microscopic regional spread. Several surgical series have identified that *therapeutic* node dissection confers an inferior survival compared with *prophylactic* node dissection.[39] McDougal[40] found a 5-year OS after inguinal node dissection of 92% for patients with clinically N0 disease, compared with 33% for those with clinically involved nodes. Modified inguinal lymphadenectomy, sparing the saphenous vein, and limiting the dissection laterally, distally, and proximally, may reduce morbidity.[36]

The reliability of physical examination is diminished markedly in the patient who is obese, so imaging is paramount. Both CT and MRI will demonstrate gross lymph node enlargement but will not detect a small metastasis in a normal-sized node. Nonetheless, CT is the imaging modality recommended to examine the inguinal regions and pelvis as well as to rule out more distant metastases, with a sensitivity and specificity of 36% and 100%, respectively. The combination of positron emission tomography (PET)/CT using the radiopharmaceutical fluorodeoxyglucose (^{18}F-FDG) has been shown[41] to increase sensitivity to 80%. The combination of ultrasound and FNAC has been shown to detect 80% of metastatic disease in

nonpalpable nodes (12 out of 15) with an overall sensitivity and specificity of 87% (48 out of 55) and 99%, respectively.[42]

Stage and histopathologic factors should be used to identify patients at high risk for microscopic regional spread to selectively offer surgical staging of lymph nodes. Chaux and Cubilla[43] have published a stratification system to estimate the likelihood of lymph node metastases based on grade, extent and depth of invasion, and the presence of perineural invasion. T category and lymphovascular invasion are also reported to be predictive for nodal relapse.[44,45] The risk of nodal involvement in patients at high-risk is 64% to 83%, 20% to 33% in intermediate risk, and 0% to 8% in low risk.

The difficulty with applying histopathologic information to decision making in RT is that the primary tumor is not available for complete examination. Invasion of the corpora may be underappreciated clinically. Diagnostic biopsies are often superficial and unreliable in determining the depth of invasion, the presence of lymphovascular invasion, or the ultimate tumor grade.[46] However, if the biopsy shows high-risk features, surgical assessment of regional lymph nodes is recommended. Ultrasound-guided FNAC is a valuable tool to evaluate suspicious inguinal nodes,[47] with reported sensitivity and specificity more than 90%.[48] A 4- to 6-week trial of antibiotics is no longer recommended.

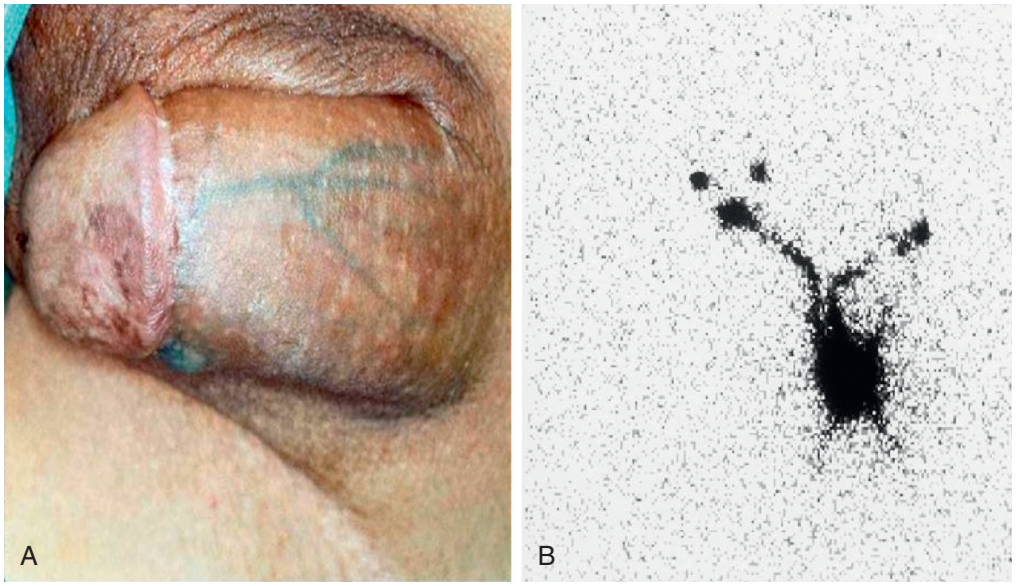
The current European Association of Urology (EAU) guideline recommends observation of the lymph nodes for carcinoma in situ (Tis), verrucous (Ta), and T1-grade 1 tumors because these are associated with less than a 10% incidence of lymph node positivity.[49] T1 grade 2 tumors are classified as intermediate risk and observation is recommended only for those with a superficial growth pattern and no vascular invasion. Category T2 or higher or grade-3 tumors and those with vascular invasion have a higher than 50% risk of lymph node involvement and should have surgical staging. Patients with T1 grade 2 tumors with high-risk features such as tumor thickness or vertical growth should also be considered for surgical staging. Close follow-up of patients at high risk is important.[50]

Dynamic sentinel lymph node mapping uses a gamma probe after intradermal peritumoral injection of technetium-99m and is becoming more widely available for detection of early lymph node involvement (eFigure 57-2). False-negative rates, although initially in the 18% to 25% range, have fallen to 5% to 7% in the recent literature from high-volume centers with experienced surgeons.[51,52] Complication rates of 5% are reported.[53] Lam et al[54] described long-term follow up of 500 inguinal basins in 264 patients with T1G2 or higher disease and nonpalpable nodes managed with ultrasound or FNAC and DSNB. Sensitivity of DSNB alone per inguinal basin was 92% and with ultrasound with or without FNAC 95%. Routine serial sectioning along with cytokeratin immunohistochemistry, exploration of groins with low or no signal, and ultrasound with FNAC to detect positive lymph nodes that may have altered lymphatic flow[55] have helped to decrease false-negatives. The use of PET/CT may further decrease the risk of false-negatives from tumor blockage and rerouting of lymphatics.[56] Superficial inguinal lymph node dissection is still considered the gold standard in centers lacking the expertise for Dynamic Sentinel Node Biopsy (DSLB) because the consequences of a false-negative may be an increased risk of death from disease.

PRIMARY THERAPY

Surgery

Circumcision is generally the first step. Small tumors that are limited to the prepuce can be treated by circumcision alone. Penis-conserving surgical techniques, such as laser or Moh's surgery, may be suitable for selected tumors. Moh's surgery[57] for carcinoma in situ or superficial tumors involves excision of tissue in successive layers until margins are histologically clear. Complete microscopic scanning of each horizontally cut layer identifies any tumor outgrowths that may extend beyond the visible or palpable lesion.



Laser surgery using carbon dioxide or neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers has been reported to provide a superior functional and cosmetic result compared with standard surgical techniques for selected premalignant and malignant lesions (Tis/T1).[58-61] Both carbon dioxide laser (depth of penetration 0.1 mm) and Nd:YAG laser (penetration 6 mm) are used. Tumor-base biopsies to ensure negative surgical margins will reduce failures.[61] High rates of resumption of sexual activity and overall satisfaction are reported. Although local recurrence rates are 17% to 19% at 10 years, many can be retreated with laser, reducing the ultimate amputation rate to about 5%.[59,62] Extended, careful follow-up is required because only 57% of local recurrences occur within the first 2 years, 30% between 6 and 10 years, and 15% after 10 years. Whether these late failures represent true local recurrences or new primary tumors is unknown.

Selected cases, especially those involving only skin, can be treated by wide excision, but local wedge excision is associated with a high recurrence rate. Limited excision of the glans, and glansectomy with reconstruction by a split-thickness skin graft to spare the penile shaft represent surgical strategies to maintain function and penile length.[63] Although Veeratterapillay 2012[64] has reported a 6% local recurrence rate at 40 months in 65 patients, many with T2 disease and intermediate to poor differentiation, local failures increase with longer follow up; 25% occur after 5 years.[65] Traditionally, an adequate resection margin is considered to be 2 cm, but closer margins of 10 mm or less may be acceptable if tumor-free on frozen section. Agrawal et al[66] reported that tumor grade correlated with microscopic spread, with the maximum extent being 5 mm for grade-1 to grade-2 tumors and 10 mm for grade 3. Limited excision is not appropriate for deeply invasive and high-grade tumors. All patients managed with penile-sparing surgical techniques remain at a higher risk for local recurrence. Total or partial penectomy is indicated for tumors greater than 4 cm in diameter, grade 3, or deeply invading. Partial penectomy is possible when the tumor involves the glans or the distal shaft, and the penile remnant will allow the patient to direct the urinary stream. Total amputation and perineal urethrostomy is indicated for larger or proximal tumors.

Radiation Therapy

Radical RT in the form of brachytherapy or EBRT is effective in achieving local control in a high percentage of patients (Table 57-2). Often, series span several decades, during which time treatment techniques and dose prescriptions have evolved. Staging systems have also undergone significant modifications (see Table 57-1).

Interstitial brachytherapy yields a 5-year local control rate of 77% to 87%, with penile preservation rates at 5 years ranging from 72% to 88%. For EBRT, local control rates are less favorable, 41% to 70% at 5 years, and the consequent increase in surgical salvage decreases penile preservation rates to 36% to 66%. Careful extended follow-up is recommended because local failures can occur several years after treatment. Crook et al[75] found that although five of eight local failures in a series of 67 men occurred in the first 2 years, the remaining three occurred at 4.5, 7, and 8 years. Similarly, Mazeron et al[33] reported that 18% of local failures occurred between years 5 and 8, and de Crevoisier et al[68] reported 20% after 8 years. This late recurrence pattern is strikingly similar to that seen after

eFigure 57-2 Sentinel lymph node study: **A,** Blue dye is seen in the lymphatic vessels of the shaft; **B,** radiotracer is seen in the primary tumor and then branching right and left to bilateral inguinal nodes.

TABLE 57-2 Summary of Literature Results for Brachytherapy and External Beam Radiation Therapy

penile-conserving laser treatment[59] and necessitates careful long-term follow-up because the majority can be successfully salvaged.

Surgery for Salvage

Surgery for salvage is successful in more than 80% of failures.[32,74] Local excision is rarely appropriate. The choice between total and partial penectomy[32,34,35,74] depends on penile length and the proportion of shaft irradiated by the primary treatment. The localized nature of brachytherapy should result in less radical salvage operations.

Patient Selection for Radiation Therapy

Several prognostic factors have been identified for penile preservation. For EBRT, a total dose of less than 60 Gy, a protracted treatment time of more than 45 days, and a daily fraction size of less than 2 Gy are all associated with an increased risk of local failure.[2,74]

For brachytherapy, the volume of tumor and depth of invasion are predictive of local control. The ideal tumor for brachytherapy should be less than 4 cm in its maximum diameter, with less than 1 cm of invasion.[3,33,34,76] Local failure rates of 50% to 60% for tumors larger than 4 cm in diameter have been reported, compared with 14% to 30% for those less than 4 cm. Use of more than six brachytherapy needles and tumor volumes greater than 8 mL are also associated with an increased risk of failure.[3,32,34] Crook et al[67] found that wider needle spacing was associated with a decreased risk of failure ($p = 0.006$). Wider spacing results in a wider lateral margin, ensuring more generous margins around the tumor (Figure 57-2).

Histopathology does not appear to be a factor in local control. Moderate to poor differentiation influences OS and the risk of nodal involvement[77] but does not preclude a penile-conserving approach.

LOCALLY ADVANCED DISEASE AND PALLIATION

Although a penile-sparing approach may be warranted for a T3 tumor in a younger patient, most locally advanced tumors require a primary surgical approach with partial or total penectomy, perineal urostomy, and bilateral groin dissection.

Node-Positive Disease

Involved nodes should be resected if possible. As in squamous cancers of the vulva, patients with pathologic findings of multiple positive nodes or extracapsular spread should be offered postoperative RT.[77-79] If dissection of deep pelvic nodes is negative, treatment can be limited to the involved groin. A direct anterior electron field of suitable energy to deliver a dose of 45 Gy to 50 Gy over 5 weeks to the depth of the nodes is

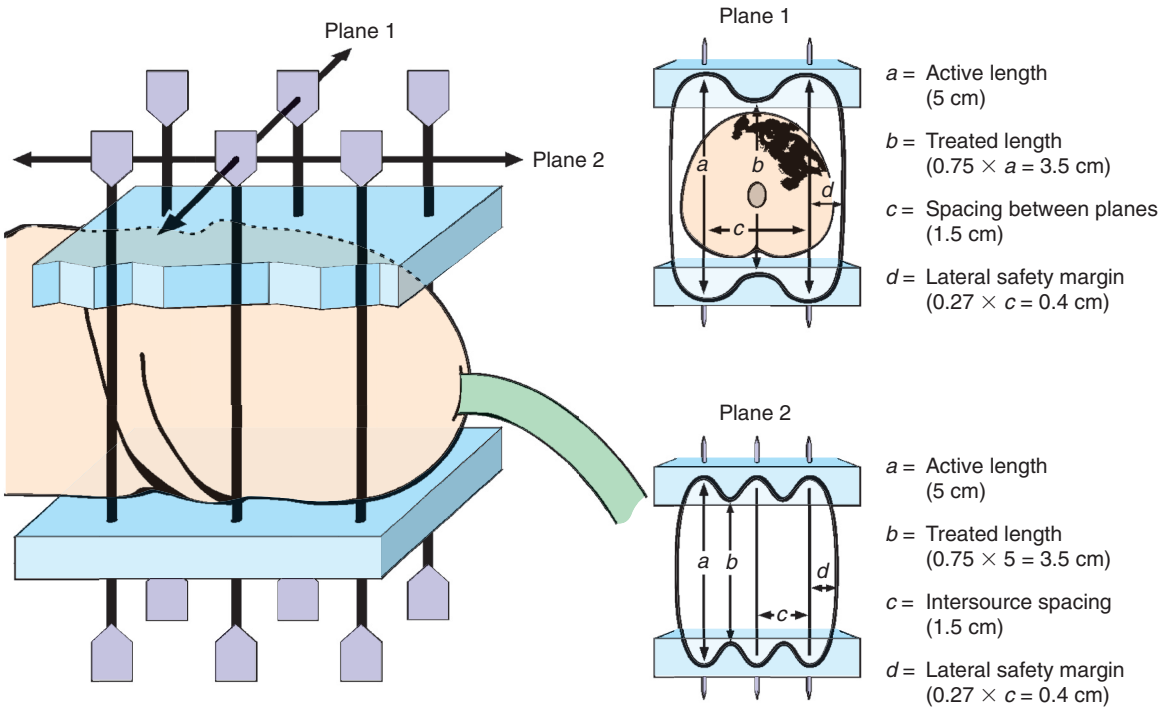

Figure 57-2 Schematic of Paris system of dosimetry for two-plane interstitial implants. Dimensions of treatment isodose can be predicted from length and spacing of radioactive sources.

appropriate. If the status of the pelvic nodes is unknown, they should be included in the treatment volume.

Unresectable nodes are rarely controlled by RT alone but can be palliated. A combined approach of concurrent chemotherapy and radiation should be considered (Figure 57-3) in view of the improved local control in other squamous carcinomas when compared with either EBRT alone (cervical cancer) or sequential chemoradiation (CRT; head and neck cancers). One such site is locally advanced squamous cell carcinoma of the vulva,[79] in which the American College of Radiology Appropriateness Criteria[80] recommend the use of neoadjuvant chemotherapy alone only if radiotherapy is not available. The Gynecology Oncology Group (GOG) trial 101 reported that 95% of 41 women with unresectable N2-3 disease who completed CRT subsequently underwent surgical resection with 41% histologically negative. A subsequent Phase II trial (GOG 205) used weekly platinum with daily fractionated RT to a dose of 57.6 Gy in 58 patients. Of 40 who completed the treatment, 37 had a complete clinical response and 29 (50% of the entire series) were histologically negative at subsequent surgery. The role of CRT with or without surgery will be explored in an upcoming international trial for locally advanced penile cancer (InPACT) sponsored by the International Rare Cancers Initiative, using weekly cisplatinum as a radiation sensitizer.

Response rates for neoadjuvant chemotherapy are, at best, 50%. A trial of neoadjuvant paclitaxel, ifosfamide, and cisplatin at the M. D. Anderson Cancer Center has reported a response rate of 50% in 30 patients with N2 or N3 penile cancer. Surgery, CRT, or both, can be used after a response to chemotherapy.[81]

IRRADIATION TECHNIQUES AND TOLERANCE

External Beam Irradiation

EBRT has several advantages in that it is widely available, delivers a homogeneous dose, and does not require the specific expertise of brachytherapy. Well-localized carcinoma in situ (Tis) may be treated effectively using 125-kV orthovoltage beams or 9-MeV electrons with suitable bolus, using fractionation schemes commonly employed for skin cancer such as 35 Gy in 10 fractions over 2 weeks[71]; however, most such lesions would be treated by a penile-conserving surgical technique. Most cases referred for RT require irradiation to the full thickness of the penis with a full dose to the skin surface. Fraction sizes less than 2 Gy are suboptimal[2] and fraction sizes larger than 2 Gy may be associated with increased long-term sequelae.[72] Doses range from 60 Gy in 25 fractions over 5 weeks to 74 Gy in 37 fractions over 7.5 weeks, avoiding interruptions because of acute reactions (e.g., edema, pain, desquamation). A reproducible setup, easily verified by technologists, which is comfortable for the patient despite increasing local reaction, is essential.

Successful application of megavoltage EBRT to treat penile cancer must overcome the technical challenge of positioning the penis in such a way that other tissues will not be exposed to irradiation and counteracting the skin-sparing of megavoltage x-rays. Several techniques have been developed.

A 10- × 10-cm to 10- × 15-cm wax block can be constructed in two halves with a central cylindrical chamber.[71,74] The patient is positioned supine on the treatment couch, and the penis is supported in a vertical position, encased in the wax block. Tissue-equivalent material must be placed in the distal portion of the cylindrical chamber to maintain full dose to the glans. Parallel-opposed beams of cobalt 60 or 4- to 6-MV photons treat the entire length of the penis (Figure 57-4). As treatment progresses, penile swelling may require modification of the wax block. Verification of penile position within the wax is not possible, but a snug fit will prevent the penis from "slumping" inside the wax.

Perspex is a good alternative to wax and provides full buildup to the skin surface while allowing treatment by parallel-opposed beams.[2] Preconstructed blocks in a range of sizes of the central cylindrical chamber can be sterilized for reuse. Penile swelling can be accommodated easily by choosing the next larger size, and penile position within the transparent block can be easily verified visually.

An alternative approach has been described with the patient positioned prone and the penis suspended in a *water* bath. This approach is not appropriate in patients who are obese and day-to-day set up can be challenging because the penis tends to float and position itself too close to adjacent tissues.[82]

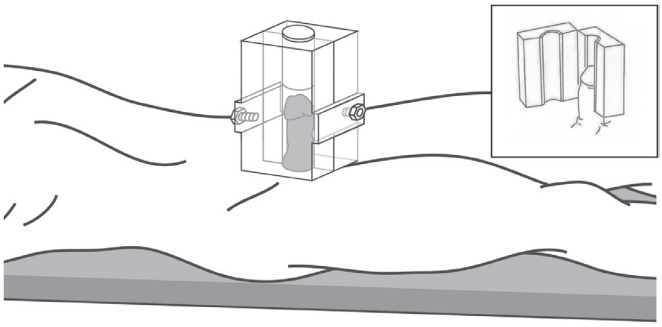

Figure 57-4 Patient positioned with Perspex block in place. Block provides full buildup and is transparent for verification of penile position. The blocks are bivalved and can be made in a range of sizes to accommodate penile swelling as treatment progresses.

Brachytherapy

The penis is well suited to brachytherapy. For centers with appropriate expertise, surface molds or interstitial techniques can be used with good effect. Circumcision should be performed before brachytherapy to ensure complete exposure of the tumor and prevent subsequent phimosis or annular fibrosis of the foreskin.

Molds

Unlike interstitial brachytherapy, a mold is not invasive and does not require anesthesia.[72] The acute reaction develops after the treatment is finished. A surface dose of 55 Gy to 60 Gy is prescribed, with a central axis dose of 46 Gy to 50 Gy over 84 hours (12 hr/day) and may be delivered using a Perspex tube or silicon monomer.[72] Application is limited to superficial tumors of known depth of invasion.

Interstitial Brachytherapy

There is experience with interstitial brachytherapy for T1 or T2 penile carcinoma from many European countries and from Canada. A joint consensus guideline has recently been published by the American Brachytherapy Society and Groupe Europeen de Curiethérapie.[83] Ideally patients should have tumors less than 4 cm in diameter with no or limited invasion of the corpora or involvement beyond the coronal sulcus. Implants can be performed with the patient under general or local anesthesia. The Paris system of dosimetry[84] is applicable to manually afterloaded implants and remote afterloading pulse-dose-rate systems, although for the latter some optimization can be introduced.

Circumcision should always precede penile brachytherapy to allow full visualization of the tumor and to remove any portion involving the foreskin. The foreskin is prone to necrosis and if left in situ during brachytherapy the ensuing painful ulceration can be slow to heal and result in a chronically adherent or phimotic foreskin.

Penile brachytherapy is generally performed as a "volume" or multiplane implant delivering irradiation to the full-thickness of the penis. Only well-selected, superficial tumors may be treated with a single-plane implant. A video of penile brachytherapy is available on the Expert Consult website. For volume implants, two or three parallel planes of sources are inserted, with two or three needles in each plane. Intersource and interplane spacing should be equal, in the range of 12 mm to 18 mm. The distribution, spacing, and total number of needles depend on tumor size. Planes are usually oriented with the needles passing from the dorsal to the ventral surface of the glans, but a left-to-right orientation may work for some tumor locations. Visual verification of coverage can be readily accomplished. Needle placement should be planned such that the prescription isodose will cover 10 mm beyond visible or palpable tumor. Care must be taken to adhere to the rules of the Paris system[66] and to be aware of the relationship of the treated volume to the needles such that placement ensures that the entire tumor and desired margin are within the high-dose volume (Figure 57-5). Specific considerations of needle placement for meatal tumors or unilateral tumors have been described.[53]

Needle placement requires 30 minutes to 45 minutes in the operating room. Catheterization aids in identification of the urethra so as to avoid transfixing it with implant needles. For manually afterloaded iridium-192 wire, 19.5-gauge needles

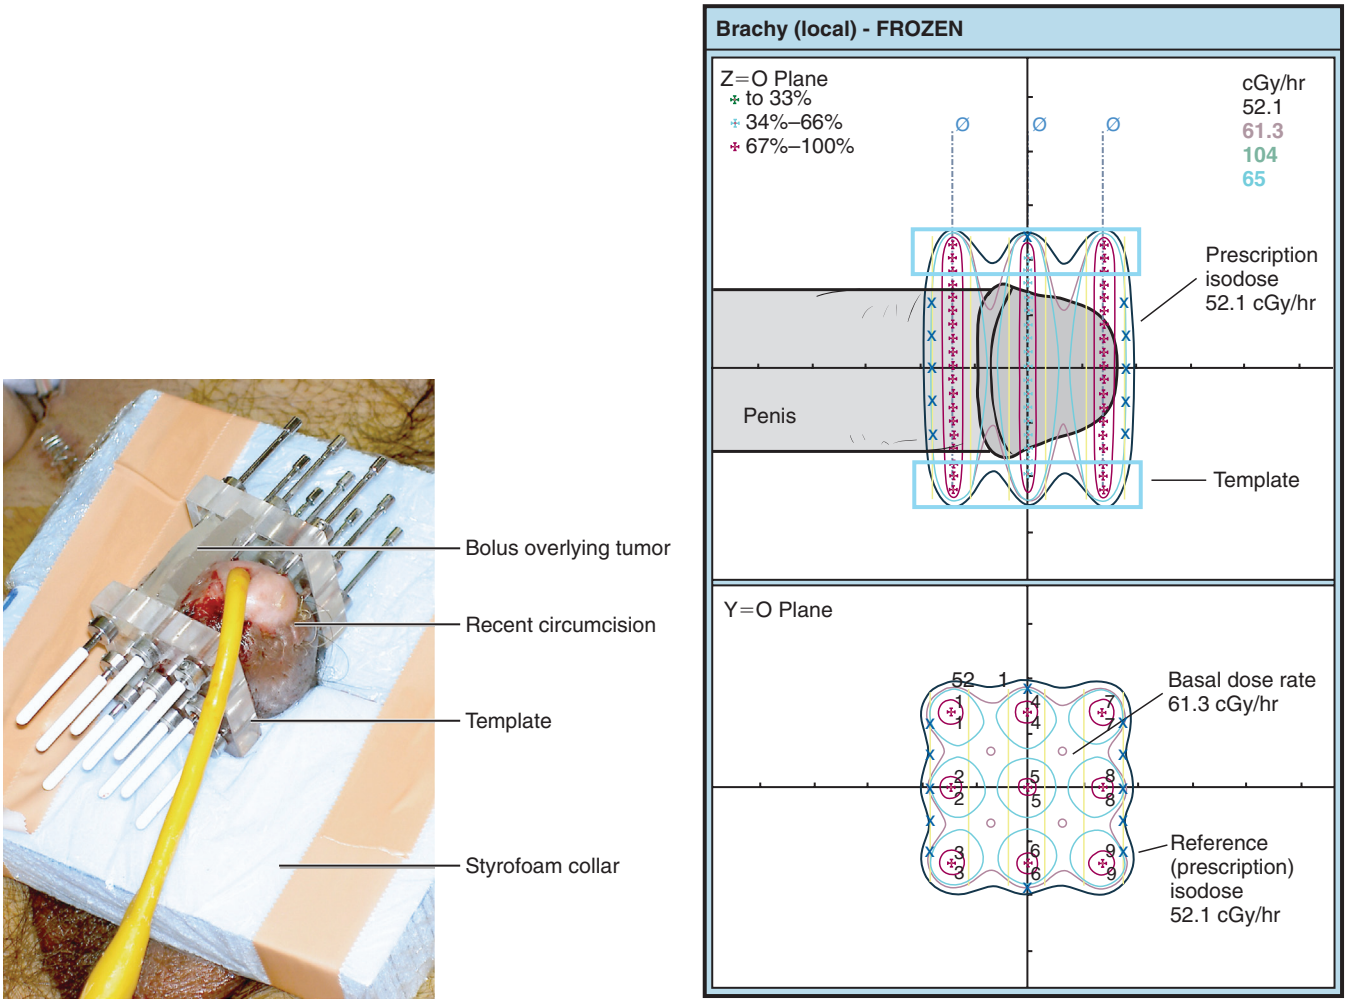

Figure 57-5 Interstitial brachytherapy according to the Paris system of dosimetry.[66] **A,** Six-needle, two-plane implant. **B,** Nine-needle, three-plane implant. **C,** Dose distribution for B. According to the Paris system, dose rate minima in the central plane (61.3 cGy/hr in this case) are the basal dose rate. The prescription isodose is 85% of the basal dose rate (52.1 cGy/hr in this case).

are appropriate, whereas, for a pulse-dose-rate remote afterloader, 17.5-gauge needles are compatible. The needles are stabilized through the duration of treatment with predrilled Plexiglas templates. The prescribed dose is generally 60 Gy at a dose rate of 50 cGy/hr to 60 cGy/hr over 100 to 120 hours (4 days to 5 days). No dose rate correction is required for pulse-dose-rate therapy (hourly fractions) compared with continuous low-dose-rate therapy. A Styrofoam or sponge collar positioned around the base of the penis proximal to the needles supports the penis, distances the implant from the testes, and minimizes unnecessary irradiation of adjacent tissue. A thin sheet of lead can be inserted into the supporting collar to decrease transmitted dose to the testes if subsequent fertility is an issue.

The brachytherapy needles are generally well tolerated. The patient remains catheterized and in bed for the duration of the implant, although with pulse-dose-rate therapy the source cables can be disconnected from the needles to allow the patient to mobilize for brief periods between fractions. Sufficient analgesia is usually provided by acetaminophen, with or without codeine. Leg exercises and embolus prophylaxis are recommended. Removal of the needles occurs at the bedside after premedication with a narcotic analgesic.

Although high-dose-rate (HDR) brachytherapy is becoming widely available, at present there is little evidence on which to base treatment recommendations for penile cancer. One report of 10 patients treated over 8 years used twice-daily fractions of 3 Gy to deliver 54 Gy over 9 days.[85] No necrosis was observed but implants were small volume and the majority was single plane. Limited personal experience with 6 patients, prescribing fractions of 3.2 Gy to 3.75 Gy twice a day for a total prescribed dose of 38.2 Gy to 45 Gy, with needle spacing from 9 mm ($n = 2$) to 14 mm to 17 mm ($n = 4$), resulted in 5 patients being disease free and one local failure. Five of the 6 patients experienced delayed healing and necrosis, including the one with local failure. Of the 5 patients who were NED, one has ongoing ulceration, whereas 3 healed with conservative management including hyperbaric oxygen. CT planning is required with delineation of the gross tumor volume using fine wire. Because of the high rate of troublesome ulceration and necrosis one has to be cautious and preliminary recommendations would be to keep the V_{150} less than 20%, use needle spacing of 9 mm to 12 mm to improve homogeneity, and select cases where the PTV is limited to 30 mL or less. Complications will be worse in patients with diabetes and those who smoke. Further published experience and longer

follow-up is required before any definitive recommendations can be made regarding optimal fractionation for HDR brachytherapy in the management of penile carcinoma.

Tolerance: Acute and Chronic Reactions

Toxicity: Acute Reaction

The acute reaction after brachytherapy is limited to the implant site. Moist desquamation peaks in 2 to 3 weeks but may take 2 to 3 months to heal completely. Local hygiene is important, including frequent soaks in baking soda and water. Sterile distal urethritis is common, but urethral adhesions, causing a divided or deviated urinary stream, should be separated by passing a meatal dilator or an 18-French Foley catheter a few centimeters into the distal urethra. Intercourse can be resumed as soon as the patient is comfortable, but because the healing epithelium is fragile, additional water-based lubricant is recommended.

The acute reaction to EBRT peaks during treatment and may involve edema of the penile shaft and more extensive desquamation. Management is similar to that for patients who had brachytherapy.

Late Reactions

The two most common and significant late complications of RT for penile cancer are soft-tissue ulceration and meatal stenosis. Either can occur with EBRT or brachytherapy (see Table 57-2).

Soft-Tissue Ulceration or Necrosis

Soft-tissue ulceration is reported in 0% to 23% of patients and is more common after brachytherapy than after EBRT. Necrosis (persistent, nonhealing ulceration) is the most common reason for amputation of a tumor-free penis. The risk of necrosis increases with increasing dose more than 60 Gy, stage T3 tumors, larger implant volume (>30 mL; $p = 0.01$), and a greater number of needles ($p = 0.04$) or implant planes (>2; $p = 0.001$).[33,77]

The peak time for soft tissue ulceration is 7 to 18 months after brachytherapy, but it can occur much later. Causative factors include trauma and cold exposure. Areas of ulceration should be treated conservatively, with attention to good hygiene, antibiotics, and topical corticosteroid or vitamin E creams. Biopsy should be avoided unless there is suspicion of concomitant tumor. A deeper or painful area of necrosis may respond well to hyperbaric oxygen treatment[77] (Figure 57-6). If such treatment is available, it should be tried before resorting to amputation.

Urethral Stenosis

Urethral or meatal stenosis is reported in 10% to 45% of patients and tends to occur later in the follow-up period, but usually before 3 years. With EBRT it is more common with higher doses and fraction sizes greater than 2 Gy. For brachytherapy, Rozan et al reported that the only factor predictive of urethral stenosis was the number of needle planes used in the

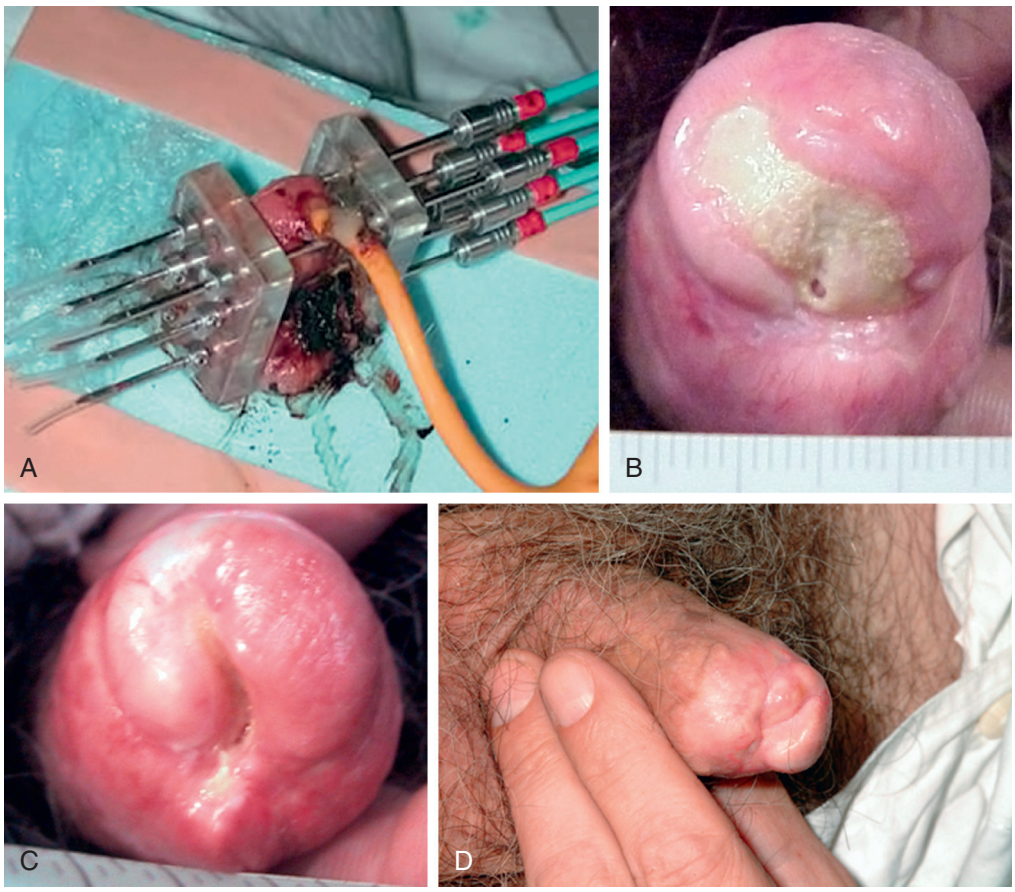

Figure 57-6 **A,** 47 year old man with deeply invasive moderately differentiated SCC, T3pN0 who had staging node dissection but refused penectomy. **B,** The patient suffered a severe necrosis following brachytherapy and tumor response. **C,** Healed with hyperbaric oxygen. **D,** Result shown 5 years later. Patient is potent and disease-free.

External irradiation is a reasonable option for T1 and small T2 tumors if brachytherapy is not available. *Bil sup,* Bilateral superficial; *EXT RT,* external radiation; *Ing,* inguinal; *LN,* lymph node; *LND,* lymph node dissection; *LN Obs,* lymph node observation; *LVS,* lymphovascular space; *M/PD,* moderately/poorly differentiated; *SLND,* sentinel lymph node dissection; *WD,* well differentiated.

implant ($p = 0.001$, if two planes).[32] When a three-plane implant is indicated because of tumor size or morphology, central plane needles will be close to the urethra.[75] A pulse-dose-rate remote afterloader allows optimization of dwell times to limit the urethral dose.

Urethral adhesions in the acute phase should be separated to avoid development of a chronic problem. Patients can be given a meatal dilator at their first follow-up visit with instructions to use it as required. Many late urethral stenoses are low grade and can be managed with repeat dilatations, or even self-dilatations, often at infrequent intervals. Severe cases may require reconstructive surgery, such as urethroplasty or meatoplasty.

Sexual Function

The impact on sexual function often is not assessed. Crook et al[77] found that in a series of 49 men treated with brachytherapy, 22 of 27 who were potent at baseline reported satisfactory potency at last follow-up. Delannes et al[35] observed that apart from one patient who developed painful erections resulting from sclerosis, "sexual function did not appear to be altered by the implant." Sarin et al[2] provided details for only 14 of the 59 patients, commenting that 12 were normal and 2 had minor impairment. Mazeron et al[33] stated that for noninfiltrating or moderately infiltrating tumors less than 4 cm in diameter, "sexual function remained the same as before treatment." A recent systematic survey of 21 French patients (median age 73 years) treated by brachytherapy a median of 80 months previously, 59% remained sexually active, and 79% maintained nocturnal erections. None reported a "loss of manliness," but 53% noted a change in sensitivity of the glans.[69]

Incorporation of a layer of 2 mm of lead into the supporting collar around the penis will limit total dose to the anterior testis to 55 cGy and 26 cGy to the posterior testis during a 60-Gy pulse-dose-rate treatment course[58] as measured by thermoluminescent dosimeter. No data are available on post-brachytherapy sperm counts.

Other Late Sequelae

Mottled hypopigmentation or hyperpigmentation, telangiectasia, and mild to moderate focal fibrosis may occur. Some atrophy of the glans in areas of deep tumor infiltration is common.

TREATMENT ALGORITHM, CONTROVERSIES, AND CHALLENGES

Penile cancer is a rare but psychologically devastating disease. The functional and sexual implications of treatment should be discussed with patients.

Our preferred treatment algorithm is shown in Figure 57-7. For Tis, T1, and T2 tumors less than 4 cm in diameter, a penile-conserving approach as primary management is warranted. Laser surgery can provide satisfactory cosmesis, function, and local tumor control, especially for Tis or small T1 lesions, with the option of retreating local recurrences with further laser surgery. The RT of choice is interstitial brachytherapy, which results in penile preservation in 70% of cases at 10 years. If brachytherapy expertise is not available, EBRT can prevent amputation in 50% to 60% of patients. For more locally advanced lesions (T2 > 4 cm, T3, ? T4), concurrent chemoradiation should be evaluated. With any penis-conserving approach, protracted follow-up is necessary because local failure can occur many years later and surgical salvage can be curative.

Observation of regional nodes is recommended for low-risk T1 and T2 tumors that are well differentiated with no evidence of lymphovascular space invasion. Moderately or poorly differentiated tumors and all T3 tumors should have surgical staging of regional lymph nodes.

Squamous cell carcinoma of the penis remains a clinical challenge. Although it is highly curable in its early stages, the challenge is to minimize the psychosexual morbidity of treatment through less aggressive surgical approaches or alternatives to surgery such as brachytherapy without compromising cure. When diagnosis is delayed and the patient presents with advanced disease, the fatality rate is high.

Rare tumors do not achieve the same level of public awareness as the more common malignancies. Public education and support groups for breast or prostate cancer are well established and successful. For penile cancer there is a need to educate the public and physicians about risk factors, warning signs, and early diagnosis. It is unfortunate that men should ever present with locally advanced disease on such a readily visible and easily examined organ.

Enhanced clinical staging with MRI may prove to be a useful adjunct to physical examination when invasion of the

corpora is suspected but not certain (eFigure 57-2). Dynamic sentinel node mapping spares patients with high-risk disease (G2 to G3 or T3) the morbidity of a staging superficial inguinal node dissection (eFigure 57-2).

Cooperative group efforts such as the upcoming trial from the International Rare Cancers Initiative (InPACT) are required to determine the most effective aggressive multimodality approach for the patient with locally advanced disease.

Overview

Gillian M. Thomas

This overview provides an introduction to the chapters on specific gynecologic tumors that follow, including discussions of cancer of the cervix, uterine corpus, vulva and vagina, and ovary. It highlights important clinical issues and areas of controversy. The etiologic and epidemiologic differences among these tumors are addressed in the relevant chapters. Progress toward improving outcomes is slow but where gains in the therapeutic ratio have resulted they are addressed for each tumor site.

Gynecologic cancers continue to be staged using the FIGO staging system. In 2009 the FIGO staging system was modified from the previous version of 1988. Each sites specific chapter will note the differences. Caution needs to be taken because changes in the FIGO staging system may not allow direct comparisons of outcomes by stage between the new and the old systems.

Conformal radiotherapy techniques including intensity-modulated radiation therapy (IMRT) and image-guided brachytherapy (IGBT) appear in some situations to have improved the therapeutic ratio of radiation principally by decreasing dose received by normal tissues and therefore an expectation for decreasing incidence of acute and late complications. Its implementation for gynecologic cancers has lagged behind that in other tumor sites for a variety of valid reasons. Caution around the possibility of geographic miss of tumor because of imposed dose constraints for normal tissues must be exercised; for cervical cancer close margins in tumor may result in underdosage if internal organ motion and changing tumor configurations are not taken into account.[1] Consistent guidelines for the use of IMRT at least in the postoperative adjuvant setting for endometrial and cervical cancer are published and are undergoing revision. This has facilitated wide uptake.[2] It is critical to deliver acceptable radiation volumes and dose, that strict measures of quality assurance for physics, dosimetry, and tumor volume delineation be practiced.

Promising novel therapies are currently being investigated in Phase I, Phase II, and some Phase III studies in cervical, ovarian, and endometrial cancers. These therapies are based on the identification of specific pathways of tumor progression that can be targeted for interruption (e.g., angiogenesis and the identification of "druggable" molecular targets).

In addition to this direction of development are the multiple progressive steps made in novel imaging techniques. It is anticipated with optimism that techniques such as positron emission tomography–computed tomography (PET-CT) scanning, magnetic resonance diffusion imaging, and spectroscopy will enable a conjunction of anatomic and functional imaging to more accurately define tumor volumes and that these techniques will act as both predictive and response biomarkers as has been observed in cervical cancer.[3,4]

Disseminated metastatic disease remains a problem but the utility of standard chemotherapeutic agents in various combinations, doses, and strategies has leveled out and is far from optimal. Thus, the identification of new biomarkers and targeted molecular therapies to these markers constitutes a rational new research direction for the management of disseminated disease. The ultimate anticipation from these advances is that individual patients or small groups of patients expressing specific biomarkers may be treated with a targeted therapy most suited to those individuals and their respective tumors. It is hoped that cancer research will lead to an era of "personalized" medicine. The splitting of population into smaller groups however, makes the conduct of Phase III trials extremely difficult.

CERVICAL CANCER

In cervical cancer, hypoxia and angiogenesis form part of a common pathway to cancer development and progression. The antiangiogenic agent, bevacizumab, was recently reported in a Phase III trial in recurrent, persistent or metastatic disease to improve overall survival (OS) in a selected population by 3.7 months compared to standard chemotherapy (median OS 17.0 versus 13.3 months, $p = 0.004$).[5]

Although Phase II data have demonstrated the tolerability of combining bevacizumab with definitive pelvic irradiation and concurrent cisplatin, recent discussions with the National Cancer Institute (NCI) and the pharmaceutical producers of bevacizumab suggest that these data will not be used to proceed to a larger randomized Phase II or Phase III trial with this agent.[6] Currently a randomized Phase II trial is proceeding with the agent triapine (ribonucleotide reductase inhibitor that inhibits radiation damage repair) added to chemoradiation.[7] The paucity of patients with cervical cancer in the developed world means that future trials to advance outcomes in locally advanced cervix cancer will of necessity be international in scope. At the present time, the international "outback trial" is proceeding, which examines the role of adjuvant chemotherapy after standard chemoradiation to the pelvis.[8] It is unlikely that further large-scale trials in locally advanced cervical cancer will be conducted until this trial completes accrual.

Although IMRT is being used widely in adjuvant treatment of cervical cancer, its role in the intact cervix is still not widely accepted given the necessity for strict quality assurance measures to ensure tumor coverage of the mobile target of the cervix and uterus.

ENDOMETRIAL CANCER

In endometrial cancer in addition to similar exploration of angiogenesis inhibitors and tyrosine kinase inhibitors is the exploration of MTOR inhibitors including temsirolimus, everolimus, and deforolimus. Forty to 80% of women with type I endometrial carcinoma have a mutation in PTEN, which up regulates MTOR activity making its inhibition a rational target. Significant response rates have been reported in patients who are chemotherapy naïve with advanced or recurrent endometrial cancer although response in this study is not correlated with PTEN status.[9] Various combinations of these MTOR inhibitors with chemotherapy or with other biologic agents are being conducted.

The relative roles of adjuvant chemotherapy and radiation in locally advanced disease remain unclear. The pending results of completed randomized Phase III trials should clarify this considerably.

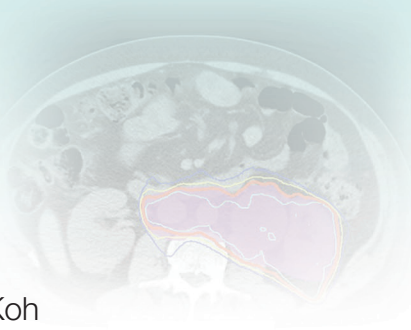
VULVAR AND VAGINAL CARCINOMA

Vaginal carcinoma treatment continues to be based on extrapolations of information from cervical cancer with its similar herpes papillomavirus (HPV) etiology. Refinements in the delivery of irradiation using conformal methods such as IMRT, at least for boosting locally advanced disease where brachytherapy is inappropriate, may help to decrease potential toxicities of radiation therapy.

The major advance in the treatment of vulvar cancer with definitive or neoadjuvant chemoradiation has been the ability also to use more conformal radiation techniques. Vulvar cancers are often difficult to image on magnetic resonance imaging (MRI) so the importance of merging planning information from scans as well as the clinical appearance of the tumor is vital. It continues to be widely important to encompass the entire tumor rather than compromising tumor volume coverage to further spare some adjacent normal tissues. Unfortunately, no level-1 evidence is available to clearly define tumoricidal doses for definitive chemoradiation. In this highly radiosensitive tumor, application of basic principles with regard to delivering the irradiation component of treatment must apply.

OVARIAN CANCER

In heritable ovarian cancer, those with *BRCAI* or *BRCAII* mutations, poly ADP ribose polymerase (PARP inhibitors), may specifically target tumor cells that are deficient in their ability to repair DNA double-stranded breaks. Several PARP inhibitors are currently under investigation in *BRCA*-deficient cancers. Early results from Phase II trials are encouraging.



In advanced ovarian cancer results of two Phase III studies were recently reported.[10,11] The combination of bevacizumab and chemotherapy followed by maintenance bevacizumab alone modestly increased the progression-free survival by 3.8 months and 1.7 months compared to the use of chemotherapy alone or with concurrent bevacizumab. This finding has major societal implications not only for patients with ovarian cancer but also for future implementation of widespread use of expensive targeting agents, which may provide some advantage in progression-free survival, not as yet in overall survival but may not be affordable for general use.

CHAPTER

58 Cervical Cancer

Akila N. Viswanathan, Don S. Dizon, Lilian T. Gien, and Wui-Jin Koh

INCIDENCE

Worldwide, cervical cancer is the third-most common cancer in women, accounting for more than 500,000 new cases and approximately 275,000 deaths. However, in the United States the incidence of cervical cancer is quite low, accounting for less than 13,000 cases annually and approximately 4,000 deaths each year.

BIOLOGY

In 80% to 90% of cases, the histologic type is squamous cell carcinoma; the frequency of adenocarcinoma is increasing. In approximately 90% of patients, there is an association with human papillomavirus (HPV) infection. Recognized tumor-associated prognostic factors are stage, tumor size, lymph node metastasis, and hemoglobin level.

STAGING EVALUATION

International Federation of Gynecology and Obstetrics (FIGO) staging includes physical examination, chest radiography, and intravenous pyelography or alternative imaging to assess for ureteral obstruction; in highly selected cases (based on relevant symptoms), cystoscopy, proctoscopy or barium enema, and bone films are needed. It is often useful, where available (but does not influence the FIGO stage), to include more accurate radiologic tests (e.g., computed tomography [CT], magnetic resonance imaging [MRI], positron emission tomography [PET], and lymph node sampling).

