There are three radioactive isotopes used in vLDR prostate brachytherapy: Iodine (^{125}I), Palladium-103 (^{103}Pd), and Cesium-131 (^{131}Cs). There is no published difference in clinical outcomes between ^{125}I or ^{103}Pd seeds.[52,53] Radiation proctitis has been reported to be more intense in the first month with ^{103}Pd as would be expected because of its shorter half-life.[54] Quality of life at 1 year is similar between the two isotopes. ^{131}Cs is being evaluated as an alternative isotope.[55] The dose characteristics and half-life are listed in Table 15-1.

HDR brachytherapy, on the other hand, uses high-activity Iridium-192 (^{192}Ir). The advantage of HDR includes remote afterloading of the source and dosimetry that can be optimized to the implant. Also the high fraction sizes associated with HDR brachytherapy theoretically take advantage of the potentially low alpha-to-beta ratio of prostate cancer cells.[56] The advantages of HDR brachytherapy include the ability to implant patients with large prostates (>60 cc), patients with extra-capsular extension, and in those patients who have had previous transurethral resection of the prostate (TURP).[57,58] There are no specified dose tissue constraints for HDR prostate brachytherapy secondary to the variety of dose options available. The urethral dose range has been reported at <110% of prescription dose to <125% of prescription dose depending on the dose and fractionation. The rectal doses range from D2cc <70% of prescription dose or volumes receiving 80% of the prescription dose <0.5 cc.[59]

Indications for Monotherapy

Patients with low-risk prostate cancer are appropriate for vLDR monotherapy and have shown good outcomes in the literature.[60,61] The use of vLDR monotherapy has also been evaluated in patients with intermediate-risk prostate cancer with or without the use of androgen deprivation with good results.[62] The results of the RTOG 0232 trial will be valuable in determining whether EBRT is required in the intermediate-risk group. The literature for HDR monotherapy is not as robust. The disadvantage of HDR monotherapy is the potential need for multiple implants to attain an effective dose. Dose fractionations of between one and nine fractions have been described. The clinical outcomes for HDR monotherapy show good 5-year local control (LC) and biochemical relapse-free rate in the order of 95% LC and 83% to 95% biological freedom from recurrence despite a heterologous group of patients.[63-67] A recent American College of Radiology (ACR) appropriateness paper did not support more hypofractionated monotherapy regimens and felt that the more fractionated regimens had longer follow-up and support for use.[56]

TABLE 15-3 Dose Ranges Reported for HDR and vLDR Prostate Brachytherapy

Dose Range	Monotherapy	Boost
HDR*	12-13.5 Gy × 2 10.5 Gy × 3 9.5 Gy × 4 6.5 Gy × 6 7.25 Gy × 6	15 Gy × 1 10.5 Gy × 2 7 Gy × 3 6 Gy × 4
vLDR		
Iodine-125	140-160 Gy	108-110 Gy
Palladium-103	110-125 Gy	90-100 Gy

**No particular dose fractionation can be recommended because of heterogeneity of reported doses in the literature.*

Indications for Boost

There is increasing evidence that increased radiation dose in patients at high risk results in improved LC and prostate cancer metastasis-free survival.[59,68-72] Dose escalation can be with EBRT alone or using brachytherapy as a boost. Hoskin et al randomized 220 patients to EBRT alone 55 Gy in 20 fractions or EBRT 35.75 Gy in 13 fractions followed by an HDR boost of 17 Gy in 2 fractions. The HDR boost group showed improved biochemical relapse-free survival (bRFS) and had a lower incidence of acute rectal symptoms.[71]

The dose for both LDR and HDR must be adjusted to account for the addition of EBRT (Table 15-3). Sequencing of the brachytherapy component can be before or after the EBRT or in the case of HDR sandwiched between. RTOG 0321 was a prospective Phase II trial of HDR brachytherapy in combination with EBRT (2 HDR fractions of 19 Gy were used in combination with 45 Gy in 25 fractions of EBRT). The grades 3 to 4 gastrointestinal (GI) or genitourinary (GU) toxicity rate was 2.6% at 18 months.[73] A Canadian trial showed that further hypofractionation of the dose was achievable with acceptable toxicity (15 Gy in a single brachytherapy fraction following 37.5 Gy in 15 fractions EBRT).[74] Trimodality therapy with androgen deprivation therapy, EBRT, and brachytherapy boost is becoming a standard for patients at high risk.

Acute urinary retention is <5% in the HDR literature and ranges from 5% to 10% in vLDR literature.[75] For HDR, late

grade 3 GU toxicity is reported in approximately 3% of patients, but late grade 3 rectal toxicity is rare.[66,76] In the vLDR literature, late rectal toxicity ≥RTOG grade 2 is 9%.[77-79] Erectile dysfunction rates appear to be similar between vLDR and HDR literature with preservation of potency in 40% of patients.[68,80]

Brachytherapy is also being evaluated as salvage treatments in patients with recurrence after previous radiation. Salvage brachytherapy has been reported in the LDR, HDR, and PDR literature[81-83] and is currently under investigation in a Phase II trial (RTOG 0526). In a Phase II study by Yamada et al HDR brachytherapy salvage was used in 42 patients (32 Gy in four fractions over 30 hours with a single insertion). The 5-year bRFS was 68.5% and cause specific survival (CSS) 90%. There was only 7% grade 2 late urinary toxicity and one patient with grade 3 urinary incontinence. Rectal toxicity was minimal. These findings are in keeping with the long-term follow-up results of salvage treatment of 37 men who underwent brachytherapy for salvage treatment by Burri et al in which the 10-year bRFS was 54% and CSS 96%.[81]

Penile Cancer

Squamous cell carcinoma of the penis is a rare cancer accounting for only 1% of male cancers. Brachytherapy is an alternative to penectomy in T1 and T2 tumors confined to the glans that are less than 4 cm in size.[84] The most common technique is an interstitial technique, either template or freehand. LDR, PDR, and HDR treatments have been described.[85,86] The treatment volume includes the gross disease and a wide margin (1 cm). A multiplanar implant is recommended for most procedures to ensure dose coverage at depth. The implantation technique has been described in detail in the literature.[87] The spacing between needles for LDR and PDR is recommended to be between 1.4 cm and 1.6 cm but closer spacing (1 cm to 1.2 cm) is described for HDR techniques. The typical dose for LDR and PDR is 60 Gy at 0.5 to 0.6 Gy/hour over 5 days (assuming hourly fractions for PDR). There is less literature to support an HDR dose but recent ABS guidelines recommend 38.4 Gy in 3.2 Gy fractions twice daily over 6 days.[86]