PRIMARY THERAPY

The choice of primary therapy and the resulting overall survival (OS) are related to disease extent at the time of initial diagnosis and staging evaluation:

- For stage IA disease, either simple hysterectomy or brachytherapy result in 5-year OS of >98%. For selected patients, radical trachelectomy represents a fertility-sparing treatment option.
- For stage IA2 or limited IB1 disease, radical hysterectomy with pelvic node dissection is the preferred treatment and results in a 5-year OS of 90% to 95%. However, for patients who are not surgical candidates for whatever reason, primary irradiation with or without concurrent chemotherapy is a reasonable alternative.
- Concurrent chemoradiation (chemoRT) is appropriate primary therapy for stages IB2-IVA disease with 5-year OS dependent on stage (IB2/IIA, 80% to 95%; IIB, 70% to 85%; III, 40% to 65%; IVA, 15% to 25%).

ADJUVANT THERAPY

Radiation therapy (RT), with or without cisplatin-based concurrent chemotherapy after radical or modified radical hysterectomy, is recommended for patients with intermediate- or high-risk features. Adjuvant hysterectomy after RT is not routinely recommended and may be avoided entirely if image-based brachytherapy is feasible but may benefit occasional patients with persistent isolated cervical disease after concurrent chemoRT. Neoadjuvant chemotherapy has no proven benefit before RT or surgery for locally advanced disease. Concurrent RT has resulted in multiple positive Phase III trials for survival compared with RT alone.

PALLIATION

Strategies for symptom relief are most important for residual or recurrent disease. Cisplatin in combination with paclitaxel or topotecan chemotherapy is given but is largely ineffective in prolonging survival times. The addition to bevacizumab was associated with an approximately 4-month improvement in OS at the risk of an increase in grade-2 or higher hypertension, grade-3 or higher thromboembolic events, and grade-3 or higher gastrointestinal fistulas. Irradiation often provides excellent short-term relief of pain and bleeding, particularly in patients with no history of prior RT.

The incidence of and mortality rates from invasive cervical cancer have steadily declined in the United States over the past five decades, in part because of the successful implementation of screening programs that detect many cancers at a preinvasive stage. Unfortunately, cytologic screening programs have failed to comprehensively penetrate the population, with many medically underserved or uneducated communities at risk. Invasive cervical cancer continues to be a major public health problem internationally. In the United States, 60% of women with newly diagnosed invasive cervical cancers have not had a Papanicolaou (Pap) smear for 5 years or longer.

During the past decade, much has been learned about the etiology and biology of cervical cancer. Epidemiologic studies have long demonstrated that patterns of occurrence suggest the disease stems from a sexually transmitted agent. Nearly all cervical cancers contain HPV DNA. There is compelling evidence for a causal relationship between HPV and cervical carcinoma.

Even invasive cervical cancer is highly curable if detected at an early stage. Radiation and surgery yield comparable cure rates of 80% to more than 95% for patients with early-stage disease. RT including brachytherapy plus concurrent chemotherapy, which is the treatment of choice for patients with locally advanced disease, is curative in more than 80% of patients with FIGO stage II disease and in about 50% of patients with FIGO stage III disease.

EPIDEMIOLOGY AND ETIOLOGY

In the United States, cervical cancer is responsible for about 2% of the cancer deaths in women, with less than 13,000 new

cases of invasive disease and 3000 to 4000 deaths each year.[1] Worldwide, invasive cervical cancer is the third-most common malignant tumor in women (after breast and colorectal cancers) and accounts for nearly 500,000 cases and 275,000 deaths per year.[2] Incidence rates range from as low as 3 to 4 per 100,000 in Israel to more than 80 per 100,000 in Recife, Brazil.[3] Presumably, this wide range reflects a variation in epidemiologic risk factors that is compounded by the lack of adequate screening programs in poor communities. The relatively high international mortality rates may also reflect the greater number of women who present with advanced disease when screening programs and patient education are inadequate and access to medical resources is limited or nonexistent. Because of the lack of cancer registries, it is likely that reported incidence and mortality rates grossly underestimate the magnitude of the problem.

Risk factors for the development of carcinoma of the cervix and its intraepithelial precursors follow a pattern typical of sexually transmitted diseases. These include first coitus at a young age, multiple sexual partners, a history of other sexually transmitted diseases, and high parity.[4] Weaker associations have been suggested with cigarette smoking and the use of oral contraceptives. In contrast, the risk of developing cervical cancer is low in women who are nulliparous or virginal. Among women with only one lifetime sexual partner, past and current high-risk sexual behavior by the male partner has a substantial role in the development of cervical carcinogenesis.[5] Conversely, male circumcision is associated with a reduced prevalence of penile HPV infection and a reduced risk of cervical cancer in the current sexual partners.[6]

Until recently, the reasons for these associations were only the subject of speculation. Today, however, the epidemiologic findings, combined with the results of molecular studies (discussed in detail later), are sufficient to identify sexually acquired HPV infection as the primary etiologic agent in the development of most cervical cancers.[7,8]

Although the epidemiology of cervical adenocarcinoma is somewhat less well understood, studies also reveal the presence of HPV DNA in most cases.[9] It is interesting that in the United States, the absolute and relative incidence of adenocarcinoma appears to have increased in contrast to the steady decrease in the rate of invasive squamous carcinoma. This may reflect, in part, differences in the effectiveness of cytologic screening in detecting adenocarcinoma at a preinvasive stage.[10] Some investigators have implicated oral contraceptives as a possible risk factor for adenocarcinoma, with biological differences in gene expression potentially implicated in carcinogenesis.[11,12]

Clear cell carcinoma, a rare form of cervical and vaginal adenocarcinomas, has been clearly linked with prenatal exposure to diethylstilbestrol (DES), a drug that was used to prevent miscarriages in the 1940s and 1950s.[13] Prenatal DES exposure arrests development of the transformation zone in the upper third of the vagina, which accounts for the location of these lesions. The average age at which cancer in patients exposed to DES was diagnosed was 19 years, much younger than the average age of patients with newly diagnosed squamous carcinoma or non-DES–related adenocarcinoma. New diagnoses of DES-related clear cell carcinoma have declined now that the youngest cohort of patients exposed to DES has passed the age of peak incidence.

PREVENTION AND EARLY DETECTION

Although there have been significant changes in the fields of radiation and gynecologic oncology, the dramatic decrease in cervical cancer mortality from the 1940s to the 1980s is primarily the result of the success of mass screening programs.[14,15] The cervix is an ideal target for cancer screening because of its accessibility, the long average time interval from the initial DNA insult to the development of invasive cancer, and the high cure rate with appropriate treatment of preinvasive and early invasive lesions.

Squamous cell carcinomas originate at the squamocolumnar junction (transformation zone) of the cervix. Invasive lesions are frequently associated with adjacent preinvasive or in situ disease (low-grade squamous cell intraepithelial lesion [LGSIL] or high-grade squamous cell intraepithelial lesion [HGSIL]) (Table 58-1).

Longitudinal studies suggest a long average time to progression from HGSIL to invasive disease. Peterson[16] described 127 patients with carcinoma in situ (CIS; HGSIL) who were followed for at least 3 years. At the end of 10 years, invasive carcinoma had developed in about 30%. Koss et al[17] observed spontaneous regression of 25% in 67 patients with untreated CIS (HGSIL) who were observed for 3 years. In a later analysis of this series, the authors reported that invasive lesions had developed in 40% of the original 67 patients.[18] In another longitudinal study of patients with untreated CIS (HGSIL), Kottmeier[19] observed progression to invasive carcinoma in 71% and 80% of patients followed for 12 and 30 years, respectively.

TABLE 58-1 Relationship of the Bethesda System to Previous Classifications

Normal Limits	**Benign Cellular Changes**		**Epithelial Cell Abnormalities**			
	Infection Reactive repair	ASCUS AGUS	LGSIL HPV	HGSIL		Invasive carcinoma

TABLE 58-2 International Federation of Gynecology and Obstetrics Staging of Carcinoma of the Cervix

Stage I	The carcinoma is strictly confined to the cervix *(extension to the corpus should be disregarded).*
Stage IA	Invasive cancer identified only microscopically. All gross lesions, even with superficial invasion, are stage IB cancers. Invasion is limited to measured stromal invasion with a maximum depth of 5 mm and no wider than 7 mm. *(The depth of invasion should not be more than 5 mm taken from the base of the epithelium, either surface or glandular, from which it originates. Vascular space involvement, either venous or lymphatic, should not alter the staging.)*
Stage IA1	Measured invasion of stroma no greater than 3 mm in depth and no wider than 7 mm.
Stage IA2	Measured invasion of stroma greater than 3 mm and no greater than 5 mm in depth and no wider than 7 mm.
Stage IB	Clinical lesions confined to the cervix or preclinical lesions greater than IA.
Stage IB1	Clinical lesions no greater than 4 cm in size.
Stage IB2	Clinical lesions greater than 4 cm in size.
Stage II	The carcinoma extends beyond the cervix but has not extended onto the pelvic wall; the carcinoma involves the vagina but not as far as the lower third.
Stage IIA	No obvious parametrial involvement.
Stage IIA1	Clinical lesions no greater than 4 cm in size.
Stage IIA2	Clinical lesions greater than 4 cm in size.
Stage IIB	Obvious parametrial involvement.
Stage III	The carcinoma has extended onto the pelvic wall; on rectal examination there is no cancer-free space between the tumor and the pelvic wall; the tumor involves the lower third of the vagina; all cases with a hydronephrosis or nonfunctioning kidney should be included, unless they are known to be due to another cause. No extension onto the pelvic wall but involvement of the lower third of the vagina.
Stage IIIA	Extension onto the lower third of the vagina.
Stage IIIB	Extension onto the pelvic wall or hydronephrosis or nonfunctioning kidney.
Stage IV	The carcinoma has extended beyond the true pelvis or has clinically involved the mucosa of the bladder or rectum.
Stage IVA	Spread of the growth to adjacent organs.
Stage IVB	Spread to distant organs.

From Pecorelli S, Zigliani L, Odicino F: Special communication. Revised FIGO staging for carcinoma of the cervix. Int J Gynecol Obstet 105:107–108, 2009.

In addition, a relatively long interval appears to lapse between the diagnosis of dysplasia and the development of HGSIL. One large prospective study reported mean times for progression to HGSIL development of 58, 38, and 12 months for patients with mild, intermediate, or severe dysplasia, respectively.[20] These results are consistent with the finding that the mean age of women diagnosed with cervical intraepithelial neoplasia (HGSIL) is about 16 years younger than that of women diagnosed with invasive carcinoma.[21]

Although a number of classifications have been used, the Bethesda system is currently the most widely accepted method of categorizing cervical cytologic specimens in the United States.[22] The relationship between this system and previous classification systems is outlined in Table 58-2.

Multiple organizations including the American College of Obstetrics and Gynecology (ACOG),[23] U.S. Preventive Services Task Force (USPSTF),[24] the American Society for Colposcopy and Cervical Pathology (ASCCP), and the American Society for Clinical Pathology (ASCP)[25] have guidelines for screening for cervical cancer, and all are fairly consistent. All endorse that cervical cancer screening begin at age 21 years regardless of age of onset of sexual intercourse and discontinued at 65 years, provided that three prior consecutive tests have been negative. Before the age of 30, cytologic tests should be done every 3 years. For women older than 30 years, HPV DNA cotesting every 5 years is recommended by ASCCP and ASCP (with cytology is recommended by ACOG). However, the USPSTF recommends cytology every 3 years, though accepts cotesting for HPV and cytology every 5 years as an acceptable alternative.

Women with human immunodeficiency virus (HIV) infection, those who are immunosuppressed, those who have been exposed in utero to DES, or those who have been previously treated for cervical intraepithelial neoplasia (CIN) stage II or III or cancer may require more frequent screening. As compared with annual screening, mathematical modeling predicts the excess risk of cervical cancer with less frequent screening intervals to be approximately 3 in 100,000.[26]

Despite the proven efficacy of cytologic screening, many women remain unscreened. In the United States, 50% of women with newly diagnosed invasive cervical cancer have never had a Pap smear and another 10% have not had a Pap smear in 5 years.[8] Women who tend to be underscreened in the United States fall into groups of postmenopausal, uninsured, ethnic minority, and especially, elderly black and poor women in rural areas. In the United States, about 25% of the cervical cancer cases and 41% of the deaths occur in women who are age 65 years or older. In addition, nearly 50% of women older than 60 years have not had a Pap smear in 3 years, even though many have seen a physician for other medical reasons.

In areas of the world in which screening programs are either prohibitively expensive or the infrastructure is not available, alternative and more accessible programs have gained attention. One of these is the use of visual inspection with acetic acid (VIA), which has been evaluated in two large trials in India.[27,28] In one study, more than 150,000 women in rural India were randomly assigned into two cohorts in a planned 16-year study; both had access to cancer education but only one cohort was additionally followed with four rounds of VIA.[27,28] As presented at the 2013 American Society of Clinical Oncology Annual Meeting, VIA resulted in a reduction in the age-adjusted mortality rate compared to just education (14.4 versus 20 per 100,000 women-years of observation),

translating into a 30% reduction in the risk of death. Estimates are that this simple procedure would save almost 22,000 women a year in India alone.

PATHOLOGY AND PATHWAYS OF SPREAD

Eighty percent to 90% of cervical cancers are squamous cell lesions. Squamous cell neoplasms are frequently subcategorized as large cell keratinizing, large cell nonkeratinizing, or small cell carcinomas.[29,30] The latter should not be confused with anaplastic small cell carcinomas, which have histologic features that resemble small cell neuroendocrine neoplasms of the lung and tend to have a particularly aggressive clinical course.[31,32]

The frequency of primary cervical adenocarcinoma is about 10% to 20%, but it appears to have been increasing recently, particularly in younger women.[33,34] Cervical adenocarcinomas can originate high in the endocervical canal and can be missed with standard cytologic screening collection methods. The perceived increased frequency of cervical adenocarcinomas may be attributed to a decreased incidence of squamous cell carcinomas in the screened population without a concomitant decreased incidence of cervical adenocarcinomas. Whether conventional screening methods are insensitive to the detection of adenocarcinoma precursor lesions or whether such precursor lesions progress more quickly to invasive disease has not been determined. Nonetheless, women who participate in a cytologic screening program and develop cervical adenocarcinoma are more likely to have early-stage disease than an unscreened cohort. Most cervical adenocarcinomas are mucinous with features suggestive of endocervical glandular epithelium; about 20% demonstrate other müllerian neoplastic patterns. Others may be adenosquamous in type.

The cervix is richly supplied with lymphatics organized into three anastomosing plexuses that drain the mucosal, muscularis, and serosal layers.[35] The most important lymphatic collecting trunks exit laterally from the uterine isthmus in three groups[35,36]: the upper branches originate in the anterior and lateral cervix and follow the uterine artery, the middle branches drain to the deeper hypogastric (obturator) nodes, and the lowest branches drain posteriorly to the inferior and superior gluteal, common iliac, presacral, and subaortic lymph nodes.

The incidences of pelvic lymph node involvement for patients with FIGO stages IB, IIB, and IIIB cervical cancer are approximately 15%, 30%, and 50%, respectively.[37-40] The incidence of paraaortic lymph node metastasis also increases with tumor stage; about 5%, 20%, and 30% of patients with FIGO stages IB, IIB, and IIIB disease, respectively, have paraaortic lymph node metastasis at diagnosis.[37] For each stage, the risk of lymph node involvement is further correlated with tumor size.[41,42]

Hematogenous metastases are rarely detectable at diagnosis, and recurrent pelvic disease is seen in about two thirds of patients who relapse after treatment. Distant metastases are also a common feature of disease relapse. In a study of disease relapse patterns from the Mallinckrodt Institute of Radiology, Fagundes et al[43] reported 10-year actuarial rates for distant metastasis of 16%, 31%, 26%, and 39% for patients treated with radiation for FIGO stages IB, IIA, IIB, and III disease, respectively. These may well be underestimated if pelvic disease is detected as the first site of relapse because systematic radiologic evaluation may not be performed. The most common site of extrapelvic metastasis was the lungs, followed by the paraaortic lymph nodes. Although the lumbar spine has been reported to be a relatively frequent site of skeletal metastasis, studies that include CT scanning suggest that patients who appear to have had metastases isolated to the lumbar spine may actually have had direct tumor extension from paraaortic disease.[44]

Prognostic Factors

With the exception of distant hematogenous metastases, the presence of retroperitoneal nodal involvement represents the most significant negative prognostic factor in patients with cervical cancer.[38,45] The evaluation of other prognostic factors, however, is to a great degree predicated on whether patients have early-stage tumors that are often managed surgically or more locally advanced cancers that have received definitive chemoRT. The availability of a hysterectomy specimen for full pathologic review allows finer assessment of primary associated and extrauterine risk factors, although these factors may be superseded in larger tumors with obvious extracervical extension.

In a prospective surgicopathologic evaluation of 645 patients with clinical stage IB disease who underwent radical hysterectomy and pelvic lymphadenectomy, independent prognostic factors for disease-free survival included pelvic nodal metastases, clinical tumor size (within stage IB classification), capillary-lymphatic space invasion, and depth of tumor infiltration into the cervical stroma.[38]

In more advanced lesions, a multivariate analysis of 642 patients entered into three Gynecologic Oncology Group (GOG) prospective clinical trials of definitive RT demonstrated that the presence of positive paraaortic nodes was the single most important independent predictor for relapse and survival, overwhelming all other risk factors. The next two most important prognostic factors (pelvic nodal involvement and tumor size) retained significance only in the absence of paraaortic metastases. Other weaker prognostic variables included clinical stage, patient age, and performance status. In this analysis of more advanced tumors, cell type, histologic grade, and pretreatment hematocrit and peritoneal cytologic findings were not significant prognostic factors when the preceding variables were taken into account.[45]

MOLECULAR BIOLOGY

HPV is a small, double-stranded DNA virus that belongs to the papovavirus group. To date, more than 80 different strains of HPV have been isolated using polymerase chain reaction analysis.[42] HPV infection occurs in the basal cell layer of the epithelium, which becomes a continuous reservoir of HPV DNA as the viral genome replicates itself in the dividing cells. As the epithelial cells mature, viral DNA replication continues in the absence of basal cell division, increasing the HPV DNA copy number per cell.[46] Microscopically, this process is associated with koilocytosis, a finding considered pathognomonic of HPV infection.[47]

Of the many strains that have been characterized, HPV-16 and HPV-18 have been most commonly associated with squamous cell carcinoma and adenocarcinoma, respectively.[48,49] HPV 18 has been associated with a worse prognosis than HPV 16.[50] HPV-31, HPV-33, and HPV-35 have also been associated with malignancy, whereas HPV-6 and HPV-11 are usually associated with benign viral condyloma or mild dysplastic epithelial changes such as CIN1.[48,51-56]

HPV carcinogenesis is mediated through oncogenes *E6* and *E7*. Transgenic mouse experiments provide some of the strongest in vivo evidence linking *E6* and *E7* expression to the development of cervical cancer.[57,58] The mechanisms by which HPV influences oncogenic activity are shown in Figure 58-1. The E6 protein of HPV oncogenes binds with the E6-associated

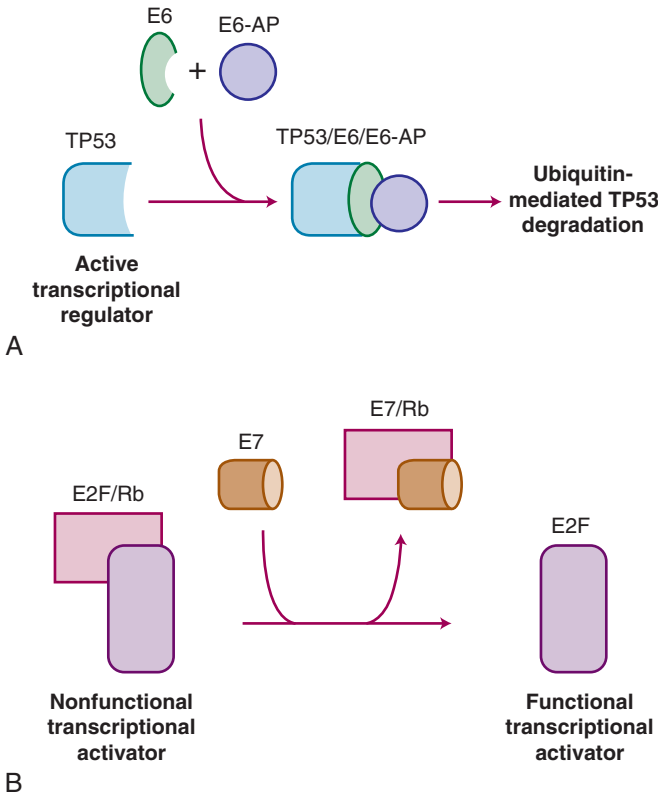

Figure 58-1 Biologic consequences of viral oncoprotein interactions with cellular tumor suppressors. **A,** Schematic representation of mechanism by which the *E6* gene is hypothesized to inactivate the TP53 protein through ubiquitin-mediated degradation of TP53. **B,** Role of *E7* gene in altering activity of the cellular transcription factor E2F via its capacity to bind the RB protein.

protein (E6-AP) to the TP53 protein, which results in the degradation of TP53, an important negative regulator of cell growth. Thus, by binding and degrading the TP53 protein, E6 proteins contribute to the pathogenesis of cancer by removing the critical and protective function of TP53.[59] The E6 proteins of oncogenes from a carcinogenic HPV strain, such as HPV-16 and HPV-18, bind TP53 more efficiently than oncogenes from HPV strains not involved in carcinogenesis, which possibly explains the differences in oncogenicity of these strains.[60] By itself, E6 is not capable of inducing transformation, but it induces immortalization of primary human keratinocytes in conjunction with E7, the protein of which binds to and functionally inactivates the gene product of the retinoblastoma *(RB)* tumor suppressor gene. This binding results in the uncontrolled release of active transcription factors (E2F) and unregulated progression through the cell cycle. Biologic differences between low-risk and high-risk HPV viruses include observations that the latter are capable of inducing chromosome abnormalities in normal keratinocytes and are more likely to interfere with cell cycle regulatory proteins and checkpoints.[61] More recently, several recurrent genomic alterations in cervical carcinomas were identified. Gene expression levels at HPV integration sites were statistically significantly higher in tumors with HPV integration compared with expression of the same genes in tumors without viral integration at the same site.[62]

The evidence implicating HPV in the pathogenesis of cervical cancer is conclusive. It includes (1) multiple epidemiologic studies demonstrating HPV infection as the most important risk factor for the development of squamous cell intraepithelial lesions and cervical carcinomas, (2) detection of HPV DNA in more than 90% of cervical cancers and their precursor lesions, (3) evidence of HPV transcriptional activity in neoplastic tissues, and (4) evidence that HPV oncogenes can mediate malignant transformation in transgenic mice.[57,58] The precise rate of development for both low- and high-grade squamous intraepithelial lesions in women infected with HPV is unknown. Longitudinal studies have demonstrated that the incidence of HPV infections among cytologically normal sexually active young women is high.[63] Most women infected with oncogenic HPV eliminate the infection and are at low or no risk for developing cervical neoplasia. The median duration of most new HPV infections is less than 1 year.[63] More than one third of women remain consistently or intermittently positive for HPV DNA, and many of these women will subsequently test positive for an HPV type that is different from the original HPV type.[64] The transient nature of HPV infections in younger women substantiates the common observation that low-grade cervical neoplasia frequently regresses to normal.[65]

Theoretically, other cofactors may interact with HPV to attenuate the body's immune response, promote persistent HPV infection, up-regulate E6/E7 expression, or enhance the genetic damage caused by HPV oncogene expression. Possible factors include smoking, oral contraceptive use, and infection with HIV.[66] Several case-control studies have linked smoking behavior to an increased risk of cervical neoplasia.[67,68] Carcinogens found in cigarette smoke are concentrated in cervical mucus,[69] and women who smoke have decreased numbers of antigen-presenting cells in cervical epithelium.[70] Thus, smoking may increase the risk for cervical cancer via changes in local immunity. Immunosuppression has long been recognized as a risk factor for the development of cervical carcinoma.[71] A positive link between oral contraceptive use and cervical cancer, however, is still uncertain.[72] Although other cofactors may be involved, the acquisition and persistence of HPV infection are critical to the development of cervical neoplasia.

With this knowledge, specific vaccines have been developed. A quadrivalent HPV (types 6, 11, 16, 18), bivalent HPV (types 16, 18), and 9-valent HPV (addition of types 31, 33, 45, 52, and 58) vaccine have been evaluated in large Phase III trials.[73-76,76a] The two initial trials, FUTURE II and PATRICIA, were designed to demonstrate efficacy in preventing incident HPV infection and high-grade premalignant lesions such as cervical intraepithelial neoplasia (CIN) grade 2 or 3 (CIN2+), or adenocarcinoma in situ (AIS).[74,75] These trials were relatively large (5500-18,500 vaccinees), blinded, randomized, and included women ages 15 years to 26 years.

All three vaccines demonstrate excellent safety and immunogenicity profiles. For these vaccines, in the cohorts with no evidence of baseline cervical cytology abnormalities, infection by any of the HPV types evaluated, or serologic evidence of past exposure to these HPV types, high efficacy against HPV type-related CIN3 was 100%.[74,75] Efficacy was lower (45%) in the analysis of cohorts that included women with prevalent infection at entry. These vaccines demonstrate partial cross-protection against infection caused by some other nonvaccine HPV types. However, the vaccines do not alter the course of established HPV infections.

Although the experience with HPV vaccination is still relatively nascent, ultimate prospects for the primary prevention of cervical neoplasia, particularly in areas of the world where screening is unavailable, are exciting, notwithstanding the currently associated costs of the required comprehensive population strategy.

Currently, the duration of protection has not been established. However, a study has demonstrated persistent serum antibodies for up to 8.4 years for the bivalent vaccine, which leads to an optimistic projection of its effectiveness.[77] The quadrivalent and bivalent vaccines are both approved by the U.S. Food and Drug Administration (FDA) for female and males 9 years to 26 years of age and are commercially available for intramuscular injection (three-dose sequence at 0, 2, and 6 months).

Using mathematical models, Kim and Goldie[78] predicted that the cost-effectiveness of HPV vaccination programs in the United States will ultimately depend on the duration of vaccine immunity and will be optimized by achieving high coverage in adolescent girls, targeting catch-up efforts for women up to 18 years or 21 years of age, and revising screening practices. Unfortunately, research has shown that targeted approaches to HPV vaccination based on specific risk factors are a poor strategy for implementation, and therefore, comprehensive strategies are recommended.[79]

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Preinvasive and minimally invasive cervical cancers are usually detected by routine cytologic screening. Most patients with more advanced disease present with some form of abnormal vaginal bleeding—postcoital, menstrual, intermenstrual, or postmenopausal—that may be associated with a clear or foul-smelling discharge. Extreme pelvic tenderness, particularly if associated with fever, should be fully evaluated to rule out complicating pelvic inflammatory disease. The triad of sciatic pain, leg edema, and hydronephrosis is almost always associated with extension of disease into the pelvic side wall. Bladder and rectal symptoms also suggest locally advanced pelvic disease and the need for specific evaluation of the urinary and gastrointestinal tracts.

Staging and Patient Evaluation

The current clinical staging system for cervical cancer by FIGO was updated in 2009[80,81] and is detailed in Table 58-2. The only changes made from the previous 1994 classification were the elimination of stage 0 (preinvasive disease) and the subdivision of stage IIA into IIA1 (tumor ≤ 4 cm in size) and IIA2 (tumor > 4 cm). The subdivision of stage IIA parallels that of stage IB disease and reflects a partial appreciation of the prognostic impact of tumor size.

According to FIGO, only the results of palpation, inspection, colposcopy, endocervical curettage, hysteroscopy, cystoscopy, proctoscopy, intravenous urography, and plain films of the lungs and skeleton can be used to influence stage assignment. Suspected bladder or rectal involvement should be confirmed by biopsy. Because sophisticated imaging is unavailable for many in developing countries with a high incidence of locally advanced disease, FIGO staging precludes the use of other imaging studies, such as lymphangiography; CT, MRI, or PET scanning; or the findings of operative procedures, including laparoscopy or open lymphadenectomy. These cannot be used to change the stage designation. However, if CT is obtained, the urographic findings may be used to rule out hydronephrosis. The results of these other tests are of prognostic value and often influence treatment decisions, but institutions that publish reports on cervical cancer must adhere strictly to FIGO's rules for staging to enable comparisons using consistent data among studies. Although FIGO continues to depend on a predominantly clinical staging approach, it recognizes other clinicopathologic risk factors, such as lymphovascular space invasion and lymph node status, and advises that these features, although not affecting staging per se, be recorded when available. FIGO also acknowledges the potential benefits of contemporary imaging studies and surgical staging, where available, in helping to guide treatment.[81]

Imaging studies used to assess the extent of lymph node involvement include CT, MRI, lymphangiography, and PET. Historically, lymphangiography has previously been used to assist the design of radiation fields; although it was determined to be a good imaging technique for assessing the status of the paraaortic lymph nodes,[8] it is no longer available in most medical communities.

MRI of the pelvis has been increasingly used to evaluate local tumor extent.[82] MRI provides better definition of the extent of disease within the cervix than CT and may be valuable in detecting extension through the periphery of the cervix; it therefore may be particularly useful in assessing patients with disease confined to the cervix for whom surgery is being considered as primary treatment.[83] MRI may also be useful for detecting extension into the uterine body. Pelvic MRI and CT are both useful for designing radiation portals, particularly in defining the position of the draining lymph nodes and, therefore, the borders of and shielding on conformal radiation fields.[83,84] Sensitivity and specificity show no clear advantage with MRI over CT for detecting involved nodes.

PET scanning has been compared with CT scanning for assessing lymph node status before planned RT. Grigsby et al[85] compared PET with CT in a retrospective study of 101 consecutive patients with newly diagnosed cervical carcinoma. CT demonstrated enlarged pelvic lymph nodes in 20% and aortic lymph nodes in 7% of patients. PET demonstrated abnormal uptake in pelvic lymph nodes in 67% and in aortic lymph nodes in 21% of patients. Surgical staging was not routinely performed to verify the accuracy of imaging findings. A multivariate analysis showed that the detection of positive aortic lymph nodes by PET imaging was the most important prognostic factor for progression-free survival. Yen et al[86] conducted a prospective evaluation of PET versus MRI or CT staging of patients with newly diagnosed (35%) or recurrent (65%) cervical cancer. Verification of lesions identified on imaging was obtained via surgical biopsy or clinical follow-up. Although its diagnostic accuracy was similar for local lesions, PET was superior to both MRI and CT in identifying metastatic lesions. As a follow-up to their previous retrospective study,[87] investigators from the Mallinckrodt Institute of Radiology at Washington University have recently published a large prospective series of 560 patients with cervical cancer who underwent pretreatment imaging with fluorodeoxyglucose (FDG) combined with PET. Overall, 47% of these unselected patients had lymph node involvement on FDG-PET, and the prognosis following therapy was highly correlated with positive lymph nodes as shown on PET, as well as the level of involved nodes.[87] As of January 2005, the Centers for Medicare and Medicaid Services (CMS) has approved the use of PET scanning in the evaluation of newly diagnosed, locally advanced cervical cancer as an adjunct to conventional anatomic imaging. Its utility in staging early disease is limited, particularly because of the relatively low incidence of extrapelvic disease in this setting. A suggested approach in the workup of newly diagnosed cervical cancer is shown in Figure 58-2.

The use of FDG-PET imaging at 3 months after completion of RT for early assessment of treatment efficacy has been correlated with survival and also assists with identification of isolated relapses amenable to aggressive salvage therapy.[88]

Surgical staging of the pelvic and paraaortic lymph nodes has been used to obtain prognostic information, to identify patients who would benefit from extended-field irradiation, and to debulk grossly enlarged lymph nodes. Early reports of high complication rates in patients treated with radiation following transperitoneal lymphadenectomy discouraged the use of this procedure,[89,90] but more recent studies have documented a significantly lower incidence of major complications if the operation is performed using a retroperitoneal approach.[91-93] Laparoscopic biopsy of pelvic and aortic lymph nodes is less invasive, with shorter times to recuperation and less potential for adhesions, thereby decreasing the potential for treatment-related bowel toxicity.[94,95] Using a variety of surgical approaches, Goff et al[96] reported that pretreatment surgical staging resulted in modifications in planned RT in 43% of patients.

In studies that have compared PET or PET-CT imaging to histologic paraaortic nodal status, the false-negative rate ranges from 5% to 17% (overall 12%).[97] Similarly, Gouy et al[98] conducted a prospective multicenter study of 237 patients treated from 2004 to 2011 for locally advanced cervical

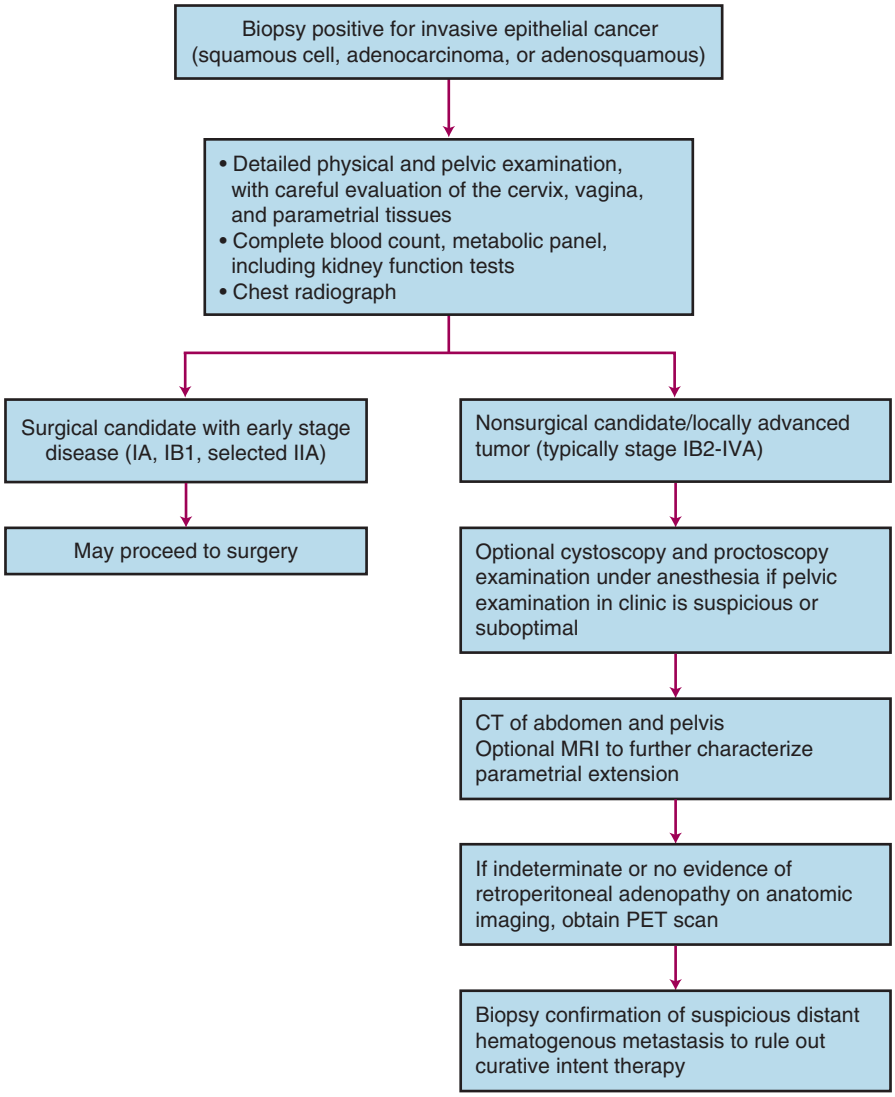

Figure 58-2 Diagnostic algorithm for cervical cancer. *CT,* Computed tomography; *MRI,* magnetic resonance imaging; *PET,* positron emission tomography.

cancer with negative PET imaging of the paraaortic region and undergoing laparoscopic paraaortic lymphadenopathy. Twenty-nine patients (12%) had nodal involvement (false-negative PET-CT result). Thirteen had a nodal metastasis measuring ≤ 5 mm, whereas 16 had a nodal metastasis > 5 mm. Those with paraaortic metastasis ≤ 5 mm and treated with extended-field chemoRT had a similar 3-year event-free survival rate to those without paraaortic lymph node involvement (69% versus 74%), whereas survival of patients with paraaortic nodal involvement > 5 mm remained poor (17%, $p < 0.001$), suggesting a possible impact of surgical staging in a subset of patients.

Overall, the value of pretreatment surgical debulking of tumor-involved lymph nodes is unproven, although the information gained from surgical staging may be valuable in selected patients.[100-102]

PRIMARY THERAPY

Because patients with cervical cancer usually present with disease that is clinically confined to the pelvis, locoregional disease control is the primary treatment challenge. Individualized treatment based on tumor characteristics has produced impressive cure rates in patients with locally confined disease (Table 58-3). Recognizing that most patients with adverse factors, such as pathologic extracervical spread (e.g., positive lymph nodes, parametrial invasion) or multiple adverse primary tumor characteristics identified after surgery, will be offered adjuvant RT or chemoRT, most surgeons now limit radical hysterectomy to premenopausal patients with limited disease, that is, those in whom the expectation is low of finding adverse factors at surgery. In general, patients should be treated with single-modality definitive therapy whether that be surgery, irradiation, or chemoRT, thereby avoiding the potential increased toxicity resulting from the use of multiple modalities.

It should be emphasized that in cervical cancer, progression-free survival (PFS) is closely tracked by OS, reflecting the extremely limited treatment options for women with locally recurrent or metastatic disease. This is unlike the situations with some other malignant tumors, such as prostate and breast cancers or lymphomas, where indolent

Only one randomized trial has been published comparing surgical staging (laparoscopic or extraperitoneal) to clinical staging (CT or MRI) in 61 patients with locally advanced cervical cancer.[99] On interim analysis, patients staged surgically had significantly worse progression-free survival than those without surgical staging, leading to premature trial closure.

TABLE 58-3 Primary Therapy and Survival by Disease Extent*

Stage	Primary Therapy	5-yr Overall Survival
IA1	Cone biopsy; simple hysterectomy; brachytherapy	>98%
IA2	Radical hysterectomy plus pelvic node dissection (PND); irradiation (RT)	≥95%
IB1/limited IIA1	Radical hysterectomy plus PND; RT	~90%
IB2/larger IIA1/IIA2	ChemoRT	80% to 85%
IIB	ChemoRT	70% to 75%
III	ChemoRT	~50%
IVA	ChemoRT; selective exenteration	15% to 25%
IVB, limited†	ChemoRT with dose escalation	5% to 15%
IVB	Chemotherapy; palliative RT	~0%

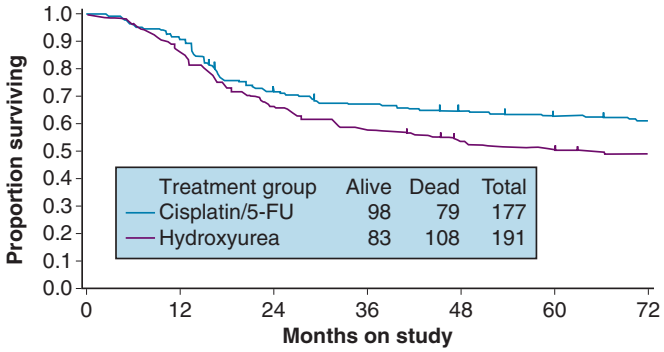
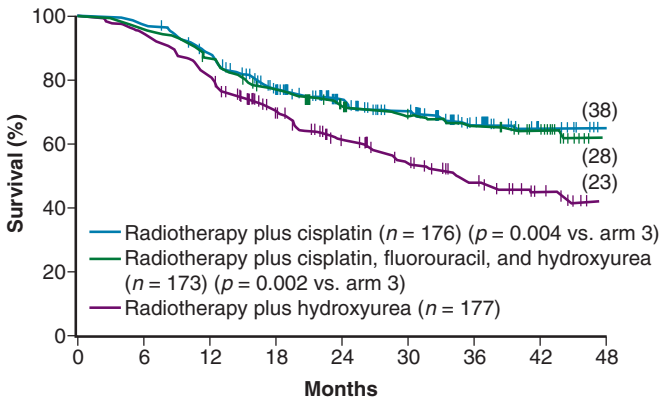
tumor biology or the availability of multiple salvage options can lead to wide variances between the preceding two outcome measures. It also highlights the importance of achieving ultimate tumor control with upfront definitive therapy in cervical cancer.

RT is effective for patients with locoregional confined cervical cancer of any stage, especially if they are not candidates for surgery. Treatment must be carefully tailored to the patient and to the extent of disease, but usually consists of a combination of external beam irradiation (EBRT) with concurrent chemotherapy and brachytherapy. Overall, historically reported 5-year OS of patients treated with *RT* alone are 75% to 85% for FIGO stage IB, 65% to 70% for FIGO stage II, 30% to 40% for FIGO stage III, and 10% to 15% for FIGO stage IVA disease.[103-107] Within stage subsets, cure rates are strongly correlated with the size of the primary tumor and the extent of regional involvement.[42,108]



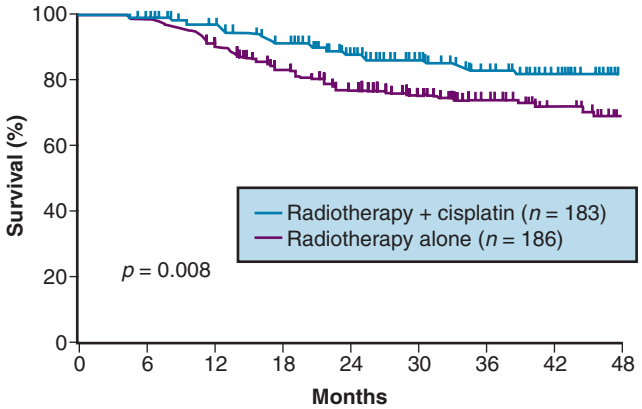
Chemoradiation

For patients with locally advanced disease, chemoRT has been the standard of care since the 1999 publication of a National Cancer Institute (NCI) alert based on the results of five Phase III randomized clinical trials (GOG 85, GOG 120, GOG 123, SWOG 8797/Intergroup 0107 [eFigures 58-1 to 58-4] and RTOG 9001 [Figure 58-3]).[109-113] The five studies had different eligibility criteria, but in total included a broad spectrum of clinical presentations:



1. Locally advanced tumors for whom chemoRT represented primary therapy
2. Bulky early-stage cancers (tumor size ≥ 4 cm) in which chemoRT was delivered before adjuvant hysterectomy
3. Adjuvant therapy following radical hysterectomy in cases with high-risk pathologic factors (positive lymph nodes, positive parametria, positive margins)

Rose and Bundy[114] summated the collective results of the randomized trials (the preceding five and one from the National Cancer Institute of Canada[115] [eFigure 58-5]) and showed a cumulative and statistically significant 36% reduction in the risk of death favoring combined cisplatin-based concurrent chemoRT over RT alone or combined with hydroxyurea[114] (Figure 58-4).



That these clinical trial results can be applied to a general population was confirmed in an analysis in which Pearcey treated patients with cervical cancer between 1992 and 2001[114] and that found a significant improvement in cervical cancer OS, which could not be explained by differences in stage presentation or an imbalance in cases selected for primary surgery. The investigators attribute the survival gains to the generalized and appropriate use of concurrent, predominantly cisplatin-based chemoRT in the majority of patients receiving RT for cervical cancer.[115] Specific details of the seminal

Phase III trials of RT compared with chemoRT are detailed in eTable 58-1.

In North America, where cisplatin-based chemoRT is currently considered the standard of care, there remains ongoing debate as to what specific regimen to use when cisplatin is combined with RT. The Gynecologic Oncology Group (GOG) has selected weekly cisplatin at 40 mg/m^2 (maximum 70-mg weekly dose) for up to six cycles, concurrent with EBRT, as its foundation for chemoRT of cervical cancer. Whether to combine 5-flourouracil (5-FU) with cisplatin remains a topic of discussion as the positive arm of RTOG 90-01 included both concurrent cisplatin and 5-FU, given on a 3-week cycle (cisplatin 75 mg/m^2, 5-FU, 1000 mg/m^2/day for 4 days). However, a subsequent randomized trial of protracted venous infusion fluorouracil with standard weekly cisplatin was closed prematurely because 5-FU/RT had a higher risk of treatment failure (relative risk [RR] 1.29) and a higher mortality rate (RR 1.37), with an increase in distant failure in the 5-FU arm.[116]

The benefit of chemoRT for cervical cancer is one of the single largest contemporary therapeutic gains in the management of patients with cancer. Updates with significantly longer follow-up periods continue to confirm the survival advantage with the administration of cisplatin-based chemoRT.[118-120] They also suggest that for future trials in locally advanced cervical cancer, estimates of PFS and OS with median follow-up intervals of 3 years represent fairly mature results.

Although there is general acknowledgment of the efficacy of cisplatin in combination with RT, various investigators have formally evaluated other non-cisplatin chemoRT regimens, including carboplatin[121] and gemcitabine.[122] A Phase II study demonstrated the feasibility of administering bevacizumab concurrently with cisplatin and pelvic radiation.[123] Current studies are looking at every week versus every 3-week administration of cisplatin.

Role of Systemic Therapy after Definitive Chemoradiation

The risk of distant relapse is as high as, if not higher than, pelvic relapses following chemoRT.[117,118] Adding adjuvant chemotherapy to a "backbone" of concurrent cisplatin and RT may provide a therapeutic benefit, in terms of both distant and locoregional tumor control.[117] In a post hoc subset analysis of Intergroup 0107, Peters et al[112] found that the number of cycles of chemotherapy given with pelvic RT (including up to two cycles following completion of RT) correlated with an improved outcome.

In a prospective randomized trial, Duenas-Gonzalez et al evaluated the administration of chemoRT with cisplatin versus cisplatin plus gemcitabine and additional systemic therapy after chemoRT completed.[124] With a median follow-up of 3 years, women who received cisplatin plus gemcitabine with RT and then as post-RT treatment had a 32% reduction in progression (hazard ratio [HR] 0.68, 95% confidence interval [CI] 0.49 to 0.95) and a higher rate of PFS at 3 years compared to those treated with cisplatin alone (74% versus 65%, respectively). In addition, cisplatin plus gemcitabine resulted in a 32% survival advantage (HR 0.68, 95% CI 0.49 to 0.95). Concerns from other reports indicate that the combination of cisplatin, gemcitabine, and pelvic irradiation may result in high toxicity rates.[125,126] Enthusiasm for added systemic therapy, whether with conventional cytotoxics or new biologic agents, must be tempered by consideration of toxicity and impact on quality of life.

Based on the observations of Intergroup 0107[112] and a meta-analysis[117] that suggested possible therapeutic benefit of extra cycles of chemotherapy given after RT, two international Phase III trials have been activated to evaluate the role of additional chemotherapy (carboplatin and paclitaxel in four cycles) following cisplatin and RT. One trial addresses patients at high risk after hysterectomy who have positive lymph nodes, positive margins, or parametrial extension, whereas the second evaluates outcome in patients with locally advanced intact cervical cancer (stages IB2 to IVA) treated with definitive chemoRT (OUTBACK ANZGOG-led trial).

Radiation Treatment Variables

The delivery of radiation for patients with cervical cancer requires careful consideration and integration of several critical treatment decisions. These include the role of concurrent chemotherapy with RT, the use and timing of brachytherapy in combination with EBRT, the total dose and overall duration of RT, and the volume of elective nodal coverage. These treatment variables should be judiciously balanced against tumor risk factors, overall patient performance status, and the risk of complications.

Brachytherapy Plus External Beam Irradiation

The importance of brachytherapy in the curative treatment of intact cervical cancer is indisputable. Clinicians have sometimes been inclined to deemphasize the use of brachytherapy in patients with FIGO stage III disease, arguing that disease at the pelvic wall is beyond the reach of traditional intracavitary therapy. Reports from the Patterns of Care Study[127] and from the M. D. Anderson Cancer Center (MDACC),[108] however, have demonstrated significantly better survival rates for patients treated with a combination of EBRT and intracavitary irradiation. In the MDACC report of 1007 patients treated with irradiation for FIGO stage IIIB disease, the disease-specific survival (DSS) was 43% for patients who had intracavitary irradiation versus 21% for those treated with EBRT alone. Patients treated during periods when policies emphasized the use of brachytherapy had significantly better survival rates. Patients who received higher doses of EBRT (and concomitantly lower doses of intracavitary irradiation) to the central pelvis had poorer survival rates. The rate of major complications was also correlated with the proportion of central pelvic treatment given with EBRT, and this correlation suggested that the therapeutic ratio narrows when the dose of EBRT given to the whole pelvis exceeds 45 Gy.[108] More recently, a SEER analysis showed a decline in the use of brachytherapy starting in 2003 and continuing over a decade, with a 34% (HR 0.66, 95% CI 0.6 to 0.74) increase in OS in patients that received versus did not receive brachytherapy.[128] A 2005 to 2007 survey through the quality research in radiation oncology (QRRO, formerly Patterns of Care study) showed that although 87.5% of patients had received brachytherapy treatment, the proportion of patients treated without brachytherapy had doubled compared to the 1996 to 1999 survey.[129] A careful balance between EBRT and brachytherapy components of therapy, accounting for tumor volume, anatomic presentation, and disease regression rate, represents the hallmark of appropriate cervical cancer radiotherapy planning.

Radiation Dose and Duration

Historically, a cumulative dose (linear-quadratic dose equivalent [LQED] 2 Gy per fraction or low-dose rate [LDR] equivalent) of 80 Gy to 85 Gy or higher to point A was considered desirable for patients receiving primary RT for locally bulky cervical cancer (stages IB2 to IVA), with a dose of at least 45 Gy via external beam radiation to all volumes at risk for microscopic tumor spread. Over the past decade an increasing number of institutions have transitioned from specifying dose to point A to instead contouring a tumor volume on either CT or MRI.[130] Although these dose guidelines are widely quoted

In another study 234 women were randomly assigned to standard EBRT (50 Gy in 25 fractions) or hyperfractionated RT (52.80 Gy in 33 fractions) with a second randomization to concomitant 5-FU (1 g/m^2 daily for during the first and last 4 days of RT) or no additional chemotherapy. With a median duration of follow-up of 59 months, there were no differences in survival or pelvic control among these arms.[117] Of note, patients in this trial did not receive concomitant cisplatin, and hence, it specifically evaluated 5-FU as a single-agent chemosensitizer for women with cervical cancer.

and used by cooperative groups, the dose prescription should clearly be carefully tailored to tumor- and patient-specific factors. Smaller and earlier tumors (stages IA to IB1) may be treated to somewhat lower overall doses of 75 Gy to 80 Gy. Many centers favor initiating whole-pelvis EBRT to a dose of 40 Gy to 45 Gy before proceeding with brachytherapy. Gross parametrial or pelvic nodal disease can then be boosted with limited and conformal EBRT fields, blocking critical central pelvic structures, to a cumulative dose of 55 Gy to 65 Gy, or even higher (combining EBRT and brachytherapy components), depending on disease volume and the ability to avoid adjacent normal tissues. Other institutions prefer to emphasize and initiate brachytherapy earlier, at whole-pelvis EBRT doses of 20 Gy to 30 Gy, especially for patients with earlier-stage and smaller-volume disease. EBRT is then continued to the pelvis, with or without midline blocking. Although recommendations have been made to try to limit the rectal and sigmoid dose to 2 cc (D2cc) to 70 Gy and 75 Gy, respectively, and to the bladder D2cc to 80 Gy to 100 Gy,[131] it is recognized that the most important consideration is to deliver adequate tumoricidal doses, even if the normal tissue dose recommendations are somewhat exceeded. Use of the International Commission on Radiation Units and Measurements (ICRU) rectal and bladder points for determining maximal doses is a practice continued in institutions that lack access to CT or MR imaging. On the other hand, a total D90 clinical target volume (CTV)[132] or point A dose of 85 Gy to 90 Gy for intact bulky cervical cancer represents a reasonable limit, based on integral doses to surrounding normal pelvic structures. For adjuvant RT following primary surgery, where there is no gross tumor residual, an EBRT dose of 45 Gy to 50 Gy to the pelvis is considered tolerable.

These preceding dose discussions are based on a conventional EBRT fractionation of 1.8-Gy to 2-Gy daily and LDR brachytherapy. The use of altered fractionation or, in particular, high-dose-rate (HDR) brachytherapy necessitates a different system of reference doses and is discussed in greater detail later.

The adverse impact of treatment duration protraction in cervical cancer has been evaluated by several investigators. There is general consensus that prolonging a course of radical RT beyond approximately 7 weeks is associated with a 0.5% to 1% decrease in pelvic control per extra day.[133-138] Although debate remains about whether an increase in treatment duration adversely affects outcome or is simply a reflection of unfavorable tumor or patient characteristics or whether this pertains to patients treated with chemoradiation, there is compelling radiobiologic demonstration of accelerated tumor repopulation that mitigates the efficacy of RT.[139] In contrast, there is no evidence that prolongation of treatment duration results in a reduction of late normal tissue sequelae.[138] Therefore, it is now considered prudent to complete a course of definitive RT for cervical cancer within 7 weeks to 8 weeks by eliminating all elective treatment breaks, delivering EBRT parametrial boosts between, or interdigitated with, brachytherapy insertions, and actively supporting patients through acute toxicities so as to avoid RT interruptions.

Role of Extended-Field Irradiation

The prognosis of patients with cervical carcinoma is inversely related to the extent of regional and nodal involvement. Because hematogenous metastasis is usually a late event in the course of this disease, however, patients with lymph node metastases often can be cured with regional EBRT if pelvic disease can be controlled. Even patients with documented paraaortic lymph node metastases have 5-year OS of 20% to 50%, depending on the extent of pelvic disease.[131-136]

Two groups have explored the use of prophylactic extended-field EBRT in patients who do not have overt paraaortic metastases. A trial from the European Oncology and Radiation Therapy Consortium (EORTC)[140] was conducted before the use of concurrent chemotherapy. Randomized patients had more locally advanced pelvic disease (bulky FIGO stage IIB, FIGO stage III, or biopsy-proved pelvic lymph node metastases). Disease-free survival (DFS) of patients in the two treatment arms was not significantly different at 4 years, although the rate of relapse in the paraaortic lymph nodes was higher in patients who had not received RT to this site. OS was not reported.

The results of RTOG 90-01 clearly indicate that concurrent chemotherapy with pelvic RT leads to significant improvements in OS and DFS over extended-field EBRT without chemotherapy in patients with FIGO stages IIB to IVA disease (plus stages IB-IIA tumors 5 cm or larger or biopsy-proven pelvic nodal metastases).[118] Underlying the question of benefits of prophylactic paraaortic RT is the assumption that the paraaortic nodes may represent isolated occult extrapelvic disease in some patients for whom sterilization by RT would translate to cure (assuming achievable pelvic control and no distant metastases). The results of RTOG 90-01, which showed significant reductions in both pelvic and distant relapse with chemoRT (Table 58-4), suggest that the use of concurrent chemotherapy to some degree addresses subclinical metastases beyond the volume of RT. Unanswered is the question of whether prophylactic extended-field RT in addition to systemic chemotherapy would provide additional therapeutic gain.

Practice patterns vary for patients with negative paraaortic nodes but who are deemed to be at elevated risk for occult disease in this nodal chain. At the University of Washington, prophylactic paraaortic nodal EBRT to 45 Gy in 25 fractions over 5 weeks, concurrent with chemotherapy (to the level of the renal vessels, or at the L1 to L2 vertebral interspace), is often considered for patients with the highest potential risk of subclinical paraaortic disease (i.e., those with common iliac adenopathy on surgical staging or those who have negative paraaortic nodes but extensive pelvic lymphadenopathy by radiologic imaging [recognizing the limitations of even the best imaging modalities to detect microscopic tumor]).

TABLE 58-4 Patterns of Relapse in RTOG 90-01, Comparing Pelvic Irradiation with Concurrent Chemotherapy (CT/RT) versus Extended-Field Radiotherapy without Chemotherapy (EFRT)

Pattern of Relapse	CT/RT	EFRT	Relative Risk*	*p* Value

**A value less than 1 indicates an advantage in favor of CT/RT.*

Whereas the efficacy of such an extended-field prophylaxis approach has not been proven, especially in the era of chemoRT, the use of concurrent cisplatin-based chemotherapy with extended-field RT has been shown to be tolerable in several Phase II trials.[141,142]

Impact of Anemia and Tumor Hypoxia on Radiation Therapy Outcome

The adverse association of anemia on outcome following primary RT for cervical cancer has been well documented in many previous clinical reviews.[140,143,144] Whether this association reflects cause and effect or whether anemia is simply a surrogate for worse prognostic and predictive variables, such as larger and more radiation-refractory tumors, is still being debated. Potential mechanisms for a negative impact of anemia on cervical cancer RT outcomes may be linked to tumor hypoxia and consequent radioresistance, as well as induction of angiogenesis, increased tumor aggressiveness, and enhanced metastatic potential.

Some retrospective reports have suggested that anemia is an independent negative prognostic factor, with the average hemoglobin level during RT being more predictive than the level before therapy.[145,146] Only one small prospective randomized trial directly addressing the value of transfusion has been completed, and that was in the 1970s. This study indicated improved pelvic control for irradiated patients whose hemoglobin level was corrected by transfusion, but the analysis was hampered by limited patient numbers and lack of stratification.[147]

In an attempt to provide definitive answers, the GOG conducted a prospective Phase III trial (GOG protocol 191) in which patients with locally advanced cervical cancer undergoing primary chemoRT (concurrent weekly cisplatin at a dose of 40 mg/m^2) were randomized to hemoglobin maintenance at a level of 10 g/dL versus aggressive intervention to raise hemoglobin levels to 12 g/dL to 13 g/dL (by transfusion and erythropoietin). However, concerns about an increased incidence of thromboembolic events and a possible negative impact on survival associated with erythropoietin in several other disease sites, although not statistically significant in this trial, led to its early closure, leaving the impact of maintaining optimal hemoglobin levels on outcome following chemoRT still undetermined.[117] Although erythropoiesis-stimulating agents have been previously used to correct anemia and may be considered in highly selected cases, their generalized use is currently discouraged because of concerns of thromboembolism and possible tumor progression.[148]

As standard of practice, radiation oncologists attempt to maintain patient hemoglobin levels at generally 10 g/dL during treatment for cervical cancer. Although the impact of maintaining this hemoglobin level on tumor control is unclear (recognizing that the studies discussed previously had noted optimal outcome at hemoglobin levels of 12 g/dL), it is recognized that lower hemoglobin levels adversely affect patient quality of life and may affect the ability to tolerate aggressive chemoRT. Besides the use of transfusion, every effort should be made to minimize cervical trauma and blood loss during a patient's evaluation and treatment. Local hemostatic agents (Monsel's solution) and vaginal packing should minimize blood loss after necessary biopsies and examinations. When local hemostatic measures fail to control bleeding, radiotherapeutic hemostasis may be achieved with prompt initiation of EBRT, possibly using 2 or 3 days of hyperfractionated pelvic RT. In patients with curable cancers, use of a hyperfractionated EBRT approach (e.g., 1.5 Gy to 1.8 Gy per fraction twice daily for 2 to 3 days) achieves the same likelihood of hemostasis as larger daily fractions while preserving normal tissue tolerance and ultimate treatment planning flexibility. Although some authors have recommended emergency intracavitary therapy to control bleeding, this approach may likely compromise subsequent curative treatment or be infeasible.

Tumor hypoxia, as measured by oxygen electrodes, has been identified in many cervical cancers and is a predictor of poor outcome.[149] Although there may be a link, the relationship between host status (anemia and hemoglobin level) and tumor milieu (hypoxia) remains ambiguous. To exploit hypoxia as a potential therapeutic target, the GOG opened a randomized Phase III trial (GOG 219) that investigated the efficacy of a new-generation bioreductive drug, tirapazamine, added to the present standard of concurrent cisplatin and RT for locally advanced cervical cancer. In addition to its radiosensitizing effects, tirapazamine had generated significant interest because it is itself a potent and selective hypoxic cell cytotoxin and is also potentially synergistic with cisplatin.[150,151] However, the lack of expected benefit for the combination of tirapazamine, cisplatin, and RT in a large Phase III trial of head and neck cancers,[152] and subsequent loss of sponsorship support, led to premature closure of GOG 219.

The issue of anemia and hypoxia as prognostic factors, and therapeutic targets, in cervical cancer remains unresolved. Future trials in this arena will require safer and more tolerable pharmacologic agents and should be limited only to patients in whom radiobiologically significant anemia or hypoxia can be accurately and reliably measured.

Recent studies have identified significant modulations of gene expression in hypoxic tumors that may be associated with tumor aggressiveness and progression, including hypoxia-inducible factor 1, TP53, vascular endothelial growth factor (VEGF), platelet-derived endothelial cell growth factor, nitric oxide synthase, and matrix metalloproteinases.[153] These biomolecular markers provide potential new targets for future therapeutic investigations.

Smoking and Cigarette Cessation during Radiotherapy

Smoking is a known risk factor for the development of cervical cancer. Several retrospective series have shown conflicting correlations between smoking and cervical cancer prognosis. A recent prospective, multicenter analysis, however, strongly suggested that smoking during chemoRT was associated with poorer outcomes compared with those in patients who had never smoked or who had quit smoking before treatment. An added strength of this study was the use of urine cotinine levels to confirm patient-reported smoking status.[154] In another large retrospective review, smoking has also been associated with an increased risk of late complications following pelvic RT for cervical cancer.[155] Although the mechanisms underlying smoking and treatment outcome and toxicity remain to be elucidated, and even though it is not a specific cancer treatment variable, it seems intuitive that concerted efforts to assist patients in smoking cessation during cervical cancer therapy would be reasonable and may contribute to better outcomes.

The Role of Neoadjuvant Chemotherapy

Although concurrent cisplatin-based chemoRT has become the widely accepted standard of care, caution is raised regarding the use of strategies employing neoadjuvant chemotherapy before RT or surgery.[156] Multiple randomized trials, most with small patient numbers, have not identified an optimal strategy of neoadjuvant chemotherapy followed by definitive RT or surgery. A systematic review and individual patient data meta-analysis showed no benefit and, indeed, an overall trend to detriment, for patients receiving neoadjuvant chemotherapy (predominantly cisplatin-based) before definitive local treatment.[157] In two of the randomized trials, it was reported that the neoadjuvant chemotherapy approach, although

associated with a reasonable initial response, ultimately resulted in statistically significant inferior pelvic control and OS compared with definitive RT alone.[158,159] A plausible explanation for the lack of benefit seen with chemotherapy preceding RT is that although responses can be seen with systemic cytotoxics alone, the remaining clonogens undergo accelerated repopulation, thereby offsetting the efficacy of RT.[139]

At this time, there is no consistent benefit with neoadjuvant chemotherapy, in either survival or reduction of radiotherapy use, to justify its use for these reasons. The use of neoadjuvant chemotherapy strategies should be considered only in the context of carefully designed clinical trials. Unless more effective cytotoxic agents are identified, there is no current reason to consider neoadjuvant chemotherapy followed by definitive surgery, RT, or chemoRT in patients with localized, curable cervical cancer.

Primary Therapy by Disease Stage

Preinvasive Disease

Preinvasive lesions are usually treated with local ablative procedures (cryosurgery or laser ablation) or excisional procedures (loop excision or cervical conization). Hysterectomy is an appropriate treatment option for women with high-grade cervical dysplasia who no longer desire fertility preservation. Ablative treatment is contraindicated if the entire transformation zone has not been well visualized, if there is a marked discrepancy between Pap smear results and colposcopy findings, or if colposcopy evaluation with biopsies leaves unresolved the presence of invasive disease. In these situations, conization should be performed to exclude the presence of invasion. In particular, given the associated challenges in pathologic assessment, patients with AIS on cervical biopsy should always undergo conization to assess the presence of invasive adenocarcinoma.

Microinvasive Disease (FIGO Stage IA Disease)

Early microinvasive (FIGO stage IA1) disease is conventionally treated with nonradical abdominal or vaginal hysterectomy after the depth of invasion has been confirmed by cone biopsy. However, for selected patients who wish to maintain fertility and who agree to close follow-up, therapeutic conization of the cervix may be adequate treatment.

Approximately 10% to 15% of cervical cancers will occur in women during the reproductive years, and some of these patients are hesitant to undergo radical pelvic surgery or RT with resulting permanent loss of fertility. A number of investigators have subsequently reported their experiences with fertility-preserving surgery for early-stage (predominantly IA2 but also including women with IB tumors no larger than 2 cm) cervical cancer using both vaginal and abdominal approaches.[166-170] The rate of cancer relapse following these fertility-sparing procedures appeared to be comparable to that of women undergoing radical hysterectomy. Although the rate of relapse following vaginal trachelectomy has historically been higher for larger tumors (>2 cm), recent advances, including the adoption of abdominal trachelectomy techniques, as well as possible neoadjuvant chemotherapy in larger-sized lesions, may broaden the feasibility of fertility-sparing options for more patients (see subsequent section).[171]

For women with medical contraindications to surgery, brachytherapy can be an effective treatment with 10-year PFS of 98% to 100% reported. Treatment usually consists of one or more intracavitary insertions that deliver a total of 65 Gy to 75 Gy to point A in LDR equivalents, with a maximal vaginal surface dose of 100 Gy to 120 Gy, depending on the extent of microinvasive disease, size of the cervix, and normal tissue anatomy.[172-174]

Although the risk of regional lymph node spread from FIGO stage IA2 carcinomas is less than 5%, early reports of conservative surgery for IA2 cervical cancer yielded suboptimal cancer control results.[175] Most patients with stage IA2 cervical cancer have, therefore, traditionally undergone radical hysterectomy with node dissection.

More recent analyses, with contemporary emphasis on quality of life, have led to a reappraisal of the surgical extent required for these early-stage tumors. Based on a low risk of parametrial involvement in prior radical hysterectomy series for patients with small tumors and good prognostic factors, in the future, such patients may be good candidates for nonradical surgery.[176-179]

As with stage IA1 disease, the use of irradiation for stage IA2 cancer is usually reserved for those who refuse, or have medical contraindications to, primary surgery. Brachytherapy alone may be used, with doses to point A of 70 Gy to 80 Gy (LDR equivalents). For patients with lymphovascular space invasion on the cone specimen, a combination of EBRT and intracavitary irradiation may be used, in which 40 Gy to 45 Gy of pelvic EBRT (often with midline blocking) is combined with intracavitary brachytherapy to deliver a cumulative point A dose of 70 Gy to 80 Gy. The 5-year cancer-specific survival rate with either surgical or radiation treatment is at least 95%.

Recognizing the outstanding cure rates with RT alone in stage IA cervical cancer, combined with the fact that irradiation is typically used in lieu of primary surgery in such patients with early-stage disease who have significant medical comorbidities, the use of concurrent chemoRT for these cases is not routinely justifiable. Furthermore, clinical trials to evaluate the role of chemoRT in this population of patients, who have an excellent cancer control rate, would not be statistically feasible.

Previous reports of "microinvasive" cervical cancer have focused on squamous cell tumors; however, accumulating evidence suggests that early-stage adenocarcinoma of the cervix have similar oncologic outcome to early stage squamous cell carcinoma. Smith et al[180] identified 560 cases of early cervical adenocarcinoma (200 with stage IA1, 286 with stage IA2, and 74 with "localized" disease) in the Surveillance, Epidemiology, and End Results (SEER) registry. Simple hysterectomy was performed in 272 (49%) and radical hysterectomy in 210 (38%). Combining their data with all other published series of early cervical adenocarcinomas, they identified 1170 cases, including 585 stage IA1, 358 stage IA2, and 227 "others" with less defined early disease. Among 531 patients who underwent lymph node biopsy, 15 (1.3%) had one or more positive nodes; of these 15 patients, 11 (73%) later relapsed or died. For IA1 versus IA2 disease, there were no significant differences in the frequency of positive lymph nodes, relapse, or death. However, the cases that were considered "others" based on less well-defined tumor dimensions, as well as those with lesions larger than IA2, were at increased risk of relapse.[180] The authors concluded that well-defined early invasive adenocarcinoma (stages IA1 and IA2) has an excellent prognosis, and conservative surgery may be appropriate.[181] Reynolds et al performed a meta-analysis including 25 published reports and 735 cases of microinvasive adenocarcinoma.[182] There were 367 cases that met criteria for FIGO stage IA (217 stage IA1, 47 stage IA2, and 103 stage IA not further stratified). There were 294 cases with information regarding the type of surgery, and of these, 193 had radical surgery. There were no reported cases of parametrial involvement. Of the 210 patients who underwent lymphadenectomy, 2 demonstrated lymph node metastasis.[182] These retrospective data suggest that the management of patients with stage IA1 and stage IA2 cervical

The efficacy of neoadjuvant chemotherapy prior to surgery has also been investigated. This strategy may reduce the tumor bulk and increase the possibility of negative resection margins. Evidence demonstrates that those who have response to neoadjuvant chemotherapy can have a reduction in tumor size, and reduction of other poor prognostic factors, such as lymphovascular space invasion (LVSI), parametrial invasion, and lymph node metastases.[106-163] Although response rates have been observed with neoadjuvant chemotherapy, recent meta-analyses of the published literature have not demonstrated a survival advantage.[164,165] The major concern with the neoadjuvant approach is that a delay in therapy for those that are not sensitive to chemotherapy, and the impact of chemotherapy in terms of increasing toxicity, may prohibit patients from receiving curative chemoRT. In addition, the likelihood of some patients requiring postoperative chemoRT is high, resulting in unnecessary increased toxicity.

Several retrospective studies have reviewed large cohorts of patients with early cervical cancers who underwent radical hysterectomies to determine the risk of parametrial involvement.[176] Covens et al[177] identified 536 patients who were defined as low risk, including patients with tumor size ≤ 2 cm, negative pelvic nodes, and depth of tumor invasion ≤ 10 mm. The incidence of parametrial involvement in this group of patients was 0.6%.[177] Similar findings have been described by Kodama et al,[178] where among 200 patients with radical hysterectomy for stage IB1 cervical cancer, the patients with a depth of invasion ≤ 10 mm and no LVSI had a 1.1% rate of parametrial involvement, and by Gemer et al,[178] where among 530 patients with radical hysterectomy specimens, those with tumor size ≤ 2 cm, no LVSI, and negative pelvic nodes had a rate of parametrial involvement of 0%. These findings illustrate that patients with these criteria could be candidates for nonradical surgery without removal of the parametria.

Several studies have also reported good oncologic outcomes for patients with early-stage cervical cancer treated with simple hysterectomy. Landoni et al[179] conducted a prospective study where 125 patients with stages IB1 and IIA cervical cancer ≤ 4 cm in size were randomized between simple hysterectomy ($n = 62$) and type III radical hysterectomy ($n = 63$). Adjuvant RT was given to patients with paracervical involvement, positive or close (<3 mm) resection margins, LVSI close to resection margins and positive lymph nodes. Sixty-nine percent of the simple hysterectomy arm received radiotherapy compared to 55% in the radical hysterectomy arm ($p = 0.11$). Pelvic recurrences were equal in both groups. After a minimum follow-up of 280 months (>20 years), 5-year OS was 85% for simple hysterectomy group versus 95% in the radical hysterectomy group ($p = 0.11$). There was no statistically significant difference in survival for patients with tumors measuring ≤ 3 cm (15-year OS 76% versus 80%, $p = 0.88$). This trial suggests that nonradical surgery may be appropriate for patients with small tumors and good prognostic factors.

adenocarcinomas need not differ from their counterparts with squamous cell lesions.

Overall, the management of early-stage cervical cancer continues to evolve. Nonradical surgery may be appropriate for women with small tumors and good prognostic factors and can subsequently reduce the morbidity associated with radical surgery. Ongoing prospective studies may help guide management for early stage cervical cancer in the future.

FIGO Stages IB and IIA Disease

Primary surgical management is probably best suited for physiologically fit patients with small FIGO stage IA or IB1 cervical cancers without clinical evidence of regional metastasis, parametrial or vaginal spread. Depending on the size of the cervical tumor, surgeons may vary somewhat in the extent of resection of the paracervical tissues and uterosacral ligaments (Figure 58-5). The risk of major complications, particularly bladder and rectal dysfunction or ureteral injury, is proportional to the extent of surgical resection and may therefore be greater when radical hysterectomy is used to treat larger tumors. The ovaries of premenopausal women are usually not removed, which provides an advantage for radical surgery over irradiation in young women with relatively small tumors. Massive obesity and other medical problems that increase the risk of a major pelvic surgical procedure are usually considered relative contraindications to a primary surgical approach.

Reported results of treatment with radical hysterectomy versus those of RT for FIGO stage IB cervical carcinomas are comparable, with 80% to 90% of patients surviving after 5 years; however, complications are much higher in patients treated with a radical hysterectomy that require postoperative radiation because of intermediate- or high-risk prognostic features.[183] Surgeons tend to select young patients who have relatively small tumors for surgical treatment and to refer patients who have large tumors or evidence of regional spread for RT.

For patients with FIGO stages IB and IIA disease, treatment results are strongly correlated with tumor size, and this factor thus influences the appropriate selection of primary therapy. Most FIGO stage IB1 tumors can be treated effectively with radical hysterectomy or combined EBRT and intracavitary irradiation; both have cure rates of 85% to 90%.[184]

In a report of the only randomized trial comparing radical surgery (with or without postoperative RT) with RT alone, Landoni et al[183] reported 5-year OS of 87% for patients with FIGO stages IB to IIA tumors of 4 cm or less in diameter treated with primary surgery compared with 90% for patients treated with definitive RT. Morbidity was somewhat greater in patients initially treated with surgery because many also received postoperative pelvic RT per the protocol for parametrial or lymph node involvement, positive tumor margins, or deep invasion into the stroma. In the same study, 5-year OS of patients with bulky FIGO stages IB2 and IIA tumors larger than 4 cm was similar for both treatments (70% for patients treated with surgery and 72% for patients treated with RT). However, 84% of patients with the larger lesions had the aforementioned high-risk features and received postoperative pelvic RT. As a result, morbidity was again greater in patients who had undergone surgery upfront, as compared with those who had received definitive RT alone.[183] The equivalent survival results were obtained even though the combined dose of EBRT and LDR intracavitary irradiation used to treat patients in this study (median cumulative dose to point A was 76 Gy) was lower than that recommended as standard dose levels internationally.[185]

Although some authors recommend radical surgical treatment for patients with FIGO stage IB2 cervical carcinomas

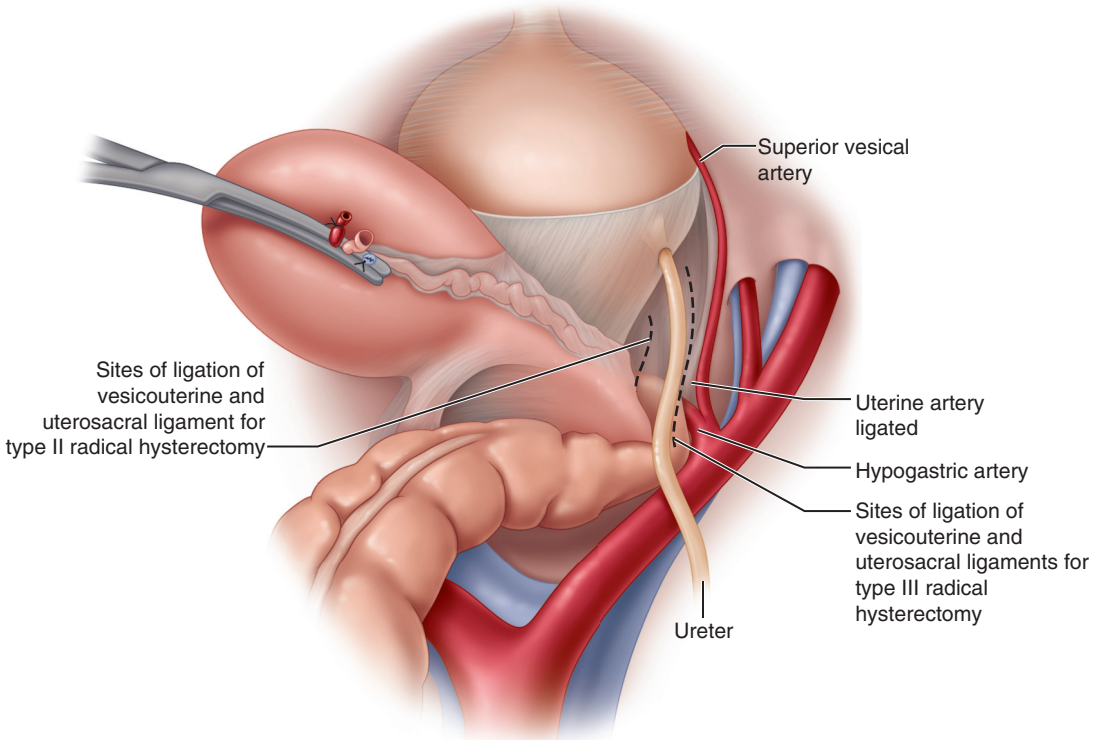

Figure 58-5 Sites of ligation of the vesicouterine and uterosacral ligaments for a type II or type III radical hysterectomy.

regardless of size, the risk of complications after postoperative pelvic radiation and the risk of pelvic recurrence are high for most of these patients. To avoid exposing these patients to the combined risks of a radical hysterectomy and RT, concurrent chemoRT without surgery is often preferred as the primary treatment. For the same reason, other findings that have been associated with an increased risk of pelvic lymph node metastasis and pelvic recurrence (extensive lymphovascular space invasion, deep stromal penetration) are considered by some clinicians to be contraindications to surgery as primary disease management. Unfortunately, the presence or absence of these factors cannot be reliably determined with conventional clinical staging. A recent cohort analysis suggested that elevated preoperative squamous cell carcinoma antigen levels predicted an increased likelihood of postoperative RT and cancer relapse.[186] Although intriguing, these observations should be validated with further studies.

In patients selected for primary RT for stages IB to IIA tumors, the use of concurrent chemotherapy should be based on tumor size or the presence of pelvic lymphadenopathy. In small-volume disease (IB1) with no clinical evidence of pelvic nodal disease, RT alone provides excellent tumor control and cure rates. Similar to patients with stage IA tumors, many of these cases are referred for irradiation based on medical conditions that render primary surgery less desirable. However, with increased tumor size (i.e., stage IB2 disease) or the presence of pelvic nodal metastases, present evidence indicates the benefit of concurrent cisplatin-based chemoRT.

Minimally Invasive Surgery

Several surgical innovators have applied their laparoscopic or vaginal surgical skills to the treatment of cervical cancer as an alternative to the abdominal operation.[187-192] In a prospective study of various approaches to pelvic lymphadenectomy for surgical staging, consecutive patients scheduled for radical surgery were randomly assigned to transperitoneal, extraperitoneal, or laparoscopic pelvic lymphadenectomy. Extraperitoneal and laparoscopic approaches were feasible and as effective as transperitoneal lymphadenectomy. Although laparoscopic pelvic lymphadenectomy showed a significantly longer operative time, both extraperitoneal and laparoscopic approaches minimized some postoperative complications and reduced the length of stay compared with transperitoneal surgery.[187]

For early cervical cancers, there are numerous retrospective studies describing laparoscopic-assisted radical vaginal hysterectomies (LARVH)[188] and total laparoscopic radical hysterectomies (TLRH).[189] In general, laparoscopic surgery has several advantages over abdominal surgery, including shorter hospitalization time, less blood loss, faster overall recovery time, and better cosmetic results. Despite the benefits of laparoscopic surgery, the uptake of this surgical technique has been slow, likely reflective of the long learning curve, two-dimensional views with reduced depth perception, and rigid instrumentation.

The advent of robotic technology has added another dimension to minimally invasive laparoscopic surgery. Robotic-assisted surgery has rapidly been adopted within a relatively short period of time.[193] Advantages include improved dexterity with increased range of motion, three-dimensional (3D) views, tremor reduction, and more ergonomic positioning for the surgeon. Some surgeons without previous experience in laparoscopy are able to perform robotic-assisted surgery with shorter learning curves.[194] However, the increased cost of this surgical technique can be prohibitive for some institutions. After many case series documenting the feasibility and clinical efficacy of robotic surgery, comparative studies are now emerging, and a Phase III trial has been initiated.[193-201]

Sentinel Lymph Nodes Assessment

In early-stage cervical cancer, the incidence of pelvic lymph node metastasis is approximately 15%.[38] Therefore, more than 80% of patients do not benefit from a full pelvic lymphadenectomy, but may suffer from the associated morbidity of the procedure, such as blood loss, neural injury, lymphocyst formation, and lymphedema. The sentinel lymph node is the first lymph node to receive lymphatic drainage from a particular anatomic location, and the first node where metastatic disease will spread from a primary tumor. Conceptually, if the sentinel node is negative, then the other lymph nodes in the regional basin are also negative, and a full lymphadenectomy can be avoided.

Many single-institution series have been published in the literature, demonstrating their experience and feasibility of the sentinel node procedure in cervical cancer. A systematic review included 23 studies comprising a total of 842 patients.[202]

Prospective multicenter studies are needed to confirm the safety of omitting the full lymphadenectomy in patients with negative sentinel lymph nodes. Over time and with increased experience, it is anticipated that sentinel lymph node mapping will eventually become a standard part of surgical management of early-stage cervical cancer.[206]

Fertility-Preserving Surgery

Dargent et al reported their pioneering experience with laparoscopic pelvic lymph node dissection and radical vaginal trachelectomy for patients with highly selected, nonbulky stages I and IIA disease. The cervix, parametria, and upper vaginal cuff were removed, preserving the uterine corpus and adnexae, and an isthmic cerclage was placed around the lower uterine segment that is sutured to the vaginal cuff.[207]

A number of investigators have subsequently reported their experiences with fertility-preserving surgery for early-stage (predominantly IA2 and IB tumors no larger than 2 cm) cervical cancer using both vaginal and abdominal approaches.[166-168,208-210] In patients with these early-stage tumors, studies suggest that radical trachelectomies have similar oncologic outcomes compared to radical hysterectomies.

Radical abdominal trachelectomy has also been reported in the literature as a fertility-sparing option.[211] The oncologic outcome of radical abdominal trachelectomy is reasonable with a relapse rate of 4.8%.[211] The rate of relapse following radical trachelectomy, however, has historically been higher for larger tumors (>2 cm). In reports that have subdivided tumors into two groups, either smaller than 2 cm or larger than 2 cm, relapse occurred in 1.9% of patients with tumors less than 2 cm versus 20% in those larger than 2 cm.[211] Patients who desire fertility preservation should, therefore, be carefully selected and adequately counseled with regard to the risks.

Adjuvant Postoperative Irradiation

Postoperative irradiation is most commonly recommended in two clinical situations: (1) when pathologic findings in specimens resected during radical hysterectomy suggest a significant risk of pelvic disease recurrence without adjuvant treatment, and (2) when findings in specimens resected during simple hysterectomy show clinically unsuspected invasive cervical cancer.

Most clinicians recommend postoperative pelvic RT when histologic examination of a specimen resected during radical hysterectomy reveals involved positive lymph nodes, parametrial involvement, or positive tumor margins. Historically, the use of adjuvant RT in these patients led to an improvement in pelvic control but without clear evidence of survival benefit.[215,216] However, present evidence, based on a randomized controlled trial, clearly shows an outcome advantage,

Steed et al[191] retrospectively compared 71 patients who underwent LARVH with 205 patients who underwent radical abdominal hysterectomy for stages IA to IB cervical carcinoma. Both groups were similar with respect to age and Quetelet (obesity) index. There were no differences in tumor size, grade, histologic type, depth of invasion, lymph node metastasis, or surgical margins. All laparoscopic procedures were completed successfully, with no conversions to laparotomy. Differences in laparoscopic versus abdominal factors included blood loss (300 mL versus 500 mL; $p < 0.001$), operative time (3.5 hours versus 2.5 hours; $p < 0.001$), and intraoperative complications (13% versus 4%; $p < 0.03$). Intraoperative complications in the LARVH group included cystotomy (7), ureter injury (1), and bowel injury (1). The median time to normal urine residual was 10 days versus 5 days ($p < 0.001$), and the median length of hospital stay was 1 day versus 5 days ($p < 0.001$). Two-year relapse-free survival (RFS) was 94% in both groups. These data showed that LARVH yielded similar efficacy and relapse rates to radical abdominal hysterectomy. The major benefits are less blood loss and a shorter hospital stay. However, laparoscopic-assisted radical vaginal surgery is associated with an increase in intraoperative complications and an increased time to return to normal bladder function.[191]

Similarly, Frumovitz et al[192] retrospectively reviewed 35 patients who underwent total laparoscopic radical hysterectomy compared to 54 patients who underwent abdominal radical hysterectomy between 2004 and 2006. The mean blood loss was significantly lower in the laparoscopic group (319 versus 548 mL; $p = 0.009$), and the median hospital stay was significantly shorter (2.0 versus 5.0 days, $p < 0.001$). However, the mean operative time was significantly longer in the laparoscopic group (344 versus 307 minutes; $p = 0.03$). There was no difference in the amount of parametrial tissue, vaginal cuff, or negative margins obtained. Postoperative infections were much less common after laparoscopic surgery (18% versus 53%; $p = 0.001$).

Boggess et al reported on a cohort of patients treated with robot-assisted radical hysterectomy compared with a historical control group of patients treated with open radical hysterectomy[195]; robotic procedures resulted in less blood loss, a shorter operative time, a higher lymph node yield, and a shorter length of hospital stay.[195] Postoperative complications were lower in the robotic surgery group, but the difference was not statistically significant.

Other similar studies have confirmed these results.[194,196] Although several studies have demonstrated the feasibility of this operative procedure, few have assessed the long-term outcomes. Cantrell et al assessed the survival outcomes for women undergoing robotic radical hysterectomy for cervical cancer compared to a historical cohort of those undergoing open radical hysterectomy.[197] Between 2005 and 2008, there were 63 evaluable patients with robotic radical hysterectomies; 32% of these patients received chemoRT. Median follow-up was 12.2 months. Three-year PFS and OS was 94%, which was not significantly different in the historical cohort of open radical hysterectomies (PFS 89%, $p = 0.27$; OS 93%, $p = 0.47$).[197]

Soliman et al compared the perioperative and pathologic outcomes of 30 open radical abdominal hysterectomies (RAH), 31 laparoscopic radical hysterectomies (LRH), and 34 robotic radical hysterectomies (RRH) performed between 2007 and 2010.[198] There were no differences in age, body mass index, or other baseline characteristics. Pathologic findings were similar among all groups. Operative time was significantly shorter in the RAH group (265 minutes versus 338 minutes for LRH versus 328 minutes for RRH, $p = 0.002$). Estimated blood loss was significantly lower in the LRH group ($p < 0.001$). Median length of stay was shorter in RRH (1 day) compared with LRH or RAH (2 versus 4 days, $p < 0.01$).

In a review by Kruijdenberg et al,[189] 27 studies were included, accounting for 342 RRHs and 914 total LRHs. There was no difference mean operative time, blood loss, and number of lymph nodes retrieved. Both methods resulted in similar adjuvant chemoRT rates and relapse rates. Major postoperative complications were more frequent in robotic surgery patients (9.6%) compared to patients who underwent laparoscopic surgery (5.5%, $p < 0.05$), which could be reflective of the smaller number of robotic cases.

Obermair et al[201] have initiated a Phase III randomized trial comparing LRH or RRH with abdominal radical hysterectomy for the treatment of stage IA1 (with lymphovascular invasion), IA2, and IB1 cervical squamous cell carcinomas and adenocarcinomas. Researchers hope that this study will eliminate the selection bias of retrospective analyses and elucidate the optimal surgical approach for early-stage cervical carcinoma.[201]

For sentinel lymph node assessment, the tumor is injected peripherally with blue dye or technetium-99 (^{99}Tc) radioactive tracer. Intraoperatively, the sentinel node is detected when it is blue, or by high radioactive counts with a gamma probe. The sensitivity of sentinel lymph node mapping in early cervical cancer was 92% (95% CI 84% to 98%) and the detection rate was 97% (95% CI 95% to 98%) when the combined technique of radioactive tracer and blue dye was used. The sensitivity is improved when restricting to tumors measuring ≤ 20 mm, compared to larger tumors.[203] Benefits of sentinel node mapping include minimizing morbidity by avoiding a full lymphadenectomy, identifying aberrant pathways of drainage, which could ultimately alter treatment decisions, and detection of micrometastases by ultrastaging that may not be identified by standard hematoxylin and eosin staining.[204] In up to 80% of cases the sentinel lymph node is the only node harboring metastatic disease.[205]

If lymphatic metastases are not identified and left untreated, this places the patient at increased risk of relapse and possible death. False-negative rates can be minimized if there is adherence to specific criteria and quality assurance of the sentinel node procedure. The procedure should be restricted to patients with early stage disease (FIGO stages IA-IB1) because patients with larger tumors have a higher rate of lymph node replacement by tumor, impairing lymphatic drainage. Any enlarged lymph nodes should be removed, even if they are not the sentinel node. Each hemipelvis should be assessed even if the sentinel node is detected unilaterally. Additionally, a collaborative effort of the gynecologic oncologist, gynecologic pathologist, and nuclear medicine expert is important to gain experience with sentinel lymph node mapping and improve the quality of the procedure.[171]

Beiner et al[170] compared 90 patients who underwent radical vaginal trachelectomy for cervical cancer of 2 cm or less with fertility-sparing intent, to a similar group of patients who were clinicopathologically matched which were treated with radical hysterectomy. Patients were matched for age, tumor size, histology, grade, depth of invasion, LVSI, pelvic node metastases, and adjuvant therapy. There was no statistically significant difference in 5-year RFS or OS between the two groups. Their analysis also indicated that histologically typed adenocarcinoma can be treated safely with radical trachelectomy when patients are appropriately selected (this type was found in 50% of the patients and its frequency is increasing in younger women). Although some have reported an increased relapse rate in patients with lymphovascular space invasion, these authors postulate that lymphovascular space invasion alone (found in 68% of their cases), without other adverse pathologic prognostic factors, did not jeopardize the outcome in patients undergoing fertility-sparing surgery.[170]

A retrospective study by Marchiole et al[208] compared 118 patients with radical vaginal trachelectomy to 139 radical vaginal hysterectomies in the same time period. There was no statistically significant difference between the two groups with respect to 5-year RFS or OS.

With regard to obstetrical outcomes, more than 250 pregnancies have been reported following radical vaginal trachelectomy.[171,209] In reports that include information on the number of women attempting pregnancy, pregnancy rates of 41% to 79% were achieved.[209,210] Overall, approximately 40% of all pregnancies resulted in a term delivery (>37 weeks).[209,210] Preterm birth rates range from 20% to 30%.[209,210]

Neoadjuvant chemotherapy has been used in small limited series to reduce tumor size prior to fertility-sparing surgery. Pelvic lymphadenopathy should be performed.[212] Robova et al[213] reported on 15 women with tumors larger than 2 cm that have not infiltrated more than two thirds of the stroma. Chemotherapy was followed by simple trachelotomy and pelvic lymphadenopathy. Fertility was preserved in 12 patients. There were three relapses, one resulting in death. Seven pregnancies were achieved, six delivered at time of reporting, two of which were premature deliveries.[213] In another study, treatment consisted of laparoscopic pelvic and paraaortic lymphadenectomy, and when no nodal metastasis was detected, neoadjuvant chemotherapy followed by radical vaginal trachelectomy.[214] In a cohort of 18 women eligible for the study, 12 (67%) were diagnosed with metastasis after laparoscopic lymphadenectomy, and therefore underwent primary chemoRT. Six underwent neoadjuvant chemotherapy with cisplatin, paclitaxel, and ifosfamide. Three patients had a complete response, whereas only three had more than 50% size reduction. After a mean follow-up of 30.6 months, there were no relapses. The assessment of lymph nodes, which may include PET imaging before initiating neoadjuvant chemotherapy, may be warranted in this early stage IA or IB1 population to guide management.[214] Further investigation with careful selection and follow-up of a larger number of patients to validate this conservative approach is needed.

including an OS benefit, for combined chemoRT in such patients, who may be collectively defined as having pathologic evidence of extracervical disease following radical hysterectomy for clinical early-stage disease.[112] In the absence of any gross tumor residual, a dose of 50 Gy to the whole pelvis is typically prescribed as adjuvant treatment. Although some clinicians also add a vaginal brachytherapy boost, the added therapeutic benefit of this is unclear, and it should be remembered that the results from the aforementioned trial were achieved without the use of intravaginal brachytherapy. Tumor features associated with a high risk of local recurrence, especially nodal metastases, also tend to be predictors of distant metastasis, decreasing the benefit of improved local control on survival rates. In addition, a number of factors may reduce the efficacy of postoperative RT.[217] Higher doses of irradiation may be required to sterilize microscopic disease in a disturbed operative site. Furthermore, clinicians' fears of causing major complications in patients who have had an extensive transperitoneal pelvic surgical procedure often limit the irradiation dose that can be administered safely.[218-221]

More controversial indications for adjuvant postoperative RT may include findings of a single microscopically positive node, bulky primary disease, deep stromal penetration, invasion into the lymphovascular space, or high-grade adenocarcinoma. The GOG conducted a trial (GOG 92) of postoperative RT versus observation alone following radical hysterectomy in stage IB cervical cancer with risk factors limited to the primary tumor (without extracervical spread or nodal metastases).[222] Eligible patients were those modeled to have an approximately 3-year risk of relapse of 30% following surgery alone, based on varying combinations of tumor size, lymphovascular space involvement, and depth of cervical stromal invasion. They are sometimes referred to as "intermediate-risk" patients. A total of 277 eligible patients were entered into the study between 1988 and 1995. Patients randomized to postoperative RT (no concurrent chemotherapy) received 50.4 Gy of whole-pelvis RT, without a vaginal brachytherapy boost. There was a statistically significant improvement in RFS at 2 years (88% versus 79%) favoring the RT arm over the observation-only controls. There was also a higher incidence of severe toxicity in the radiation therapy cohort (6%) compared with the surgery only cohort (2.1%). An updated analysis with approximately 10 years of at-risk follow-up confirmed that adjuvant pelvic RT significantly reduced the risk of relapse and prolonged the PFS time in patients with intermediate-risk early-stage cervical cancer. Although there was a trend toward improved OS for adjuvant RT, this did not reach conventional statistical significance ($p = 0.074$), which may have reflected an underpowered trial.[223] An interesting observation from GOG 92 was that postoperative RT seemed particularly beneficial for patients with nonsquamous cell histologic findings (adenocarcinoma, adenosquamous cancer). Although not a primary analysis endpoint of the trial, and not adjusted for by multivariate analysis, the magnitude of the reduction in relapse for nonsquamous cell versus squamous cell histologic types was statistically significant ($p = 0.019$).[223] At present, the use of adjuvant RT following radical hysterectomy for node-negative patients with multiple risk factors confined to the cervix is generally recommended, but its use should be based on careful consideration of patient physiology, surgicopathologic findings, and multidisciplinary consultation between the patient, surgeon, and radiation oncologist.