The 5 year LC is 70% to 87% with penile preservation in 70% to 88% of the cases.[86,88-92] The rate of soft-tissue necrosis ranges between 0% and 26% and increases with doses over 60 Gy and large-volume disease. The rate of urethral stenosis ranges between 9% and 45% and relates to the proximity of the needles to the urethra.[86]

Urethral Cancer

Brachytherapy solely or with EBRT can be part of the treatment in urethral cancers in women or men. For any tumor more than 5 mm, an interstitial technique (Figure 15-7) is required and for higher stage disease multimodality treatment is recommended.[93] The doses are similar to that described for penile brachytherapy. In the treatment of female urethral cancers the entire length of the urethra can be implanted. The dose for LDR monotherapy is 60 to 65 Gy in 3 to 5 days or 20 to 25 Gy if prescribed as a boost.[94] In a review by Milosevic et al,[95] the outcomes of 34 women treated with either EBRT alone (14 patients), EBRT with brachytherapy (15 patients) or brachytherapy alone (5 patients) were evaluated. Brachytherapy led to improved LC 77% versus 32% in the no brachytherapy cohort. OS was 41%, at 7 years which is similar to other reports in the literature. Fistula formation was reported in 15% of patients.

Breast Cancer

Breast-conserving surgery followed by whole-breast irradiation (WBI) is a standard of care for many early breast cancers. The rationale for partial breast irradiation comes from reports

Figure 15-7 Interstitial brachytherapy implant of a urethral cancer in a female patient.

of in-breast failure patterns following partial mastectomy versus partial mastectomy and WBI where the location of failure was most often in the region of the primary lesion or the surgical bed.[96,97] Partial breast irradiation therefore allows for decreased volume of normal tissue receiving radiation and the potential to decrease the overall treatment time (accelerated partial breast irradiation [APBI]). Radiobiologically there may also be benefit to APBI because the alpha-to-beta ratio for the tumor is relatively low and reported as between 3.4 and 4.1.[98,99]

The publication of large randomized trials is awaited for the APBI technique.[100-102] Patient selection remains uncertain with consensus statements from organizations differing.[103-105] Factors that are considered when contemplating APBI as a treatment modality include: patient age, size of tumor, margin status, histology, lymphovascular space invasion, and nodal status (Table 15-4). Husain et al[106] published a SEER patterns-of-care analysis of APBI using brachytherapy to compare with the ASTRO consensus statement groupings.[105] Of the 4172 patients who received APBI through brachytherapy between 2002 and 2007, 60% would have been grouped in the ASTRO cautionary/unsuitable categories.

There are many techniques for APBI. Interstitial multicatheter techniques using LDR were the first reported (Figure 15-8, *A, B*), this technique has now evolved for HDR and PDR treatment. HDR is the more typical treatment because of dose optimization and outpatient treatments. Multiple catheters are placed percutaneously through the lumpectomy cavity, commonly in the postoperative setting under image guidance using a template. Typically the CTV is the lumpectomy cavity plus an additional 1- to 2-cm margin. Multiplanar implants are required to cover the CTV with catheter spacing between 1 and 1.5 cm.[107] Polgar et al have recently published the 10-year results of their single-institution randomized trial of APBI with multicatheter interstitial HDR brachytherapy (5.2 Gy × 7 fractions) or electrons (50 Gy/25 fractions) versus WBI. The 10-year local recurrence (LR) results between APBI and WBI were similar (5.9% versus 5.1%), with superior cosmesis in the APBI cohort.[102] Similarly Shaw et al reported 12-year follow-up of a matched pair analysis of 199 WBI and 199 APBI patients.

There was no difference seen in rates of LR or regional recurrence or disease-free survival.[108]

RTOG 95-17 was a Phase II trial of multicatheter brachytherapy for APBI. One hundred patients with either stage I or II breast cancer <3 cm in size, ≤3 lymph nodes involved (no extracapsular extension) were eligible. Brachytherapy treatments consisted of either LDR 45 Gy in 3.5 to 5 days (33 patients) or HDR 34 Gy in 10 fractions twice daily over 5 days (66 patients). The trial was not designed to compare the two brachytherapy arms, but similar rates of in-breast failure (3% to 6%) were seen at 6 years using the two brachytherapy techniques.[109] Cosmesis was rated excellent/good in 66% of patients. However fibrosis was reported in 45%, skin catheter marks in 54%, and symptomatic fat necrosis in 15%.[110] Wazer et al published pooled analysis of outcomes predicting for suboptimal cosmetic outcome and toxicity. The factors associated with increased toxicity were number of source dwell positions, volume receiving 150% of the dose (V150), volume