An NCI consensus conference concluded that "primary therapy should avoid the routine use of both radical surgery and RT."[8] If clinical evaluation reveals risk factors that would require pelvic RT after radical hysterectomy, RT should be considered the primary treatment of choice. Although improvements in imaging technology allow better determination of nodal disease and may eventually permit evaluation of more subtle intratumoral risk features, such as depth of stromal invasion and lymphovascular space involvement, the only tumor parameter that can be routinely evaluated before hysterectomy is tumor size. It is clear that the larger the cervical lesion, the more likely the indications for postoperative RT following radical hysterectomy. For this reason, many clinicians avoid primary surgery in patients with tumor diameters greater than 4 cm (stage IB2) because 50% to 80% of such cases undergo recommended postoperative RT.[183,224,225]

Although it is standard practice to screen women for cervical cancer before a hysterectomy is performed for any reason, unsuspected invasive cancer is occasionally discovered in the resected specimen from a simple hysterectomy performed for benign disease or CIN. If cancer invasion is more than 3 mm or if there is extensive invasion into the lymphovascular space, then there is a significant risk of paracervical or pelvic lymph node involvement, and postoperative pelvic RT or chemoRT for risk factors is indicated. With this treatment, the prognosis is still good, with 5-year OS of approximately 80% if the tumor appears to have been confined to the cervix and if surgical margins are negative.[226]

Patients who have gross residual disease after hysterectomy may still be curable but have 5-year OS of only approximately 30%. Given the presence of gross residual disease after "cut-through" hysterectomy, concurrent chemoRT is indicated.

The use of brachytherapy in addition to EBRT should be individualized. It is reasonable to consider a brachytherapy boost for patients with positive vaginal mucosal margins. For patients with radial or parametrial positive margins, the rapid dose fall-off from intravaginal brachytherapy may not provide sufficient coverage, and a highly conformal EBRT boost of additional 10 Gy to 15 Gy may be considered following whole-pelvis RT to 45 Gy to 50 Gy. This conformal EBRT boost will include the vaginal cuff and parametria and must extend to the pelvic sidewalls to adequately cover the margin given the retraction of the parametrial tissue to the sidewall after a hysterectomy. For patients with gross residual tumor, a boost with interstitial brachytherapy or intraoperative electrons may be needed.

Adjunctive Surgery

In a retrospective study of cases from the University of Texas MDACC, Durrance et al[227] suggested that the rate of central disease recurrence after radiation therapy of bulky (≥6 cm) endocervical cancers may be reduced when irradiation is combined with an extrafascial hysterectomy. Authors of a subsequent report emphasized that acceptable complication rates could be achieved only if the dose of irradiation was reduced and if surgery was limited to a simple (type I) extrafascial hysterectomy performed with careful, sharp dissection.[228] After these reports, the use of combined treatment increased, and some clinicians began arbitrarily extending the use of adjunctive hysterectomy to treat patients with smaller endocervical tumors (<6 cm in diameter) and tumors with an exophytic morphology.

In 1992, Thoms et al[229] reexamined the experience of the MDACC and concluded that biases that led to the selection of patients with more favorable disease for combined treatment made it impossible to compare meaningfully the relative efficacy of the two approaches. Mendenhall et al[230] compared the outcome of patients treated before or after treatment policy changed at the University of Florida to include planned adjuvant hysterectomy. No difference in outcome was seen between patients treated before or after the change in policy.

The GOG conducted a Phase III trial (GOG 71) in patients with stage IB2 cervical cancer randomized to receive RT alone versus RT followed by extrafascial hysterectomy (this trial did not use concurrent chemotherapy). Although adjuvant hysterectomy following primary RT appeared to modestly reduce the rate of local recurrence, there was no improvement in OS.[231]

More recently, in the era of image-planned brachytherapy, equivalent outcomes with less toxicity (3% versus 15%) were seen after brachytherapy rather than adjuvant hysterectomy.[232] There are no clear data to support the routine role of adjuvant hysterectomy after primary RT for bulky tumors confined to the cervix, particularly after optimal doses of irradiation have been delivered. In a large retrospective analysis of almost 3000 patients with stages I to II squamous cell cervical cancer treated with definitive RT, Eifel et al[233] reported low central disease (cervix, upper vaginal, proximal paracervical tissues) recurrence rates of 6.8%, 7.8%, and 9.6% at 5, 10, and 20 years, respectively. This indicated that few patients might benefit from adjuvant hysterectomy following adequate RT.[233] However, surgery may be selectively applied in patients with a poor tumor response to RT, in those whose tumor and pelvic anatomy precluded good brachytherapy geometry, or as salvage treatment for isolated cervical cancer recurrence.

LOCALLY ADVANCED DISEASE AND PALLIATION

The treatment of choice for most patients with locoregionally advanced disease (IB2 to IVA) is definitive RT with concurrent chemotherapy, usually cisplatin-based. RT consists of a combination of EBRT and brachytherapy. Most authorities today consider optimal RT as a cumulative CTV or point A dose of 80 Gy to 90 Gy (in conventional equivalents), with all treatment completed within 8 weeks. Five-year OS of patients treated with chemoRT now approach 70% to 90% for stage IIB disease, 50% to 70% for stage IIIB disease, and perhaps 15% to 25% for stage IVA disease[109-113,118,119] (see Table 58-4). With aggressive treatment, even patients with massive, locoregionally advanced tumors have a realistic chance of being cured.

Treatment of Recurrent Disease

Isolated Locoregional Relapse

Following primary management for cervical cancer, a small percentage of patients will present with isolated locoregional relapse for whom radical therapy may be contemplated, including the options of pelvic exenteration, chemoRT, and intraoperative irradiation (IORT) with electrons or HDR brachytherapy. Patient selection, careful "restaging," and individualization of therapy are essential.[236] The most important determinant of therapy options is the type of prior treatment the patient has received.

Patients who experience local recurrence after initial surgery alone may be candidates for radical RT plus concurrent chemotherapy (as extrapolated from the primary management of locally advanced disease). Customized combinations of EBRT, often using highly conformal techniques including IMRT and intracavitary or interstitial brachytherapy, ideally with imaging to help guide insertion and treatment planning,[237] are used. Salvage RT is particularly effective for small central relapses limited to the vagina or paravaginal tissues, with 5-year OS of 69% reported in one series.[238,239] Novel techniques of placing a hydrogel spacer between the rectum and the cervix or vaginal hold promise to further reduce normal tissue doses.[240]

There are limited reports of radical reirradiation for patients who relapse following prior pelvic RT.[241,242] However, radical surgery forms the primary cornerstone of salvage treatment for isolated pelvic recurrences without pelvic side wall disease in previously irradiated patients. In most cases, the only potentially curative option is pelvic exenteration. For highly selected patients with central recurrence, in whom pelvic exenteration is successfully completed, 5-year OS of approximately 50% may be achieved.[241,243,244]

Proximity or fixation of locally recurrent tumor to the pelvic sidewall is an adverse prognostic finding, leading most investigators to suggest that attempted surgical salvage be abandoned with intraoperatively detected side-wall involvement. However, some patients previously considered incurable with exenteration have survived with the incorporation of preoperative chemoRT (EBRT dose is dependent on the amount of prior RT) followed by maximal resection plus IORT (electrons or HDR brachytherapy) directed to the initially involved pelvic side wall (i.e., to narrow or involved margins of resection).[245,246] (See Chapter 17, Intraoperative Irradiation, for information on techniques for multiple disease sites, including the cervix, and their results.)

Advanced Disease and Palliation

The prognosis is extremely poor and survival times are short for patients with recurrent or metastatic cervical cancer that is not amenable to surgery or irradiation with curative intent. Systemic chemotherapy is a therapeutic option often used, although no trials to date have compared chemotherapy with the best supportive care for palliation.

Chemotherapy

For women who relapse, combination cisplatin-based chemotherapy is the national standard (eTable 58-2). Compared with cisplatin alone, Omura et al[247] showed a higher objective response rate and PFS with cisplatin plus ifosfamide; however, there was no improvement in OS, and toxicity rates with combination chemotherapy were significantly increased. Another GOG Phase III trial demonstrated no advantage with the addition of bleomycin to the cisplatin plus ifosfamide combination.[248] The GOG has compared single-agent cisplatin with a combination of cisplatin plus paclitaxel with quality-of-life assessments included among outcome measures. The combination of cisplatin plus paclitaxel resulted in a higher objective response rate, longer PFS, and higher toxicity rate, with no apparent decrement in patient-reported quality of life.[249]

GOG 204 was a four-arm study comparing four cisplatin doublets with paclitaxel, topotecan, gemcitabine, and vinorelbine. After 513 patients were enrolled, a planned interim analysis recommended early closure of the trial based on the fact that none of the other arms would ever statistically show benefit over the control arm of cisplatin plus paclitaxel, demonstrating the challenge in achieving major progress for this patient population.[250] PFS was as short as 4 months to 6 months. Although multiagent systemic therapy remains an active area of investigation, the benefits of salvage chemotherapy remain modest at best (see eTable 58-2).

It is now recognized that a majority of patients who recur after initial therapy are not platinum-naïve, having received platinum-based chemoRT as definitive or adjuvant therapy. Previous exposure to platinum clearly influences the potential response when platinum is used in a palliative setting. In an analysis of prognostic factors for response to cisplatin-based systemic chemotherapy for recurrent or metastatic disease, Moore et al[100] identified five factors as independent predictors of a poor response: African American patient, Eastern

For patients with gross paraaortic nodal disease, doses to the entire paraaortic chain of 45 Gy in 25 fractions over 5 weeks followed by dose escalation to the paraaortic nodes has been shown to be feasible at the University of Washington. Sequential treatment doses of 20 Gy in 2 Gy fractions for a total up to 65 Gy have been administered with good effect; careful maintenance of normal tissue dose constraints, including kidney, spinal cord, and small bowel are critical. Daily prophylactic proton-pump inhibitor therapy as well as antiemetic medication should be considered. An intensity-modulated radiation therapy (IMRT) planning constraint for the small bowel (contouring contrast-enhanced loops) of 5 mL less than 55 Gy has resulted in few small bowel toxicities.[234] For patients with large nodal disease adjacent to the duodenum, duodenal planning dose constraints of a volume receive 55 Gy (v55) less than 15 mL and a dose to 2 mL of less than 60 Gy are also recommended to prevent possible fatal duodenal perforations.[235] An alternative to the EBRT boost dose following 45 Gy over 5 weeks would be restaging 2 weeks to 4 weeks later followed by an exploratory laparotomy with removal of gross nodal disease plus intraoperative electron irradiation (IOERT).

eTABLE 58-2 Phase III Trials of Cisplatin and Cisplatin-Containing Regimens in Advanced, Recurrent, or Metastatic Cervical Carcinoma

Author	Year	Regimen	No. Patients	OR (%)	CR (%)	PFS (mo)	OS (mo)

Cooperative Oncology Group (ECOG) performance status score greater than 0, pelvic disease, prior radiosensitizer, and time interval from diagnosis to first recurrence of less than 1 year. They suggest that with a simple prognostic index, which combines the risk factors, a subgroup of patients can be identified who are unlikely to benefit from cisplatin-containing regimens and who should be evaluated for other novel investigational agents or best supportive care.[100]

Recently, incorporation of bevacizumab into the first-line setting was evaluated in GOG 240, which enrolled more than 450 patients between 2009 and 2012 randomly assigned patients to platinum-based chemotherapy with or without bevacizumab.[251] These patients were in their 40s and predominantly had squamous histologies (approximately 70%). The majority had recurrent disease and has previously received cisplatin. Approximately half of these patients had pelvic disease. The addition of bevacizumab to chemotherapy increased OS (17 versus 13 months; HR for death, 0.71; 98% CI, 0.54 to 0.95; $p = 0.004$ in a one-sided test) and resulted in higher response rates (48% versus 36%, $p = 0.008$). Bevacizumab, as compared with chemotherapy alone, was associated with an increased incidence of hypertension of grade 2 or higher (25% versus 2%), thromboembolic events of grade 3 or higher (8% versus 1%), and gastrointestinal fistulas of grade 3 or higher (3% versus 0%). Despite this outcome, the median survival is still less than 2 years.

Irradiation

Radiation therapy can also play an important role in the palliation of patients with incurable advanced disease. Hypofractionated pelvic irradiation usually controls bleeding and frequently provides some relief of pelvic pain. There is a paucity of data and no randomized trials on optimal palliative irradiation regimens. A variety of fractionation schemes have been used. No standardized instruments for measuring symptom relief have been used.[252] The choice of dose and fractionation schedule will be influenced by expected survival times, patient performance status, symptoms, site(s) and bulk of tumor involvement, adjacent normal tissue considerations, medical comorbidities, and logistic considerations.

The RTOG reported the results of a Phase I/II study in which patients with advanced pelvic malignant disease were given up to three fractions of 10 Gy at 1-month intervals with misonidazole.[253] The overall objective response rate was 57%, but the rate of grade-3 and grad-4 toxicities was high (45%), although it is unclear if some of the complications may have been the result of tumor progression. Studies of the MDACC experience with this method have demonstrated a symptomatic response rate of approximately 75% with two fractions of 10 Gy but have also revealed an unacceptable rate of major complications when a third fraction of 10 Gy was given.[254,255]

In a second RTOG study, accelerated split-course EBRT was used as palliative treatment for patients with advanced pelvic malignant disease. Patients received up to three courses of 14.8 Gy given in 3.7-Gy fractions twice daily over 2 days. A 3-week to 6-week rest interval was given between courses. Patients who completed three courses of EBRT had an overall response rate of around 60%, with complete relief of pain achieved in 50% of patients.[256]

Other typically used fractionation schemes, such as 30 Gy in 10 fractions or 20 Gy in 5 fractions, have been used with some success. Prolonged fractionation is rarely indicated for palliation of patients with extraregional metastases from cervical cancer because the median life expectancy for these patients is short. Above all, these patients benefit from close monitoring of their symptoms; prompt, aggressive treatment with analgesic drugs; and sensitive, supportive care. Anesthetic or neuroablative treatments may be helpful in selected cases, and prompt referral to a multidisciplinary pain service is warranted for patients with intractable pain.

IRRADIATION TECHNIQUES AND TOLERANCE

External Beam Irradiation (EBRT)

In the radical radiation treatment of carcinoma of the cervix, EBRT is used to treat central disease and to sterilize known or suspected regional metastases. For patients with bulky central disease, a course of EBRT to the pelvis usually causes significant tumor regression, potentially improving the dose distribution of subsequent intracavitary irradiation by shrinking endocervical disease or by reducing exophytic tumor that would have caused undesirable caudad displacement of intracavitary vaginal applicators. For these reasons, patients who have locally advanced disease usually begin treatment with EBRT.

The proportion of treatment given with EBRT or intracavitary irradiation must be balanced carefully, however. Because of the relatively large volume of bladder, rectum, and small bowel included in EBRT pelvic fields, the dose of intracavitary therapy that can be safely given is relatively compromised when a high dose (>45 Gy to 50 Gy) of whole-pelvis EBRT is delivered.

Some radiation oncologists prefer to begin intracavitary irradiation as early as possible, even in patients with initial bulky disease, shielding central normal structures with a midline block on anteroposterior/posteroanterior (AP/PA) fields after 20 Gy to 30 Gy. In the past, use of a midline block of 3 cm to 4 cm in diameter was considered standard.[257] A review of urinary tract complications in patients treated with RT for FIGO stage I cervical cancers at the MDACC demonstrated a significantly higher rate of ureteral stenosis when parametrial EBRT was combined with relatively high doses of intracavitary therapy, presumably because the relatively narrow standard central blocks failed to protect the ureters from irradiation.[258] For this reason, customized blocks are preferred when higher doses of parametrial irradiation are given.

To optimize the match between EBRT and intracavitary irradiation, Perez et al[259] developed an elaborate central gradient step-wedge block designed to compensate for the lateral dose gradient from intracavitary treatment. For this method, one of several standard gradient blocks is matched to the patient's intracavitary distribution and used to shield central structures on AP/PA fields. They were able to deliver high paracentral RT doses by using intracavitary therapy to give most of the central treatment. However, the gradient blocks can only be matched to the dose distribution calculated in a single plane (usually, in the center midcoronal plane of the implant). Theoretically, anterior and posterior structures (such as the uterosacral ligaments) may be underdosed with this method, although the survival rates reported by Perez et al[259] have generally been excellent.

Alternatively, a somewhat higher dose of EBRT (35 Gy to 45 Gy) may be given to the whole pelvis before intracavitary RT. Although this approach somewhat reduces the total paracentral dose that can be delivered via brachytherapy, it may be advantageous to deliver a more homogeneous dose sufficient to eradicate microscopic disease to the entire pelvis, particularly for locally advanced tumors. Additional tailored EBRT can be delivered to disease involving the pelvic wall or lymph nodes after the first intracavitary treatment. The medial edge of such boost fields is usually placed at about the 50-cGy/hour isodose margin of the intracavitary dose distribution

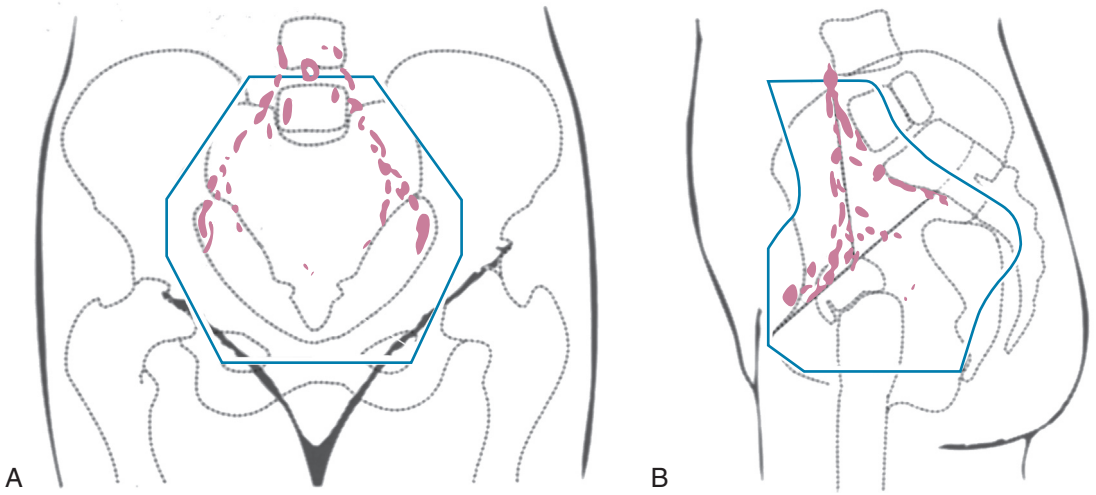

Figure 58-6 Typical anteroposterior-posteroanterior **(A)** and lateral **(B)** fields for treatment of carcinoma of the cervix. On the lateral view, external iliac nodes are typically centered about a plane between S1 to S2 and the tip of the pubis and common iliac nodes along a plane from the anterior aspect of L4 to the bisector of the external iliac plane. Care must be taken to design fields that cover regional lymph nodes and the primary tumor with margin.

or about 0.5 cm from the lateral surface of the vaginal applicator.

EBRT tends to cause some contraction of the vaginal apex. Because the vaginal capacity may limit the size of vaginal applicators, small tumors in women who have a narrow (usually postmenopausal) vagina may be more effectively treated by administering intracavitary irradiation before or early in the course of EBRT.

In all cases, care must be taken to include all areas at risk for disease in the pelvis. Conventional field arrangements for treating the pelvis typically include the use of four fields (anterior, posterior, and two lateral fields). Occasionally, especially in thinner patients, anterior and posterior opposed fields are used, and this is generally tolerable as long as EBRT doses do not exceed 40 Gy to 45 Gy. Historically, field borders that define the volume of the EBRT have been based on empirically derived bony anatomic landmarks. These bony landmarks, which are still widely promulgated in textbooks and RT protocol guidelines, represent the careful attempts of past clinical investigators to match skeletal anatomy, which can be readily appreciated radiographically, with potential soft-tissue tumor extent, nodal drainage, and pathways of regional spread. These "standardized fields" for "field-based planning" are illustrated in Figure 58-6 for a four-field "box" technique. The anterior and posterior fields usually incorporated an inferior border placed at the mid or lower obturator foramina or at least 3 cm to 4 cm below the lowest extent of clinically appreciated cervical or vaginal disease, and lateral borders were placed approximately 1.5 cm to 2 cm beyond the bony margins of the true pelvis. Lateral fields generally were placed with an anterior border anterior to the symphysis pubis; the posterior border previously was historically described as passing through the S2 to S3 junction, but clinical examination and contemporary pelvic imaging have suggested that such a conventional posterior border would frequently shield gross tumor in patients with disease extending posteriorly, particularly in the uterosacral ligaments. Without the benefit of modern imaging techniques to approximate tumor extent, shielding of the anterior-superior border of the lateral fields must be done with care or possibly omitted because of the possibility of shielding disease in the upper external iliac nodes. Although broadly useful, the routine use of "standardized fields" based on bony anatomy has been questioned as lacking in precise individual case coverage based on intraoperative measurements and imaging studies.[84,260-262]

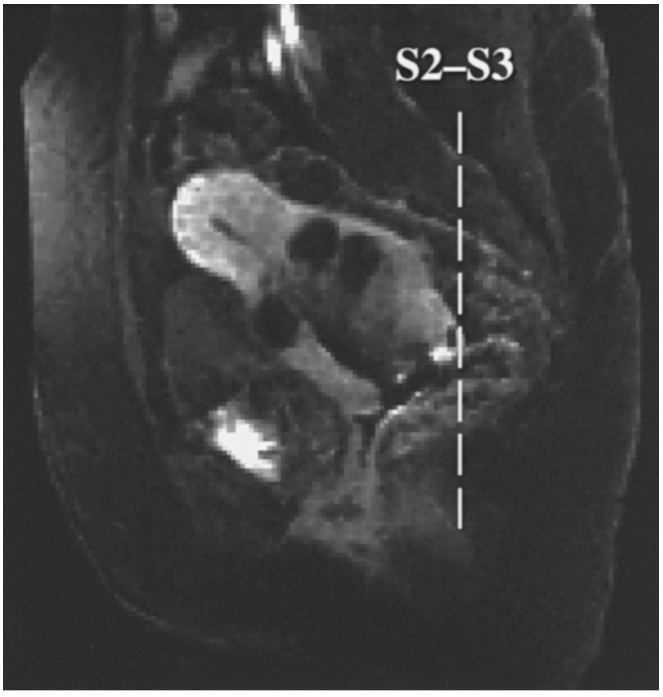

Figure 58-7 Sagittal magnetic resonance imaging (MRI) of a patient with a bulky stage IB2 adenocarcinoma. MRI demonstrated a normal uterine fundus and a bulky endocervical tumor, clarifying the site of origin of this lesion. The study also illustrates the risk of using a "standard" posterior margin for lateral fields because the posterior extent of gross disease extends posterior to the S2 to S3 interspace.

Most centers use image-guided CT or MRI planning to design radiation volumes[84] (Figure 58-7). Although even these imaging techniques are inaccurate and may underestimate the extent of microscopic spread within the pelvis, they do at least

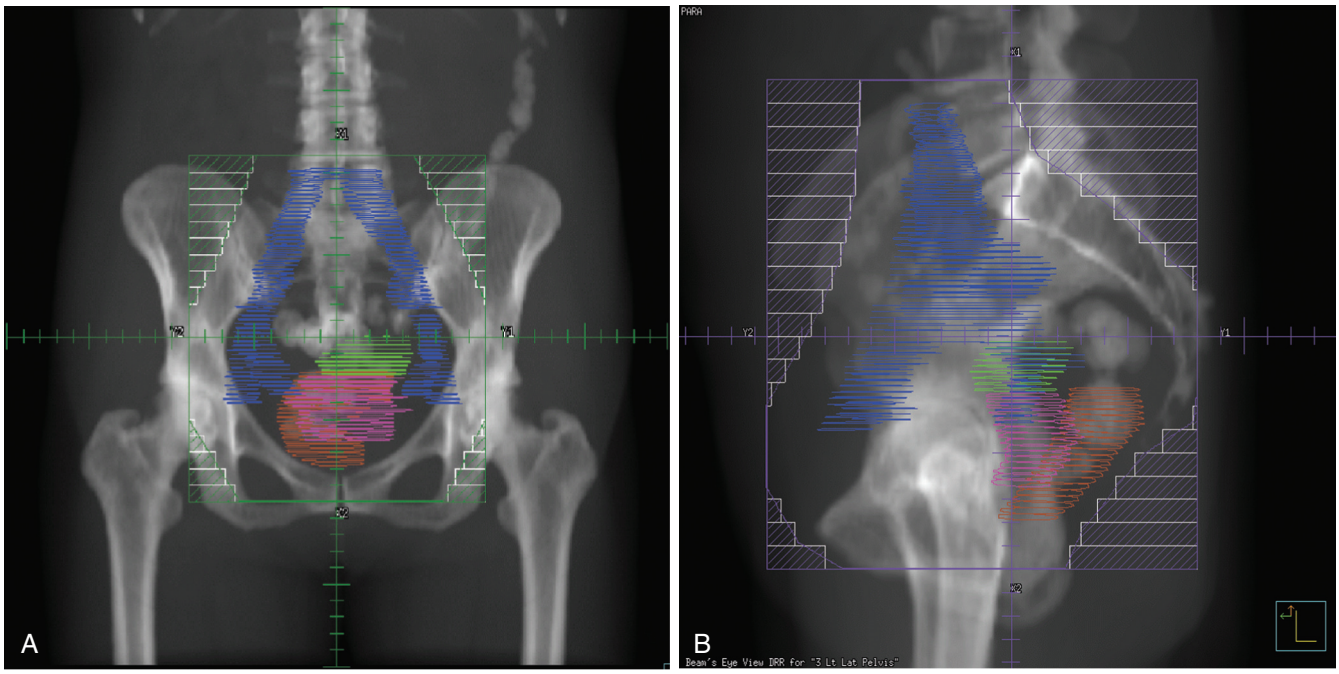

Figure 58-8 Anterior **(A)** and left lateral **(B)** digitally reconstructed radiographs (DRRs) of external beam pelvic fields for a patient with stage IIIB cervical cancer with bilateral parametrial extension and left pelvic side wall involvement but without nodal metastases on radiologic imaging. (Areas selectively illustrated: *pink*, cervical tumor gross volume; *green*, fundus; *brown*, rectum; *blue*, pelvic vessels as surrogates for nodal basins, including internal iliacs, external iliacs, and common iliacs. Other organs such as the bladder and small bowel can be alternately turned on or off on the computer screen to facilitate visualization.)

allow a somewhat better approximation of the location of the nodes and gross disease. These imaging technologies clearly improve the ability to define gross tumor extent, but they also underscore several critical issues that need to be addressed. To take full advantage of these imaging modalities, radiation oncologists must have adequate training and formalized experience in interpreting radiologic studies. Findings from a detailed pelvic examination must be carefully incorporated into the treatment plan because there are areas of potential tumor extension, such as in the vagina and parametria, which are imprecisely defined by imaging alone. Planners must have a clear awareness of the potential pathways of regional and nodal spread from cervical cancer because it is not possible to obtain images of microscopic disease, and lack of such recognition may lead to inadequate coverage of the volume at risk. There are no data examining the necessity for inclusion of the whole uterine body, but most recommend its inclusion in the treated volume given the potential for myometrial extension of disease from the cervix.

Examples of EBRT ports for patients with cervical cancer based on contemporary CT simulation are shown in Figures 58-8 and 58-9. An example of a composite EBRT dosimetry plan is illustrated in Figure 58-10. Although CT-based treatment planning and field design allow customization based on individual patient findings, it should be noted that the general similarity of these fields to the traditional "standardized" bony anatomy–based fields serve as a testament to the clinical acumen and observational skills of previous clinicians who did not have access to the imaging modalities of today.

Intensity-Modulated Irradiation

Modern technologies in radiotherapy delivery such as IMRT allow the delivery of highly conformal dose distributions

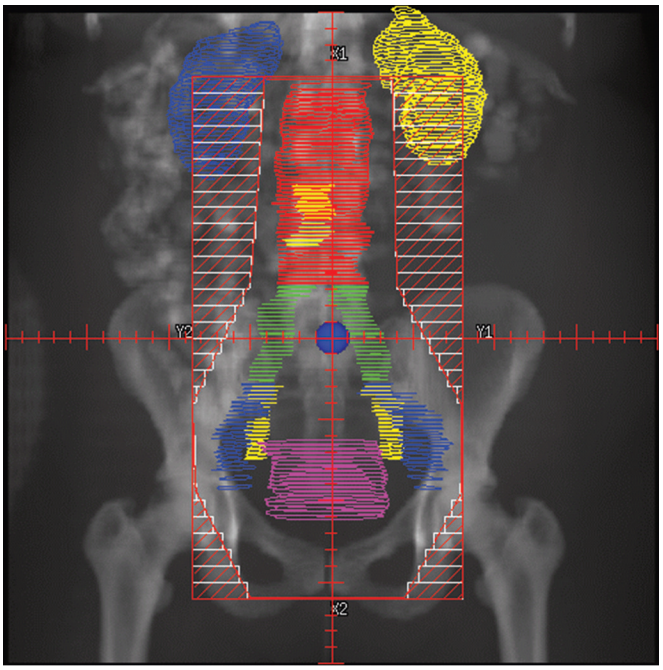

Figure 58-9 Anterior digital reconstructed radiograph of an extended pelvic and paraaortic external beam field in a different patient with stage IIIB cervical cancer and multiple pelvic and low paraaortic lymph node metastases. Areas selected on this image included the cervical tumor gross volume *(pink),* the areas of gross nodal involvement as determined by computed tomography/positron emission tomography (CT/PET) imaging *(yellow),* the associated pelvic and paraaortic nodal basins, and the bilateral kidneys.

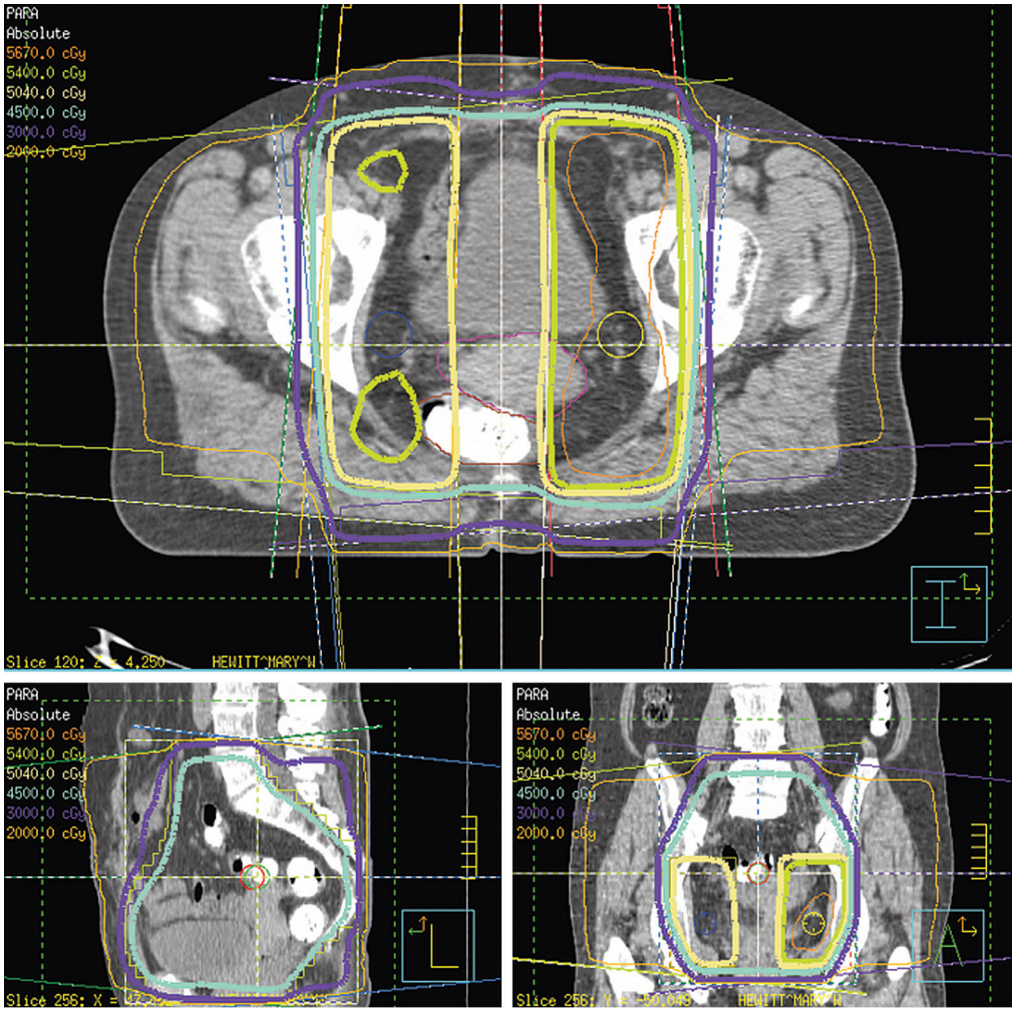

Figure 58-10 External beam dosimetry planning (for patient shown in Figure 58-8). The prescribed dose was 45 Gy to the whole pelvis, with parametrial boosts to 50.4 Gy to the right and 54 Gy to the left (patient had bulkier disease on the left, with extension to the pelvic side wall). The central dose in this patient was supplemented by intracavitary brachytherapy.

unachievable using conventional approaches. They combine high-resolution imaging, advances in computer treatment software and linear accelerator collimation capabilities, inverse planning, and radiation beam flux modulation. IMRT has been most widely used in head and neck and prostate cancers, simultaneously allowing sparing of surrounding normal structures and dose intensification to the tumor target volume. The success of highly conformal RT such as IMRT in various tumor sites is heavily dependent on the accuracy of tumor delineation through imaging. Dosimetric evaluation of its use in gynecologic cancers suggests IMRT may significantly reduce unwanted radiation exposure to adjacent bowel and bladder while preserving tumor coverage.[263] Early clinical experience at the University of Chicago has demonstrated a reduction in acute gastrointestinal toxicity for patients with gynecologic cancer undergoing pelvic IMRT compared with contemporaneous historical controls treated with traditional standard techniques.[264] Recent analysis has also indicated a decrease in acute hematologic suppression, favoring patients treated with IMRT, especially in those who also received chemotherapy.[265] Although there is excitement about the potential eventual application of IMRT to definitive cervical cancer RT, questions remain about accurate target definitions, treatment standardization, intrapatient and interpatient reproducibility, and time-intensive requirements for treatment planning and delivery.

Currently, there is an emerging consensus that IMRT may be a useful technique in posthysterectomy irradiation. It may allow greater sparing of normal tissues, especially the small bowel, displaced into the pelvis, provided that meticulous attention is paid to anatomic detail and contouring of targets. However, issues regarding dose heterogeneity within the target volume and broad "low-dose scatter" remain to be resolved.[266] The RTOG atlas "Consensus Guidelines for the Delineation of the CTV in the Postoperative Pelvic Radiotherapy of Endometrial and Cervical Cancer" for posthysterectomy contouring is available at www.rtog.org/CoreLab/ContouringAtlases/GYN.aspx. A normal tissue contouring atlas is also available at www.rtog.org/CoreLab/ContouringAtlases/FemaleRTOGNormalPelvisAtlas.aspx RTOG-0418, a Phase II trial evaluating the use of pelvic IMRT in the posthysterectomy setting for patients with endometrial or cervical carcinoma showed general feasibility for the use of posthysterectomy IMRT in multiinstitutional trials when stringent guidelines are specified and quality assurance measures are employed.[267] However, a high proportion

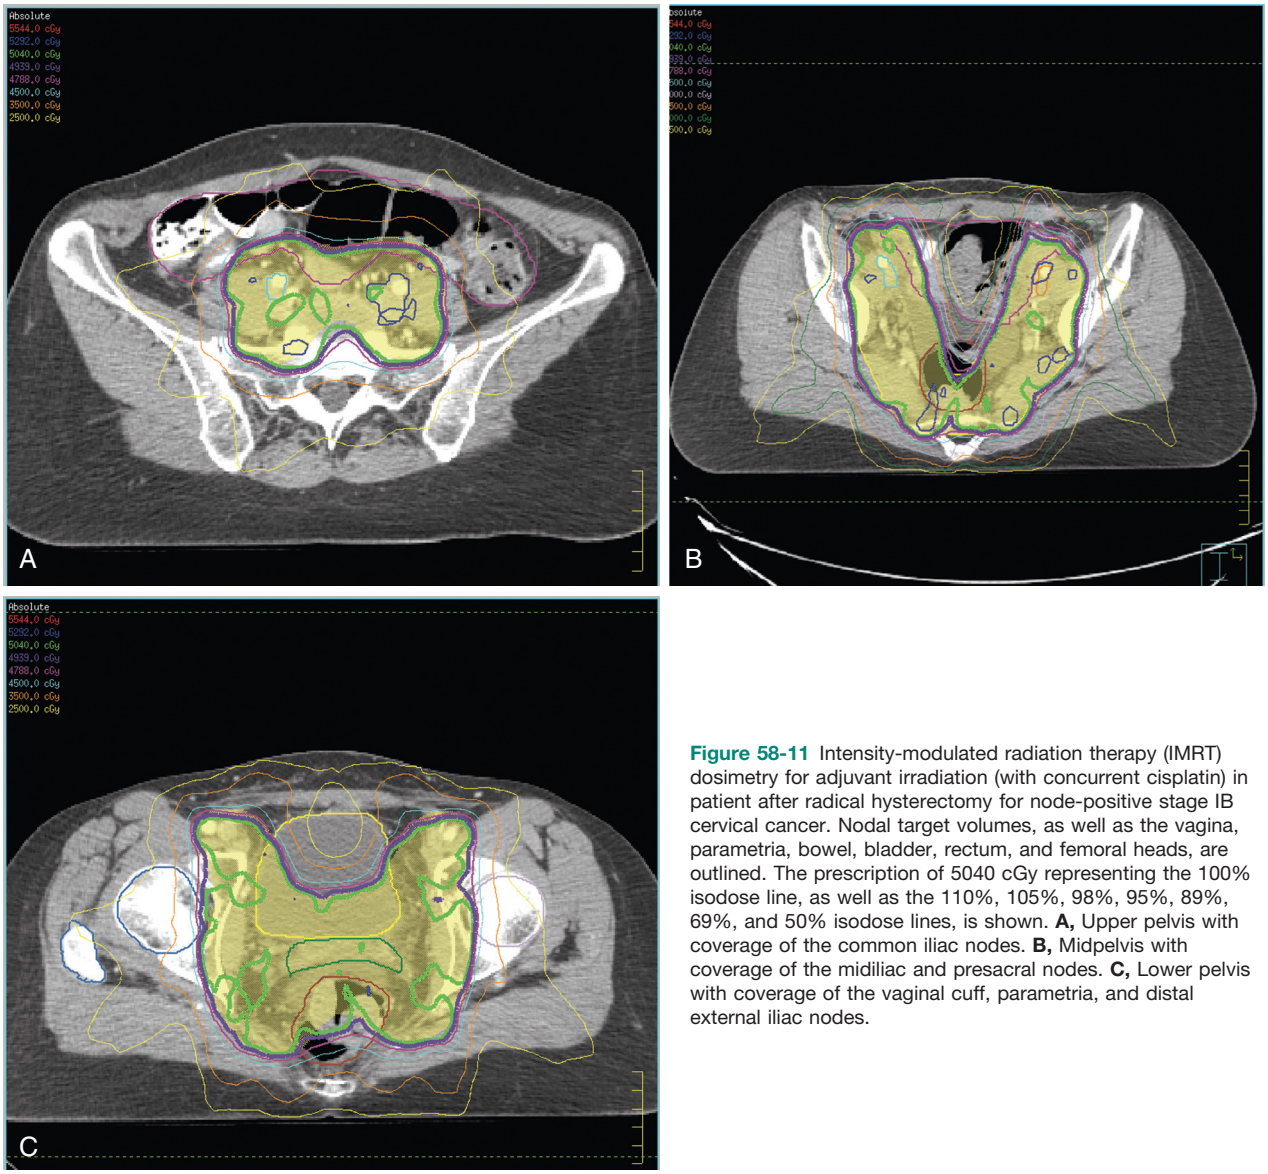

Figure 58-11 Intensity-modulated radiation therapy (IMRT) dosimetry for adjuvant irradiation (with concurrent cisplatin) in patient after radical hysterectomy for node-positive stage IB cervical cancer. Nodal target volumes, as well as the vagina, parametria, bowel, bladder, rectum, and femoral heads, are outlined. The prescription of 5040 cGy representing the 100% isodose line, as well as the 110%, 105%, 98%, 95%, 89%, 69%, and 50% isodose lines, is shown. **A,** Upper pelvis with coverage of the common iliac nodes. **B,** Midpelvis with coverage of the midiliac and presacral nodes. **C,** Lower pelvis with coverage of the vaginal cuff, parametria, and distal external iliac nodes.

of patients did not meet the IMRT planning constraints, and therefore less stringent constraints were written for subsequent trials. Current Phase III trials in postoperative irradiation following radical hysterectomy for cervical cancer (RTOG 0724, GOG 263) permit the use of IMRT but require detailed institutional and individual investigator credentialing, as well as "real-time" central review of the first IMRT protocol case treated. An example of IMRT dosimetry in a patient undergoing adjuvant chemoRT following radical hysterectomy for node-positive stage IB cervical cancer is shown in Figure 58-11; it shows highly conformal shaping of the higher isodoses, with relative sparing of small bowel, bladder, and some rectum compared with a more traditional four-field pelvic technique, despite the use of generous target volumes for the IMRT plan.

The role of IMRT for intact cervical cancer remains more nascent and must be considered investigational at present despite considerable current implementation. Target mobility, as well as tumor deformation/regression during a course of RT, is of greater concern in intact cancer cases than in the posthysterectomy setting.[268-270] A preliminary attempt at target volume consensus in intact cervical cancer (based on a single case study) was recently published and showed appreciable variability in target volumes even when assessed by experienced gynecologic radiation oncologists.[271] Prospective multicenter trials of IMRT in intact cervical cancer have been proposed but have not yet been activated.

Brachytherapy

Encapsulated radium sources were first used to treat cervical cancers shortly after Marie Curie's discovery more than a century ago. The origin of cervical cancers at the mouth of a hollow, relatively radioresistant organ made the disease ideal for intracavitary treatment. With careful placement of sources in the uterus and vagina, clinicians are able to capitalize on the inverse-square law, delivering a high dose of radiation to the central cervical tumor while relatively sparing radiation exposure to critical surrounding normal tissues such as the bladder, rectum, and small bowel.

Empirical evidence, in vitro studies of the effect of dose rate on tumor cell kill and late normal tissue effects, available technology, and radiation protection considerations led to the initial use of sources that delivered ionizing radiation at relatively low dose rates over time. Although LDR intracavitary brachytherapy had traditionally been used for most patients with cervical cancer treated in the United States, HDR brachytherapy use has increased dramatically in the past decade.[272]

Over the past two decades, manufacturers have withdrawn support for LDR systems. Comparison data from several randomized trials,[273-276] reviews,[277] and large single-institutional retrospective experiences[278,279] have led to an increasing acceptance of the efficacy and tolerability of HDR brachytherapy for cervical cancer. Large clinical cooperative trial groups such as the GOG and RTOG accept that when performed appropriately and within clearly specified guidelines of dosing and fractionation, HDR and LDR intracavitary cervical brachytherapy regimens are therapeutically similar. Faced with issues related to LDR-associated personnel exposure, source regulation and storage, source replacement, and withdrawal of technical support from suppliers, most centers now use outpatient-based HDR brachytherapy for cervical cancer. In a patterns-of-care survey of cervical cancer cases treated between 1996 and 1999, 16.4% of patients who underwent brachytherapy had at least part of their therapy delivered using an HDR regimen.[280] By 2005 to 2007, a new survey indicated that 68.5% of patients undergoing intracavitary brachytherapy for cervical cancer were treated with HDR techniques.[129] Primarily in Europe, pulsed-dose-rate (PDR) brachytherapy is utilized, arguing that it is more radiobiologically similar to LDR therapy and may cause fewer late complications.

Low-Dose-Rate Intracavitary Therapy

Historically, until the early 1980s, most intracavitary therapy was delivered using radioactive radium (radium-226 [^{226}Ra]). Cesium-137 (^{137}Cs), an artificially produced isotope of similar average energy, gradually began to replace ^{226}Ra in most practices. Because the half-life of ^{137}Cs is only about 30 years, the sources had to be replaced periodically. Commercially available cesium sources are usually slightly shorter (≤17 mm to 20 mm) than ^{226}Ra sources. Therefore, standard loadings designed for radium produce higher dose rates to critical structures if short cesium sources are used without spacers.

Many intracavitary applicator systems have been used to position sources in the uterus and vagina. All include a central uterine tandem; the major differences are in the design of the vaginal source holders. In the United States, most radiation oncologists use some variation of the Fletcher-Suit-Delclos applicator system that was first developed at MDACC. The most characteristic feature of this system is the pair of cylindrical vaginal colpostats that are placed against the cervix on either side of the tandem. Ideally, these holders position the axis of the vaginal sources approximately perpendicular to the uterine tandem (Figure 58-12). This positioning is designed to take advantage of the anisotropy of the sources, and combined with the anterior and posterior tungsten shields incorporated in the design, to reduce the volume of bladder and rectum exposed to high doses of radiation while spreading the dose laterally to the parametria. For patients with a narrow vagina, unshielded miniovoids and Lucite cylinders of various sizes can be used to position the intravaginal sources. Another applicator system used successfully by a number of groups, including the Memorial Sloan Kettering Cancer Center, is the Henschke applicator. With this system, the vaginal sources are positioned parallel to the axis of the intrauterine tandem.

Today, all these systems are afterloading, to minimize personnel exposure to the radiation. Radiation exposure from LDR implants can be further reduced to negligible levels with computerized remote afterloading equipment that removes the cesium sources automatically when persons enter the room.

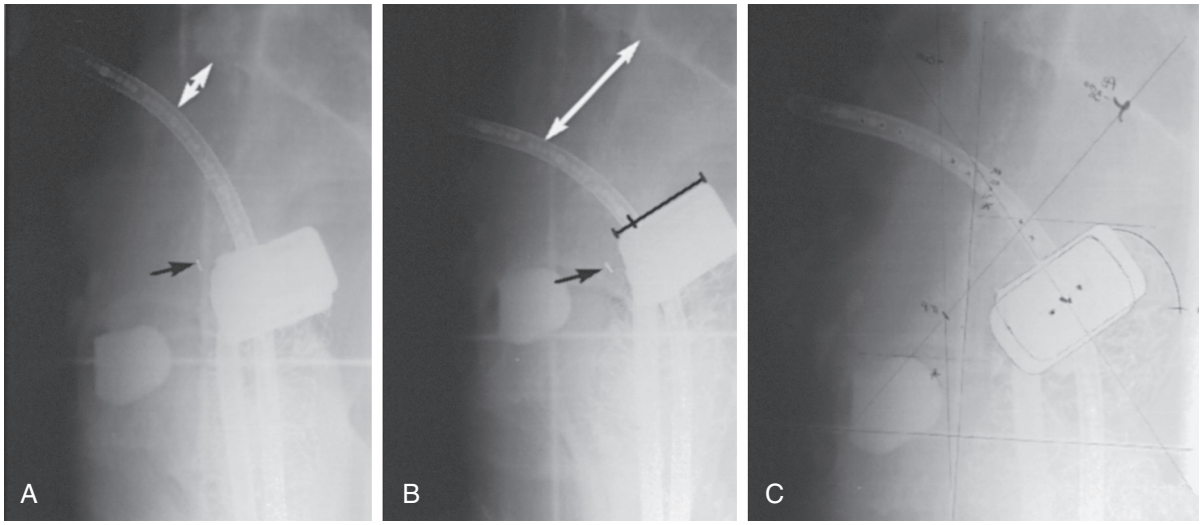

Figure 58-12 Lateral views of Fletcher-Suit-Delclos intracavitary placements in a young woman with a FIGO IB2 endocervical tumor. **A,** The patient had a pliable vagina, and aggressive packing pushed the uterus and the system high in the pelvis against the sacrum, potentially trapping bowel between the intracavitary system and the sacrum. **B,** The system was repacked using a suture slipped through the cervix to provide countertraction during packing. This kept the system lower in the pelvis, but the ovoids were allowed to fall posteriorly. This position can lead to overdosage of the rectum, particularly cephalad to the ovoids. **C,** A second repacking resulted in a good placement with acceptable positioning of the system midway between the sacrum and bladder. Ovoids are bisected by the tandem and are close to the cervical marker seeds; posterior packing protects the rectum. It is rare to need two adjustments of an intracavitary system, but the significant improvement achieved with this effort should improve the therapeutic ratio for this patient and underscores the importance of intraoperative radiographs in cervical cancer brachytherapy.

Successful intracavitary therapy requires experience, skill, some pragmatism, and a willingness to persist until an "optimal placement" has been achieved.[281] Proper positioning of the applicator and packing is essential to maximize local control.[282] Radiation sources must be positioned in the uterus and vagina in a way that avoids underdosing areas in the cervix and paracervical tissues with a sensitivity to the limits of mucosal tolerance. Every tumor presents a somewhat different challenge because of the wide variations in tumors and patient anatomy encountered clinically. A thorough discussion of the methods that can be used to address these variations is beyond the scope of this chapter, but some basic principles apply to most common clinical situations.

Although there has been considerable debate regarding the "optimal" intracavitary brachytherapy system, and there is no doubt that brachytherapy requires technical skill and attention to detail, it is also apparent that whether intracavitary brachytherapy is used is more important than the details of how it is placed. In the United States, most radiation oncologists are familiar with some variation of the Fletcher-Suit-Delclos applicator system, but other systems are also used. What is clear is that the introduction of radioactive sources into the endocervical and endometrial canal permits a central tumor dose intensification that is unachievable by any EBRT technique, regardless of the nuances of source placement (Figure 58-13). It is this high radiation dose, placed in direct juxtaposition to the tumor, within a radiotolerant organ, that allows for control of even large cervical cancers.

Placement of the system can be performed under intravenous sedation with monitored anesthesia care; general or regional anesthesia may be preferred, unless the patient is at increased risk for anesthetic complications, because it permits a good examination of the pelvis and provides maximal relaxation of the perineal musculature during placement and packing of the intracavitary applicator. The system should be packed in place with lubricated gauze, preferably a type that contains a radiopaque thread, while the vagina is retracted by an assistant. Packing should be carefully placed anteriorly and posteriorly, displacing the rectum and bladder away from the system. Care should be taken not to force the cervix away from the colpostats during the packing. Gradual withdrawal of the retractors during the procedure permits placement of additional packing in the space occupied by the retractors. With firm packing, the risk of displacement during a 48-hour to 72-hour placement is minimal. However, when vaginal cylinders are used instead of packing or when a remote afterloading device is used, a stitch should be placed in the labia and secured to the system to prevent displacement. The accuracy of the applicator position should be confirmed while the patient is still under sedation by anteroposterior and lateral radiographs. If the placement is unsatisfactory, the system should be repositioned and repacked. For patients undergoing LDR brachytherapy with prolonged immobilization, thromboprophylaxis with subcutaneous heparin and sequential compression devices should be initiated as early as during anesthesia for insertion, given the elevated risk for deep venous thrombosis in this setting.

Dose Specification

Several conventional standardized methods have been used to specify the radiation dose delivered by an intracavitary system. In the Manchester system, the dose and dose rate are specified to a paracentral point (point A) and to a point near the pelvic wall (point B) (Figure 58-14). Point A is placed 2 cm lateral and superior to the applicator along the axis of the intrauterine tandem, although a number of methods have

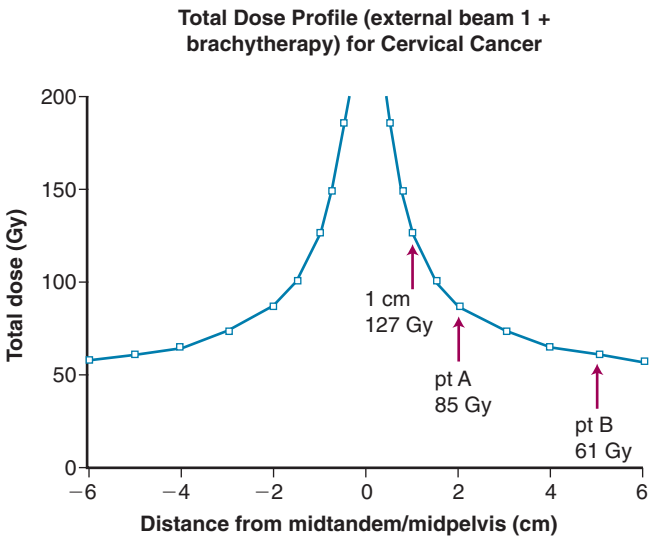

Figure 58-13 Illustration of the central dose escalation achieved when combining intracavitary brachytherapy with external beam radiation therapy. Although the diagram is idealized, it is based on current GOG guidelines for radiation dosing in locally advanced cervical cancer: 45 Gy to the whole pelvis, intracavitary brachytherapy to an LDR equivalent dose of 85 Gy to point (pt) A, and an additional external beam parametrial boost of 4.5 Gy to 9 Gy with central structures shielded. The *x* axis represents the distance from the centrally placed tandem toward each pelvic side wall, along the transaxial plane encompassing bilateral point As.

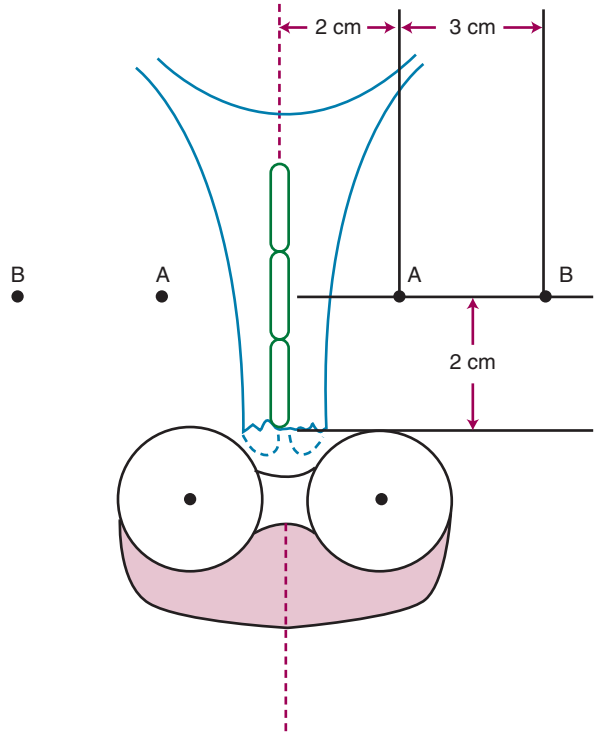

Figure 58-14 Location of point A and point B using the method recommended in ICRU 38.
From International Commission on Radiation Units and Measurements: Dose and volume specifications for reporting intracavitary therapy in gynecology, vol 38, Bethesda, MD, 1985, ICRU, pp 1–23.

Conventionally for most cases, the highest sources in the tandem should extend superiorly at least 6 cm above the external os or, if the uterus is small, as high as possible in the uterine cavity. A relatively long line of sources will provide better lateral dose penetration and coverage of high endocervical tumor, as well as providing some incremental dose to pelvic side wall nodes. A tandem of 6.5 cm to 8 cm will accommodate 35 mgRaEq to 40 mgRaEq of cesium distributed in three linear sources spaced with their centers 22 mm to 25 mm apart. Typical loadings (cephalad to caudad) of LDR linear cesium sources would be 15-15-10 mgRaEq for relatively large tumors that still expand the endocervix at the time of intracavitary placement or 15-10-10 mgRaEq for smaller tumors. The caudad source in the tandem should not protrude more than a couple of millimeters below the superior surface of the colpostats to avoid a hot spot in the adjacent bladder and rectum. Similar distributions can be achieved with remote afterloading units by distributing 5-mgRaEq point sources along the length of the tandem.

The choice of vaginal applicator is determined by the vaginal capacity and by the distribution of any vaginal disease. Vaginal cylinders are usually reserved for patients who have a narrow vagina or significant vaginal mucosal disease where the dose needs to be delivered inferiorly in the vagina. In general, when colpostats are used, their medial surfaces should be separated by 1 cm or less to avoid a central cold spot. Instead, to maximize the dose deliverable from intravaginal sources and optimize the relative depth dose, the vagina should be fitted with the largest ovoids that can be placed snugly against the cervix. The anterior and posterior lips of the cervix should always be marked with radiopaque seeds (see Figure 58-12) so the relationship between the cervix and vaginal applicators can be verified on intraoperative films. Significant caudad displacement of the colpostats will dramatically reduce the dose to the cervical tumor and lead to increased vaginal stenosis and probable fistula risk. The colpostats should be centered over the cervical portion; unless the anterior or posterior lip is disproportionately involved, the colpostats should be bisected by the tandem on the lateral view. Very posterior displacement of the colpostats usually results in an underdosage to anterior disease and an unacceptable overdosage to the rectum, particularly to the portion of the rectum that is superior to the colpostat. The standard loadings for Fletcher-Suit-Delclos ovoids are 10 mgRaEq or 15 mgRaEq for 2 cm (small); 15 mgRaEq or 20 mgRaEq for 2.5 cm (medium); 20 mgRaEq or, rarely, 25 mgRaEq for 3 cm (large); and 5 mgRaEq to 10 mgRaEq for miniovoids. These loadings will result in a dose rate at the lateral vaginal surface of 75 cGy/hr to 110 cGy/hr. The higher-activity sources are used when the placement is excellent or when the patient has bulky central disease. The lower activities tend to be used for patients with small tumors, for suboptimal (but acceptable) positioning, and to keep the total vaginal surface dose beneath the cumulative maximum of 120 Gy to 140 Gy.

been used to identify the position of this reference point. Of note, point A was redefined for an upcoming ICRU document and published by the American Brachytherapy Society.[283] Because point A lies in a region of steep dose gradient, relatively small variations in its position can result in substantial differences in the calculated dose rate. For this reason, the use of point A or similar reference points was criticized by the ICRU in its 1985 report on intracavitary dose and volume specification.[284] The commission recommended a system, used in some parts of Europe, in which the volume of tissue treated to a certain dose (usually, 60 Gy) and the reference air kerma (in micrograys [μGy] at 1 m) are specified. Some physicians place an additional emphasis on the vaginal surface dose, substituting mgRaEq hours for reference air kerma as a means of limiting pelvic integral dose and relying on a set of empirically derived rules concerning the position and activity of the radiation sources. When point A is used as a reference point for dosing and reporting, attention must also be given to the 3D isodose distributions surrounding the entire implant. Unexpected results can occur when a standard dose is delivered to point A from a system that is poorly positioned or has unusual source arrangements. For this reason, the use of point A to specify the dose from interstitial implants is not recommended; rather 3D conformal dosimetry after CT or MR contouring of a tumor volume are recommended for interstitial brachytherapy.[285]

High-Dose-Rate Brachytherapy

Computerized remote afterloading technology has now made it possible to deliver intracavitary irradiation at high doses in minutes instead of hours or days. Worldwide use of HDR brachytherapy as an alternative to LDR brachytherapy has increased rapidly in recent years. Because HDR treatment is always delivered with remote afterloading equipment, radiation exposure to personnel is eliminated. Patients do not have to be hospitalized for treatment, providing a possible economic advantage, and the delivery of treatment in several short fractions may permit greater control over the position of sources during treatment. The most important concern has been that treatment with large HDR fractions reduces the opportunity for recovery of sublethal normal tissue injury and therefore may narrow the therapeutic ratio between tumor control and complications. Other possible disadvantages include the labor intensity of the process and the opportunity for an irreversible error that is not discovered during a short duration of exposure.

Investigators have been reporting their experiences with HDR brachytherapy for more than 20 years, describing thousands of patients with cervical cancer who were treated with this approach. The authors of numerous retrospective studies have demonstrated that HDR treatment is feasible, effective, and safe.[277] In addition, there have been four randomized trials of HDR versus LDR brachytherapy[273-275] (Table 58-5). Although each study had flaws, the data would suggest, in total, that HDR brachytherapy, within carefully applied dosing and fractionation guidelines, provides therapeutic equivalency to traditional LDR approaches.

The biologic effect (particularly to normal tissues) of a nominal dose of radiation will be significantly greater when it is given with HDR as compared with LDR brachytherapy, and this depends on the fraction size. This factor leads to the need for increasing fraction numbers when using HDR versus LDR therapy. To select an HDR schedule that may be comparable with LDR treatment, it is helpful to consider the fractionation and dose-rate effects and, specifically, applications of the linear quadratic (LQ) model used to describe these effects.

The LQ model has been used to describe a biologically effective dose (BED), given as

$$\text{BED} = \text{Total dose}\,[1 + \text{dose per fraction}/(\alpha/\beta)]$$

where α/β describes the varying influence of fraction size on radiation effects in different tumors and normal tissues. This is then converted to the EQD2 (equivalent dose in 2 Gy fractions) using BED/1.2 for the $\alpha/\beta = 10$ for tumor.

TABLE 58-5 Randomized Trials of High-Dose-Rate (HDR) Versus Low-Dose-Rate (LDR) Brachytherapy in Cervical Cancer

Author	No. Patients	Survival	Severe Late Toxicity	Comments
Patel[244]	Group I: early stage			Equivalent outcomes for HDR and LDR in local control, survival, and late toxicity
	LDR: *n* = 36	72% (5-yr OS)	GI 3%	
	HDR: *n* = 34	82% (5-yr OS)	GI 0%	
	Group II: bulky/advanced tumor			No severe late GU toxicity noted
	LDR: *n* = 210	55% (5-yr OS)	GI 2%	
	HDR: *n* = 202	54% (5-yr OS)	GI 1%	
Teshima[245]	LDR: *n* = 171	Stage I/II/III (5-yr CSS) 93%/78%/47%	4%	Unbalanced randomization; includes older patients specifically referred for HDR
	HDR: *n* = 259	Stage I/II/III (5-yr CSS) 85%/73%/53%	10%	Equivalent local control and CSS Higher late toxicity with HDR, but still considered within acceptable levels
Hareyama[246]	Stage II			No significant differences in DSS and complication rates
	LDR: *n* = 26	87% (5-yr DSS)	13%	
	HDR: *n* = 22	69% (5-yr DSS)	10%	
	Stage III			
	LDR: *n* = 45	60% (5-yr DSS)	—	
	HDR: *n* = 39	51% (5-yr DSS)	—	
Lertsanguansinchai[247]	LDR: *n* = 109	70% (3-yr RFS)	3%	Comparable local control, RFS, and complication rates
	HDR: *n* = 112	70% (3-yr RFS)	7%	

CSS, *Cause-specific survival; DSS, disease-specific survival;* GI, *gastrointestinal;* GU, *genitourinary;* n, *number;* OS, *overall survival;* RFS, *relapse-free survival;* yr, *year.*

A well-placed LDR system loaded according to the preceding recommendations will produce a dose rate at point A of approximately 45 cGy/hr to 55 cGy/hr. Somewhat higher activity loadings have been recommended and used successfully. However, higher activity sources will result in higher dose rates and may have a somewhat greater biologic effect with the number of brachytherapy insertions limited to one or two; dose rates of more than 65 cGy/hr to point A should be used with caution. In a prospective randomized study, Haie-Meder et al[286] reported an increased rate of major complications when the dose rate to point A was increased from 40 cGy/hr to 80 cGy/hr.

Patients who have bulky central disease and favorable anatomy can usually be treated to a combined dose of "85 [Gy] to 90 Gy" to point A (40 Gy to 45 Gy with EBRT and 40 Gy to 50 Gy with brachytherapy), with an acceptable risk of late complications. Higher doses of central EBRT tend to compromise the total paracentral dose that can be delivered. Somewhat lower doses (75 Gy to 85 Gy) are usually recommended for smaller (IA to IB1) tumors. Adjustments to these doses and to the distribution of sources in the intracavitary applicators may be needed, however, taking into account the position of the system in relation to other pelvic structures and the distribution of tumor as determined by physical examination and imaging studies.

LDR brachytherapy has been used successfully in combination with EBRT since the 1950s to treat thousands of patients and to achieve high local control and cure rates with a low risk of complications. The radiobiologic advantages of delivering brachytherapy at LDR have been emphasized by many, and a number of clinicians continue to express skepticism about the comparability of HDR therapy, particularly in the treatment of patients with unfavorable anatomy, for whom the dose to critical normal tissues may be similar to the paracentral dose.[287] On the other hand, increased acceptance of, experience with, and training in HDR brachytherapy techniques have led many to adopt outpatient-based HDR brachytherapy. Whether using LDR or HDR therapy, the importance of attention to anatomic detail, an understanding of normal tissue tolerance, an appreciation of radiobiologic principles, and an adherence to guidelines for loading and fractionation cannot be overemphasized.

The use of the LQ equation allows one to calculate and approximate the biologic equivalency of HDR-based to traditional LDR-based dosing. Typically, an α/β ratio of 10 is used for tumor and acutely responding tissues and a ratio of 3 is used for late-responding normal tissues. Using the LQ equation, tumor doses of 80 Gy to 85 Gy to point A in LDR equivalent would result in BEDs of 96 Gy_{10} to 102 Gy_{10}. Conservatively accounting for late-responding normal tissue tolerances, LDR equivalent doses of 70 Gy to the rectum and 75 Gy to the bladder correspond to 120 Gy_3 and 125 Gy_3, respectively.

There is emerging evidence that small volumes of the rectum and bladder can tolerate a total of 130 Gy_3 to 140 Gy_3. Ogino et al[288] did not observe any severe grade-4 rectal complications with a dose equivalent of less than 147 Gy_3 to the rectum. Lower grade-2 to grade-3 rectal toxicity was reported in less than 5% of patients with a BED of less than 119 Gy_3 and in less than 10% with a BED of less than 146 Gy_3. Their current fractionation schedules are designed to keep the BED for late-responding tissues to less than 119 Gy_3 for early-stage disease and to less than 147 Gy_3 for locally advanced cancers, allowing a tailoring of dose to disease extent.[288] In the era of CT or MR imaging after brachytherapy applicator insertion, contouring and calculation of the dose-volume histogram (DVH) values for the normal tissues has been standardized. A D2cc dose of 70 Gy to 75 Gy for the rectum and sigmoid, and 80 Gy to 100 Gy to the bladder is recommended.[131] A dose limit for the bowel is not clear, though a recommendation of 5cc < 55Gy[234] or D2cc < 65 Gy may be considered. Contoured bowel (small and large bowel may be indistinguishable) at the time of brachytherapy 5.

Although point A remains the most commonly reported tumor specification point, in the past 10 years, an increase in the use of imaging has permitted contouring of tumor volumes. The GEC-ESTRO guidelines describe, for MR-imaging after brachytherapy applicator insertion, a high-risk CTV encompassing the entire cervix and tumor extension into the parametria, vagina or uterus at the time of brachytherapy, and the intermediate-risk CTV, which is the disease extension at diagnosis. In practice in the United States, the high-risk CTV D90 is used for dose calculations (goal 80 Gy to 90 Gy), and therefore the high-risk CTV is the most commonly contoured volume, and also correlates the most with the CT-contoured CTV.[130] CT does not permit imaging of the superior border of the cervix, and therefore an estimate of the superior border is made where the shape of the cervix changes and the broad ligament ends. CT contours are wider than MR-based contours, though it is not clear whether this difference has any meaningful dosimetric impact.[289]

HDR fractionation schedules reported in the literature vary markedly, with insertion numbers and point A dose fraction sizes ranging from 2 Gy to 7 Gy and 3 Gy to 14 Gy, respectively.[277] Assuming an α/β ratio of 3 for late damage to normal tissues, Stitt et al[290] used the LQ model to predict how a dose of HDR brachytherapy would have to be divided so its effect on normal tissue was comparable to that of 70 Gy of LDR brachytherapy. According to their model, five or six fractions are sufficient if the dose to critical normal tissues is 80% or less of the dose to the paracentral reference point. If the anatomy is somewhat less favorable and the normal tissue dose is 90% of the tumor dose, however, more fractions may be considered.

A detailed analysis of 24 reported series studying HDR brachytherapy in locally advanced cervical cancer failed to identify a dose-response relationship for either tumor control or late tissue complications.[291] Although this does not refute the importance of radiobiologic considerations and calculations in the implementation of HDR brachytherapy, it does underscore the complexity of patient- and treatment-related variables involved in the radiotherapeutic management of cervical cancer and the difficulty in reducing HDR dosing issues to a simple mathematical formula.

Viswanathan et al[185] reported on a recent survey of international HDR brachytherapy practice among members of the Gynecologic Cancer Intergroup (GCIG). The average EBRT dose to the pelvis approximated 45 Gy. For stages IB to IIA tumors, the three most common regimens were 6 Gy for five fractions, 6 Gy for four fractions, and 7 Gy for three fractions, with brachytherapy doses predominantly prescribed to point A. For stages IIB to IVA tumors, the three most common regimens were 6 Gy for five fractions, 7 Gy for four fractions, and 7 Gy for three fractions. For its most recent protocols in locally advanced cervical cancer (where HDR therapy was permitted), the GOG had prescribed a whole-pelvic dose of 45 Gy, supplemented by an HDR boost of 6 Gy to point A for five fractions, as well as a 5.4-Gy to 9-Gy parametrial boost to the involved side(s). This regimen, when converted using the LQ model, corresponded to a calculated LDR/conventional equivalent dose of 85 Gy to point A. However, it has recently been recognized that absolute adherence to inflexible guidelines does not take into consideration the uncertainties in assumptions and applications of the LQ model, nor the specific tumor geometry and patient factors associated with each case, leading to potential increased toxicity. Although the LQ model is a useful tool for comparing fractionation schemes, no mathematical formula can take the place of clinical judgment and observation. Going forward, the GOG has proposed modifications of its dosing parameters in locally advanced cervical cancer as follows: a whole-pelvis dose of 41.4 Gy to 45 Gy, followed by HDR brachytherapy of 5.4 Gy to 6 Gy for five fractions, with optional parametrial boosting based on tumor regression during EBRT. This new "scheme," although seeking to maintain a minimal LDR equivalent dose of 80 Gy to point A, provides for flexibility in HDR application and allows for dose escalation to 85 Gy as clinically appropriate. To preserve biologic equivalency dosing to late-reacting normal tissues, the GOG has recommended that the ICRU rectal dose point receive no more than 4.1 Gy (68% of the point A dose) and the bladder dose point no more than 4.6 Gy (77% of the point A dose) per insertion, though using DVH values and D2cc limits is recommended with 3D-image based brachytherapy.. The increased flexibility in dose shaping with HDR brachytherapy may be useful in optimizing tumor-to-normal-tissue dose ratios.

Planning for brachytherapy begins at the time of initial diagnosis. Patients must be made aware and prepared for the procedure, and the physician should carefully document the clinical examination, and initial imaging such as MRI and PET findings. Careful examination while the patient receives external beam allows assessment of tumor regression; the physician should determine which applicator is most appropriate based on the tumor extension at diagnosis and remaining disease at the time of brachytherapy. Commonly used applicators include the tandem and ovoid or tandem with interstitial template, and in HDR systems, the tandem and ring, or tandem and ring/ovoid with additional interstitial needles extending through the ring/ovoid.

As with LDR brachytherapy, the timing of HDR insertions depends on the stage and volume of disease and its response to EBRT. For small cervical cancers, brachytherapy may be initiated during the first 2 weeks of RT; for more locally advanced lesions, brachytherapy is performed near or at the end of EBRT. If most or all of the EBRT is to be given before brachytherapy, two, or even three, HDR fractions may be delivered per week to avoid unnecessarily protracting the

Figure 58-15 Magnetic resonance (**A** and **B**) versus computed tomography (**C** and **D**) axial and sagittal views of an intracavitary tandem and ring insertion for HDR afterloading brachytherapy. The source dwell positions selected for "loading" include those in the intrauterine tandem, as well as the lateral positions in the ring corresponding to the lateral vaginal fornices, thereby mimicking the dosimetry distribution of tandem and ovoids. Computerized brachytherapy or magnetic resonance imaging dosimetry allows visualization of dose in the traditional planes of calculation (coronal, sagittal, and transverse) but also permits three-dimensional representation of dose distribution that may be exploited to conform better to unusual tumor geometries.

overall treatment time (which should generally not exceed 8 weeks).[292] EBRT can be interdigitated with HDR brachytherapy; however, on days in which HDR brachytherapy is performed, EBRT to an overlapping treatment volume must not be given.

The literature describes a wide range of sedation methods used during the administration of HDR brachytherapy, including general, spinal, oral, or intravenous conscious sedation, which involves administration of intravenous midazolam and fentanyl by a trained nurse. To accommodate conscious sedation in the radiation oncology clinic, the patient must at least be continuously monitored by pulse oximetry and blood pressure measurements. The physician and nurse must be certified in conscious sedation procedures, be up to date on cardiopulmonary resuscitation measures, and have ready access to a resuscitation cart.[293] After review of an MRI if available, the first HDR insertion in each patient may be facilitated with transabdominal ultrasound guidance for placement of the intrauterine tandem. If the endocervical card is difficult to negotiate for insertion of the tandem, an intrauterine Smit sleeve may be placed at the first implant to facilitate subsequent applications. When available, an MRI or CT performed after insertion can allow assessment of applicator position in 3D, contouring of the normal tissues and tumor, and dose optimization off these critical tissues. A contouring atlas is available at www.nrgoncology.org/Resources/Contouring-Atlases/GYN-Cervical-Brachytherapy.[293a]

At present, most standard HDR loading schemes attempt to recapitulate the familiar and symmetric "pear-shaped" dose distribution typically used in LDR brachytherapy. This isodose distribution can be obtained by designating a series of dose points surrounding the tandem and colpostat and using the dosimetry program to calculate source dwell times in each source location to create the desired dose distribution (inverse planning). After creating a standard plan, this plan should be "optimized" to allow sculpting of the dose away from normal tissues and to optimize coverage of the CTV as seen on CT or MR. The physician may specify the relative weight of each selected dwell position in the brachytherapy apparatus, somewhat analogous to the loading of individual sources in an LDR system. Most HDR practitioners use tandem and ovoids that are based on the LDR Fletcher-Suit-Delclos applicator. Others, however, favor a tandem and ring system that has the advantage of having fixed geometry and may be faster to insert (Figure 58-15).

As with LDR, practitioners of HDR must be well trained and sufficiently experienced in the system of brachytherapy they ultimately choose to use. Extensive international efforts in 3D image-guided and adaptive brachytherapy recommend exerting caution to maintain the central symmetry of a classical pear-shaped distribution inherent in the point A system but with a gentle shift to a more conformal and often asymmetric dose distribution biased toward residual tumor volume and away from normal tissues. A prospective trial of 705 patients with cervical cancer, of whom a subset received chemoRT followed by either plain film or 3D (mainly CT) image-based PDR brachytherapy. Patients treated chemoRT with CT image-based brachytherapy had a 20% reduction in toxicity, 5% improvement in local control, and 9% increase in OS.[294] CT imaging can help in delineating adjacent organs at risk and suffices to treat tumor target volumes in patients that do not have or have minimal parametrial extension.[130] MRI-based brachytherapy is preferable for defining large tumor target volumes, particularly

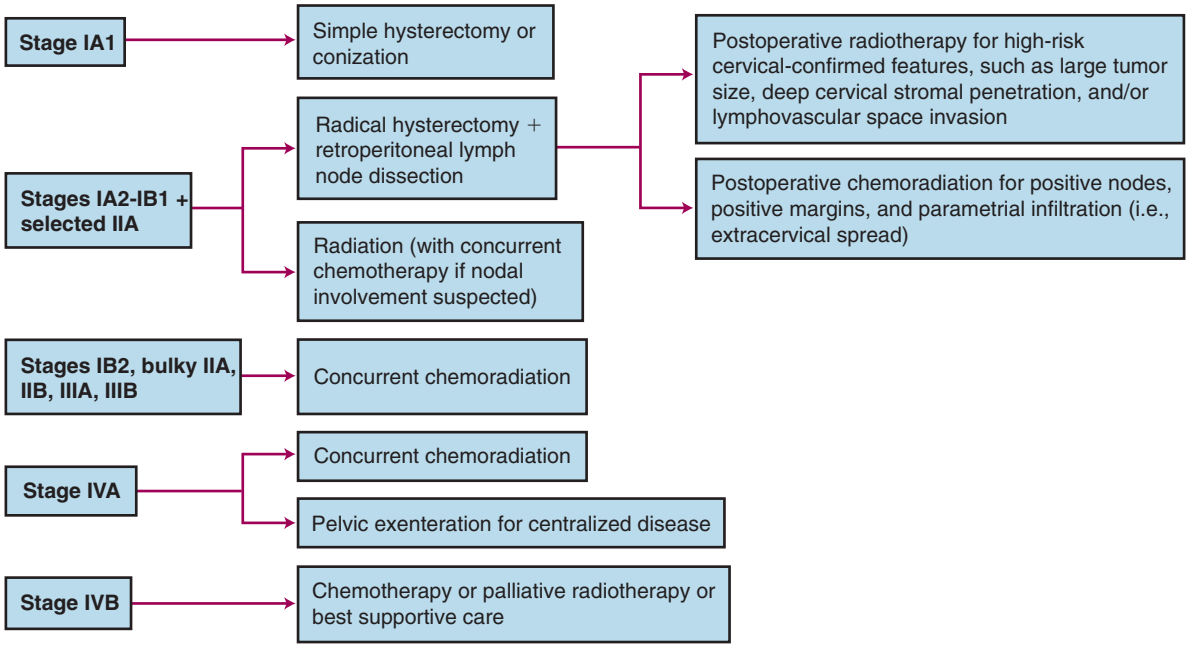
in patients with large residual disease after chemoRT, those with adjacent organ invasion, or those with parametrial extension, where the discrepancy between CT and MRI may be greatest.[130,289,295] It has been suggested that MRI image-guided brachytherapy allows customization that decreases the dose to adjacent organs at risk when treating small tumors, while permitting dose escalation in larger tumors to improve local control.[131,132,296] To further tailor the brachytherapy dose, investigators have developed an applicator that combines a tandem and ring or ovoids with templated parametrial interstitial needles and have reported enhanced and effective brachytherapy coverage with dose escalation of asymmetric, bulky tumors.[297]

Although it is intriguing, the use of image-guided brachytherapy remains to be standardized and validated on a wide scale; this forms the basis for the ongoing Int**E**rnational study on **M**RI-guided **BR**achytherapy in locally **A**dvanced **CE**rvical cancer (EMBRACE) trial.[296] Interobserver reproducibility of target definitions and normal tissues[298] to published principles (such as the GEC-ESTRO guidelines)[295] and multiinstitutional assessment of tumor control and complication rates will be evaluated. A clear danger would be underestimation of residual tumor volume for brachytherapy planning. Also of concern is that strict adherence to proposed dose volume constraints for organs at risk may result in tumor underdosage compared with that achieved with conventional dosing. Furthermore, there remain unanswered the issues of resource utilization and whether multiple MRI scans and complex planning are feasible for the majority of patients with cervical cancer. A survey of practice patterns by members of the American Brachytherapy Society showed that the numbers of centers in the United States using MRI-based brachytherapy is increasing (from 2% to 23%). Although the majority of physicians used CT postimplantation imaging rather than plain films for visualizing the gynecologic brachytherapy apparatus, most (76%) still prescribe to point A alone, indicating the need for further development and experience with 3D image-guided brachytherapy dosimetry.[299]

Interstitial Brachytherapy

Interstitial brachytherapy has long been used to treat patients with massive volume residual disease, extensive vaginal involvement, adjacent organ invasion, or vaginal disease recurrence after hysterectomy, to encompass all areas of involvement. Several groups have advocated a broader role for interstitial irradiation by reporting on the use of large interstitial implants, usually guided by a perineal template, for patients with a variety of clinical presentations, including poor anatomy, bulky disease, or extensive involvement in the parametrium or pelvic wall.[285] Reports of this technique report high local control rates[300-302] (see Chapter 15, Brachytherapy). It is critical to place a tandem with the interstitial implant, rather than just needles alone, in cases with an intact uterus.[303] However, a review of 1992 to 1994 practice patterns from the Patterns of Care Study indicates that less than 6% of patients in the United States are treated with interstitial brachytherapy. Comparisons across series are rendered difficult by patient selection and the inherent case individualization in technique and dosimetry.

To visualize the tumor, image guidance should be considered, using either iterative CT or MR in a CT or MR simulator or procedure room with the patient under general or epidural anesthesia.[237] An alternative is laparoscopic guidance in the operating room. This decreases the risk of needles entering the bowel. Excellent results have been obtained with the image-guided approach.[237] Either LDR iridium-192 (^{192}Ir) may be used, or HDR ^{192}Ir; in some centers the patient treated twice a day until completion, while kept in the hospital under patient-controlled anelgeesia when feasible, whereas at Washington University this procedure may be performed as an outpatient.[292,303a]



Normal Tissue Effects of Irradiation

An appreciation of the tolerance of normal tissues to irradiation is needed to determine optimal treatment doses. Experience suggests that the upper third of the vaginal mucosa can tolerate radiation doses as high as 120 Gy to 140 Gy, whereas the lower two thirds usually should not receive more than 80 Gy to 85 Gy. Most institutions do not exceed 75 Gy to 80 Gy (combined EBRT and LDR intracavitary dose) to the ICRU bladder reference point and 70 Gy to 75 Gy to the ICRU rectal point, based on orthogonal plain film dosimetry.[304] These reference doses should be used only as general guidelines, however. It has long been recognized, using CT-based dosimetry, that small volumes of rectum and bladder routinely receive much higher doses than those calculated from orthogonal films.[305] Also, concern about reference dose limits should always be balanced against the need to deliver a tumoricidal dose to the cancer.

Historical reports of severe late normal complications, usually defined as injury to the bladder, rectum, or small bowel requiring hospitalization or surgical intervention, typically range from 5% to 10% using crude estimates, but they may be higher using actuarial calculations.[105,306] Complications are related to the presenting stage and volume of disease, as well as to the dose delivered to the individual normal tissues. The severe complications occur in the first 3 years to 5 years after completion of RT, but there remains a small but continuous added risk thereafter.[306] Smoking during RT has been associated with a significantly higher risk of late complications.[155] Most reports of late morbidity have focused on severe gastrointestinal and genitourinary toxicities; only recently have rigorous efforts been made to monitor for less severe sequelae that, although not requiring surgery or extensive medical care, still have an impact on patients' quality of life. Other late effects, such as pelvic insufficiency fracture, vaginal stenosis, lymphedema, and neuropathy, are now recognized as important consequences.[307]

The recent use of concurrent chemoRT has been clearly shown to increase acute toxicities, especially with respect to hematologic and gastrointestinal function, compared with RT alone, but although there does not appear to be a coincident increase in late morbidity, accurate long-term follow up data are scant.[308] Unfortunately, most prospective clinical trials have based much of their toxicity assessment on the NCI common toxicity criteria scales, which favor acute effects reporting. Newer trials that emphasize late effects and employ validated quality-of-life assessment tools will give us much needed and useful information.

Radiobiology principles may predict an unacceptable complication rate for patients treated with curative HDR brachytherapy if the rectum and bladder receive the same dose as point A. With careful retraction and packing, however, the doses to these normal tissues can usually be substantially reduced, and studies generally have not demonstrated an increased complication rate when the dose of HDR therapy is adequately fractioned.[273,277] As with LDR brachytherapy, careful technique and the expertise of the brachytherapist may be as important as any other factor. These parameters are difficult to evaluate. Studies have suggested that the complication rates from HDR treatment

Notes:
1. Concurrent chemotherapy may be weekly cisplatin, or cisplatin combined with 5-FU every 3 to 4 weeks
2. Brachytherapy is a critical component of radiotherapy for intact cervix cancer

Figure 58-16 Treatment algorithm for cervical cancer.

of cervical cancer tend to decrease with increasing institutional experience.[309-311]

TREATMENT ALGORITHM, CONCLUSIONS, AND FUTURE POSSIBILITIES

Although cytologic screening programs have made it possible to prevent most invasive cervical cancers, and the promising development of HPV vaccines may lead to primary prevention, cervical cancer remains a major public health problem worldwide.

Both radical hysterectomy and RT achieve high cure rates for patients with stage IB1 disease (Treatment Algorithm, Figure 58-16). The rates of major toxicity from the two treatments are similar, but the types of side effects differ. Surgery tends to be the preferred treatment for young women with small squamous cell carcinomas or adenocarcinomas to avoid radiation-related ovarian relapse and to minimize the risk of sexual dysfunction.

Aggressive radiation therapy, including a combination of EBRT and brachytherapy, given concurrently with cisplatin-based chemotherapy, is now the primary treatment of choice in the management of bulky and locoregionally advanced disease. Irradiation remains the most active single modality for the treatment of cervical cancer not amenable to surgical resection or sterilization. Improvements in RT targeting and delivery are being realized by advances in imaging modalities, including PET scanning, careful conformal radiation treatment planning, and appropriate incorporation of brachytherapy. Current efforts in image-guided RT, including brachytherapy, may eventually provide confirmation that such techniques reduce toxicity or allow for appropriate tumor-directed dose escalation that can improve tumor control and cure.

Adjuvant hysterectomy has not been shown to improve the outcome of patients treated with radiation therapy for stage IB2 disease if adequate doses of RT are delivered. Radical RT or chemoRT is also preferred over a combination of radical hysterectomy and postoperative RT because the increased cost and complications of combined treatment are not justified by any significant improvement in local control or survival rates. Although treatment is successful in most primary cervical cancer cases, pelvic disease recurrence continues to be an important problem, particularly for patients who present with extensive locoregional disease. Recent studies have emphasized the influence of radiation dose, volume, fractionation, and treatment time on locoregional control and survival rates for patients with locally advanced disease.

The present focus on improving outcomes in bulky and locoregionally advanced cervical cancer is related to attempts to identify promising systemic agents such as antiangiogenic and antiepidermal growth factor receptor agents to add to the current standard of concurrent cisplatin and radiotherapy and to use for patients with locally advanced, locoregionally recurrent, or metastatic disease not amenable to definitive surgery, irradiation, or chemoRT.

CHAPTER

59 Endometrial Cancer

Carien L. Creutzberg and Gini F. Fleming

INCIDENCE

Endometrial cancer is the most common gynecologic malignancy, and according to the Surveillance, Epidemiology and End Results (SEER) statistics for 2006 to 2010 it is the fourth-most common cancer in women, with an age-adjusted incidence rate in the United States of 24.3 cases per 100,000 women per year.

The estimated incidence for U.S. women in 2015 was 54,870 cases. The age-adjusted mortality rate is 4.3 deaths per 100,000 women per year, with an estimated 10,170 deaths in 2015.

BIOLOGIC CHARACTERISTICS

Two prototypes of endometrial carcinoma have been distinguished: type I, which is associated with estrogen and has a favorable prognosis, and type 2, which is unrelated to estrogen, is more often nonendometrioid, and has an inferior outcome.

More than 75% of endometrial cancers are endometrioid carcinomas, whereas 5% to 10% are serous, 1% to 5% clear cell, and 1% to 3% mucinous carcinomas. Up to 5% are other histologies, including uterine sarcomas (i.e., carcinosarcoma, leiomyosarcoma, and endometrial stromal sarcoma).

Risk factors for worse outcomes include tumor stage, histologic cell type, tumor grade, depth of myometrial invasion, lymphovascular space invasion, lymph node metastases, and the patient age.

STAGING EVALUATION

Evaluation should include the patient's history and physical examination, including vaginal inspection and bimanual pelvic examination, endometrial biopsy or D and C, chest radiography, complete blood cell count, and chemistries. The International Federation of Gynecology and Obstetrics (FIGO) staging is based on the surgical and pathology findings.

Computed tomography (CT) or magnetic resonance imaging (MRI) of the abdomen and pelvis is indicated for locally advanced disease and patients with medically inoperable disease. Positron emission tomography/computed tomography (PET/CT) labeled with 18F-fluorodeoxyglucose (^{18}FDG) may be a promising method for the presurgical evaluation of pelvic node metastases and for evaluation of relapse during follow-up.

PRIMARY THERAPY AND RESULTS

Primary therapy is surgical including abdominal hysterectomy and bilateral salpingo-oophorectomy. The surgery may be accomplished by laparotomy, laparoscopy, or robot.

The role of lymphadenectomy remains a subject of controversy. It is used primarily for staging purposes and to tailor adjuvant therapy. It may have therapeutic value for grade-3 cancers, unfavorable histologic types, and advanced disease; however, no survival benefit has been seen in Phase III trials.

The 5-year overall survival (OS) rate for women with endometrial carcinoma is 80% to 90% for patients with stage I endometrial carcinoma, 60% to 80% for stage II, and widely divergent for stage III (30% to 80%), because of the diverse disease extent for tumors classified as FIGO stage III.

Primary radiation therapy for medically inoperable patients provides 5-year OS of 50% to 85% and local control rates of 70% to 90% for stage I disease.

ADJUVANT THERAPY

Radiation therapy can significantly improve local control and disease-free survival (DFS) for patients with stage I disease, but it confers no OS advantage. For "intermediate-risk disease," the indications for radiation therapy are tailored to prognostic factors. Patients with grade-3 tumors with outer 50% myometrial invasion, advanced age, or lymphovascular space invasion should be considered for adjuvant pelvic irradiation. Brachytherapy alone may be considered for grade-1 or grade-2 disease with outer 50% myometrial invasion, and for grade-3 or unfavorable histologies with no or inner 50% myometrial invasion.

Adjuvant therapy is not indicated for treating low-risk disease (i.e., FIGO 2009 stage IA, grades 1 to 2 endometrioid carcinoma).

Pelvic irradiation is indicated for high-risk and locally advanced disease. Adjuvant chemotherapy, concurrent chemoradiation, or sequential irradiation and chemotherapy should be considered, preferably within the scope of clinical trials because the utility of these approaches although widely used, is still unproven.

LOCALLY ADVANCED DISEASE

Optimal treatment for patients with locally advanced pelvic disease has not been defined. Radiation may proceed or follow surgical attempts to complete hysterectomy or "debulk disease." These patients should be considered for clinical trials of chemotherapy or concurrent chemoradiation or innovative biologic agents.

Gross residual disease should be considered for palliative treatment.

PALLIATION

Metastatic disease or nonresectable local disease can be treated with chemotherapy or hormonal therapy. Targeted agents are currently being investigated in clinical trials.

Endometrial cancers are highly responsive to irradiation. Therefore, palliative irradiation should be offered to symptomatic patients because it provides excellent relief of symptoms, such as blood loss, vaginal discharge, pain and edema caused by local disease or lymphadenopathy, and symptoms from distant metastases, such as pain caused by bone involvement or symptomatic brain metastases.

Endometrial carcinoma is the most frequent gynecologic malignancy diagnosed in the United States and European countries, and it is the fifth-most common cancer in women. Because most patients present with early-stage disease, their prognosis is usually favorable. The relative 5-year survival rate is 82.8% for all patients. Patients with disease confined to the uterus have a 5-year relative survival rate of 95.3%, compared with 67.5% for those with regional involvement.[1]

Even after the publication of multiple randomized trials, controversies in the management of stage I endometrial carcinoma remain. The optimal extent of surgery, especially the role of pelvic and paraaortic lymphadenectomy, is one of these issues. The indications for external beam pelvic irradiation and the use of brachytherapy and of chemotherapy and combinations thereof, are also a source of dispute. Trials investigating these issues are being conducted.

Despite the favorable outcome for most patients, there remain patients with advanced disease or unfavorable histologic subtypes who have poor prognoses. The optimal treatment for these patients is the challenge for current research, including studies of full staging surgery, sentinel node biopsy, and appropriate systemic adjuvant therapies, such as concurrent and adjuvant chemotherapy or novel biologic agents with or without pelvic radiation therapy or brachytherapy. Clinical and basic research continues to investigate the biology, especially of nonendometrioid cancers and to search for new molecular markers and targeted therapies, including biologic agents.

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

The incidence of endometrial cancer in the United States is 24.6 cases per 100,000 women per year, and rates for new endometrial cancer cases have been rising on average 1.1% each year over the last 10 years whereas death rates have increased by 0.4% in the same period. In 2015, there were an estimated 610,804 women living with endometrial cancer.[1] The U.S. incidence rates are among the highest in the world. Incidence rates are especially high in developed countries and have been rising as a result of aging of the population and increased obesity rates. The American Cancer Society estimates that a total of 54,870 new cancers of the uterus diagnosed in 2015.[1a] This is based on all women; because 20% to 30% of women in the United States have had a hysterectomy by age 50, rates are even higher when only women with a uterus are considered.[1a] European countries report age-standardized incidence rates ranging from 12 to 20 cases per 100,000 women.[2,3] The estimated incidence of 54,870 new uterine cancers in 2015 represented 3% of all cancers, and 6.1% of the estimated 805,500 new female malignancies. Endometrial cancer is the most common gynecologic malignancy and the fourth most common cancer in women. The mortality rate for uterine cancer in the United States is 4.3 deaths per 100,000 women per year, and the estimate for 2015 is 10,170 deaths, which is 1.4% of all cancer deaths, 3.0% of cancer deaths among women, and 29% of all deaths from gynecologic malignancies. The mortality rate decreased from 5.3 to 4.1 deaths per 100,000 women between 1973 and 1995 and has remained more or less stable since 1995.

Uterine cancer is typically a cancer of postmenopausal women between 55 and 85 years old. Incidence rates exceed 80 per 100,000 women in those aged 60 to 80 with a peak incidence of 95 per 100,000 in women aged 65 to 69.[1] Less than 5% of the patients are younger than age 40 years. The median age at diagnosis is 62, and at death 71 years. Uterine sarcomas also manifest primarily in the postmenopausal population. Leiomyosarcomas occur at an earlier age than carcinosarcomas.[4]

Etiology

The cause of the common type of endometrial cancer, endometrioid carcinoma, is related to exposure of the endometrium to unopposed increased estrogens both exogenous or endogenous.[5] Early menarche, late menopause, obesity, nulliparity, infertility, and estrogen-producing ovarian tumors are classically associated with the development of endometrial cancer. In obese women, elevated estrogen levels caused by increased peripheral conversion in fat of androstenedione may be the underlying mechanism for the increased risk. Endometrial cancer has also been associated with conditions such as hypertension and diabetes, but it is not clear whether these are true independent risk factors or related to obesity.[6,7] Unopposed exogenous estrogen levels have a strong association with the risk of endometrial cancer.[8] The use of tamoxifen for the prevention or treatment of breast cancer has been documented to statistically increase the risk of subsequent endometrial cancer.[9,10] Despite its antiestrogenic effects on breast tissue, tamoxifen has some weak estrogenic effects on other organs of the body, including the uterus, which accounts for this risk.