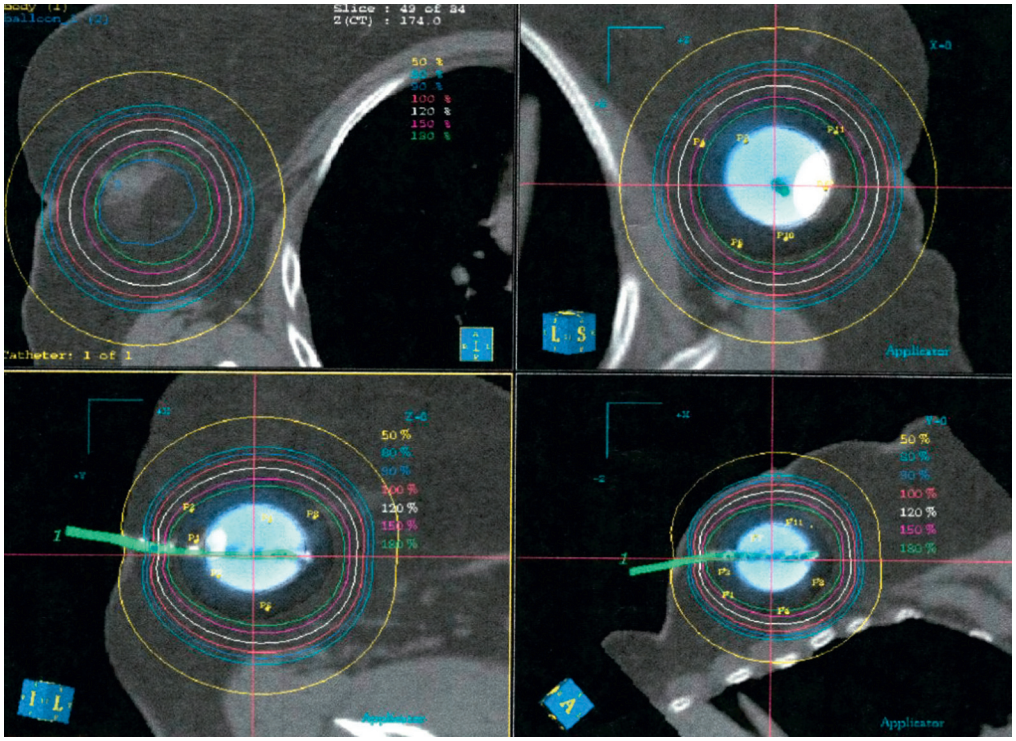

Figure 15-9 Single-lumen catheter within the breast seroma. The treatment planning images illustrate uniform radiation dose delivery.

receiving 200% of the dose (V200) as well as the dose homogeneity index (DHI). Large V150 hotspots were associated with symptomatic fat necrosis.[111]

Balloon-Based Intracavitary Technique

Mammosite (Hologic Inc, Bedford, MA) was developed and marketed as an accessible way to perform APBI. This single-lumen catheter can either be placed into the surgical cavity at the time of surgery or postoperatively under ultrasound guidance. Once the catheter is placed into the surgical bed, a balloon around the catheter is inflated to fill the cavity and compress the adjacent breast tissue. The limitation of this technique is that it had only a single dwell position and hence the dose distribution was uniform around the catheter and could not be optimized to irregular volumes or to avoid chest wall or skin (Figure 15-9). The spacing of the catheter to the chest wall and skin was found to relate to toxicity leading to recommendations of skin spacing ≥7 mm.[112,113] The final analysis of the American Society of Breast Surgeons MammoSite Breast brachytherapy registry trial has been published. In this trial 1449 women were treated with 34 Gy in 3.4 Gy fractions, the majority (87%) of whom had invasive breast cancer. The median follow-up was 63.1 months. The 5-year actuarial recurrence rate for in-breast recurrences was 3.8% (3.7% invasive breast cancer, 4.1% ductal carcinoma in situ). Only the tumor size and estrogen receptor (ER) negative status were associated with in-breast recurrence. There was a trend toward increased in-breast recurrence in the case of positive margins and ASTRO "unsuitable" status ($p = 0.06$ and $p = 0.07$) but these were not significant.[114] The rate of seroma at any time in this trial was 13.4%, symptomatic fat necrosis 2.5%, infection 9.6%, and telangiectasia 13%. At 84 months 90.6% of patients were rated with excellent/good cosmesis.

Further enhancements of the intracavitary techniques led to multichannel balloon–based catheters and a multichannel strut-adjusted volume implant (SAVI) applicator. The multichannel catheters allow for multiple dwell positions and were found to be dosimetrically superior to the single lumen/single dwell MammoSite with improved target coverage and decreased dose to the chest wall and skin even in cases where the skin and chest wall were ≤7 mm.[115-118] The Contura catheter is a multichannel balloon catheter with one central catheter and four peripheral catheters offset from the center by 5 mm. The MammoSite Multi-Lumen has one central catheter surrounded by three peripheral catheters. The SAVI applicator has a central catheter surrounded by 6, 8, or 10 peripheral catheters. The peripheral catheters once placed into the surgical cavity are expanded to fill the cavity. The dosimetry of the SAVI applicator is more similar to the multichannel interstitial implants in terms of dose inhomogeneity of multiple dwell positions. The SAVI applicator has been found to be useful in cases of close skin spacing or small breast size.[119]

Electronic balloon brachytherapy (Xoft Axxent) differs from other balloon-based treatments because the radiation source is an electronic x-ray tube that produces a 50-kVp photon range as opposed to the average of 380 keV for Iridium-192. The advantage of this technique includes increased access as a radiation vault is not required and rapid dose fall off results in decreased dose to normal tissues. In dosimetric comparisons between electronic brachytherapy and HDR the doses to the planning target volumes (PTV) were comparable, but the electronic brachytherapy had higher dose at the surface of the balloon and decreased dose to the heart and ipsilateral lung.[120,121] Further follow-up of this technique is required to evaluate outcomes and toxicity, especially given that the radiobiological effective dose using low energy photons differs from standard HDR treatments.

Interstitial permanent seeds are also being evaluated for partial breast irradiation (PBI) in the low-risk population with the potential advantage of a further reduction in the time a patient would be required to be undergo treatment as well as decreased dose to critical normal structures because of the relatively low-dose penetration of the ^{103}Pd isotope.[122,123] Patient selection for this technique is limited by general

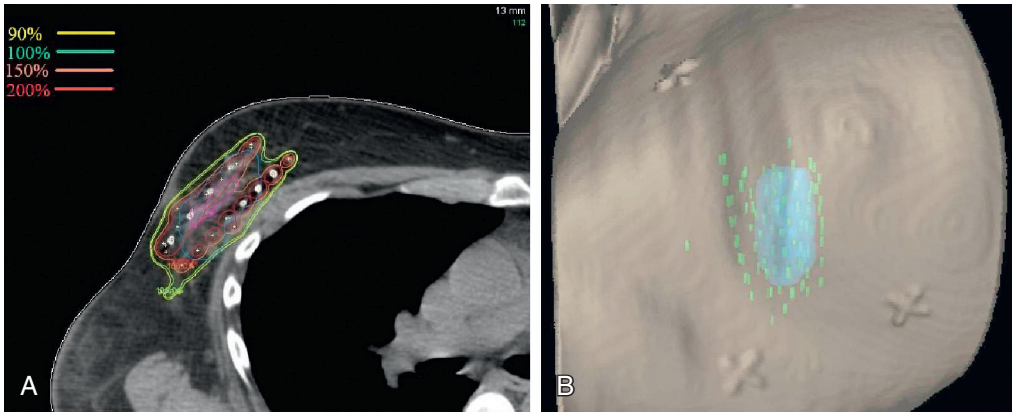

Figure 15-10 **A,** Axial image of an interstitial breast implant with permanent seeds showing dose distribution and **B,** 3D rendering of the breast with the CTV and seed strands.