Hyperplasia with atypia is considered a premalignant phase of endometrioid carcinoma and has a similar origin[11]; when endometrial biopsies confirming complex hyperplasia with atypia, there is a 30% to 40% risk of subsequent development of endometrial cancer.

An increased risk associated with a family history of endometrial cancer has been observed, especially in women younger than 50 years, but less than 1% of all endometrial cancers were attributable to familial and potentially genetic factors.[12-14] Familial clustering of ovarian and endometrial cancers specific to the endometrioid morphology has been reported.[15] The risk of developing other malignancies, especially of the colon and breast, is increased after the diagnosis of endometrial carcinoma.[16-18] Women with mutations in the *MLH1, MSH2,* or *MSH6* genes, which are responsible for the hereditary nonpolyposis colorectal cancer (HNPCC) syndrome, are at increased risk for developing endometrial cancer.[19] HNPCC, or Lynch syndrome, is classified based on the presence or absence of tumors other than colorectal cancers. Patients with HNPCC syndrome type II have a high risk of endometrial cancer, second only to that of colorectal cancers.[20,21] These women have a 20% risk of developing endometrial cancer before 50 years of age, which increases to 60% by age 60 years.[22] Different screening policies for Lynch syndrome in young patients with endometrial cancer have been evaluated, based on microsatellite instability (MSI) or immunohistochemisty (IHC) of tumor specimens for mismatch repair protein expression, indicated either by age younger than 50 or 60 years, or by age and a first-degree relative having a Lynch-associated cancer, or by the Amsterdam criteria. Of these, IHC triage of women with endometrial cancer having at least one first-degree relative with a Lynch-associated cancer seemed most cost-effective.[23,24] Germline DNA mutation testing should be offered to those patients whose tumor shows loss-of-function of MMR protein(s) when analyzed for MSI or by IHC. MSI and IHC have a sensitivity of 80% to 100% and specificity of 60% to 80% for detecting a mutation in an MMR gene, and false-positive tumor test results because of somatic hypermethylation of the MLH1 gene promoter should be excluded.[25]

PREVENTION AND EARLY DETECTION

No measures that may contribute to prevention of endometrial cancer other than avoiding unopposed estrogen use and

avoiding obesity have been identified. Prophylactic hysterectomy is recommended in patients with known hyperplasia with atypia,[26] and prophylactic hysterectomy and oophorectomy is advised in HNPCC type II gene carriers, for whom the risk of concurrent or subsequent endometrial cancer is substantial.[27]

Screening for endometrial cancer has not been performed in the general population. The early symptoms and favorable prognosis of this disease preclude efficacy of population screening.[28] Vaginal ultrasound studies alone have not been found effective for screening purposes.[29] Prompt analysis of every patient with postmenopausal or abnormal vaginal bleeding with vaginal ultrasound and endometrial biopsy is indicated.

Screening of patients taking tamoxifen has been suggested, but the characteristic endometrial hyperplasia on ultrasound leads to high false-positive rates and subsequent frequent invasive diagnostic procedures in asymptomatic tamoxifen users.[30,31] In a prospective ultrasound screening study of 247 tamoxifen users, it was shown that of 52 asymptomatic patients with a thickened endometrium, most had an atrophic endometrium and only 1 had cancer, whereas in 2 of 20 patients with vaginal bleeding, endometrial cancer was diagnosed.[30] The study authors concluded that routine ultrasound screening is not indicated in asymptomatic women using tamoxifen, but that all women with abnormal bleeding should be evaluated.

Screening programs of gene carriers for the HNPCC syndrome not electing prophylactic surgery have shown increased efficacy when using annual endometrial biopsy plus vaginal ultrasonography.[32] An evaluation of gynecologic surveillance among 175 mutation carriers (503 surveillance visits during 759 person-years at risk) using vaginal ultrasonography and endometrial biopsy at 94% and 74%, respectively, of the visits showed that 11 of 14 endometrial cancer cases were diagnosed by surveillance and 8 by endometrial biopsies. Vaginal ultrasonography indicated only four patients with endometrial cancer and missed 6 other cases. Endometrial biopsy detected 14 additional cases of potentially premalignant hyperplasia. The stage distribution and survival tended to be more favorable, although not statistically so, in the 14 cases of endometrial cancer in the surveillance group (no deaths) than in a group of 83 symptomatic mutation carriers of whom 6 died of endometrial cancer.[33]

PATHOLOGY AND PATHWAYS OF SPREAD

Pathology

Almost all uterine epithelial cancers are adenocarcinomas. The World Health Organization (WHO) has described several subtypes (eBox 59-1). The most common type of endometrial adenocarcinoma is the endometrioid type, which accounts for 75% of cases.[34] Other nonendometrioid histologic types include serous (5% to 10%), mucinous (1% to 3%), and clear cell (1% to 5%) carcinomas. Uterine mesenchymal and mixed tumors, usually called the *uterine sarcomas*, include leiomyosarcoma, endometrial stromal sarcoma, and carcinosarcoma (or malignant mixed müllerian tumor). The WHO classification of mesenchymal and mixed tumors of the uterus is summarized in eBox 59-2. Carcinosarcoma is the most common type of uterine mesenchymal and mixed tumor (45%), followed by leiomyosarcoma (40%) and endometrial stromal sarcoma (10% to 15%). Carcinosarcomas are composed of malignant epithelial and stromal components; because of this biphasic appearance, their origin has long been debated. Based on molecular genetic analysis, the current opinion is that these cancers should be considered metaplastic carcinomas. Clinical data support this view that carcinosarcomas should be considered high-risk carcinomas, particularly because the epithelial component is usually of high grade.[35,36]

Nonendometrioid histologic types have a poorer prognosis. Serous and clear cell carcinomas are uniformly identified in this category. Serous adenocarcinoma has previously been called previously called *uterine papillary serous carcinoma* (UPSC). It is histologically similar to its ovarian counterpart. Uterine UPSC, first described in 1982, was found to have a higher rate of peritoneal failure similar to that of ovarian cancer.[37] This entity can be confused with the papillary villoglandular, a subtype of endometrioid adenocarcinoma with a significantly more favorable prognosis. Serous carcinoma is frequently diagnosed at a higher stage than endometrioid adenocarcinomas. Clear cell carcinoma has also been reported to have a poor prognosis, with more advanced disease at diagnosis.[38] Early-stage serous and clear cell carcinomas have been shown in some analyses to have outcomes similar to grade-3 endometrioid carcinoma, although recurrence rates for serous cancers were highest.[39-41]

Adenosquamous cell carcinoma has been suggested by some investigators to be another poor-prognosis histologic subtype,[38,42] but others think the prognosis of these patients is no different from that for the typical endometrioid adenocarcinoma.[43,44] Zaino et al evaluated a large population of patients who were part of a Gynecologic Oncology Group (GOG) study and found a parallel between the glandular grade and the degree of differentiation in the squamous component. It was subsequently suggested that the name of this histologic subtype should reflect the lack of importance of this feature by calling it adenocarcinoma with squamous differentiation.[43]

Endometrial hyperplasia with atypia frequently precedes endometrioid endometrial carcinoma. Endometrial intraepithelial carcinoma has been associated with the development of nonendometrioid carcinoma. The International Society of Gynecological Pathologists has identified two architectural forms of endometrial hyperplasia, simple and complex. Where marked architectural abnormalities are displayed it is designated as *complex hyperplasia;* lesions with a lesser degree of architectural abnormalities are designated *simple hyperplasia*. Atypical nuclear changes can be associated with the simple or complex types and are regarded separately from hyperplasia that is not displaying atypia. Progression of simple hyperplasia without atypia to endometrioid carcinoma is rare (<2%), whereas progression to carcinoma occurs in 30% to 40% of the patients with simple and complex hyperplasia with atypia.[11,45] The risk of subsequent endometrial cancer warrants hysterectomy in patients with atypical hyperplasia.

Not all endometrial cancers arise in a setting of atypical hyperplasia. Nonendometrioid cancers, especially serous carcinomas, appear to represent malignant transformation of atrophic endometrium, which is found in the adjacent endometrium of up to 90% of serous carcinomas.[46]

Pathways of Spread

Most endometrial cancers remain confined to the uterine body for a long time. The initial spread is by local extension along the endometrial surface. Longitudinal growth may result in involvement of the lower uterine segment and the cervix, initially involving the endocervical glands and later spreading by cervical stromal invasion. The tumor can also extend along the cornua to the fallopian tubes. Radial growth results in myometrial invasion, of varying depth and ultimately penetrating to the subserosa and serosa. Two patterns of myometrial invasion have been described: an expansive growth pattern with pushing borders and an infiltrating growth

pattern with cancer cells and nests penetrating the myometrium haphazardly.[47] The infiltrating growth pattern is associated with frequent lymphovascular space invasion (LVSI) and early lymphatic spread. Foci of adenomyosis may be seen deep within the myometrium. The prognostic significance of tumor cells in adenomyosis is unclear. Tumor cells may grow only superficially from these foci located deep in the myometrium. They may not carry the same worse prognosis as those penetrating directly from the endometrium. After the tumor breaches the serosa, transperitoneal dissemination can occur, with a pattern resembling that of ovarian cancer. Occasionally, after extensive penetration of the myometrium or the cervix, direct invasion of the bladder or the rectum may occur, or the tumor may involve the pelvic soft tissues and continue to reach the pelvic sidewall. Peritoneal seeding can result from growth through the serosa or from transtubal spillage of tumor cells into the peritoneal cavity.

As the tumor invades the myometrium more extensively, the risk of lymph node metastasis is higher.[48,49] The endometrium has few lymphatics, but after the tumor penetrates the myometrium and especially when it reaches the lymphatic-rich subserosa, spread by lymphatic invasion is common. LVSI as diagnosed in the hysterectomy specimen is thus an early marker of disease spread.[50] Lymphatics from the uterine fundus can drain directly to the paraaortic lymph nodes. Typically, the internal and external iliac lymph node groups are the first echelon of spread although isolated para-aortic nodal involvement also occurs. Sentinel node detection studies[51-53] have shown the sentinel nodes to be located in the obturator, external iliac, and paraaortic regions. Lymphatic spread is also believed to be responsible for involvement of the vagina and for isolated adnexal involvement.

Overall, about 11% of patients with clinical stage I and occult stage II endometrial carcinoma and 5% to 7% of patients with tumors confined to the uterus have pelvic or paraaortic lymph node involvement.[48,54] The extent of myometrial invasion correlates strongly with the histologic grade of the tumor, and the depth of invasion and tumor grade correlate with the risk of lymphatic involvement for endometrioid tumors. For serous tumors depth of invasion is not well-correlated with risk of lymph node involvement; one older series of 50 serous cancers, of which 66% were pure serous cancers and 72% had extrauterine spread, showed a 36% rate of lymph node involvement for tumors with no myometrial invasion.[55] The risk of intraabdominal dissemination is also higher in patients with clear cell carcinomas. Abdominal involvement of endometrioid carcinoma is associated with other risk factors, such as lymph node involvement, adnexal involvement, and LVSI.

Hematogenous spread is uncommon in endometrial cancer, occurring mainly with high-grade tumors, unfavorable histologies, or advanced stages. The most common metastatic sites include the lungs, liver, and bones. Distant nodal metastases (i.e., supraclavicular or inguinal) result from extensive lymphatic involvement or from hematogenous spread.[56]

BIOLOGIC CHARACTERISTICS AND PROGNOSTIC FACTORS

Biologic Features

Two different types of endometrial carcinoma have been identified and described first by Bokhman in 1983.[57] Type I tumors are estrogen related, are often preceded by hyperplasia, and are typically low-grade endometrioid histology. They usually develop in an estrogen-rich environment (e.g., obesity, premenopausal and perimenopausal phases), and they have a good prognosis. Type II tumors are unrelated to estrogen and develop in atrophic endometrium, presumably preceded by endometrial intraepithelial carcinoma, and they are more often serous and clear cell carcinomas. Patients with type II tumors are older and postmenopausal and have high-grade, deeply invasive tumors with an unfavorable prognosis. A summary of the differences between these two groups is shown in Table 59-1. The genetic abnormalities involved in the carcinogenesis of endometrial cancer are different for type I and II carcinomas.

TABLE 59-1 Predominant Features of Types I and II Endometrial Cancer

Characteristic	Type I	Type II
Clinicopathologic Features		
Estrogen relation	Yes	No
Precursor lesion	Hyperplasia	Intraepithelial carcinoma
Age	Younger	Older
Histologic type	Endometrioid	Nonendometrioid
Grade	1 or 2	3
Stage	1	More advanced
Prognosis	Good	Poor
Genetic Features		
Ploidy	Diploid	Aneuploid
TP53 mutation	10%-20% (late event)	60%-90% (early event)
PTEN inactivation	35%-50%	5%-10%
ERBB2 protein overexpression	10%-15%	20%-25% (serous: 60%)
EGFR overexpression	10%-30%	60%-80%
KRAS mutation	15%-30%	0%-5%
Microsatellite instability	20%-30%	0%-5%

Specific molecular alterations have been found in type I and II endometrial cancers, supporting and refining the clinicopathologic distinction by molecular data, such as loss of *PTEN;* mutations of *TP53, KRAS,* and *PIK3CA;* MSI; and overexpression of ERBB2, epidermal growth factor receptor (EGFR), and P16.[58,59] In type II cancers, *TP53* mutations have been found in up to 90% of cases (invasive and intraepithelial carcinomas), suggesting it to be an early event in carcinogenesis. ERBB2 protein overexpression has been reported in a significant proportion of serous carcinomas, and about 20% to 30% of serous carcinomas are found to have amplification of the *ERBB2* gene. The ERBB2 gene product, similar to EGFR, is a transmembrane receptor protein that plays an important role in the ERBB signaling network that is responsible for regulating cell growth and differentiation. ERBB2 overexpression is associated with aggressive biologic behavior and poor survival. The Cancer Genome Atlas Project (CGA) has provided a comprehensive genetic characterization of endometrial cancer and confirmed previous findings that *PTEN* mutations are uncommon in serous tumors and common in low-grade endometrioid cases; that *TP53* mutations are common in high-grade and serous cancers, whereas *PIK3CA* mutations are distributed across histology and grade. These alternatives and others offer the opportunity for exploration of biologic targeting agents specific to the abnormality.

No specific abnormalities have been associated with type I cancers in general, which suggests that type I is a heterogeneous group of tumors with different combinations of abnormalities. *TP53* mutations have been found in 10% to 20% of

Targeted therapy using trastuzumab, a monoclonal antibody to ERBB2, is theoretically one such treatment strategy.[60] However, the one prospective clinical trial testing single-agent trastuzumab in heavily pretreated endometrial carcinomas with ERBB2 overexpression or amplification reported no major responses.[61] A randomized trial of carboplatin and paclitaxel with or without trastuzumab in women with HER2-positive, platinum-sensitive endometrial cancer is ongoing. EGFR overexpression occurs in 60% to 80% of type II cancers, and it correlates with advanced-stage disease and poor prognosis.[62] Targeted therapy with anti-EGFR agents including tyrosine kinase inhibitors such as gefitinib, lapatinib, and erlotinib as well as monoclonal antibodies such as cetuximab has been investigated in Phase II studies.[63,64] Results thus far have been modest. The National Cancer Institute of Canada (NCI Canada) reported the best results with a 12.5% response rate to single-agent erlotinib for chemotherapy-naïve tumors. There was no correlation found between response and *EGFR* gene mutations or amplification.[63] In a trial of the dual EGFR/HER2 inhibitor lapatinib (which showed a 3% response rate overall), three mutations in EGFR were identified. Two of these were not associated with response or progression-free survival, but, a newly identified mutation in exon 18, E690K, was found in the tumor of the patient with a partial response.[65]

type I cancers. Mutant TP53 protein expression has been associated with advanced stage and other adverse factors, such as grade 3, deep invasion, and poor survival.[66,67] In the recent The Cancer Genome Atlas (TCGA) analysis, 25% of high-grade endometrioid cancers cluster with serous tumors and have extensive copy number alterations, few DNA methylation changes, low estrogen receptor/progesterone receptor (ER/PR), and frequent TP53 mutations.[68] More general markers of genetic damage such as DNA aneuploidy have consistently been associated with an inferior outcome.[69,70]

PTEN is frequently altered in endometrioid endometrial carcinomas (37% to 61%) and is considered an early event in carcinogenesis. The loss of *PTEN*, with consequent activation of the phosphatidylinositol-3-kinase (PI3k)-serine/threonine-specific protein kinase (AKT)-mammalian target of rapamycin (mTOR) signaling pathway, has been found in 32% to 83% of endometrioid-type endometrial carcinomas.[71] Comutations are common; most tumors with loss of *PTEN* have mutations in PIK3CA or PIK3RA as well. TOR is the central component of a complex signaling network that regulates cell growth and proliferation and is interconnected with the PI3K/AKT signaling pathway. *PIK3CA* mutations are frequently found in association with myometrial invasion, advanced stage, and adverse prognostic factors.[72-74] Inhibition of the mTOR pathway is currently regarded as an important "druggable" target for therapy.[75] Phosphorylated mTOR overexpression has been found in both type I and II endometrial carcinomas.[76]

In vitro data have suggested that inhibiting the PI3K/AKT pathway reverses progestin resistance in endometrial cancer,[79] and attempts have been made to improve results of endocrine therapy by combining it with an mTOR inhibitor (analogous to the approved use by the Food and Drug Administration of everolimus with exemestane in patients with breast cancer). Multitargeted growth factor TKIs such as brivanib and pazopanib are also being studied.

Gene expression clusters based on high expression of mitotic genes, hormonal genes, and immunoresponsive genes have been identified. The mitotic cluster was found to contain serous and serous-like tumors; the hormonal cluster contained samples with greater ER/PR expression, and the immunoresponsive cluster contained immune activated genes, identifying endometrial cancers with distinct clinical behavior. Genomic instability increases as tumors become less differentiated, with high frequencies of chromosomal losses and gains in grade-3 and serous tumors.[68]

As listed in Table 59-2, some molecular abnormalities such as *PTEN* and *KRAS* mutations, have been associated with favorable and unfavorable outcomes.[85] Recently, L1CAM expression was identified as a promising molecular prognostic factor.[86] In most multivariate analyses, however, the prognostic significance of these molecular markers is lost in the presence of the traditional major prognostic factors: stage, grade, depth of invasion, and histologic subtype. The major promise of the molecular markers is the identification of specific targets for therapy and development of individual, effective therapeutic strategies for patients with advanced or metastatic disease.

TABLE 59-2 Prognostic Value of Genetic Abnormalities

Genetic Abnormality	Prognostic Value
Aneuploidy	Decreased survival
TP53 mutation	Decreased survival
PTEN inactivation	Conflicting data
ERBB2 overexpression	Decreased survival
EGFR overexpression	Decreased survival
KRAS mutation	Conflicting data
Microsatellite instability	No prognostic significance

Prognostic Factors

Numerous comprehensive retrospective analyses and prospective, randomized studies have identified the major clinically identifiable prognostic factors in endometrial carcinoma. These are stage, patient age, histologic cell type, tumor grade, depth of myometrial invasion, and presence of LVSI.[50,87,88] Randomized trials have confirmed the prognostic value of these factors.[89,90] In stage I endometrial cancer, grade has been found to be a major factor, with grade-3 tumors associated with a threefold to fivefold increased risk of relapse and cancer death.[91,92] In most studies, grade-2 tumors do not have significantly different outcomes compared with grade 1, and a two-tiered grading system, low risk compared with high risk has have been proposed to overcome the limited clinical value and poor reproducibility of the intermediate grade.[47,93] The specific binary grading system proposed by Lax et al is based on the proportion of solid growth, the pattern of myometrial invasion, and the presence of tumor cell necrosis.[47] A simple two-tiered system, dividing tumors into low or high risk based on the proportion of solid growth (<50% versus >50%), was shown to have superior prognostic power and greater reproducibility over the FIGO grading system.[94] Alternatively, the FIGO grading system may be used as a binary system by dividing tumors into grades 1 and 2 versus grade 3. This has been shown to have strong prognostic significance, and it has the additional advantages of being highly reproducible and familiar to practicing pathologists worldwide.[94,95]

In most studies, depth of myometrial invasion had less prognostic value than tumor grade. Deep invasion, particularly into the outer third or half of the myometrial wall is associated with increased risk of relapse and inferior outcome. A diffusely infiltrating pattern of myometrial invasion, as opposed to an expansive growth pattern with pushing borders, has been suggested to be a stronger adverse prognostic factor than the depth of invasion.[92,96] Because the effluent lymphatics and capillaries are mainly located in the subserosa, the tumor-free distance from the serosa may prove to be the strongest prognostic factor. In a multivariate analysis of 153 patients, tumor-free distance, especially when only a few mm, was found to be a highly significant predictor of relapse and death from disease, stronger than depth of invasion, and to have greater reproducibility.[97]

LVSI has been found to be a major prognostic factor that significantly and independently increases the risk of relapse, especially distant relapse.[50,90,98,99] In an analysis of 609 patients with stages I to III endometrial cancer, those with LVSI were found to have a 5-year relapse rate of 39%, in contrast to 19% for patients without LVSI ($p < 0.0001$). Even in otherwise low-risk stage I disease (defined by low grade and depth of invasion), the presence of LVSI significantly increased the risk of relapse (28% with versus 14% without LVSI). In patients with stage I disease with high-risk features, those with LVSI had a 43% relapse rate.[84]

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Clinical Manifestations

Abnormal uterine bleeding is the most common presenting sign of patients with endometrial cancer. Because blood loss is an early sign of endometrial proliferation, 75% of patients

Phase II trials using mTOR inhibitors including deforolimus, temsirolimus, and everolimus have been performed. The most promising preliminary results thus far have been reported by the NCI Canada in women with chemotherapy-naïve disease, in whom a 14% response rate to single-agent therapy with temsirolimus was observed.[77] To date, despite extensive exploration of patient samples on studies of mTOR inhibitors, no markers of activation of the PI3K/AKT signaling pathway have proven to be predictive of response to mTOR inhibitors in patients. Newer agents, including pan-PI3K inhibitors, PI3K isoform-specific inhibitors, dual PI3K/mTOR catalytic inhibitors, mTOR-specific catalytic inhibitors, and AKT inhibitors are in development. On the basis of tight interactions between the PI3K and RAS/RAF/MEK pathways,[78] combinations of agents designed to block both pathways seem of interest. The Gynecologic Oncology Group (GOG) has recently opened GOG#2290, a randomized Phase II study of the MEK inhibitor Trametinib alone or in combination with GSK2141795, an AKT inhibitor.

In a Phase II trial of everolimus compared with everolimus/letrozole in 63 patients, the response rate was 31% for everolimus/letrozole compared with 0% for everolimus alone in a similar patient population.[80] However, the GOG found no advantage to the addition of temsirolimus to the combination of megestrol acetate and tamoxifen (response rate 14%) when compared to temsirolimus alone (response rate 22%) in tumors unselected for histologic subtype or ER/PR expression.[81] Other potential targets include Fibroblast Growth Factor Receptor 2 (FGFR2)[82,83] and VEGF: Vascular Endothelial Growth Factor (VEGF).[84]

present with early-stage disease. However, only about 15% to 20% of the patients with postmenopausal bleeding are found to have endometrial cancer. Another, rather nonspecific symptom is profuse, watery discharge. In premenopausal or perimenopausal patients, the presenting symptom may be irregular blood loss or menorrhagia. It is unusual for screening cervical cytology to be the method of diagnosis, but malignant endometrial cells occasionally may be found in routine Papanicolaou (pap) smears. Normal-appearing endometrial cells in a Pap smear in woman who is postmenopausal may also be a sign of malignancy. One recent study of 1183 Pap cytology cases (739 with normal endometrial cells, 423 with atypical endometrial cells, and 21 with endometrial cancer cells in women 40 years or older) noted that significant endometrial lesions were found in 2.7% of cases with normal endometrial cells, 18.4% of cases with atypical endometrial cells, and 100% of cases endometrial cancer cells.[100] Ongoing research is evaluating DNA from Pap smears a screening test for endometrial and ovarian cancers.[101] Pain is usually absent unless there is pyometra. Patients with more advanced stages of endometrial cancer can present with abdominal symptoms, gastrointestinal symptoms, back pain, or lymphedema.

Patient Evaluation

Patient evaluation for confirmed or suspected malignancy includes a medical history and physical examination, including vaginal inspection and bimanual pelvic examination. Medical history should include the presence of risk factors associated with endometrial cancer, such as obesity, hypertension, diabetes mellitus, estrogen or tamoxifen use, nulliparity, a family history, especially of colon, endometrial, breast, or ovarian cancers, and (especially for sarcomas) prior pelvic radiotherapy.

Most patients with endometrial carcinoma have early-stage disease and do not have significant abnormalities on pelvic examination. However, a complete pelvic examination should be performed to exclude gross cervical extension, vaginal metastases, and adnexal pathology.

Outpatient procedures, such as transvaginal ultrasonography and endometrial biopsy or aspiration curettage, establish the diagnosis in more than 90% of patients suspected to have endometrial cancer. Various endometrial biopsy tools are available, such as a small Novak curette, Pipelle instrument, or Vabra aspirator, that permit the endometrial biopsy to be performed as an outpatient procedure without general anesthesia. If these procedures are not conclusive, a formal dilation and fractional curettage (D&C) should be performed, with or without hysteroscopy. Hysteroscopy allows direct visual assessment of the endocervix and the endometrial cavity and can be useful in guiding biopsy of any visible abnormality in symptomatic patients when other procedures have been nondiagnostic. Figure 59-1 presents a diagnostic algorithm for patient workup and evaluation.

Staging

After a diagnosis of malignancy is established, the preoperative evaluation and staging workup are done. Definitive staging according to the FIGO system is based on the surgical and pathology findings. In 2009, a revised FIGO staging system was published, and this has replaced the 1988 FIGO staging system.[102] Table 59-3 lists the 2009 FIGO staging and the differences between the 1988 and 2009 systems. The changes in stages IA, IB, and IC especially should be kept in mind when evaluating literature data because FIGO 1988 stages IA (no myometrial invasion) and IB (less than 50% myometrial invasion) have been grouped together in FIGO 2009 as stage IA and because FIGO 1988 stages IC (greater than 50% myometrial invasion) is IB in FIGO 2009. The previous nonsurgical (clinical) FIGO staging system continues to be used for patients not undergoing surgery.

The patient's general evaluation should include standard blood tests and a chest radiograph. Patients with endometrial

TABLE 59-3 Federation of Gynecology and Obstetrics (FIGO) 2009 Surgical Staging System for Endometrial Carcinoma[102]

Stage and Grade		Description
I		Tumor confined to the corpus uteri (and or cervical mucosa)
IA	(G1, 2, 3)	No or less than half myometrial invasion
IB	(G1, 2, 3)	More than half myometrial invasion
II	(G1, 2, 3)	Tumor invades cervical stroma but does not extend beyond the uterus*
III		Local and/or regional spread of the tumor
IIIA	(G1, 2, 3)	Tumor invades the serosa of the corpus uteri or adnexae
IIIB	(G1, 2, 3)	Vaginal or parametrial involvement
IIIC	(G1, 2, 3)	Metastasis to pelvic or paraaortic lymph nodes†
IIIC1	(G1, 2, 3)	Positive pelvic lymph nodes
IIIC2	(G1, 2, 3)	Positive paraaortic lymph nodes with or without pelvic nodes
IV		Tumor invades bladder or bowel mucosa, or distant metastasis
IVA	(G1, 2, 3)	Tumor invasion of bladder or bowel mucosa
IVB	(G1, 2, 3)	Distant metastasis, including intraabdominal metastases or inguinal lymph nodes
FIGO Histologic Grading		
G1		<5% nonsquamous or nonmorular solid growth pattern
G2		5%-50% of a nonsquamous or nonmorular solid growth pattern
G3		>50% of a nonsquamous or nonmorular solid growth pattern

**Endocervical glandular involvement should be considered stage II.*

carcinoma are often elderly and frail and may have a number of concurrent medical problems, including morbid obesity and diabetes, that influence selection of the appropriate treatment. CT and MRI are not routinely performed for patients with clinical stage I disease who will be undergoing surgery, but imaging should be done if locally advanced disease is suspected. The major limitations of CT are its unreliability in assessing myometrial invasion, especially in atrophic uteri, and the failure to detect minimal parametrial, lymph nodal, or local extrauterine invasion.[103] The greatest value of CT may be for staging in patients with clinical stage III or IV disease and in medically inoperable patients, for whom CT is useful for evaluating the size and extent of the tumor, for excluding gross extrauterine disease, and for planning of appropriate target volumes for radiation therapy. MRI using an intravenously administered contrast agent is superior to CT in determining myometrial invasion and diagnosing stage II disease.[104]

Initial studies of the potential role of FDG-PET/CT suggest a promising role for evaluation of relapse during follow-up and for presurgical evaluation of pelvic node metastases. In an analysis of PET/CT in 25 women with suspected relapse during follow-up, lesion site–based sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV), and accuracy of PET/CT were 94.7%, 99.5%, 94.7%, 99.5%, and 99.0%, respectively.[105] Other follow-up studies confirmed the efficacy of PET or PET/CT in detecting relapse both in asymptomatic and symptomatic patients, with sensitivity of 100% and specificity, PPV, NPV and accuracy of 83% to 100%.[106,107]

Although the FIGO staging system requires a pelvic lymphadenectomy, the role of lymphadenectomy and the optimal extent of lymphadenectomy (e.g., lymph node sampling, selective or complete lymphadenectomy, and pelvic and aortic lymphadenectomy and its proximal extent) are subjects of controversy, as is the question of whether lymphadenectomy is a purely diagnostic and prognostic procedure or whether therapeutic benefit can be obtained. Most commonly, lymphadenectomy is reserved for those with high-grade malignancy or with deep myometrial penetration detected at surgery.

PRIMARY THERAPY

Surgery

Surgery is the mainstay of the initial treatment of endometrial carcinoma. The standard surgical procedure has for decades been a total abdominal hysterectomy with bilateral salpingo-oophorectomy (TAH-BSO). The standard surgical approach has traditionally been laparotomy through a midline incision, which allows full exposure of the abdomen, pelvic areas, and lymphatic sites. Surgical evaluation includes thorough examination and palpation of the pelvic and abdominal organs and lymph node regions, and sampling of any suspicious sites and variably collection of ascites or peritoneal lavage fluid for cytologic evaluation.

More recently, laparoscopic and robotic techniques have been explored for clinical stage I disease and evaluated in randomized trials.[109-111] The advantages of laparoscopy are the shorter hospitalization and recovery time and decrease of surgical morbidity.[109,111,112] Disadvantages are the increased length of the operation and the learning curve involved with laparoscopic techniques.

The first randomized trials comparing laparoscopy to laparotomy were powered for morbidity and showed similar OS and relapse-free survival (RFS) rates with lower postoperative complication rates and better short-term quality of life, most notably better physical and functional well-being and body image.[109,112,116,117] The largest randomized trial, the GOG-LAP2 study, was powered to establish noninferiority of laparoscopy, the primary endpoint being noninferiority of the recurrence-free interval (defined as a maximum hazard ratio [HR] of 1.4 for laparoscopy relative to laparotomy).[110] This trial recruited 2616 patients with clinical stages I to II endometrial cancer, and at a median follow-up duration of 59 months, the estimated HR for laparoscopy relative to laparotomy was 1.14, with a 95% confidence interval (CI) upper level of 1.46. However, the actual recurrence rates were lower than anticipated, with estimated 3-year recurrence rates of 11.4% after laparoscopy compared with 10.2% after laparotomy. The estimated absolute difference in 3-year recurrence rate was only 1.14%. Estimated 5-year OS was 84.8% on both arms, and sites of first recurrence and use of postoperative adjuvant therapy (in 31% of patients) were also similar. It should be noted that 70% of patients had early-stage disease with no or superficial myometrial invasion. Only a minority had risk factors such as deep myometrial invasion, grade-3 or stage II disease.[110] The rate of conversion from laparoscopy to laparotomy was 26%, higher than in the other trials (10.8%[109] and 2.4%[112]), mostly because of the requirement on this protocol for full lymphadenectomy even in patients at low risk. Laparotomy remains preferable to laparoscopy in patients who are morbidly obese, in patients with intraabdominal adhesions, and those with more advanced disease.

In situations with gross cervical involvement (macroscopic stage II disease), a radical or modified hysterectomy can be considered, although preoperative external beam radiation therapy (EBRT) is also used. Retrospective data support the

PET/CT detected relapse in 3 patients with elevated tumor markers but negative CT findings and altered treatment in 22% of patients.[107] Diagnostic accuracy of PET/CT was evaluated among 37 patients with high-risk endometrial cancer, of whom 9 (24%) had pelvic node metastases on histopathologic analysis. Patient-based sensitivity, specificity, PPV, NPV, and accuracy of PET/CT for detection of nodal disease were 77.8%, 100.0%, 100.0%, 93.1%, and 94.4%, respectively. Nodal lesion site–based sensitivity, specificity, PPV, NPV, and accuracy of FDG-PET/CT were 66.7%, 99.4%, 90.9%, 97.2%, and 96.8%, respectively, showing that PET/CT has a high NPV and may be useful in selecting patients for lymphadenectomy.[108]

Completeness of the surgical staging procedure can upstage the disease in patients otherwise considered as having stage I disease, and the problems of stage migration and patient selection preclude definitive conclusions on the value of lymphadenectomy in the absence of randomized data. The approach to these surgical staging issues varies among gynecologists and gynecologic oncologists and among different countries. Although knowledge of nodal involvement may be useful to aid in choosing any adjuvant therapies, the low incidence in low-risk disease precludes utility in the low-risk setting. Significant lymphedema may occur with systematic node dissection. The variability in staging of patients clearly affects the reported distribution of stages in patients with endometrial cancer.

Initially, increased risks of malignant cells in the peritoneal cytology specimen[113] and vaginal cuff recurrence or port-site metastases[114] were reported with laparoscopic techniques. The importance of early occlusion of the fallopian tubes and uterine artery and avoidance of intrauterine manipulators to prevent such peritoneal spread and vaginal cuff recurrence has been stressed.[115]

TABLE 59-4 Risk Factors for Lymph Node Metastases†

Risk Level	Lymph Node Metastasis	
	Pelvic Nodes (%)	Aortic Nodes (%)
ALL CLINICAL STAGE I		
Low Risk		
Grade 1, endometrium only, no intraperitoneal disease	0	0
Moderate Risk		
No intraperitoneal disease		
Inner-middle invasion or grade 2 or 3	3	2

use of radical hysterectomy in macroscopic stage II disease to clear potential parametrial disease, although a survival advantage over TAH-BSO and pelvic radiation therapy has not been proven.[118,119]

The role of pelvic and paraaortic lymphadenectomy or lymph node sampling in endometrial cancer has been widely debated. Determination of nodal involvement has prognostic implications, and in patients with nodal involvement it may direct further therapy. The potential therapeutic implications of lymphadenectomy are directly related to the risk of nodal disease in the population studied. Prospective and retrospective studies of lymphadenectomy in patients with clinical stage I or II endometrial carcinoma without extrauterine spread identified at surgery have shown the rates of pelvic and aortic nodal involvement to be 7% to 9% and 2% to 3%, respectively.[48,120] The risk of lymph node involvement varies with the major risk factors, as was demonstrated in the landmark GOG surgical pathologic staging study[48] (Table 59-4).

For the majority of patients with clinical stage I or occult stage II disease, the risk of nodal involvement is extremely low. Therefore, it is difficult to justify staging in all patients.[127]

Two randomized trials investigating the role of lymphadenectomy in clinical stage I endometrial cancer have been published and show no benefit. In the U.K. Medical Research Council ASTEC trial, 1408 patients were randomized: 704 to TAH-BSO with pelvic lymphadenectomy and 704 to TAH-BSO alone.[128] The baseline characteristics were well balanced between the groups: 9% of the lymphadenectomy group had nodal involvement. The 3-year OS rates were 89% (TAH-BSO alone) and 88% (TAH-BSO plus lymphadenectomy), and 3-year RFS was superior in the TAH-BSO alone arm (HR 1.35, $p = 0.017$; HR 1.25 after adjustment, $p = 0.14$). An Italian randomized trial comparing TAH-BSO with pelvic lymphadenectomy (30% had also paraaortic lymphadenectomy, with a median of 23 [pelvic] to 30 [pelvic and paraaortic] nodes removed in the patients in the lymphadenectomy study arm) with TAH-BSO alone for stage I endometrial carcinoma confirmed these results.[129] Although the rate of nodal involvement was 13% in the lymphadenectomy arm as compared with 3% in the standard arm, rates of DFS, OS, and relapses were the same in both arms. Even the pattern and sites were similar, with vaginal recurrences in 2.6% versus 2.4% and lymph node recurrences in 1.5% versus 1.6% of patients in the lymphadenectomy versus standard study arms.[129]

The ongoing controversy regarding the role of lymphadenectomy staging compared with uterine prognostic factors directing adjuvant therapy, especially for high-risk tumors, has prompted design of a randomized trial. This is being developed by groups collaborating in the Gynecological Cancer InterGroup (GCIG).[130]

Sentinel node detection may be an alternative way to identify patients at high risk for relapse while sparing most patients the risks and added toxicities of lymphadenectomy. However, it is not without side effects including lymphocyst formation, infection, bleeding, and lymphedema. For patients with low-risk disease, the potential benefits should be weighed against detecting micrometastatic disease in only 3% to 6%.

Evaluation of sentinel node biopsy is especially promising in patients with high-risk factors. This will be an integral part of the planned GCIG lymphadenectomy trial.

Primary Radiation Therapy: Indications and Results

The approximately 3% of patients who are medically inoperable because of comorbidity can be offered primary curative radiation therapy (RT). Substantial local control and DSS rates have been reported, although these patients have a high mortality rate because of their coexisting medical conditions. Patients at low risk for extrauterine spread potentially may be treated with intrauterine brachytherapy alone, but it may be impossible to encompass an enlarged uterus in the clinical target volume using only an intrauterine tandem. Pelvic EBRT is based on the risk of extrauterine disease or uterine size. It is usually employed in cases with grade-3 disease, larger uterine volume, or cervical involvement. Some patients are not candidates for curative irradiation because of their coexisting illnesses. They should be offered palliative RT to stop bleeding.

Several studies have demonstrated the efficacy of primary RT for clinical stage I disease. With the use of uterine brachytherapy with or without EBRT, 5-year uterine control rates of 70% to 90%, and DFS ranging from 50% to 80% have been reported.[133-137] Inferior survival rates with radiation instead of surgery are related to inferior control of uterine disease. Patients with low-grade tumors and smaller uteri, brachytherapy can be a good alternative to hormonal treatment or observation for morbidly obese patients.[134,135] Grade-3 tumors had significantly lower pelvic control and survival rates than grade-1 or grade-2 disease, and usually a combination of EBRT and brachytherapy is used. Studies that included patients with stage II disease reported 5-year pelvic control rates of 40% to 60% and DSS of 50% to 60%.[134]

Surgical Results: Early-Stage Disease

Many retrospective studies have reported invariably good outcomes for stages IA and IB grade-1 and grade-2 endometrioid carcinoma treated with surgery alone, with a 5-year RFS of 95% and 5-year vaginal relapse rates of 2% to 5%.[138,139]

Some of these features can be identified at the time of hysterectomy and have been used to evaluate the indication for lymph node dissection. As discussed previously, the risk of extrauterine spread for serous tumors is much higher and for serous cancers, full surgical staging including omentectomy and peritoneal biopsies is recommended (see section on unfavorable histologic types). The addition of lymphadenectomy, especially if pelvic and aortic lymphadenectomies are performed, prolongs operation time and has side effects, such as leg edema (5% to 10%), lymphocysts (symptomatic in 5% to 7%), increased rates of deep vein thrombosis (2%) and small bowel obstruction (up to 5%), and increased blood loss and higher transfusion rates (5% to 10%). The studies suggesting a survival advantage of lymphadenectomy have been small, single-center retrospective analyses that were flawed by patient selection and stage migration.[121-123] The larger National Cancer Institute and Duke University analyses reported a survival benefit with full lymphadenectomy for grade-3 cancers, whereas no benefit was found for grade 1 or 2 disease.[120,124] Analysis of data from the SEER program did not show benefit from lymphadenectomy for patients with stage I grade 1 or 2 disease but suggested improved disease-specific survival (DSS) for those with stage I grade 3 or more advanced-stage disease.[125,126] Lymphadenectomy should therefore be considered for patients with grade-3 disease, cervical involvement, and high-risk histologic findings.[126] It has been shown that if pelvic lymphadenectomy is performed, a minimum of 11 nodes should be removed from multiple sites.[123] Retrospective analyses are, however, flawed because of elimination of patients from earlier-stage categories (i.e., stage migration) and exclusion of patients at increased surgical risk as a result of advanced age or concurrent morbidities (i.e., selection bias).

Although many U.S.-based gynecologic oncologists continue to advocate nodal staging in patients with low-risk disease despite level-one evidence, the data do not support the routine use of lymphadenectomy for patients with stage I endometrial carcinoma. Subsequent therapy in the ASTEC trial was not determined by the lymph node status found at time of surgery, and the trial therefore tested the therapeutic value of lymphadenectomy per se, not whether any subsequent treatment based on lymph node status could affect outcomes. In the Italian trial, the use of adjuvant therapy was only slightly and not significantly different between the study arms; the rates of patients receiving radiation therapy, chemotherapy, or both were 17%, 9%, and 6%, respectively, in the lymphadenectomy study arm and 25%, 6%, and 4%, respectively, in those who did not have lymphadenectomy. Ten of 59 patients received extended-field radiation therapy (EFRT) in the lymphadenectomy group versus 5 of 74 who did not have lymph nodes removed. There was, however, no difference in rates of total (12.8% versus 13.2%), intraperitoneal (3% versus 2.8%), or other relapses.

Initial results show the combined use of radiocolloid labeling and patent blue dye results in sentinel node detection rates of 82% to 94%, with identification of two or three sentinel nodes per patient.[51-53,131,132] The sentinel nodes were located in the obturator, external iliac, or paraaortic regions. Ultrastaging techniques are also used to identify micrometastases and isolated tumor cells in the sentinel nodes. The clinical significance of micrometastases and isolated tumor cells is however unknown, although other risk factors such as LVSI may be present, which can be used to direct further treatment.[52] Increasing surgical volume (and experience) has been shown to be associated with increased detection rates (77% versus 94% after at least 30 cases).[132] Additional larger studies are needed to further explore this concept, establish optimal techniques, and develop reliable accuracy data.[53]

Several investigators stressed that lymphadenectomy is not indicated in these patients with low-risk disease.[54,138,140] In some studies, vaginal brachytherapy was used.[140] The addition of brachytherapy to surgery may reduce vaginal relapse rates from between 2% and 5% to between 0% and 2% but without a survival difference and at the considerable procedural cost and the (albeit minimal) morbidity. In a randomized trial of vaginal brachytherapy versus observation among 645 patients with low-risk endometrial carcinoma, the rate of vaginal recurrences was 1.2% in the brachytherapy group versus 3.1% in the control group (difference not statistically significant, $p = 0.114$). The overall relapse rate and survival rate were similar.[141]

Salvage treatment with RT is available for the occasional patient with vaginal relapse alone or plus pelvic relapse. Depending on size and grade, 5-year and 10-year DFS in the range of 70% to 80% and OS of 50% to 70% are obtained (see the section on adjuvant therapy).[142-144] EBRT is not indicated for patients with low-risk endometrial cancer because their outcome will not be improved and EBRT may even contribute to decreased survival as a result of late toxicities and secondary tumors.[145,146]

Adjuvant Therapy: Stages I and II

Four randomized trials have been published that evaluated the role of pelvic EBRT in endometrial carcinoma.[88-90,147] They are summarized in Table 59-5.

The Norwegian trial, published in 1980, included 540 women with clinical stage I endometrial carcinoma. After hysterectomy and postoperative vaginal brachytherapy (60 Gy to the mucosal surface), patients were randomly assigned to additional pelvic irradiation (40 Gy in 2-Gy fractions, with a midline block after 20 Gy) or observation. Although additional pelvic irradiation reduced vaginal and pelvic relapse rates (2% at 5 years versus 7% in the control group), more distant metastases were found in the pelvic irradiation group (10% versus 5%), and survival was not improved (89% versus 91% at 5 years). An exploratory subset analysis identified the subgroup with grade-3 tumors and deep (>50%) myometrial invasion seemed to have improved local control and survival after pelvic irradiation (18% verus 27% cancer-related deaths), although, however, there were too few patients in this category to reach firm conclusions.[88] In a recent update of this series with a median of 20 years follow-up of these patients, treated with old techniques between 1968 and 1974, the absence of any OS benefit of EBRT in early-stage endometrial carcinoma was confirmed. In patients with low-risk disease younger than age 60 years, pelvic radiation even decreased survival and increased the risk of secondary cancer.[146]

In the first Postoperative Radiation Therapy in Endometrial Carcinoma (PORTEC) trial, 714 patients with stage I endometrial carcinoma, grade 1 or 2 with deep (>50%) myometrial invasion or grade 2 or 3 with superficial (≤50%) ("intermediate high-risk") invasion were randomized after TAH-BSO to receive pelvic EBRT (46 Gy in 2-Gy fractions) or no further treatment.[89] The 10-year locoregional relapse rates were 5% in the radiation therapy group and 14% in the control group ($p < 0.0001$). There was no significant survival difference between the treatment arms with 10-year OS of 66% (irradiation) and 73% (controls; $p = 0.09$).[149] Endometrial cancer-related death rates were 10% in the RT group and 8% in the control group ($p = 0.47$). The patients younger than age 60 years (both study arms) had a 5-year locoregional relapse rate of 3%, compared with 9% for patients 60 to 70 years old and 10% for those older than 70 years. Patients with grade-2 tumors with superficial invasion had a 5-year locoregional relapse rate of 5%. Risk criteria for relapse were grade 3, age older than 60 years, and outer 50% invasion. Long-term data confirmed the conclusions that radiotherapy should be avoided in those with low-risk disease and only be considered in patients with risk factors.[150]

An analysis of survival after relapse in the PORTEC trial showed 5-year postrelapse survival of 13% in the RT group and 48% in the control group ($p < 0.001$). High salvage rates after local (vaginal) relapse were found, with 5-year survival of 70% after vaginal relapse in the control group. Most (87%) of the 39 patients with isolated vaginal relapse could be treated

TABLE 59-5 Comparison of the Randomized Trials of Adjuvant Radiation Therapy for Stage I Endometrial Carcinoma

Trial (years)	No. Eligible Patients/Stage‡	Surgery	Randomization	Locoregional Recurrence	Survival	Severe Complications

with curative intent, usually with pelvic EBRT and brachytherapy (BT) and with surgery in some. A complete remission was obtained in 89%, and 77% remained in complete remission after further follow-up.[142] (It is unclear whether those with vaginal mucosal relapse benefit from the addition of EBRT, although this is common practice). In contrast, only 4 of 10 patients who were treated for pelvic relapse reached a complete remission, and the outcome after pelvic and distant relapse was poor, with only 6% and 11% of patients, respectively, surviving 5 years.

The GOG-99 trial included 392 evaluable patients with stage IB, IC, or IIA endometrial carcinoma of any histologic grade who were randomized after TAH-BSO and limited lymphadenectomy (confirmed node negative) to receive pelvic irradiation (50.4 Gy in 1.8-Gy fractions) or no additional treatment.[90] A high-intermediate risk group was defined based on similar prognostic factors identified in the PORTEC study: of age, histologic grade, myometrial invasion, and additionally the presence of LVSI. This group (33% of the study population) had a 2-year incidence of relapse of 27% in the no-additional-treatment arm in contrast to 6% for those without these risk factors (i.e., low-intermediate risk group [67% of patients]). RT resulted in similar hazard reductions for the high- and low-intermediate risk subgroups (58% and 54%, respectively), but in absolute terms the differences were greater for the patients with high-intermediate risk disease, with a reduction of 4-year cumulative relapse from 27% (in the group with no additional treatment) to 13% (those with irradiation). There was a small, although nonsignificant survival benefit: 4-year OS was 86% for the no-additional-treatment group and 92% for those who had RT. The 2-year estimated vaginal and pelvic failure rate was 12% in the no-additional-treatment group and 3% in the RT group, for a 58% hazard reduction by irradiation. These results are strikingly similar to those obtained in the PORTEC study without lymphadenectomy. However, the 4-year crude rate of severe complications in GOG-99 was 13% for patients who had received EBRT, compared to a 3% 5-year actuarial rate in the PORTEC trial, which underlines the increased risk of toxicity when combining extended surgery with lymph node dissection and pelvic RT.[90] Most notable was the rate of gastrointestinal (GI) toxicity in the GOG#99 trial; 8% grade-3 and grade-4 GI toxicity, including 6 (RT) compared with 1 (NAT) women with intestinal obstruction.

The multicenter randomized ASTEC/EN5 trial included 905 patients with stages I to IIA endometrial carcinoma with high-risk features (deep invasion or grade 3 with superficial invasion or serous histology), who were randomly allocated to EBRT or observation. Brachytherapy was permitted in both study arms, and 53% of the patients received vaginal brachytherapy (VBT). Again, there was no difference in OS (84% at 5 years in both groups).[147] The HR for isolated vaginal or pelvic RFS was 0.46 ($p = 0.02$), with 5-year cumulative incidence rates of 6.1% (observation only) versus 3.2% (RT). The relatively low rate of isolated vaginal or pelvic recurrence can probably be explained by the fact that 53% of the patients in the observation study arm received VBT. A meta-analysis of pooled data from the ASTEC/EN5, GOG-99, and PORTEC-1 trials reliably excluded an absolute survival benefit of pelvic EBRT of more than 3%.[147] This was confirmed in the updated Cochrane review and meta-analysis.[145]

An inevitable conclusion is drawn from these trials that (1) overall adjuvant pelvic EBRT for patients with stage I endometrial carcinoma provides a highly significant improvement in local control but offers no survival advantage. (2) A large proportion of patients with endometrial cancer have a favorable prognosis. These patients should be observed after TAH-BSO because use of EBRT in patients with low-risk disease could be detrimental for long-term survival and increase the risk of second cancers.[145,146,150] (3) RT is an effective salvage treatment for vaginal relapse in patients not previously irradiated.[142]

The data suggest that the use of postoperative RT should be limited to the group of patients at sufficiently high risk for locoregional relapse to accept the risk of treatment-associated morbidity to maximize initial local control and RFS. These data from randomized trials has resulted in a reduction of the use of pelvic EBRT and use of high-intermediate risk criteria to determine indications for RT. In the PORTEC study, patients with two of the three major risk factors (grade 3, age 60 or older, and outer 50% myometrial invasion) were found to have the highest absolute benefit from pelvic irradiation. The 10-year locoregional relapse rates in this high-intermediate risk category were 5% in the RT group and 20% in the control group.[149] In the GOG-99 trial, similar high-intermediate risk criteria were identified, with reduction of isolated 4-year local relapse in the high-intermediate risk group from 13% to 5%.[90] The risk criteria as defined in the PORTEC and GOG-99 trials and the relapse-risk reduction with radiation therapy in the high-risk groups are listed in Table 59-6.

Because most relapses occur in the vagina especially after extensive surgical staging, the use of VBT alone has been advocated. Vaginal control and complication rates for high-dose-rate (HDR) VBT are comparable to those of low-dose-rate (LDR) therapy.[151] Data from mostly retrospective studies that used VBT alone for stage I endometrial cancer have shown the 5-year risk of vaginal relapse to be 0% to 7%.[151-155] Pelvic and distant failure rates, however, remain similar to those of patients treated with surgery alone, which is the reason that

TABLE 59-6 Comparison of the Risk Groups in the PORTEC and GOG-99 Trials and Risk Reduction with Radiation Therapy

most studies included only or mainly patients with low-risk disease (i.e., grade-1 to grade-2 disease with no or superficial invasion). Local control rates of 98% and higher were obtained with modest doses (e.g., 30 Gy to 35 Gy LDR to the surface or 21 Gy HDR to 5-mm depth in three fractions). The use of higher doses did not further increase local control, but complication rates were higher. Several studies of HDR after surgical staging included patients with high-risk stage I or II disease. Vaginal control rates were 98% to 100%. Subsequent pelvic and distant relapses were found mainly in the patients with stage I or II with high-risk features.[153-155]

The results of the randomized trials for intermediate-risk endometrial carcinoma suggested that, in view of the absence of survival benefit with EBRT and of the fact that most recurrences were located in the vagina, VBT alone for patients with high-intermediate risk features might suffice for local control with fewer side effects than EBRT and better quality of life. This was the rationale for the randomized PORTEC-2 trial (2002 to 2006), which compared EBRT and VBT for efficacy and health-related quality of life. In this trial, 427 patients with stage FIGO 1988 stages I to IIA endometrial carcinoma with high-intermediate risk features (i.e., age of at least 60 years, grade-1 or grade-2 tumors with outer 50% invasion or grade 3 with inner 50% invasion) were randomly assigned after surgery (TAH-BSO without lymphadenectomy) to EBRT (n = 214) or VBT (n = 213). Quality of life was significantly better in the patients in the VBT arm. Patients who had brachytherapy reported better social functioning ($p < 0.002$) and lower symptom scores for diarrhea, fecal leakage, the need to stay close to the toilet, and limitation in daily activities because of bowel symptoms ($p < 0.001$). The data for patients in the brachytherapy arm remained at the level of population controls. At baseline, 15% of patients were sexually active; this increased significantly to 39% during the first year ($p < 0.001$). Sexual functioning and symptoms did not differ between the treatment arms but were somewhat lower than for age-matched population controls, probably reflecting the impact of gynecological cancer diagnosis and treatment.[156,157] Final results of the PORTEC-2 trial confirmed the efficacy of VBT. At median follow-up of 45 months, estimated 5-year rates of vaginal recurrence were 1.8% for VBT and 1.6% for EBRT (p = 0.74). Five-year rates of locoregional relapse (vaginal recurrence or pelvic recurrence) were 5.1% and 2.1% (p = 0.17). Only 1.5% versus 0.5% (p = 0.30) presented with isolated pelvic recurrence; other pelvic recurrences were part of widespread disease relapse, whereas rates of distant metastases were similar (8.3 versus 5.7%, p = 0.46). There were no differences in OS (84.8% versus 79.6%, p = 0.57) and DFS (82.7% versus 78.1%, p = 0.74). Rates of grade-1 to grade-2 GI toxicity were significantly lower in the VBT group.[148]

In a Swedish randomized trial VBT alone was compared to combined EBRT and VBT in 527 patients with (high-) intermediate-risk disease. Five-year locoregional relapse rates were 1.5% after EBRT plus VBT and 5% after VBT alone (p = 0.013), whereas 5-year OS was 89% and 90% (p = 0.548). The authors concluded that such combined EBRT with brachytherapy boost should be reserved for high-risk cases.[158]

In view of the efficacy of VBT with few side effects and better quality of life than EBRT, VBT alone has internationally become the standard adjuvant treatment for patients with high-intermediate risk disease, both with and without lymphadenectomy. Controversy remains, however, as to the relative benefits of VBT compared with observation when disease recurrence is rare and salvage of vaginal recurrence is high.

In the absence of a survival benefit for RT, some groups have decided to omit any radiotherapy or brachytherapy in endometrial cancer.[159,160] In a population review from Denmark of treatment outcomes of 1166 patients with endometrial carcinoma the consequences of the decision to omit RT for patients with stage I, low-risk (grade 1 or 2 with <50% invasion) and intermediate-risk (grade 1 or 2 with >50% invasion, or grade 3 with <50% invasion) endometrial cancer were evaluated. After 14 years, 6.3% of patients with low-risk, 22% of those with intermediate-risk, and 32% of patients with high-risk disease had relapsed. High-intermediate risk was, in the absence of information on LVSI, defined as either age older than 50, grade 2 and more than two thirds myometrial invasion, or age older than 70, grade 1, and more than two thirds invasion. Patients with such high-intermediate risk features had 25.8% relapse, of which 11.4% were vaginal relapse and 6.1% were pelvic relapse.[144] This should be compared to 1.8% and 3.8%, respectively, after 5 years in the vaginal brachytherapy arm of the PORTEC-2 trial.[148] The Danish population review confirmed that most recurrences in patients with low- and intermediate-risk disease were locoregional, whereas distant relapses were prominent in high-risk disease. Treatment of vaginal recurrence in patients with low- and intermediate-risk disease was effective. The survival rates had not changed compared to previous Danish population-based data.[144] A Swedish randomized trial of VBT compared with observation in 645 patients with low-risk disease showed low locoregional (2.6%) and distant (1.4%) recurrence rates, with 1% versus 3% locoregional recurrence for brachytherapy and for control. This trial again confirmed that patients with low-risk disease do not benefit and should not have additional treatment after surgery. Adjuvant treatment should be tailored to prognostic factors.[141]

In an attempt to resolve the controversy as to whether adjuvant VBT should be given to all patients with high-intermediate risk features compared with only the 15% patients with local relapse, albeit more intensively with EBRT and VBT, the randomized PORTEC-4 trial has been initiated and is currently ongoing.[161] Omitting adjuvant VBT in patients with stage I, high-intermediate-risk features spares 85% of patients the cost (both in terms of healthcare costs and burden of travel and so on for the patient) and (minor) morbidity of VBT. However, for the 15% of patients who relapse, the toxicity, intensity, and psychological burden of full curative-intent treatment for relapse are much greater than simple adjuvant therapy with VBT alone. First results of a patient preference study showed that patients tend to prefer adjuvant VBT over a watchful waiting policy at low risk of relapse.[162] Several groups have published nomograms to help establish individual patient risks, which can be helpful in shared decision making.[163-165]

FIGO 2009 Stage IB, Grade-3 Disease (High Risk, Early Stage)

Clinical stage I endometrial carcinoma, grade 3 with outer 50% myometrial invasion is usually regarded as a separate group among patients with stage I disease because this subgroup is at increased risk for pelvic relapse and distant metastases and has lower survival rates.[91,166,167] In an analysis of 220 patients with FIGO 1988 stage IC endometrial cancer who had surgical staging including pelvic and paraaortic lymphadenectomy, 99 (45%) patients treated with RT (pelvic EBRT or VBT alone; selection criteria not specified) were compared with 121 (55%) who did not receive RT. The 5-year DFS were significantly lower for the observation group (75% versus 93%), but OS were similar (90% versus 92%). Among the 47 patients with grade 3 and outer 50% myometrial invasion, 5-year DFS were 90% after RT and 59% for the observation group.[166] During the inclusion period of the PORTEC-1 trial, 99 evaluable patients with grade-3 tumors with deep myometrial invasion but without staging were registered and received pelvic EBRT. The 5-year actuarial vaginal and pelvic relapse rate was 13% in this

group, significantly higher than for other patients with stage I disease, who had excellent pelvic control after RT (97% to 99%). The 5-year rates of distant metastases were 20% for grade-3 disease with less than 50% invasion and 31% for grade-3 disease with more than 50% invasion, compared with 3% to 8% for grade-1 and grade-2 diseases. OS at 5 years was 58% for those with grade-3 disease and outer 50% invasion and 74% for those with grade-3 disease and inner 50% invasion compared with 83% to 86% for the patients with grade-1 and grade-2 tumors ($p < 0.001$).[91] In multivariate analyses, grade-3 disease was the most important adverse prognostic factor, with HRs for any relapse and for endometrial carcinoma-related death of 5.4 ($p = 0.0001$) and 5.5 ($p = 0.0004$), respectively.

Whether surgical staging has been performed or not, pelvic irradiation is usually recommended for grade-3 tumors with deep myometrial invasion.[168,169] An increasing number of authors, however, recommend VBT alone for patients with FIGO 2009 stage IB grade-3 disease who underwent surgery with full lymphadenectomy.[155] It is unclear how much reduction in relapse risk or change in relapse sites is present if lymph nodes are negative, but high-risk factors are present in the uterus. In view of the small numbers, with patients with grade-3 disease always being a small minority in clinical trials, firm data are lacking. In view of the increased risk of abdominal and distant relapse and cancer-related death, both adjuvant chemotherapy and combined chemotherapy and radiotherapy are being investigated by several groups (see section on adjuvant chemotherapy).

Stage II Disease

Stage II endometrial carcinoma includes patients with minimal microscopic involvement of the cervical stroma (often called stage II occult) and those with macroscopic gross cervical involvement, even though these two groups have different prognoses. Cervical involvement has been associated with a poorer prognosis because of the increased risk of LVSI and pelvic lymph node metastases.[73] Patients with minimal extension to the endocervix used to be in stage IIA; however, in the FIGO 2009 staging endocervical glandular involvement has been included in stage I because outcomes are identical to those of patients with stage I disease. Their treatment should be the same as for stage I disease. Patients with FIGO 2009 stage II (former stage IIB) disease have a less favorable outcome.[170]

Patients with occult stage II disease have already undergone TAH-BSO or TLH-BSO. Pelvic EBRT often with vaginal cuff brachytherapy boost is usually recommended for stage II disease treated with TAH-BSO because cervical involvement increases the risk of parametrial lymphatic disease.[171] Its contribution, however, to better outcomes is unclear. For stage I disease, the addition of VBT does not significantly add to local control when pelvic EBRT is used, but it does increase toxicity.[172,173] For occult stage II disease, because a vaginal cuff is usually not taken at TAH-BSO, most investigators continue to recommend a cuff boost. Two retrospective analyses, however, did not find any difference in recurrence with or without brachytherapy.[170,174] Reported adverse prognostic factors for stage II disease are grade 3, lymphovascular space invasion, and advanced age.[175,176] VBT alone has been advocated for stage II disease after full surgical staging and in absence of risk factors such as deep invasion, high grade, and LVSI. This analysis is flawed, however, because 30% of patients with FIGO 1988 stage IIA disease would now not be considered stage I.[176]

Patients with macroscopic gross stage II disease should be considered either for initial radical hysterectomy, if surgically suitable, with adjuvant pelvic irradiation depending on the surgical findings (e.g., parametrial or vaginal extension, lymph node involvement, surgical margin involvement) or for primary radiation with "completion hysterectomy." Retrospective studies have shown that radical hysterectomy alone for macroscopic stage II endometrial cancer has local control and survival rates similar to those obtained with TAH-BSO plus risk-based radiotherapy.[119,177-179] Some studies reported improved survival after radical hysterectomy compared with TAH-BSO alone, but the selection criteria for radical hysterectomy and for RT were unclear and might have influenced the results.[177,178,180] Pelvic irradiation improved local control for patients with macroscopic stage II disease treated with TAH-BSO.[175,177] A SEER analysis of 1577 women with stage II endometrioid type endometrial carcinoma included 1198 women who underwent simple hysterectomy (76%) and 379 who underwent radical hysterectomy (24%). Radical hysterectomy had no significant effect on survival ((HR, 0.86; 95% CI, 0.61 to 1.23). Patients who did not receive radiation were 48% (HR, 1.48; 95% CI, 1.14 to 1.93) more likely to die than those who underwent adjuvant RT. The survival benefit from irradiation was most pronounced in women who underwent radical hysterectomy.[181] Recent data from the SEER registry, however, show that selection factors in such analyses may determine outcome.[182] Although the selection criteria are unclear, patients with high-risk stage II tumors seem to benefit from RT, even after radical hysterectomy. An overview of the results for stage II disease is presented in Table 59-7.

Patients with macroscopic stage II tumors with bulky cervical extension, precluding radical hysterectomy with adequate margins, should be treated with preoperative pelvic EBRT, followed by hysterectomy if feasible. In case of insufficient tumor regression after pelvic irradiation, intrauterine brachytherapy should be added although special applicators are to be used as it is difficult to achieve a satisfactory dose distribution including the whole uterine body with a single tandem. Depending on the regression and clinical situation after brachytherapy, completion hysterectomy should again be considered, because the excess of failures when primary radiation is used instead of surgery occurs often in the enlarged uterine body, where the radiation dose may be suboptimal. The risk of distant metastases, however, is increased and determines final outcomes.[183]

Unfavorable Histologic Types

Serous and clear cell cancers, approximately 10% and 5% of endometrial carcinomas, respectively, have been identified as histologic types with an inferior prognosis because of aggressive growth and spread patterns with frequent diffuse intraabdominal and distant dissemination. These histologic types often present with advanced disease (46% stage II to IV, compared with 21% for all endometrial cancers). Different treatment approaches (e.g., extended surgery, surgery with whole-abdomen irradiation, surgery with adjuvant chemotherapy) have been suggested.[184,185] Several studies have shown that serous and clear cell carcinomas have similar relapse and survival rates compared with grade-3 endometrioid carcinomas.[39,40,186,187] In an analysis of 5694 surgically staged endometrial cancers in the 25th annual report of FIGO, 3996 were stage I. Serous and clear cell cancers represented 5.2% of stage I cancers, and grade-3 carcinomas accounted for 8.1%. Five-year survival rates were 72% and 81%, respectively, for serous and clear cell cancers, compared with 76% for grade-3 disease. Postoperative RT was associated with an about 8% improvement in survival for these histologic types (76% versus 68% for grade 3; 74% versus 66% for serous cancers; and 83% versus 77% for clear cell carcinoma), but these differences were not significant.[40] A retrospective analysis of treatment results of 119 patients with grade-3 endometrioid, 211 with serous and 40 with clear cell carcinomas showed that although clinicopathological risk factors varied among the subtypes, survival did not differ significantly. The 5-year CSS rates in stages

I to II were 85%, 90%, and 84%, respectively, with LVSI being the only independent prognostic factor. For stage III, 5-year OS rates were 49% and 40%, respectively, for grade-3 endometrioid and serous cancers; 18% and 41%, respectively, of these cancers had received adjuvant chemotherapy only, 9% and 6%, respectively, EBRT only, and 7% in each group chemotherapy and EBRT. Age, LVSI, unresectable nodal disease, and regional radiotherapy were prognostic factors, whereas chemotherapy alone had no significant impact on outcome.[186] In a SEER analysis of 4180 women with serous (1473), clear cell (391), and grade-3 endometrioid (2316) cancers, these unfavorable histologic types accounted for 10%, 3%, and 15% of all endometrial cancers, but for 39%, 8%, and 27% of the cancer deaths, respectively. The 5-year DSS were 55, 68, and 77%, respectively ($p < 0.0001$), showing serous cancers to have poorer outcomes.[188] The question is whether lack of pathology review and of a uniform definition of serous cancer (any percentage of serous component, or at least 10% or 25% within otherwise endometrioid cancers) influenced the results.

Generally, full surgical staging (TAH-BSO plus lymph node dissection [LND] and omentectomy and peritoneal biopsies) is recommended for serous and clear cell cancers to confirm stages I to II disease extent, and complete debulking of visible tumor in more advanced disease.[189,190] In case of limited volume surgical stage IA disease, VBT alone has been suggested to be safe and effective adjuvant treatment.[191,192] Single-center analyses of outcomes of patients with early stage serous[193] or clear cell cancers[191] suggested better survival with pelvic radiation therapy for patients with additional risk factors. Some authors have explored the addition of adjuvant chemotherapy to VBT for early stage serous cancers, but the impact on survival remains unclear.[186,194,195] Initial results from the GOG 249 trial, which compared pelvic EBRT to three cycles of adjuvant carboplatin and paclitaxel plus VBRT for early-stage high-intermediate and high-risk disease, were presented in 2014.[196] Similar 2-year RFS and OS rates were found, with no evidence of superiority for adjuvant chemotherapy in this trial population, which included 15% serous and 5% clear cell cancers.

For clear cell cancers, evidence for sensitivity to endometrial or ovarian type chemotherapy is lacking.[190] However, the number of patients with advanced stage clear cell disease is exceedingly small, so firm conclusions cannot be made.

Current conclusions from these analyses are that serous and clear cell cancers should be treated similarly to grade-3 carcinomas, but ideally based on their specific cell type. Adjuvant treatment using radiation therapy should be considered, with concurrent or sequential systemic therapy preferably within clinical trials.

Adjuvant Hormonal Therapy

Adjuvant hormonal therapy for endometrial cancer has been extensively studied in view of the high incidence of progesterone receptor positivity and the 18% to 34% response rates

It has been suggested that clear cell cancers are related more closely to clear cell cancers of other organs than to other endometrial cancers and have gene expression profiles similar to ovarian or renal clear cell cancers. Inaugural studies based on cell type rather than tissue of origin for clear cell cancer are under way.

to progesterone therapy seen in metastatic grade-1 or grade-2 disease. However, a meta-analysis of six randomized trials with a total of 3544 patients did not show a survival benefit for adjuvant progesterone treatment.[197] A randomized trial enrolling 1148 patients showed a higher intercurrent death rate in the progesterone group owing to an increased risk of thromboembolic disease.[198] Among the 461 high-risk patients, a tendency toward fewer cancer-related deaths in the progesterone group was observed, but OS was unchanged. The COSA-NZ-UK trial showed a decrease in the rate of relapse with 3 years of adjuvant progestins, but it did not show a difference in DSS.[199] In general, tumors showing high ER/PR receptor expression rates are usually low-risk, grade-1 tumors and have higher response rates to progesterone therapy when recurrent.[200]

Adjuvant Chemotherapy

Optimal therapy for advanced and high-risk nonendometrioid cancers has not been defined. Three randomized trials have evaluated the efficacy of adjuvant chemotherapy as compared with radiation therapy (Table 59-8).

The results of GOG-122, a randomized trial comparing whole-abdominal irradiation (WAI) to combination doxorubicin-cisplatin chemotherapy in advanced endometrial carcinoma (i.e., stages III to IV; up to 2-cm residual disease after surgery allowed) showed combination chemotherapy to improve PFS and OS, with a predicted difference in DFS of 12% at 5 years (50% versus 38%) and 5-year OS difference of 13% (55% versus 42%).[201] The OS for patients who received chemotherapy was substantially higher than their RFS, suggesting that salvage treatment, often by RT, contributed importantly to their survival.[169] Relapses remained common in both arms (55%) and longer follow-up seemed to suggest delay rather than eradication of metastases. Twenty-five percent of initial recurrences on the WAI study arm and 35% on the chemotherapy arm were limited to the pelvis; 30% and 28%, respectively, of recurrences were intraabdominal.

The chemotherapy used in GOG-122 was the most aggressive of the regimens in adjuvant trials to date, with seven cycles of doxorubicin 60 mg/m^2 plus cisplatin 50 mg/m^2 every 3 weeks followed by an eighth cycle of single-agent cisplatin. Most have abandoned this regimen now in favor of carboplatin and paclitaxel.

The Japanese multicenter randomized JGOG-2033 trial compared whole-pelvic EBRT (at least 40 Gy) with three or more cycles every 4 weeks of cyclophosphamide (333 mg/m^2), doxorubicin (40 mg/m^2), and cisplatin (50 mg/m^2) (CAP) chemotherapy in 385 evaluable patients with FIGO 1988 stages IC to IIIC endometrioid adenocarcinoma (intermediate risk; 60% stage IC, median age 59; 55% grade 1). At a median follow-up of 5 years, no differences in PFS (whole-pelvis RT 83.5% versus CAP 81.8%) and OS (85.3% versus 86.7%) were seen. Relapse rates were similar: 15.5% versus 17.2% of the patients had a relapse, with 6.7% and 7.3% being pelvic and 13.5% and 16.1% extrapelvic, respectively.[202]

An Italian randomized trial used a design similar to that of the JGOG trial but in a somewhat higher-risk group of patients.[203] The Italian study compared whole-pelvis irradiation (45 Gy to 50 Gy) with five cycles every 4 weeks of cyclophosphamide (600 mg/m^2), doxorubicin (45 mg/m^2), and cisplatin (50 mg/m^2) chemotherapy and included 345 evaluable patients with stages IC to IIIC endometrioid adenocarcinoma. In this trial, most patients had stage III disease (64% stage III, 36% stage IC to II, grade 3). After a median follow-up of 95.5 months there were no significant differences in PFS and OS, with 5-year OS of 69 (EBRT) versus 66% (CAP regimen) and 5-year PFS of 63% versus 63%. RT appeared to delay pelvic relapses and chemotherapy appeared to delay distant metastases (both nonsignificant trends).[203]

Where pelvic radiation has been omitted, increased pelvic relapse rates have been reported. A retrospective series used adjuvant chemotherapy alone in patients with high-risk or advanced-stage endometrial carcinoma.[204] Of the 67% who relapsed, 40% had pelvic recurrence and 56% had distant relapse. The 3-year pelvic failure rate was 47%, and in 31% the pelvis was the first or only site of relapse.

Because these data support the use of pelvic RT in patients with high-risk and advanced-stage disease undergoing adjuvant chemotherapy, the use of combined chemoradiation has been explored (Table 59-9). Initial pilot studies had indicated combined therapy to be tolerable.[208] The first early randomized trial, using single-agent doxorubicin after completion of radiotherapy, did not show any benefit.[205] This trial, with only 181 patients, was underpowered, and 25 of the 92 patients assigned to doxorubicin received no chemotherapy. A small Finnish trial randomly assigned 156 patients to pelvic radiation therapy alone (split-course irradiation, 56 Gy in 2-Gy fractions with 3-week interval after 28 Gy) versus pelvic EBRT plus three cycles of cisplatin 50 mg/m^2, epirubicin 60 mg/m^2, and cyclophosphamide 500 mg/m^2.[206] The first cycle of chemotherapy was given 1 to 2 weeks after surgery, the second during the pause in RT, and the last within 2 weeks after completion of the second course of RT. Women with FIGO 1988 stages IA/B grade-3 and IC to IIIA grade-1 to grade-3

TABLE 59-8 Adjuvant Trials which Tested Radiotherapy versus Chemotherapy

§*Includes LR as component of distant failure.*

Strangely there appeared to be no significant differences in relapse rates in the pelvis or abdomen in GOG-122, although chemotherapy appeared to somewhat reduce distant metastases. Benefit from chemotherapy was observed for both those with stage III and those with stage IV disease, although a significant difference was only obtained after adjusted analyses. Adverse effects were substantial, especially in the doxorubicin/cisplatin study arm, although current antiemetic therapy and use of granulocyte colony-stimulating factors might have mitigated many of the observed toxicities. Because those with residual intraabdominal disease were included, this trial did not study true adjuvant treatment for microscopic disease; it is debated whether the radiation dose used would be appropriate for macroscopic residual disease.

In a post hoc subset analysis of JGOG-2033 the subgroup of high- to intermediate-risk cases (stage IC > 70 year, IC grade 3, stage II or stage IIIA [cytology], $n = 120$) was suggested to have a survival benefit for CAP, whereas no PFS or OS difference was found among 75 high-risk cases (stages IIIA to IIIC). Grade-3 to grade-4 toxicity rates were 1.6% (whole-pelvis irradiation) and 4.7% (CAP), $p = 0.08$. Bowel obstructions were the main toxicity in the group undergoing whole-pelvis irradiation, and myelosuppression was the most common toxicity in the chemotherapy group.[202]

cancers were enrolled; the overall prognosis of the group was better than anticipated with 4-year DSS of 84.7% and 82.1%, respectively, in the group with RT alone versus combined chemoradiation groups. There were no differences in the rates of local recurrence.

The Radiation Therapy Oncology Group (RTOG) has reported a nonrandomized Phase II trial (Phase IIR) of concurrent pelvic radiotherapy (45 Gy in 1.8-Gy fractions and a brachytherapy boost) and cisplatin (two cycles of 50 mg/m^2 on days 1 and 28), followed by four cycles of cisplatin (50 mg/m^2) and paclitaxel (175 mg/m^2 as a 24-hour infusion) every 28 days after RT for high-risk or advanced-stage endometrial carcinoma.[209] A total of 46 patients were included: 44 were evaluable, 15 had stages I to II disease with high-risk features and 29 (66%) had stage III disease. Surgery consisted of TAH-BSO with or without additional surgical staging. The 4-year rates of pelvic, regional, and distant relapse were 2%, 2%, and 19%, respectively. There were no relapses among patients with stages IC and II disease, suggesting possible additive effects of chemotherapy and irradiation.

Sequential chemotherapy and radiotherapy (either sequence) were investigated and compared to pelvic EBRT alone in the randomized NSGO-EC-9501/European Organization for Research and Treatment of Cancer (EORTC)-55991 trial, which included 382 patients with stages I to III disease (85% stage I) who had risk factors for relapse (one or more of grade-3 tumor, deep myometrial invasion, nondiploid DNA, or serous/clear cell/anaplastic histology). Chemotherapy regimen and timing of administration was not standardized and could be doxorubicin/cisplatin, paclitaxel/doxorubicin/cisplatin, paclitaxel/platinum, or paclitaxel/cisplatin/epirubicin. First results showed a 7% improvement in PFS in the chemotherapy arm (at 5 years, 79% versus 72%, p = 0.03) and a nonsignificant 8% increase in OS (82% versus 74% p = 0.08).[210] Final results of this trial were published in a pooled data analysis with the Italian MaNGO ILIADE-III trial, which had been closed prematurely and had accrued 157 patients, with stage II (30%) and stage III disease (65%), for a combined total of 534 evaluable patients. Pooled results were similar, with a statistically significant difference in 5-year PFS favoring the combined arm (78% versus 69%, HR 0.63, p = 0.009), but only a trend for improved 5-year OS (82% versus 75%, HR 0.69, p = 0.07).[207] Interestingly, for patients with serous and clear cell tumors, although they were few in number (n = 140), there was no evidence of benefit from adjuvant chemotherapy (HR for PFS 0.83, p = 0.59 and for OS 0.94, p = 88).

Since these first reports of possible efficacy of adjuvant chemotherapy, three trials (two recently closed for completed accrual, and one with preliminary data presented) have followed that further explore the relative contributions of concurrent chemoradiation, radiation, or adjuvant chemotherapy. As noted previously, in GOG 249, similar 2-year RFS and OS rates were found, with no evidence for superiority of adjuvant chemotherapy in this trial population, which included 15% serous and 5% clear cell cancers.[196] All trials are better powered than their predecessors and should help resolve many of the uncertainties regarding which patients may benefit from chemotherapy as well as the role of radiotherapy (eTable 59-1).

Although adjuvant chemotherapy for women with serous carcinomas is widely practiced and systemic therapy is rational in view of the propensity for metastases even with minimal endometrial disease, its benefits remain unproven in the randomized trials.[201,207,213] Despite similar response rates (approximately 40%) to doxorubicin/cisplatin or doxorubicin/cisplatin/paclitaxel (42%) chemotherapy for endometrioid, serous and clear cell cancers, the subset analyses of GOG 122 and NSGO–EORTC adjuvant trials did not show benefit.[201,207]

LOCALLY ADVANCED DISEASE AND PALLIATION

Locally Advanced Disease: Stages III and IV

The FIGO stage III category includes patients with a wide variation in tumor volume and local extension and with a wide range of survival rates. In the FIGO 2009 revised staging system, positive peritoneal cytology as an isolated finding has been removed from stage IIIA because data have shown that positive cytology as a sole adverse factor has a risk profile similar to stage I disease.[214,215] To best assess treatment, stage III disease must be evaluated as several different entities with different disease extents rather than as a single stage.

Most patients with stage III endometrial carcinoma in retrospective analyses have been treated with adjuvant pelvic irradiation.[216,217] In view of the high rate of abdominal relapse, the use of whole abdominal irradiation (WAI) has been investigated, and several studies have demonstrated favorable results with this modality.[218] However, because of the toxicity and limited efficacy of WAI and the risk of distant metastases, adjuvant chemotherapy has been studied. The results of GOG-122,[201] a randomized trial comparing WAI with doxorubicin-cisplatin chemotherapy in advanced (stages III to

The protocol completion rate in the RTOG Phase IIR trial was 98%. During the adjuvant phase, 35 of the 44 patients received all four cycles. Acute toxicities during chemoradiation were grade 3 in 27% and grade 4 in 2%. During adjuvant chemotherapy, 21% grade-3 and 62% grade-4 toxicity was observed, with severe toxicity being primarily hematologic. Late toxicity was grade 3 in 16% and grade 4 in 5%. Four-year DFS and OS were 81% and 85% for the whole group and 72% and 77% for patients with stage III disease.

Women with early-stage serous carcinomas were eligible for both the PORTEC-3 and GOG-249 studies. Hopefully accrual of these subsets will be adequate to show if the benefit of adjuvant chemotherapy is different between endometrioid and serous cancers.

The ongoing ENGOT-EN2-DGCG trial investigates the role of adjuvant chemotherapy vs no adjuvant treatment (vaginal brachytherapy permitted in both arms) for early stage, high-risk, node negative disease. Target accrual is 678 patients.

eTABLE 59-1 Adjuvant Trials Testing Radiotherapy versus Combined Modality

IV) endometrial carcinoma were discussed previously (see Adjuvant Chemotherapy section). Current studies are focusing on the relative benefits of chemotherapy and pelvic or involved field (pelvic and paraaortic) irradiation, alone or combined.

Stage IIIA Disease

FIGO stage IIIA disease varies from serosa breakthrough or isolated adnexal metastasis to extensive macroscopic involvement of the pelvic tissues and ovaries. Patients with microscopic stage IIIA disease have a better outcome than those with gross clinical stage III disease.[216] Patients with stage IIIA disease because of the involvement of the serosa have a better DFS (42% versus 20%) than patients with multiple extrauterine disease sites.[219,220] The number of extrauterine disease sites correlates with probability of relapse. Patients with one, two, and three or more extrauterine sites had 5-year DFS of 68%, 56%, and 0%, respectively.[221] In a large series of 126 patients with stage III disease, isolated ovarian or tubal involvement (usually associated with low-grade histology) had a better outcome (60% 5-year survival) than pelvic peritoneal or parametrial involvement (44%). Local control and survival were improved with surgical resection.[216]

Stage IIIA disease should be treated with curative intention whenever possible. Complete debulking surgery plus radiation or chemotherapy based on histologic findings is the preferred treatment approach, preferably within the scope of a randomized trial.[220,222,223] For unresectable disease, depending on the tumor extent and patient condition, irradiation or chemotherapy could be considered followed by surgery if the tumor becomes resectable. Patients with advanced disease or poor general condition should be considered for palliative hormonal therapy or radiation therapy in case of symptoms.[223]

Stage IIIB Disease

Because stage IIIB disease is rare (<1% of all endometrial carcinomas), outcome data are scarce. FIGO 2009 staging has included tumors with parametrial extension in the IIIB category.[102] Treatment of patients with stage IIIB disease should be individualized with respect to sites and volume of disease and the degree of vaginal extension. It may involve radical surgery plus RT and brachytherapy or primary pelvic RT.

Stage IIIC Disease

Stage IIIC disease varies from microscopic involvement of a single pelvic node to extensive macroscopic disease involving the pelvic and paraaortic nodes. Patients with stage IIIC disease with nodal involvement only have a more favorable outcome compared with patients with both nodal and adnexal diseases or extensive pelvic involvement. Women with only pelvic node metastases have a better outcome than those with metastases in pelvic and paraaortic nodes, and DFS up to 80% has been reported.[224-227]

The standard treatment approach to stage IIIC disease is generally agreed to be TAH-BSO with debulking of all macroscopic nodes (or complete pelvic and paraaortic lymphadenectomy) followed by pelvic and paraaortic RT.[227-229] In a retrospective analysis of 71 women treated for stage IIIC endometrial cancer, 50 received definitive pelvic or extended field radiotherapy (EFRT) with or without systemic therapy (regional RT group), whereas 18 received adjuvant platinum-based chemotherapy or hormonal therapy without EBRT.[228] Five-year pelvic-RFS (98% versus 61%, $p = 0.001$), DSS (78% versus 39%, $p = 0.01$), and OS (73% versus 40%, $p = 0.03$) were significantly better for the regional RT group than the systemic therapy group.

DSS in the aforementioned analysis was not significantly correlated with number of nodes removed in the regional RT group but was in patients treated without regional RT ($p = 0.001$).[228] Relapses in patients treated with EBRT primarily occurred in patients with grade-3 cancer who may be most likely to benefit from combined chemoradiation.

In a recent multicenter retrospective analysis of 265 patients with optimally resected stage IIIC disease, 45 had received RT alone, 46 chemotherapy alone, and 161 had both RT and chemotherapy, with 3-year RFS of 73%, 56%, and 73%, respectively. Those patients receiving chemotherapy alone had lowest 3-year OS rates (78%, compared to 95% and 90% for RT and combined RT and CT, $p = 0.005$).[230]

The risk of microscopic paraaortic disease increases with clinical stage. Microscopic paraaortic nodal metastases were diagnosed in 10%, 22%, and 71% of patients with clinical stage I with high-risk factors, stage II, and stage III disease, respectively.[231] EFRT is indicated for documented paraaortic node involvement. Complete removal of macroscopic ($n = 50$) or microscopic ($n = 17$) paraaortic nodal disease followed by EFRT resulted in a 5-year OS of 46% and 53%, respectively; patients with residual macroscopic nodal disease or omission of paraaortic field radiation had significantly decreased survival rates (13% to 18%).[35,232,233] The combination of extended surgery and EFRT has, however, a substantial complication rate, with reported intestinal obstruction rates of 12% to 27%.[231,234] These results are reported from a time period when intensity-modulated radiation therapy (IMRT) was not available to potentially increase the dose delivered to the nodal area while giving better sparing of organs at risk for radiation damage. EFRT therefore should be reserved for patients with suspected or proven paraaortic lymph node involvement.

The randomized GOG-184 trial confirmed that chemotherapy can be given after EFRT if granulocyte colony-stimulating factor is used. Women (mostly with stage III disease) were treated with "involved-field" RT (pelvic RT in women with negative paraaortic nodes and pelvic RT plus EFRT in women with positive paraaortic nodes or no nodal sampling) followed by six cycles of doxorubicin/cisplatin or doxorubicin/cisplatin/paclitaxel chemotherapy.[236] No survival differences were observed with the addition of paclitaxel to doxorubicin/cisplatin chemotherapy in this setting, with 3-year RFS of 64% and 62% with and without paclitaxel.

Stage IV Disease

Patients with stage IV disease have a poor prognosis with reported median survival of 12 months to 15 months. Patients with extensive abdominal disease, particularly those with serous carcinomas, may benefit from initial cytoreductive surgery. Retrospective analyses have shown that maximal cytoreduction is an important prognostic factor, with median survival of 18 months to 30 months for optimal (<2 cm) cytoreduction, in contrast to 3 months to 7 months without debulking.[237] However, if debulking did not result in optimal cytoreduction, survival was severely impaired owing to a 37% rate of major postoperative complications and a 13% mortality rate. In an analysis of 45 patients with stages III to IV treated after surgery (usually TAH-BSO) with chemotherapy (four courses of cisplatin, epirubicin, and cyclophosphamide) and radiation therapy, 9-year PFS and OS of 30% and 53%, respectively, were reported.[238] The randomized GOG 122 trial showed 5-year OS and PFS rates of about 30% and 15%, respectively, after optimal debulking (residual < 2 cm) and eight cycles of doxorubicin and cisplatin in the 28% of patients with stage IV disease.[201]

Patients with bulky disease should be considered for clinical trials. Targeting agents are being investigated in clinical trials. Because many patients are elderly and have concurrent morbidities, such trials should include quality-of-life analysis. Outside the scope of clinical trials, treatment of these patients

After adjustment for stage and grade, patients in the multicenter analysis receiving chemotherapy alone had a HR of 2.2. for relapse and 4.0 for death, whereas there was no difference for the groups treated with RT alone or RT plus chemotherapy suggesting an essential role of RT for stage IIIC disease.[230] Similar results were found in an analysis of 119 uterine grade-3, 211 serous, and 40 clear cell carcinomas, in which regional radiotherapy was found to be an independent prognostic factor for stage III disease, whereas chemotherapy alone did not impact on survival.[186] Nonetheless, these analysis are all subject to the uncertain biases of retrospective reviews, and the contribution of radiation to the treatment of stage IIIC endometrial cancer should be definitively answered by GOG#258, described previously.

Some alternatives have suggested, however, that EFRT should be used prophylactically for patients with positive pelvic nodes in combination with other adverse factors such as grade-3 disease.[224] Mariani et al stressed the importance and complementary role of both complete removal of all involved nodes and pelvic and paraaortic radiotherapy.[235]

The cumulative probability of a late grade-3 or higher treatment-related GI adverse event was 5% in the GOG-184 trial (all RT groups combined). As seen in other reports, grade-1 endometrioid disease even in the advanced disease setting had a relatively good prognosis: compared to grade-3 the RFS HZ was 3.12 for grade 3, similar to the HR of 3.45 for clear cell histology. Serous histology had the largest effect on RFS relative to grade-1 endometrioid adenocarcinoma, with a HR of 4.43.

Recent first results of the GOG-209 randomized noninferiority trial comparing paclitaxel, doxorubicin, and cisplatin with carboplatin and paclitaxel chemotherapy suggest that carboplatin and paclitaxel can be used with similar efficacy and reduced toxicity.[239] Neoadjuvant chemotherapy (carboplatin/paclitaxel) followed by cytoreduction was used in a series of 30 patients with stage IV disease. Partial and complete response rates were 67% and 7%, respectively. Despite achieving optimal debulking in 80%, the median PFS and OS were only 13 months and 23 months.[240] In a small group of 28 patients grade-1 or grade-2 endometrioid subtype and zero and one sites of extraperitoneal metastasis appear to be independent predictors of survival, whereas neither surgery as primary therapy nor optimal cytoreduction was significantly related to OS.[241] The indication for surgery and decision to undertake maximal surgery or use a palliative approach should be carefully made.[223]

is highly individualized, depending on the extent of the disease and the patient's condition.

Radiation Therapy for Recurrent Disease

The management and prognosis of locoregional recurrent disease requires consideration of patient, treatment, and tumor-related factors, including tumor histology and grade, prior surgical and radiation therapy, size, extent and location of the relapse, the presence of distant metastases, the relapse-free interval, and the performance status of the patient.[242-245]

Reported local control rates after radical treatment for isolated vaginal relapse in patients who were previously unirradiated range from 80% to 90% for patients with recurrences confined to the mucosa to 60% to 80% for those with more advanced disease. Five-year OS are 40% to 70%.[142,242,245-248] For patients previously treated with pelvic irradiation, survival rates after vaginal relapse of 10% to 30% have been reported. In the PORTEC trial, the 5-year actuarial survival rate after vaginal relapse was 38% in the RT group and 70% in the control group.[150]

Curative treatment for isolated vaginal recurrence in patients not previously irradiated has consisted of EBRT and VBT although it is not clear that EBRT is necessary for all patients because not all vaginal relapses may be accompanied by other occult pelvic disease. The use of a brachytherapy boost is essential.[248,249] Distal vaginal recurrence in the suburethral region or more extensive vaginal recurrence requires careful individualized BT planning to encompass the target volume with vaginal cylinder or interstitial BT, or both.[250]

Pelvic and distant relapses generally have a poor prognosis. Complete remission rates of treatment for pelvic relapse range from less than 5% for patients who had previous pelvic RT and those with sidewall disease to 5% to 30% for patients not previously irradiated.[142,251] To try to improve prognosis for recurrent vaginal or pelvic disease, the GOG has initiated a randomized trial (GOG-238) of pelvic RT with or without concurrent weekly cisplatin in patients with pelvic-only relapses. This may be preceded by surgical resection.

Selected patients with pelvic relapse may be candidates for a curative approach with extended surgery alone or with preoperative chemoradiation, intraoperative irradiation (IORT), or both. Patients with isolated distant metastasis (i.e., single lung nodule) may have long symptom-free periods after local resection or consideration of stereotactic body radiation.

The frequency of follow-up examinations and their value in detecting asymptomatic relapses have been subject of discussion.[252-254] It has been argued that 50% to 75% of women with disease relapse were symptomatic and that regular follow-up is not cost effective because patients can only occasionally be salvaged after relapse. However, patients with early-stage disease treated with surgery alone (usually low risk) should be cautioned about symptoms of vaginal bleeding, which almost always signals vaginal relapse, because salvage rates are high. Routine surveillance rarely detects asymptomatic recurrence. Follow-up examinations should include a careful history focusing on symptoms of recurrence or of side effects of treatment and visual inspection of the vagina and bimanual rectovaginal examinations. Biopsy should be taken if abnormalities are found. Because distant relapse only occasionally can be treated with a view to a long symptom-free interval, it cannot be recommended to actively screen for distant metastases outside the scope of clinical trials. In general, after the first 2 years less frequent and more patient-directed follow-up visits are preferred, after specific patient education with written information as to which symptoms would necessitate evaluation and with contact numbers they could use for rapid access.[254]

Radiation Therapy for Palliation

Radiation therapy has an important role in palliation of symptoms from locally advanced, recurrent, or metastatic endometrial cancer. Vaginal bleeding, vaginal discharge, or pain from advanced or recurrent disease or lymphedema from enlarged pelvic lymph nodes can be successfully palliated with RT. Optimal doses of palliative radiation have not been established Commonly used schedules include a short course of fractionated EBRT using 3-Gy to 4-Gy fractions to a dose of 20 Gy to 30 Gy over 1 to 2 weeks or, depending on the general condition and symptoms, shorter schedules of 1 to 3 in 8-Gy fractions can be used. Other sites of symptomatic metastases, such as brain metastases or distant lymph node disease, are uncommon but can also be effectively palliated with similar radiation doses. Rapid and effective palliation of pain from bone metastases can be obtained using a single 8-Gy dose.[255-257]

Systemic Therapy for Recurrent or Metastatic Disease

Hormonal Therapy

Progestational agents are often chosen as the first treatment for advanced or metastatic grade-1 or grade-2 disease, especially for PR-positive tumors.[258-260] Reported response rates range from 15% to 34%, with a median response duration of several months. For PR- or ER-positive tumors response rates up to 77% have been observed, in contrast to 9% for receptor-negative tumors.[258,261] For relatively asymptomatic patients with unknown receptor status and grade-1 or grade-2 disease, progestins should be considered before the more toxic chemotherapy.

Chemotherapy

The majority of women with recurrent or metastatic disease will not have low-grade tumors. Symptomatic patients with recurrent or metastatic disease, especially grade-3 or receptor-negative or unknown tumors should be considered for chemotherapy.