criteria for PBI as well the size of the postoperative cavity (≤2.5 cm) and planned implant volume (≤120 cc). Imaging of the tumor bed using ultrasound or CT is performed and similar to permanent prostate brachytherapy a preplan with the desired placement of needles and seeds is made (Figure 15-10, *A, B*). A vLDR dose of 90 Gy to the tumor bed plus margin is planned keeping the dose to the skin ≤90% of the prescription.[124] The implant is performed under image guidance using local anesthetic and conscious sedation. This technique continues to be evaluated through a multiinstitutional registry trial. A dosimetry study of ^{131}Cs versus ^{103}Pd has shown a potential theoretical advantage to using ^{131}Cs with decreased V200 but this may not be clinically significant.[125]

Breast brachytherapy is also being evaluated as a boost technique either through conventional HDR techniques described or using a noninvasive breast brachytherapy (NIBB) technique with Accuboost (Billerica, MA). NIBB uses image guidance and immobilization to target the tumor cavity. The mammography-based visualization system that allows the applicators to be centered on the target[119] while the breast is immobilized. This allows for directed photons at the cavity without the usual PTV margin required for standard EBRT boost resulting in comparatively smaller treatment volumes with the potential for decreased toxicity. A 2:1 matched control study of NIBB versus EBRT boost showed that there is less combined skin and subcutaneous toxicity in patients treated with NIBB (2% NIBB versus 9.5% EBRT boost, $p = 0.046$).[126]

APBI has also been described as salvage treatment for in-breast tumor recurrence (IBTR). The GEC-ESTRO breast cancer working group reported that interstitial multicatheter brachytherapy was feasible and effective in preventing a second local recurrence and with OS equivalent to salvage mastectomy.[127] Likewise Kauer-Dorner et al reported on a prospective trial of interstitial PDR brachytherapy in 29 patients where local control of the tumor was comparable to mastectomy and ≥grade 3 late side effects were reported in 16%.[128]

Intraoperative radiation (IORT) for breast cancers has also been described as a technique to deliver partial breast radiation in one fraction with either electrons or 50 kv x-rays. However this technique differs significantly in terms of dosing and radiobiology from brachytherapy techniques. Recent updates of two large randomized trials of IORT APBI versus WBI have reported increased IBTR in the APBI arms.[129,130] The increased IBTR may be related to patient selection[131] highlighting that APBI remains investigational and if offered should be under the guidance of a trial.

Lung–Endobronchial Brachytherapy

In 1922 Yankauer described the use of radium placed endobronchially to treat lung cancer,[132] and brachytherapy continues to be used to deliver radical or palliative endoluminal therapy to the bronchus. Local treatment can be important to improve the quality of life for lung cancer patients. A narrow bore brachytherapy tube is placed under bronchoscopic guidance, which extends at least 2 cm past the tumor, and is firmly secured at the nostril. The dose is delivered, usually using HDR, as a single or multiple fractions. The 2001 ABS guidelines recommend dose prescription at 1 cm[133]; however, in the era of CT planning the orientation of the catheter within the bronchus has been identified as an area of concern (Figure 15-11). High localized doses to surrounding blood vessels are demonstrated when the catheter position is offset against the luminal wall.[134] This may be overcome by using placement methods which stabilize the catheter centrally[135,136] or by individualized dose prescription.[134] This is important since fatal hemoptysis rates ranged from 7% to 22% in randomized trials.[137-139]

ABS guidelines recommended the use of endobronchial brachytherapy for palliation, particularly for endobronchial lesions not amenable to laser or stenting. A range of doses were recommended using 10 to 24 Gy in two to four fractions as sole treatment or 15 to 16 Gy in two to four fractions following EBRT[133]; these guidelines are currently being updated. Subsequently, a 2012 Cochrane meta-analysis[140] examined 14 randomized trials that used endobronchial brachytherapy, either alone or in combination with other therapies such as EBRT, chemotherapy, or laser. This showed that a variety of dose and fractionation schedules were used and they appear to be similar in OS with 14.8 Gy in two fractions showing superiority for improved LC and less hemoptysis over 15.2 Gy in four fractions. There appears to be no advantage to adding endobronchial brachytherapy to an EBRT treatment course, either palliative or radical. When used for palliation as sole therapy, 50% of brachytherapy-only cases proceeded to receive EBRT with a median time to treatment of 4 months, compared to under a third requiring brachytherapy following EBRT with a median time to treatment of 10 months.[137] Secondary analysis subsequently showed a survival advantage to EBRT with a relative risk reduction of 61%. The Cochrane review concluded that endobronchial brachytherapy can be considered for palliation in patients previously treated with EBRT with symptoms resulting from central obstruction. Recent ACR guidelines recommend that it can be used for palliation of patients with symptomatic endobronchial tumors.[141]

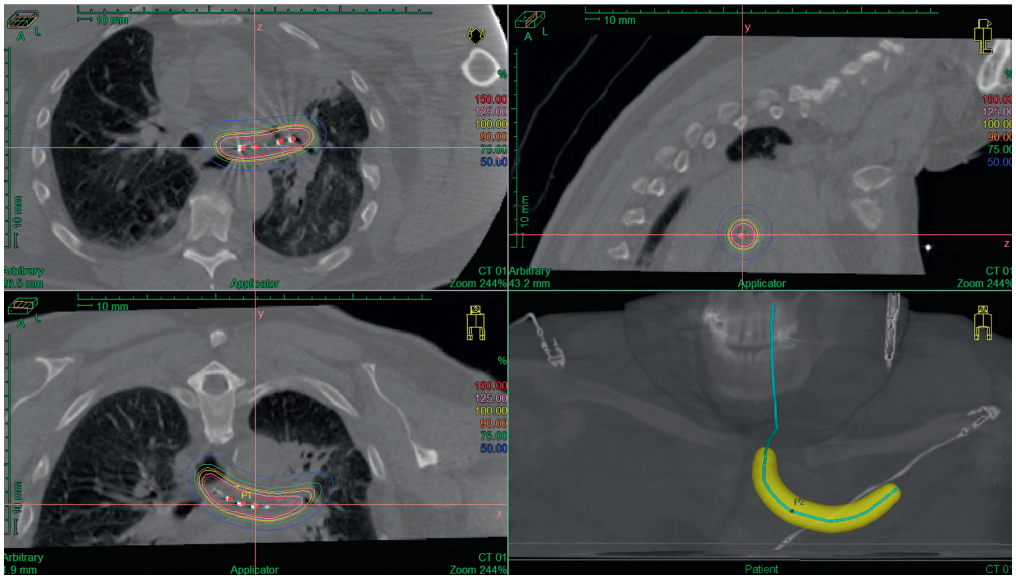

Figure 15-11 Endobronchial catheter with CT planning allowing for evaluation of the placement of the catheter and relation to clinical target volume and organs at risk, including a pulmonary vein, which is in close proximity to the implant.

Figure 15-12 Permanent interstitial seeds placed in a single plane mesh.

Thoracic Wall Brachytherapy

Interstitial seeds formed into a single plane mesh implant can be placed intraoperatively in areas at high risk of relapse (Figure 15-12). These are commonly used within the thorax but are also described in other anatomic sites, particularly in sarcoma resections. Most institutions describe the use of ^{125}I but the use of ^{103}Pd and ^{131}Cs is also described.[142-144] The use of a planar ^{125}I implant placed along the suture line following sublobar resection was described as decreasing recurrence rates over those that would be expected with sublobar resection alone.[145] However, the early results from the ACOSOG z4032 randomized trial have not shown a difference in recurrence; full results are awaited. Placement of mesh implants following close or positive surgical margins has shown lower rates of recurrence than would otherwise be expected in thoracic and para-spinal tumor resections.[145,146]

Institutions with the ability to use intraoperative brachytherapy have described the use of brachytherapy applicator placement at the time of surgery to deliver highly localized radiation to areas at operative risk. This has the benefits of target localization under direct vision and the ability to shield or displace organs at risk, resulting in reduced risk of long-term toxicity.[133]

Gastrointestinal

Esophageal Cancer

Esophageal brachytherapy can be administered in the radical and palliative settings. A brachytherapy catheter is placed over a guide wire under endoscopic guidance traversing the tumor and firmly secured at the nose. The treatment volume should extend 2 cm superior and inferior to all macroscopic disease to encompass any microscopic tumor foci. Treatment is generally prescribed at 1 cm from the source axis, though 3D planning can be used for complex cases and the dose received by organs at risk determined. If a stent is present, the dose may be attenuated by the stent with higher localized doses around the stent, 5% higher at 0.5 mm and up to 245% in the immediate vicinity of the stent.[147]

As part of the radical treatment of esophageal cancer brachytherapy can be used to deliver a highly localized boost following radical EBRT. The ABS recommends 10 Gy prescribed at 1 cm in two fractions 1 week apart following chemoradiation 45 to 50 Gy or radiotherapy alone up to 60 Gy[148] (Figure 15-13). This dose/fractionation follows the RTOG 92-07 trial, which showed complete remission rates of 74% following EBRT and brachytherapy with a 1 year OS of 49% but used a dose of 10 Gy in two fractions following unacceptable rates of toxicity using 15 Gy in three fractions.[149] A thicker applicator may minimize the hotspots that were thought to be the cause of fistulas.

For palliation, brachytherapy delivers improvement of swallowing in the majority of cases, with maintenance of swallowing in most of the remainder. A range of doses for HDR esophageal brachytherapy is considered acceptable. The ABS recommends palliative doses of 14 Gy in 1 to 2 fractions following EBRT of 30 Gy in 10 fractions and for sole treatment, 15 to 20 Gy in 1 to 2 fractions.[148] A dose comparison study of 18 Gy in 3 fractions versus 16 Gy in 2 fractions by the International Atomic Energy Agency (IAEA)[150] showed no difference in

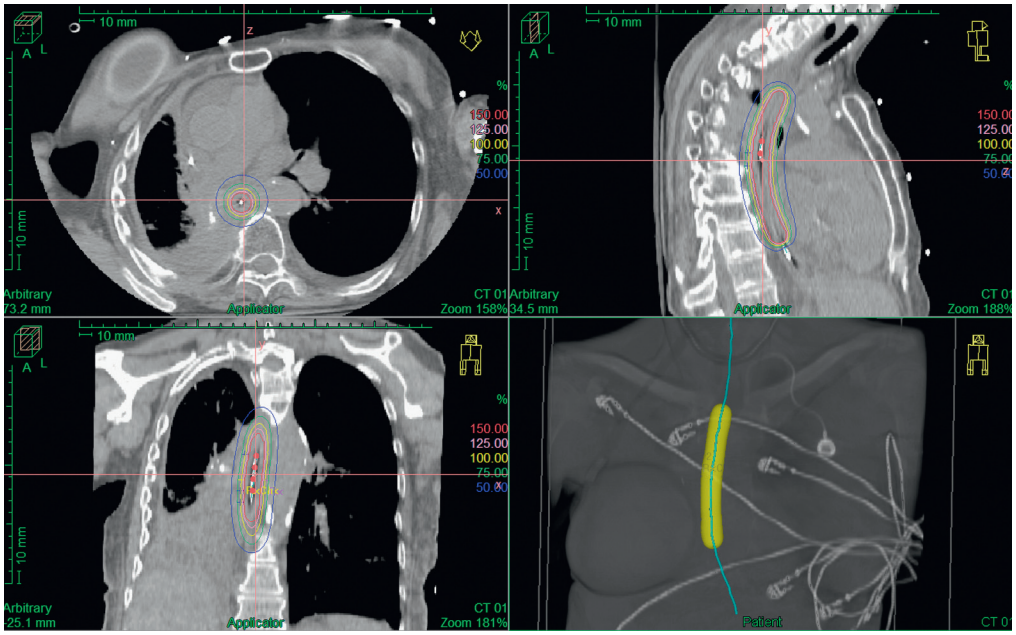

Figure 15-13 Esophageal brachytherapy prescribed 1 cm from the source axis demonstrating simple line source dose distribution.

efficacy or toxicity with an overall 11% stricture rate and 10% fistula rate. It is not known how much brachytherapy may have contributed to fistula formation but it was noted that all fistulae occurred in the presence of disease progression.