Platinum drugs, anthracyclines, and taxanes are the most active agents tested to date for endometrial carcinoma, and multiagent chemotherapy has been shown to produce higher response rates than single-agent therapy.[262-266] Platinum- or taxane-containing multiagent therapy provides response rates of 30% to 75%, respectively, with median remission durations of 6 months to 12 months.[232,235-237] Median OS on most trials of chemotherapy for measurable metastatic or recurrent endometrial carcinoma is only in the range of 12 months to 15 months. The only randomized trial showing a survival benefit for chemotherapy in the setting of advanced or recurrent disease is GOG-177, which compared doxorubicin/cisplatin to paclitaxel/doxorubicin/cisplatin with filgrastim support. The triple-drug regimen showed an improved response rate (57% versus 34%) and somewhat longer survival (58% versus 50% 1-year survival), but at the cost of significant neurotoxicity.[262] Carboplatin/paclitaxel therapy, which is the standard for ovarian cancer and is used commonly in the community, has less toxicity than doxorubicin/cisplatin or paclitaxel/doxorubicin/cisplatin, and may be equally effective.[266,267] Preliminary results of a large randomized GOG noninferiority trial comparing carboplatin/paclitaxel with paclitaxel/doxorubicin/cisplatin (GOG-209) in women with stages III, IV, or recurrent disease showed no difference in PFS (14 months in each arm) or median OS (32 months for carboplatin/paclitaxel, 38 months for paclitaxel/doxorubicin/cisplatin, not statistically significant) between the groups, while toxicity was increased for the TAP regimen.[239]

Current interest has focused on developing and evaluating molecular targeted therapies and integrating them with

Current IHC assays to determine levels of hormone-receptor positivity do not predict response to hormonal therapy. The GOG studied alternating cycles of tamoxifen and progestin therapy in an attempt to use tamoxifen to upregulate the PR, reporting a response rate of 27%.[260] This has not been compared with single-agent progestin therapy in any randomized trials. For patients with disease progression after a response to progestins, tamoxifen and aromatase inhibitors may be considered. Many of the large trials of progestin therapy were completed years ago, and it is not certain that response rates would be as high using more stringent current response criteria. Toxicity reporting was also less complete then, and progestins may cause weight gain and increase thrombosis risk in a population already prone to these complications. Grade-3 disease is unlikely to respond to hormonal therapy (<10%). High-dose therapy (800 mg/day of megestrol acetate or 1000 mg/day of medroxyprogesterone acetate [MPA]) was not found to be more effective than standard doses (160 mg/day of megestrol or 200 mg/day of MPA).[258] Some data suggest that even lower doses of MPA may be as effective. Recent attempts to combine hormone therapy with mTOR inhibition are described previously.

Because most patients with advanced disease are elderly women with comorbidities, their performance status and concurrent diseases may preclude the use of multiagent chemotherapy. Many will have had prior pelvic irradiation, and chemotherapy dose reductions or use of growth factor support will need to be considered.

The Multicentre Italian Trials in Ovarian Cancer and Gynecologic Malignancies Group (MITO) conducted a single arm Phase II trial of pegylated liposomal doxorubicin plus carboplatin in the front-line therapy of advanced endometrial cancer and reported a response rate of 59.5% and a median survival of 80.1 weeks. This might be an attractive alternative regimen for women at risk for neurotoxicity.[268]

cytotoxic chemotherapy. Trials of mTOR inhibitors and other agents affecting the AKT/PI3K/mTOR pathway are discussed previously; single-agent response rates are modest, and combinations are being explored.

TREATMENT OF UTERINE SARCOMAS

Uterine sarcomas are rare, comprising more than three distinct types with different characteristics and different outcomes: carcinosarcomas (or malignant mixed müllerian tumors), 45%; leiomyosarcomas, 40%; and endometrial stromal sarcomas, 15%. Uterine sarcomas, especially leiomyosarcomas, have a higher metastatic rate without preceding lymph node involvement compared with the adenocarcinomas.[4] Most patients present with vaginal bleeding, much like patients with adenocarcinomas, but the tumor is typically larger before this occurs. Uterine sarcoma may also be an unexpected diagnosis in a uterus resected for presumed symptomatic leiomyoma.[273] Other patients can present with local discomfort from uterine enlargement. The lungs are the most common sites of metastatic disease. Because of the high rate of metastases especially to the lung, initial evaluation should include CT of the chest.

Management varies because data from randomized studies is lacking. Because patterns of failure are different for the different sarcoma types, treatment should be tailored to the specific sarcoma type. Initial treatment is primarily focused on the initial surgery. Hysterectomy is the mainstay of treatment.

Endometrial stromal sarcoma, formerly called low-grade endometrial stromal sarcoma, is composed of cells that resemble normal proliferation phase endometrial stroma. These tumors are almost all ER- and PR-positive, are usually diagnosed at stage I (90%), and should be treated with TAH-BSO alone.

Because of the indolent growth pattern of endometrial stromal sarcomas, patients with advanced or recurrent disease usually have a long survival and may have second or third debulking surgery and several lines of hormonal therapies. For the rare hormone receptor-negative recurrence, chemotherapy may be considered.[4]

Undifferentiated uterine sarcoma, formerly called high-grade endometrial stromal sarcoma, should be treated with more extensive surgery. Carcinosarcomas and undifferentiated uterine sarcomas warrant lymph node evaluation, and most current authors favor full surgical staging, including TAH-BSO, peritoneal cytology, full pelvic lymph node dissection, and omentectomy. Several authors have pointed to a more aggressive behavior and genetic differences from high-grade cancers.[274,275]

The weight of clinical molecular and genetic data support the view that carcinosarcomas should be considered high-risk carcinomas and be treated accordingly.[35,36] The risk and patterns of relapse seem to be related to the epithelial component, Based on the data summarized previously, pelvic radiation therapy is usually considered indicated for patients with risk factors similar to those with carcinomas (e.g., high mitotic count, deep myometrial invasion, advanced age, cervical involvement) and for cases with residual microscopic or macroscopic pelvic disease.

Retrospective studies of adjuvant radiation therapy have shown improved pelvic control, especially for carcinosarcomas but no survival benefit.[276-278] In a SEER analysis among 2461 women with carcinosarcomas an OS benefit was reported for the 890 women who had been treated with radiotherapy,[279] but as with any of such population series, selection factors are unknown and may have influenced the results.[182] The EORTC-55874 prospective, randomized trial compared pelvic RT versus no further therapy in 224 patients with uterine sarcomas stage I and II (103 leiomyosarcomas, 91 carcinosarcomas, 28 endometrial stroma sarcomas). RT provided a significant reduction of pelvic recurrence for carcinosarcomas, with 5-year pelvic recurrence rates of 22% with irradiation versus 40% for the control group ($p = 0.0004$). However, survival was not improved (5-year OS of 58% and 56%, $p = 0.92$). This trial showed the need to separate the different sarcoma types. Carcinosarcomas were found to benefit from pelvic irradiation in terms of pelvic control. Leiomyosarcomas had no benefit from RT (20% versus 24% pelvic recurrence) and were most likely to relapse at distant sites. Therefore, pelvic RT should be considered only for microscopic or macroscopic residual disease, preferably within clinical trials evaluating radiation therapy with concurrent or sequential chemotherapy. There were too few endometrial stromal sarcomas in the EORTC study to allow specific analysis.[280]

Chemotherapy for recurrent or metastatic sarcomas has limited efficacy. Agents with activity against carcinosarcoma include ifosfamide, platinum drugs, and taxanes.[281-285] Combination therapy with cisplatin, doxorubicin, and ifosfamide was found to produce an overall response rate of 56%, albeit with considerable toxicity.[282]

In leiomyosarcoma, the risk of lymph node involvement is low, and lymphadenectomy is therefore not indicated. Ifosfamide and doxorubicin have single-agent activity in the treatment of advanced and metastatic uterine leiomyosarcoma, and the combination of the two has produced a response rate of 30%.[286]

Adjuvant chemotherapy has been investigated in uterine sarcomas in view of their increased risk of distant metastases. A small older ($n = 156$ total, 48 leiomyosarcoma, 93 carcinosarcoma, 15 other sarcoma) randomized study evaluating eight cycles adjuvant doxorubicin showed no benefit overall.[290] In the leiomyosarcoma subgroup, a nonsignficant decrease in the risk of relapse (44% versus 61%) was observed.

A retrospective study among 49 patients with stages I to IV carcinosarcoma showed nonsignificantly better survival after chemotherapy (carboplatin and paclitaxel) with or without RT than after RT alone (3-year OS of 66% versus 34%, $p = 0.15$).[291] A number of studies have suggested the combination of RT and chemotherapy (sequential or sandwiched) to be more effective than chemotherapy or RT alone.[292-297] A prospective GOG study using adjuvant ifosfamide and cisplatin (without radiation therapy) among 65 patients with stages I to II carcinosarcoma showed the combination to be tolerable, but impact on PFS (69%) and OS (82% at 2 years) was unclear owing to absence of controls, and the pelvic recurrence rate was high.[298] A randomized GOG trial among 232 patients with stages I to IV (45% stage III) carcinosarcoma compared chemotherapy (three cycles of cisplatinum, ifosfamide, and mesna) with WAI (30 Gy, with pelvic boost to 50 Gy). The recurrence rate was nonsignificantly lower for chemotherapy than for WAI (52 versus 58%, HR = 0.789, $p = 0.24$), and survival was nonsignificantly better (47% versus 34%, $p = 0.08$). After chemotherapy alone, more vaginal recurrences were found.[299]

IRRADIATION TECHNIQUES AND TOLERANCE

External Beam Pelvic Irradiation

Most patients receive pelvic RT in the postoperative setting. The clinical target volume for pelvic RT consists of the parametrial tissues, the proximal half of the vagina, and the pelvic lymph node areas (i.e., internal and external iliac and the lower common iliac lymph node regions; in case of cervical involvement and for node-positive disease the presacral and upper iliac lymph node regions are included). The planning target volume is derived by adding an appropriate margin around the

A GOG Phase II trial of the anti-VEGF monoclonal antibody bevacizumab in women with endometrial carcinoma with one to two prior chemotherapy regimens noted a promising 13.5% major response rate, and 40% of subjects were progression-free at 6 months.[269] Other antiangiogenic agents tested have generally not appeared as active; aflibercept showed only a 7% response rate.[270] A preliminary report suggested that sunitinib produced a 15% response rate.[271] Trials of multiple other multitargeted antiangiogenic agents, including cediranib, brivanib, cabozantanib, nintedanib, lenvatinib, and AMG 386 (trebananib) are ongoing or completed but not yet reported. A frontline randomized Phase II GOG trial testing paclitaxel/carboplatin/bevacizumab versus paclitaxel/carboplatin/temsirolimus versus ixabepilone/carboplatin/bevacizumab has been completed and results should be available soon.

Anti-ERBB2 and anti-EGFR agents (discussed previously) have not yet provided much promise. Metformin is a relatively nontoxic inexpensive oral agent widely used in the treatment of diabetes. Retrospective studies have suggested that patients with diabetes and endometrial cancer who use metformin have superior OS and RFS compared to patients with or without diabetes with endometrial cancer who do not use metformin.[7,75,80,272] In preclinical models metformin inhibited cell proliferation, induced apoptosis, and decreased tumor growth in, with one study showing the greatest response in cells harboring activating mutations in K-Ras. The GOG will shortly activate a randomized trial of carboplatin/paclitaxel/metformin versus carboplatin/paclitaxel/placebo in the frontline setting.

Hormone-replacement therapy should not be prescribed because of the tumor's hormone sensitivity. Chemotherapy and RT should not be used. In the case of pelvic or abdominal recurrent disease, debulking surgery should be employed, followed by hormonal therapy (i.e., progestins such as medroxyprogesterone acetate). Aromatase inhibitors, gonadotropin-releasing hormone agonists, and selective ER-modulators are used as second- and third-line hormonal therapy.

Two randomized trials of first-line treatment for advanced disease have compared single-agent therapy with ifosfamide to ifosfamide plus cisplatin[283] and to ifosfamide plus paclitaxel,[284] respectively. In each case the combination produced higher response rates at the cost of added toxicity. The addition of paclitaxel also improved survival, with response rates of 29% and 45% and median OS of 8.4 and 13.5 months for single-agent and combination therapy, respectively.

A prospective Phase II trial of carboplatin plus paclitaxel in patients who are chemotherapy-naive produced a response rate of 52%. This combination would appear to be better tolerated than ifosfamide-based regimens.[285] An ongoing Phase III trial, GOG 261, is testing the combination of carboplatin/paclitaxel versus the combination of ifosfamide/paclitaxel in women with newly diagnosed stages I to IV persistent or recurrent uterine carcinosarcoma. Results will hopefully justify use of the less toxic combination.

As second-line therapy for advanced and metastatic leiomyosarcoma, single-agent gemcitabine had a 20.5% response rate,[287] and the combination of docetaxel and gemcitabine, which requires growth factor support, produced a 28% response.[288] As first-line chemotherapy for metastatic uterine leiomyosarcoma the response rate to the combination was 35.8%.[289] A recently completed Phase III study, GOG 250, tested the addition of bevacizumab to the gemcitabine/docetaxel combination; results should be available soon. Other agents with some activity include temozolomide and pazopanib.

As discussed previously, carboplatin/paclitaxel is currently being compared with ifosfamide/paclitaxel in this same setting. Optimal treatment of patients with uterine carcinosarcoma has not been determined.

Trials of adjuvant chemotherapy in leiomyosarcomas are few. The French Sarcoma Group recently published results of their randomized clinical trial of adjuvant chemotherapy with doxorubicin, ifosfamide, and cisplatin followed by pelvic radiotherapy versus pelvic radiotherapy alone in patients with localized uterine sarcomas. The study was closed prematurely for poor accrual. Eighty-one patients were included, of whom 53 had leiomyosarcoma and 9 had undifferentiated sarcoma. The DFS for the leiomyosarcoma and undifferentiated sarcomas combined at 3 years was 51% (95% CI 34% to 69%) in patients receiving both chemotherapy and radiotherapy versus 40% (95% CI 25% to 58%) in patients receiving radiotherapy alone (p = NS), and DFS at 5 years was 51% (95% CI 34% to 69%) versus 29% (95% CI 16% to 47%) in arm B, respectively (P = 0.098).[300] A prospective nonrandomized Phase II trial of four cycles of adjuvant gemcitabine plus docetaxel followed by four cycles of doxorubicin for completely resected high-grade uterine leiomyosarcoma was recently reported to show a PFS of 78% at 2 years and 57% at 3 years, which compares favorably with historical controls without adjuvant chemotherapy.[301] An ongoing randomized trial, GOG 277, which is being performed in collaboration with the EORTC and Cancer Research UK (NCRI), is testing this regimen (adjuvant gemcitabine/docetaxel followed by doxorubicin) versus no further treatment after surgery for uterus-limited leiomyosarcoma. This trial prohibits whole pelvic radiotherapy.

clinical target to allow for the beam penumbra, geometric uncertainties, and variability in daily patient setup and movement of internal organs. The main organs at risk for complications are the rectosigmoid, small bowel, and bladder. Most acute and late complications are of the GI tract, and it is essential to reduce the volume of small bowel within the treatment fields as much as possible. A four-field box technique has traditionally been employed, which had a smaller volume of small bowel in the high-dose region compared with anterior and posterior parallel-opposed ports. The prone treatment position has been found to reduce the volume of small bowel within the pelvis, and special belly board devices have been designed that are more effective in pushing the small bowel out of the treatment fields than the prone position alone. Several studies have shown decreased volumes of irradiated small bowel with the use of a belly board in the postoperative setting.[302-304] In thin patients with firm abdominal walls, there may be less benefit. High-energy photons from a linear accelerator are preferred to ensure a homogeneous dose distribution.

Most RT departments are using three-dimensional CT planning, and multileaf collimators are used in all fields to shield organs at risk and reduce the treated volume. The use of CT planning has the clear advantage of delineating the actual nodal sites, instead of using standard field borders, which risk insufficiently or too generously encompassing the lymphatic chains. Determining field borders based on bony landmarks should now be considered obsolete in the developed world. Excellent contouring atlases have been published[305,306] that guide the radiation oncologist to ensure adequate delineation of the areas at risk (Figure 59-2, contouring examples in A to D and conventional CT-planned box technique with anterior-posterior and lateral fields in E and F).

A total dose of 45 Gy to 46 Gy is usually prescribed in the postoperative setting, with daily fractions of 1.8 Gy to 2.0 Gy for five fractions per week. For cases with involved margins or residual macroscopic disease, the target dose is 50.4 Gy with a boost dose to the areas of involvement using CT planning to a cumulative dose of 60 Gy to 70 Gy, depending on

the situation. Ideally, these risk areas should be marked with clips during surgery. Rarely an omentoplasty or insertion of a hydrogel spacer may be considered to move the small bowel out of the high-dose area.[307,308]

Intensity-Modulated Radiation Therapy

In view of the additional toxicities when combining surgery, EBRT, and chemotherapy in patients with high-risk endometrial cancer, several groups have investigated the use of IMRT to reduce the dose to critical organs surrounding the target tissues and reduce rates of GI toxicity and of hematologic toxicity when combined chemotherapy and RT are used.

IMRT uses multiple beams of various intensities that conform the high-dose region to the shape of the target tissues in three dimensions, minimizing the dose to the surrounding organs. Adjuvant pelvic IMRT requires careful quality assurance measures and margins for the clinical target volumes to be large enough to account for significant internal motion related to bladder and rectal filling.[306,309] Use of integrated target volume (to account for differences in organ filling) and repeated planning CT scans may be needed to ensure adequate coverage of the clinical target volume (Figures 59-3, 59-4, and 59-5). Treatment planning studies[310-312] have shown that a substantial reduction of the doses to the small bowel, rectum, and the pelvic bone marrow can be realized. The volume of small bowel irradiated to the prescription dose is reduced by a factor of 2, compared with a CT-based, conventional, three-dimensional, four-field box technique.[312] Clinical studies have shown a reduction of acute GI toxicity in patients treated with pelvic IMRT compared to three-dimensional conformal RT,[310,313,314] and of acute hematologic toxicity in patients with gynecologic cancer receiving pelvic IMRT combined with chemotherapy.[315] In an analysis of 36 patients with gynecologic cancer treated with pelvic RT with or without chemotherapy or brachytherapy (or both), IMRT also resulted in a significant reduction of patients experiencing chronic GI toxicity (11% mild symptoms compared with 50% in a historical series of patients receiving pelvic irradiation) and less severe GI complications (0% versus 3%).[316] Other somewhat larger series have confirmed these results.[313,314] Especially for the increasing number of patients with high-risk endometrial carcinoma treated with surgery, RT, and chemotherapy, IMRT may be an essential tool in reducing the chronic toxicities of multimodality treatment. A Phase II study among 58 patients with endometrial cancer conducted by the RTOG showed that pelvic IMRT can be safely delivered in a multicenter setting, provided that clear guidelines for target definition and delineation, dose prescription, quality assurance, and dose-volume constraints for the target volume and organs at risk are provided.[317] Currently a randomized trial of the RTOG (1203) is comparing acute toxicities between a four-field box and IMRT in the adjuvant setting for both endometrial and cervical cancer.[318]

Extended-Field Irradiation

Patients undergoing treatment to the pelvic and paraaortic regions are usually treated in the supine position to ensure a dorsal position of the kidneys. CT-directed planning using three-dimensional conformal radiotherapy or IMRT ensures adequate sparing of the kidneys and bowel. The superior field border is usually placed at the T12-L1 junction, but it may be individualized according to the level of detected or suspected lymph node involvement. Doses used for pelvic and paraaortic treatment are typically 45 Gy to 50.4 Gy with standard 1.8-Gy fractions. For macroscopic involved lymph nodes a boost dose may be used, preferably using IMRT.[319]

Complications of Pelvic Irradiation

Side effects of radiation therapy for gynecologic malignancies have been well documented. Complication rates are dose and volume dependent and are higher for the combination of pelvic EBRT and VBT than for EBRT alone.[172,320-323] Complication rates after EBRT are also increased if a full lymphadenectomy is added to the hysterectomy.[320,324] Other treatment-related factors associated with the risk of complications are treatment volume, daily fractionation, and irradiation technique.[325] Patient-related risk factors are prior abdominal surgery, young age, low weight, concurrent diabetes, hypertension, inflammatory bowel disease, or other pelvic inflammatory conditions, although literature data show conflicting results regarding several of these factors. The most significant complications are obstruction of the small bowel, chronic diarrhea, proctitis, fistula formation, vaginal stenosis, and insufficiency fractures of bone. The use of EBRT is associated with the risk of small bowel complications.[324,326] The addition of VBT to EBRT especially increases the incidence of vaginal and rectal side effects, such as fibrosis, stenosis, ulcers, and fistula.[321,325] Reported rates of severe complications after TAH-BSO plus EBRT range from 2% to 6%; after surgery followed by EBRT

Highlighted are the areas receiving at least 15 Gy *(white)*, 30 Gy *(blue)*, 40 Gy *(blue-green)*, 46.2 Gy (=95%, *green*), and 48.6 Gy (=100%, *yellow*) of the prescription dose.

and VBT, from 4% to 13%; after VBT alone, from 0% to 7% (dose dependent); and after EBRT and surgery, including lymphadenectomy, from 7% to 18%.

The rates of mild to moderate complications are less well established. Acute side effects of EBRT, such as diarrhea, urgency, abdominal cramps, and urinary frequency are usually not reported if they do not cause an interruption or discontinuation of treatment.[283] Mild late side effects (including increased bowel movements, episodes of diarrhea, abdominal cramps, frequent urination, and minor incontinence) are underreported.[326,327]

In the PORTEC trial, 63% of the patients were treated during standard four-field pelvic EBRT with medication or dietary measures, or both, for mild, acute symptoms. Discontinuation of irradiation because of acute symptoms occurred in 2% of cases.[328] In the ASTEC trial, any acute toxicity was reported in 57% of patients who underwent RT compared with 27% for controls and involved mostly mild (32%) or moderate symptoms. Severe acute toxicity was reported in 3% versus less than 1% of patients.[147] The 5-year actuarial rates of any late complication in the PORTEC trial were 26% in the RT group and 4% in the control group ($p < 0.001$). Most complications (67%) were mild (grade 1), and almost 50% of symptoms resolved in the course of 2 year to 3 years. GI symptoms were the predominant side effects, with a 5-year actuarial rate of (mostly mild) GI complications in the RT group of 20%. The 5-year actuarial rates of severe (grade 3 or 4) late complications were 3% in the RT group and 0% in the control group. No severe late genitourinary or vaginal complications occurred. In the ASTEC trial, slightly higher late toxicity rates were reported: grades 1, 2, 3, and 4 predominantly GI or urogenital late toxicity was reported in 30%, 22%, 7%, and 1%, respectively, of patients with EBRT, compared with 24%, 16%, 35%, and 0% among control subjects. In the GOG 99 trial, the combination of lymphadenectomy and EBRT resulted in higher GI complication rates, including more bowel obstructions.[90]

The presence of acute treatment-related symptoms is one of the most important risk factors for late complications.[328] The

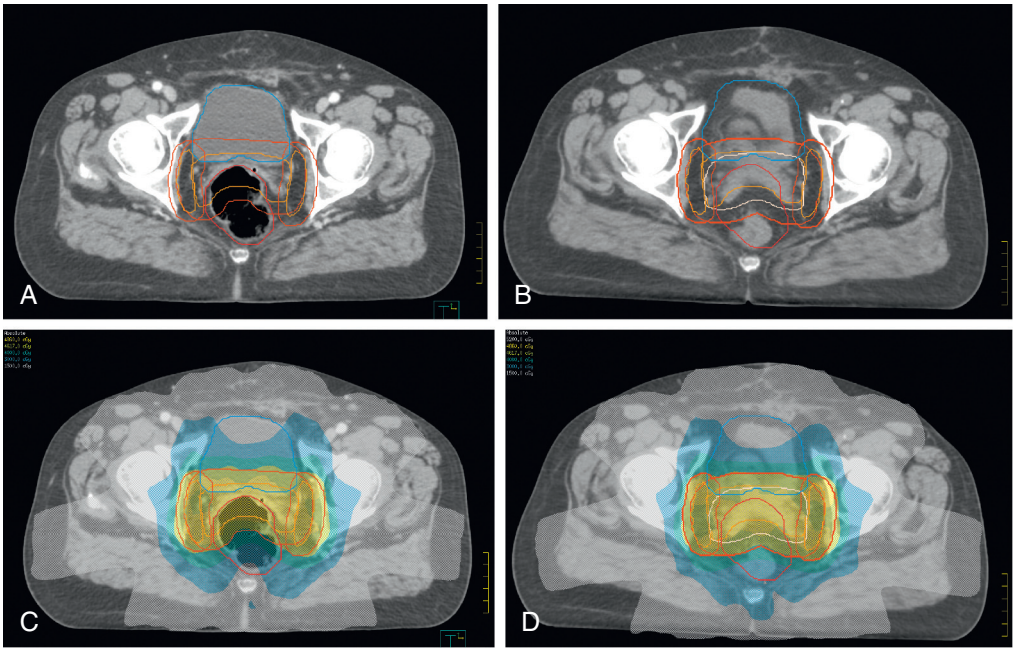

Figure 59-5 Examples of planning computed tomography (CT) scans showing differences in bladder and rectal filling with clear impact on margins and resulting treatment plans. *Left panel:* contouring and planning using the initial CT scan with full bladder; *right panel:* contouring and planning with fusion of a second planning CT scan with empty bladder and bladder and rectum; the resulting integrated target volume *(white contour)* requires a more generous dorsal margin.

association between acute and late treatment complications has become a topic of interest and research.[329,330] The fact that a subset of patients with acute toxicity have no symptom-free interval between acute and late complications supports the theory that late injury occurs as a consequence of persisting acute injury of the intestinal mucosa.[330] Pelvic RT is associated with short-term and long-term effects on GI function, most notably increased frequency of bowel actions, less bile acid absorption, and faster intestinal transit.[326] Most of these changes improve with time, but some long-term effects persist. A long-term quality-of-life analysis from the PORTEC-1 trial showed that even 15 years after treatment, patients treated with EBRT reported significant ($p < 0.01$) and clinically relevant higher rates of urinary incontinence, diarrhea, and fecal leakage leading to more limitations in daily activities. Increased symptoms were reflected by the frequent use of incontinence materials after EBRT (day and night use, 42.9% versus 15.2% for NAT; $p = 0.001$). Patients treated with EBRT even reported lower scores on the SF-36 scales for physical functioning and role-physical functioning.[331] The radiation oncologist has an essential role during follow-up of patients with gynecological cancer who underwent EBRT to evaluate and treat these late, mainly GI symptoms, which significantly impact on daily quality of life especially because specific treatments are available.[332,333] A recent randomized trial of algorithm-based management of GI symptoms among 218 patients showed that patients given targeted intervention following a detailed clinical algorithm had better improvements of their symptoms than did patients given "usual care."[333]

Results from the PORTEC-2 trial showed that rates of complications after VBT alone (700 cGy at 0.5-cm depth times three to proximal 4 cm of vagina) were low. During irradiation there was a significantly increased rate of acute RTOG grade-1 and grade-2 acute GI symptoms among patients with EBRT as compared with patients who had VBT (53% verus 12%, $p = 0.001$). This difference decreased with further follow-up and lost significance after 24 months. Late grade-3 GI toxicity was reported in four (1.9%) patients with EBRT and in one patient (0.5%) who underwent VBT and required surgery for bowel obstruction because of adhesions or fibrosis. Late grade-2 moderate mucosal atrophy (without narrowing or shortening) was significantly more frequent after VBT than after EBRT (17% versus 4% after 2 years). Grade-3 atrophy (marked atrophy with or without shortening or narrowing) was reported in only one patient (0.5%) who underwent EBRT and in four patients (1.9%) who underwent VBT. Patient-reported outcomes showed that patients who underwent VBT reported significantly better social functioning ($p = 0.005$) and lower symptom scores for diarrhea, fecal leakage, need to stay close to a toilet and limitation in daily activities because of bowel symptoms ($p < 0.001$), than those treated with EBRT. The scores of the patients who underwent VBT remained in the range of the normal population. There were no differences in sexual functioning or symptoms between the treatment groups, although both groups had lower functioning scores than an age-matched norm population, probably reflecting the impact of diagnosis and treatment of a gynecological cancer.[156,157]

Brachytherapy Techniques

LDR, pulsed-rate, and HDR brachytherapy techniques are available with a variety of manual and remote afterloading applicators for intracavitary and interstitial brachytherapy. The LDR technique has been replaced in most centers by PDR techniques simulating LDR treatment, but with the convenience of modern HDR machines.[334] Iridium-192 is used for pulsed and HDR brachytherapy. HDR techniques may be preferred to avoid the increased morbidity of prolonged bed rest required for the LDR and PDR treatment and for the convenience of the patient and staff.

In primary treatment of endometrial carcinoma, brachytherapy has traditionally been administered with LDR techniques such as Heyman packing or Simon capsules or with a

single intrauterine tube, depending on the size of the uterus. The technical aspects of intracavitary placement of a single tube are similar to those for cervical carcinoma, but different dose specification points have been used (e.g., point *My* for myometrium, 2 cm laterally and caudally to the tip of the most advanced applicator, or the *A-line*, 2 cm laterally from the tip). A small uterus can be treated with a single tube, using a stepping source and increasing the dwell times at the fundus to obtain a pear-shaped isodose distribution (i.e., inverted pear). However, an individualized approach is preferable with dose specification at the serosa at the site of the tumor. MRI or CT is used, ideally with the intrauterine tubes in place, to determine the depth of tumor invasion and the myometrial width in relation to the tubes. CT or MRI planning ensures adequate coverage of the tumor while avoiding overdosing in the bowel surrounding the uterus. Specific uterine applicators for HDR and PDR intracavitary brachytherapy are currently available. An intermediate-size uterus can be treated with a two-channel applicator (one applicator in each uterine cornu), which results in a pear-shaped isodose distribution at the fundus. For treatment of a large uterus with a tumor deeply infiltrating the myometrium, Heyman packing using Norman-Simon applicators is preferred and although rarely used. The American Brachytherapy Society has published treatment guidelines.[335]

For HDR brachytherapy alone, more commonly used fractionations include five fractions of 7.3-Gy HDR therapy prescribed at 2 cm from the midpoint of the uterine sources, or if used in conjunction with EBRT, two fractions of 8.5 Gy to four fractions of 5.2 Gy are suggested. CT or MRI is recommended to optimize dosing to the thickness of the uterine wall in individual patients.

Vaginal Brachytherapy

In patients with vaginal recurrence the most common site is the upper vagina, and adjuvant vaginal cuff brachytherapy has long been used to decrease the risk of vaginal cuff recurrence after hysterectomy. Since the mid-1990s, HDR fractionated VBT alone has been increasingly used as adjuvant therapy after hysterectomy in selected patients. There are institutional variations in the target volume for VBT, especially the length of the vagina to be treated: the vaginal cuff, proximal half or two thirds of the vagina, or the entire vagina. Vaginal recurrences are mainly located in the vaginal vault and upper vagina.[142] It is recommended that only the upper half or proximal 3 cm or 4 cm of the vagina be treated, because this is associated with lower complication rates (i.e., vaginal stenosis and fistula) than treating the entire length of the vagina. Although most radiation oncologists use vaginal cylinders treating the upper half to two thirds of the vagina, others claim that vaginal colpostats have the advantage of providing a better dose distribution around the vaginal vault with lower doses to the bladder and rectum.[151,336]

Convenient, moderate-dose fractionation schedules of VBT provide high vaginal control rates (>95%) and low morbidity rates.[337] The use of higher doses increases the risk of side effects and does not further increase the vaginal control rates. Based on these data, optimal LDR and HDR schedules seem to be those that give an equivalent of 45 Gy to 50 Gy to the mucosal surface of the upper half of the vagina. Typical examples are LDR 30 Gy, specified at a 5-mm depth at a dose rate of 60 cGy to 65 cGy per hour and given in one session of 2 days to 3 days, or HDR 21 Gy, specified at a 5-mm depth and given in three fractions of 7 Gy each, 1 week apart, as used in the PORTEC-2 trial.[148]

Usually, the dose is specified at 5 mm from the surface and 5 mm from the apex of the vagina. Because of the distention of the vagina after placement of the vaginal cylinder, it has been argued that the wall becomes less than 5 mm thick and that the reference isodose should be chosen at a 3-mm, 4-mm, or 5-mm depth, depending on a clinical estimation of the mucosal thickness. By individualizing the depth and avoiding applicators with small diameters, the rate of vaginal side effects was significantly reduced (17% and 1% for grades 1 and 2, compared with 26% and 8%), without a difference in vaginal control.[338] In individual cases, the target depth can be adjusted according to the clinical situation. For example, in case of a thick scar at the cuff the dose can be specified at 10 mm from the apex and 5 mm along the wall. CT or MRI planning should be used for treatment of such thicker targets and especially for brachytherapy treatment of vaginal recurrence. CT- and MRI-compatible cylinders and colpostats are available for this purpose.

VBT can be performed as an outpatient procedure, especially when a vaginal cylinder is used, for which no sedation or anesthesia is needed. If vaginal colpostats are used with vaginal gauze packing, intravenous sedation or general or regional anesthesia is commonly used. Most U.S. centers use fentanyl and midazolam intravenously for sedation. With the patient in the lithotomy position, an indwelling bladder catheter is inserted in the bladder and the balloon is filled with radiopaque contrast material to visualize the bladder base on applicator placement radiographs. Two radiopaque metal seed markers may be inserted submucosally in the vaginal cuff to assess applicator position on radiographs. The colpostats are positioned in the upper vagina against the cuff. Vaginal packing is used to secure the colpostats in place and to displace the bladder base and anterior rectum away. When a vaginal cylinder is used, the largest diameter that smoothly fits the vagina should be chosen to increase the relative dose at depth compared to the surface. With smaller diameters the volume of the vaginal mucosa receiving more than 150% of the dose is increased. The applicator is held in place by an external immobilization device. Traditionally, orthogonal radiographs are obtained to verify the appropriate placement of the applicator in relation to the vaginal cuff markers and for dosimetric calculations. A small amount of rectal contrast agent may be injected or a marker placed before the lateral radiograph is filmed. Increasingly, CT or MRI planning is used, especially if brachytherapy is given as a boost for treatment of vaginal recurrence. After the appropriate quality assurance checks, the HDR treatment is administered, which takes less than 10 minutes, depending on the dose and source activity. Applicators and catheters are then removed, and the patient is discharged.

For vaginal recurrences a multichannel cylinder applicator may be used to individually tailor the dose distribution to various parts of the vaginal circumference and to varying depth depending on the tumor configuration. Interstitial brachytherapy (e.g., with interstitial needles inserted through ovoids or ring applicator) may also be used when the thickness of vaginal tumor cannot be adequately treated with intravaginal sources in a (multichannel) cylinder.

TREATMENT ALGORITHM, CONCLUSIONS, AND CHALLENGES

Management of each endometrial cancer patient must consider the risk factors for tumor relapse and tolerance of the treatment that is being considered. Ideally, patient evaluation and surgery should be performed by a gynecologic oncologist or by a gynecologist with specific oncology expertise and dedication. Deciding on the indication for and extent of surgery and adjuvant therapy requires a multidisciplinary team of gynecologic oncologists, radiation oncologists, and medical oncologists. The approach to the management of

endometrial cancer patients is summarized in the treatment algorithm (Figure 59-6) and the follow-up algorithm (Figure 59-7).

The main developments in radiation therapy for endometrial carcinoma have been the reduction of indications for pelvic EBRT, shifting the role of RT in low-risk disease toward treatment reserved for patients with vaginal or pelvic relapse, the standard use of VBT alone for patients with high-intermediate-risk disease, and the studies of adjuvant chemotherapy and RT for high-risk and locally advanced disease. IMRT techniques have been developed that reduce the risk of acute and late complications, especially in conjunction with extended surgery or chemotherapy.

The role of pelvic irradiation in treating intermediate-risk endometrial carcinoma has been established with the results of randomized trials. Pelvic RT provides a highly significant improvement of local control, but it does not increase OS and does not reduce the risk of distant metastases. For patients at high-intermediate risk features based on the presence of major risk factors (grade 3, deep myometrial invasion, age older than 60 years, LVSI; PORTEC criteria, or GOG/high-intermediate-risk criteria having similar results), a treatment shift from pelvic EBRT to VBT alone has occurred based on results from the ASTEC and PORTEC-2 trials. Patients with FIGO 2009 stage IA, grades 1 and 2 disease should be observed after TAH-BSO. The inclusion of such low-risk cases in clinical

studies of the role of RT or of lymphadenectomy reduces the likelihood of observing a benefit for the higher-risk subsets and subjects these patients to increased risks of toxicity. Radiation therapy is an effective salvage treatment for vaginal relapse in patients not previously irradiated, with 80% to 90% local control rates and 5-year OS of 50% to 70%.

High-risk endometrial carcinoma is the challenge for current and future research. Ongoing trials need to evaluate concurrent chemoradiation, adjuvant chemotherapy, and targeted agents.

Recent and current trials for high-risk disease are investigating the roles combinations of adjuvant radiation therapy and chemotherapy (see eTable 59-1). The PORTEC-3 trial (pelvic radiation alone versus RT with two cycles of concurrent cisplatin followed by four cycles of carboplatin/paclitaxel) was recently closed at a total of 686 randomized patients with high risk or locally advanced stage disease. The GOG-249 trial (pelvic radiotherapy alone versus VBT followed by three cycles of carboplatin/paclitaxel) recruited 601 patients with stages I to II tumors with high-intermediate or high risk factors; first results were reported at the 2014 Annual Meeting of the Society of Gynecologic Oncology. With a median follow-up of 24 months, there were no differences in RFS or OS (RFS, 82% versus 84% for pelvic RT versus brachytherapy/chemotherapy; OS, 93% versus 92%).[196]

The ongoing GOG-258 trial aims to include 804 women with stages III to IVA disease (six cycles of carboplatin/paclitaxel with no radiotherapy versus the same regimen of RT and chemotherapy as used in PORTEC-3) (eTable 59-1). The ENGOT-EN2-DGCG trial (adjuvant chemotherapy or observation for patients with early stage high-risk disease who are node-negative after lymphadenectomy) aims to include 678 patients (adjuvant VBT is permitted in either arm). Results of these trials are awaited and may guide future adjuvant strategies.

Targeted therapies may yet prove to be effective, especially in the treatment of serous carcinoma. IMRT techniques that reduce the risk of complications should be further developed, especially in conjunction with multimodality treatment. For patients with locally advanced disease in whom trimodality treatment (i.e., surgery, irradiation, and chemotherapy) is indicated, laparoscopic staging followed by preoperative concurrent chemoradiation, restaging, and surgical resection alone or plus IORT and adjuvant chemotherapy should be evaluated.

Quality-of-life and cost-effectiveness analyses have become essential because patients with high-risk and locally advanced

stage disease are typically elderly and have concurrent medical illnesses. The approach to these patients needs to balance the benefit of more aggressive adjuvant therapies with the cumulative toxicities. The ultimate goal of treatment for endometrial cancer patients remains the maximization of event-free and complication-free survival.

CHAPTER

60 Cancers of the Vulva and Vagina

Anthony Henryk Russell and Neil S. Horowitz

VULVAR CARCINOMA

INCIDENCE

Vulvar carcinoma accounted for an estimated 5150 cancer cases and 1080 deaths in the United States in 2015, comprising 0.58% of all cancers in women, 5.1% of gynecologic malignancies, 0.36% of cancer deaths in women, and 3.5% of gynecologic cancer deaths.[1]

BIOLOGIC CHARACTERISTICS

Eighty percent to 90% of primary vulvar tumors are squamous cell carcinomas. Carcinomas of the vestibular (Bartholin) gland complex may be adenocarcinomas or adenoid cystic carcinomas, but 30% to 50% will have squamous histology as they arise in ductal epithelium.

Younger vulvar cancer patients more commonly smoke and have a higher incidence of human papillomavirus (HPV) infection, which are factors associated with vulvar intraepithelial neoplasia (VIN). In older patients, HPV infection is less prevalent, and invasive vulvar cancer is often seen arising in a background of lichen sclerosus, although only 4% of patients with lichen sclerosus will develop clinically apparent neoplasia.

STAGING EVALUATION

Primary tumor size and anatomic distribution, depth of invasion, presence of capillary-lymphatic space involvement, and width of surgical margins correlate with risk of recurrence at the primary site. Number, size, location of lymph node metastases, and extracapsular extension in metastatic groin adenopathy all correlate with risk of regional recurrence, distant dissemination, and survival. Many of these factors are included in the hybrid clinical-pathologic International Federation of Obstetrics and Gynecology (FIGO) 2009 staging formalism.[2]

Pretreatment evaluation includes patient history and comprehensive physical examination including inspection and palpation of the primary tumor and clinical assessment of inguinofemoral lymph nodes. Regional imaging assessments may include positron emission tomography/computed tomography (PET/CT), magnetic resonance imaging (MRI), ultrasonography, and the combination of blue dye and lymphoscintigraphic sentinel node localization. Regional imaging may aid in understanding extent of disease, guiding biopsies, and selecting therapeutic modalities, but regional imaging findings alone do not affect assignment of stage.

PRIMARY THERAPY

Except when surgery would compromise functionally important midline structures (clitoris, urethra, vagina, anus), radical local excision is the preferred initial therapy for invasive primary disease. When the location and extent of the primary tumor suggests that surgery will not be able to accomplish secure negative margins (≥8 mm in fixed tissue), initial chemoradiation may precede conservative local excision or definitive chemoradiation may be used.

Management of potential groin metastases will be contingent on clinical and imaging assessment as well as the degree of laterality (distance from midline) and the modality selected for initial therapy of the primary tumor. Positive sentinel node biopsy mandates further treatment to the groin, by comprehensive, therapeutic superficial, and deep groin node dissection or groin radiation or chemoradiation. Fixed or ulcerated groin nodes indicate chemoradiation should be the initial intervention.

For advanced primary lesions invading or encroaching on functionally or cosmetically important midline structures, initial chemoradiation followed by conservative excision is preferred to extirpative surgery. Chemoradiation alone may be curative in some patients with locally advanced disease for whom an exenterative procedure would be the only feasible surgical alternative.

ADJUVANT THERAPY

Adjuvant local vulvar and tumor bed irradiation may be administered for risk factors including involved or close surgical margins (<8 mm), or capillary lymphatic space involvement and deep invasion (>5 mm). For one macroscopic node metastasis, two or more microscopically involved nodes, or extracapsular extension, unilateral or bilateral radiation to the groin and low pelvic lymph nodes is given following surgical resection of inguinofemoral nodes. Controversy exists over whether the clinical target volume (CTV) should include the primary tumor bed. Generally, when adjuvant radiation is administered for nodal contamination, the CTV will include the primary tumor bed. There is no accepted role for adjuvant cytotoxic chemotherapy except when administered concurrently with radiation (chemoradiation).

Corrected 5-year survival for surgical patients with negative nodes is 96% to 70% depending on the extent of the primary (stages I to II). When groin lymph nodes are contaminated (stage III), corrected survival is approximately 50%. However, patients with only one microscopic intracapsular metastasis can expect a 5-year actuarial survival of 68% to 94%,[3,4] whereas patients with two nodes involved will have an expectation of 80%[3] and patients with three or more nodes involved or extracapsular extension will be cured in only 25% of cases.[5]

PALLIATION

Radiation therapy often provides relief of pain or bleeding. Chemotherapy alone has minimal or no impact on disseminated disease.[6]

Melanoma, basal cell carcinoma, Merkel cell tumor, sarcoma, carcinoid, apocrine gland cancer, Paget's disease, and metastatic lesions constitute rare histologic types of vulvar malignancy.

For patients with intact, small primary tumors (≤4 cm) in whom clinical or imaging assessment reveal no obvious spread to nodes, negative sentinel node biopsy with subsequent groin observation has emerged as satisfactory management instead of more morbid comprehensive groin node dissection. When groin nodes are grossly contaminated but resectable, options include debulking node surgery followed by planned adjuvant regional radiation and chemoradiation or initial radiation and chemoradiation followed by planned excision of residual nodal disease.

Late radiation sequelae may be less severe if conservative surgery can be accomplished following a moderate preoperative dose of chemoradiation rather than chemoradiation escalated to radical intensity.

Neoadjuvant chemotherapy alone before surgery for locally advanced disease has been associated with less predictable responses than chemoradiation, and complete pathologic responses are rare. Therapy with biologics is investigational.

Vulvar carcinoma is an uncommon disease, accounting for only 5.1% of all gynecologic cancers and only 0.003% of all malignancies in the United States in 2015.[1] Diversity in the location and clinical extent of disease at presentation, ranging from in situ or small-volume invasive primary disease to neglected extensive tumors that may locally extend to involve the vagina, urethra, anus, or ischial rami suggests the wisdom of individualized treatment. The presence or absence of metastatic spread to inguinal lymph nodes adds to the heterogeneity of the patient population at the time of diagnosis. The range of patient age at diagnosis, the extent of medical comorbidities, and the diversity of patient concerns regarding function and cosmesis further complicate treatment decisions. Appreciation of the broad clinical spectrum of patients afflicted with vulvar cancer and the utility of radiation and chemoradiation has resulted in major changes in disease management in the past 30 years.

Historically, radical vulvectomy and bilateral inguinal node dissection was the standard approach for the majority of patients, regardless of disease extent.[7-10] Consequent to the chronic, often debilitating physical and psychological sequelae of radical vulvectomy in long-term survivors, questions arose regarding the need for radical vulvectomy in patients with limited disease at diagnosis. Unsatisfactory rates of local-regional control in patients with advanced disease as well as the morbidities associated with exenterative surgery stimulated exploration of novel combinations of therapies. Increasing awareness of the sensitivity of squamous vulvar cancer to radiation and chemoradiation further suggested management changes.

Although optimal therapy for many situations remains to be defined, avenues of change include conservative surgery for selected patients with early disease and multimodality therapy (chemoradiation alone, or integrated with less extensive surgery) for the patients with locally advanced disease. Chemoradiation is increasingly accepted as alternative therapy for patients with disease that would require partial or total exenteration if treated by initial surgery. Pre- or postoperative adjuvant radiation or chemoradiation are now commonly used to complement conservative surgery in patients with adverse clinical or histopathologic features.

Mature published results remain sparse for patients treated on the basis of the newer concepts of integrated multimodality management tailored to the site and extent of disease. Valuable information continues to accumulate from Phase II study reports, most of which support the concept of integrated, multimodality therapy. Selecting the order in which therapies are employed, defining the intensity and scope of radiation and the extent of surgery when these complementary modalities are used sequentially, and optimizing the choice and schedule of chemotherapy when combined with radiation represent ongoing challenges in treatment refinement.

ETIOLOGY AND EPIDEMIOLOGY

No universal cause for vulvar cancer has been identified, and it is probable that the pathogenesis is multifactorial.[11] Many patients with vulvar carcinoma have had previous malignant or premalignant lesions of the genital tract.[12-14] Between 2% and 5% of VIN 3 lesions (severe dysplasia or carcinoma in situ) will progress to invasive disease.[15] The risk factors for progression to invasive cancer are poorly understood but do include advanced age. One study observed that that the relative risk for vulvar or vaginal carcinoma after treatment for cervical carcinoma was 2.9% regardless of whether the patient received radiation for treatment of the cervical cancer. Compromised immune status, whether iatrogenic in the setting of organ transplantation, congenital, or acquired based on HIV infection, leads to an increased risk for cancers in the lower genital tract, including the vulva and vagina.[16] Improvement in immune function with highly active anti-retroviral therapy (HAART) may decrease the risk in patients with HIV,[17-21] although longer survival with HAART may permit emergence of papillomavirus associated ano-genital malignancies in long-term survivors of HIV infection.[22,23]