A European randomized trial showed improved efficacy of brachytherapy 12 Gy in 1 fraction over stenting[151] with improved quality of life, longer duration of symptom palliation, and equivalent overall healthcare costs.[152] Because there is a slight delay in onset of symptom palliation with brachytherapy it was recommended that brachytherapy should be used instead of stenting in patients with a predicted survival over 2 months. If the predicted survival is under 2 months stenting should be used. A trial of fractionated treatment using 21 Gy in 3 fractions versus stenting did not show any evidence of benefit though the number of patients in the trial may have been too small to draw definitive conclusions.[153] A Cochrane meta-analysis in 2009 showed that brachytherapy has a longer duration of palliation than stenting with significantly better quality of life and lower complications (33% versus 47%)[154] and may even provide a survival advantage. Brachytherapy was seen to be comparable to laser for palliation and may improve the dysphagia-free interval when EBRT is added to the combination of laser and brachytherapy. An IAEA randomized study showed that the addition of EBRT 30 Gy in 10 fractions to 16 Gy in 2 fractions brachytherapy resulted in significantly better symptom relief than brachytherapy alone.[155] There was no difference in OS between the two groups. Thus, patients with a greater predicted survival (e.g., over 6 months) may benefit from the addition of EBRT to brachytherapy. The use of a stent implanted with iodine seeds has been described, with a small randomized trial showing a significant improvement in OS over conventional stenting at 7 months versus 4 months.[156] This technique is not currently practiced in North America.

Rectal

Brachytherapy can be considered in two situations for rectal cancer: attempting to avoid colostomy formation as organ preservation in early rectal cancer or for palliation in surgically unfit patients, either as a boost following EBRT or as sole palliation. Two methods of treatment exist, contact radiotherapy or HDR brachytherapy. A recent consensus statement on rectal cancer treatment described rectal brachytherapy as an elegant option to downstage tumors and facilitates resection but that it requires further assessment.[157]

Contact radiotherapy, often called Papillon radiotherapy, uses a 50-kVp source to deliver highly localized doses directly to the tumor with rapid dose fall off, and with the advent of dedicated modern machines, contact brachytherapy for rectal cancer is enjoying a renaissance. Following sigmoidoscopic assessment a fixed diameter applicator is placed into the rectum and the radiation delivered under direct vision to the tumor. Generally a dose of 110 Gy in 4 fractions delivered at two weekly intervals is used for sole treatment of T1 tumors and for T2 and above 85 to 90 Gy in 3 fractions is used in addition to EBRT 45 Gy in 25 fractions. In a randomized trial of patients unfit or unwilling to have surgical excision those assigned to 39 Gy in 13 fractions EBRT alone had a 63% rate of colostomy at 10 years compared to 29% in the group receiving 85 Gy in 3 fractions contact brachytherapy in addition to the EBRT.[158] Because contact brachytherapy has a higher recurrence rate than surgery, patients who are surgically eligible must be counseled accordingly and accept the requirement for increased sigmoidoscopic and MRI screening for the first 2 years. However, the majority of patients will remain colostomy free and OS is unchanged.[159]

HDR brachytherapy uses a flexible silicone applicator with multiple channels to provide a conformal dose that can treat larger fields with slightly deeper penetration than contact radiotherapy, see Figure 15-14, *A, B*. Before applicator placement, the superior and inferior extent of the tumor are marked with clips. The applicator is then inserted and the treatment field defined, preferably using CT or MRI planning. A dose of 26 Gy in 4 daily fractions is used for radical treatment or up to 30 Gy in 3 fractions for palliation, usually following pelvic EBRT. A Phase II study of neoadjuvant HDR brachytherapy has shown recurrence rates of 5% with low rates of toxicity. Matched pair analysis has shown lower rates of reoperation within 30 days with HDR brachytherapy used neoadjuvantly (in Canada) compared to short course radiotherapy or no neoadjuvant treatment (in Sweden), although different surgical techniques in the two countries may have contributed to this difference.[160]

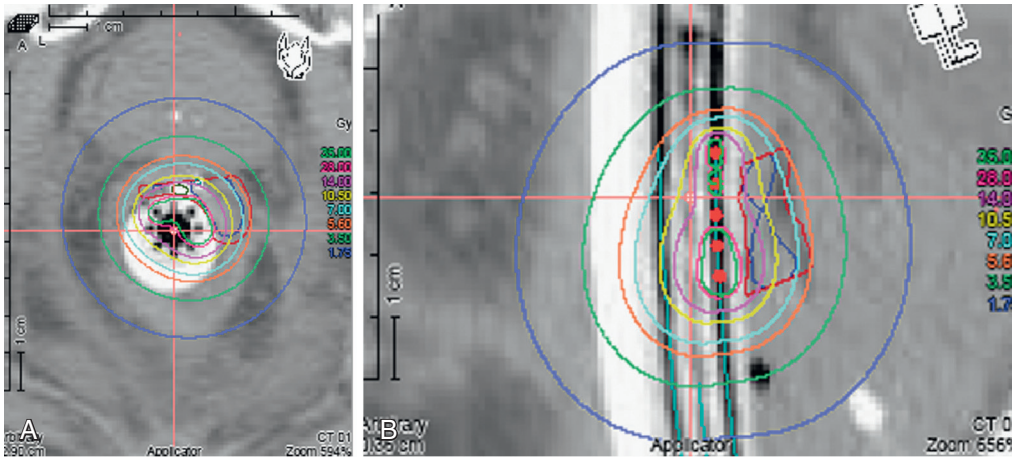

Figure 15-14 Axial **(A)** and saggital **(B)** images of a flexible silicone rectal applicator in place. A high dose rate plan has been created to cover the gross tumor volume *(blue)* with a 2-mm expansion to the planning target volume *(red)*. Note low doses received by contralateral bowel wall.

Older, medically unfit patients may be suitable for pelvic radiotherapy even if they are not fit for surgery. For those with smaller tumors contact brachytherapy may be a useful option. For institutions without access to contact brachytherapy or for patients with larger more bulky tumors HDR endorectal brachytherapy is an option. This is usually given after EBRT—either a long course with or without chemotherapy or a short course of 25 Gy in 5 fractions or 39 Gy in 13 fractions. A variety of dose/fractionation schemes have been described with up to 36 Gy in 6 fractions following EBRT[161,162] showing good tumor control with acceptable late toxicity.

Anal Cancer

Squamous cell carcinoma of the anus is a rare cancer that is usually treated with concurrent chemoradiation with good rates of sphincter preservation, disease-free survival, and OS. Relapse most commonly occurs locally with radical surgery required to achieve cure. Therefore, methods of local dose escalation for primary treatment have been explored. EBRT plus concurrent chemotherapy is used to treat the tumor and wider nodal area and the tumor boost can be delivered using EBRT, electrons, or brachytherapy.[163] Interstitial implants typically target the volume of interest using a horseshoe-shaped perineal template curved around the anus. Improved catheter placement may be achieved by the use of advanced imaging techniques such as 3D endoluminal ultrasound.[164,165] Papillon described an LDR boost using ^{192}Ir to deliver 20 to 30 Gy in 221 patients 2 months after completing EBRT. LC rates were comparable to surgical techniques.[166] Although a split course technique for anal cancer is no longer recommended, if treatment delays because of toxicity or illness occur between the Phase 1 EBRT and the boost, a brachytherapy boost may provide better local control than EBRT.[167] PDR techniques have been described with similar rates of disease control and toxicity to LDR.[168-170] HDR brachytherapy has been described but is rarely used because it may take longer to deliver as a result of the fractionation that is required in an area of normal tissue already greatly affected by EBRT. In retrospective review, an HDR dose of 14 Gy in 7 fractions over 3 days gave equivalent control to an EBRT boost with lower skin toxicity for HDR.[171]

Head and Neck Cancers

Head and neck brachytherapy was one of the first radiation therapies. The early methods were simply the placement of radium sources in or on tumors for various amounts of time to look for resolution of the tumor. The development of afterloading techniques both in Europe and the United States led to several parallel methods that have inspired modern practice. The enhancement of modern brachytherapy with PDR and HDR afterloading and computer optimization of dose has only made the conformality and utility of this surgical type of brachytherapy more attractive. A myriad of techniques have been described including the gutter guide Pierquin technique, the plastic tube technique of Henschke, the through and through technique, the loop technique, the sealed end technique, the hypodermic technique, the thread techniques, as well as direct implantation. However, the combined innovations of IMRT and chemosensitization of radiation therapy have diminished the deployment of all of these once robust forms of practice.

Brachytherapy has been described in the setting of primary localized tumors as either monotherapy or as a boost to EBRT for lip, buccal mucosa, oral tongue, floor of mouth, base of tongue and pharyngeal wall, parotid, and nasopharynx. Additionally IORT, given as HDR surface applicator brachytherapy, has been described for recurrent nodal disease in the neck.[172]

Perhaps the most adventurous of all head and neck brachytherapy, the base-of-tongue implant may serve as an illustrative example. The oropharyngeal tumors often present in the younger human papillomavirus (HPV)–associated form of cancer and require a definitive approach to potentially curable disease. The greatest challenge in this setting is to get sufficiently high dose delivered to a target between the angles of the mandible and in close proximity to the pharyngeal constrictors and the muscles of mastication. An implant will provide a highly conformal boost that will optimize the chance for cure and minimize the late effects of radiation therapy. This technique is also of significant importance in the setting of recurrent disease after previous radiation therapy. Harrison et al reported the Memorial Sloan Kettering Cancer Center (MSKCC) series in which for largely node-positive disease there were high rates of LC and distant control of disease.[173] Karakoyun-Celik et al reported the Massachusetts General Hospital series deploying the gold button technique with excellent LC and distant control.[174] Cano et al also reported reduced dose after concomitant chemotherapy and EBRT again showing excellent results in a largely locally advanced and node positive cohort.[175] The ongoing role of base of tongue implants in the IMRT era is also worth considering as to the effect on swallowing function. Teguh et al[176] and Al-Mamgani et al[177] reported significantly

more dysphagia, trismus, and dry mouth after an IMRT boost when compared to an interstitial boost.

Although there is not space for a full review of each technique, a comprehensive review of head and neck brachytherapy applications and techniques is available giving an international approach and perspective.[178]

Skin/Superficial

Brachytherapy has been described for superficial treatments of both benign and malignant skin neoplasms. The most common malignant process is nonmelanoma skin cancers (squamous cell carcinoma and basal cell carcinoma). There are a variety of treatment options with radiation for these lesions including EBRT, electrons, orthovoltage, and brachytherapy. Brachytherapy techniques can include LDR, PDR, HDR, and more recently electronic brachytherapy.[179] Brachytherapy has advantages over the other radiation treatments in areas of the body with complex superficial targets (see Figure 15-15) and allows for shorter treatment courses. Both interstitial and surface techniques have been described. Interstitial implants can often be placed under local anesthetic and are usually single plane; however, for deeper lesions multiple planes may be required to get coverage at depth. Ducassou et al reported their experience in 132 patients treated with LDR interstitial treatments for squamous cell and basal cell carcinomas. The 5-year local relapse-free survival (LRFS) was 87.3%. Patients who were treated with primary brachytherapy had better LRFS compared to patients treated at time of recurrence (HR 2.91), also the LRFS was superior in patients treated for basal cell compared with squamous cell carcinoma (90.4% versus 70.8%, $p = 0.03$).[180]

Superficial techniques can be with either custom molds or surface applicators or with commercial contact applicators such as the Leipzig applicator (Nucletron, an Elekta company, Veenendaal, The Netherlands). Superficial applicators are limited to superficial tumors. Electronic brachytherapy and the Leipzig type applicators have a surface dose of 100% and rapid dose fall off after 3 mm.[181] Other HDR surface techniques using molds or flaps have the ability to treat larger volumes and slightly deeper, but the skin dose has to be evaluated. Gauden et al treated 236 lesions with Leipzig applicators to a dose of 36 Gy prescribed at 3 to 4 mm daily in 3 Gy fractions (36 Gy/12 fractions). They reported 98% LC and 88% excellent/good cosmesis.[182] Similarly Guix et al reported LC of 98% using customized surface molds and HDR brachytherapy with ^{192}Ir with doses between 60 and 65 Gy/30 to 33 fractions. Tumors larger than 4 cm were boosted after a treatment break to 75 to 80 Gy.[183] Bhatnagar et al reported their experience using electronic brachytherapy in 122 patients treated to 40 Gy in 8 fractions given twice weekly. LC at 1 year is 100%; no grade 3 or above adverse events were noted.

Success has also been reported for palliative treatments of Kaposi's sarcoma, cutaneous metastatic melanoma, angiosarcoma, Merkel cell metastases as well as T-cell and B-cell lymphomas.[184-187] Doses and fractionation for these treatments differ significantly. Superficial treatments using brachytherapy in the postoperative setting are also described for keloid scarring using dose ranges between 15 and 20 Gy in 3to 10 fractions.[188-190]

Sarcoma

Sarcomas are a rare tumor group that can occur throughout the body. The majority of the literature for sarcoma brachytherapy comes from the trunk and extremities. Brachytherapy for sarcomas can be used as a monotherapy postoperatively to improve LC or in combination with EBRT. Although much of the initial literature for brachytherapy in soft-tissue sarcomas (STS) used LDR brachytherapy, there is now sufficient evidence to support the use of both HDR and PDR brachytherapy in the treatment of STS.

The seminal MSKCC study evaluating LDR brachytherapy in STS randomized 164 patients with superficial truncal or extremity STS following R0/R1 (no residual/microscopic residual) resection to surgery alone versus surgery and brachytherapy. LC at 5 years was observed in 82% of brachytherapy patients versus 69% with surgery alone ($p = 0.04$). The LC difference was seen in patients with high-grade lesions (5-year LC 89% versus 66%, $p = 0.0025$), but brachytherapy had no impact on LC in patients with low-grade lesions.[191] There was no improvement in OS. In this study tumor size, margin of resection, and depth had no impact on LC.

Whether brachytherapy monotherapy is sufficient for tumors with positive margins is uncertain. In early MSKCC analyses, patients with high-grade STS and positive resection margins had trends for improved LC when treated with EBRT plus brachytherapy compared to brachytherapy alone (LC in 90% [9/10] versus 59% [10/17], $p = 0.08$).[192] However, in

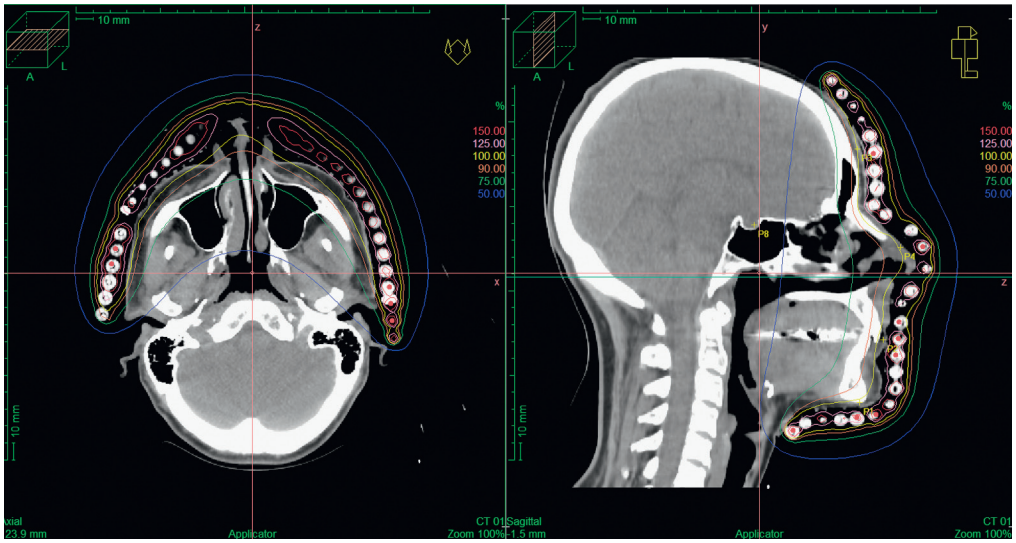

Figure 15-15 Custom surface mold with HDR applicator with an optimized treatment plan to a complex superficial target showing equivalent dose penetration despite multiple contours of the face.

subsequent publications that difference was not seen (LC 75% for brachytherapy versus 74% for EBRT with brachytherapy, $p = 0.9$).[193] Factors that may influence consideration of EBRT with brachytherapy include positive margins, low-grade tumor, size of tumor, and prior surgeries.[194] The dose for brachytherapy monotherapy and boost can be seen in Table 15-5.

The implant technique for LDR, PDR, and HDR interstitial STS brachytherapy is the same. At the time of the surgical resection the radiation oncologist and surgeon define the CTV and arrange a series of brachytherapy catheters to cover the CTV plus a margin of 1 cm to 2 cm. The catheters can be placed perpendicular to the scar or parallel with equal distance between the catheters. Typically the scar and drain sites are not included in the CTV. Single-plane implants are the most common, but multiplanar implants have also been described. The catheters are secured within the tumor bed and to the skin. CT planning allows for 3D evaluation of the CTV and normal tissues including the skin (Figure 15-16). Source loading of the implant typically occurs at least 5 days postoperatively because this has been found to decrease acute toxicity.[195] LC for brachytherapy monotherapy ranges from 55% to 100% and EBRT with brachytherapy from 71% to 100%.[196]

In a prospective cohort comparison the treatment outcomes of patients treated with brachytherapy monotherapy were compared with IMRT. The IMRT cohort had more adverse features including positive margins and tumor size, but the LC was better compared with brachytherapy monotherapy (91% versus 81%). The LC of the IMRT group was, however, comparable to other studies of brachytherapy monotherapy or brachytherapy boost as mentioned previously.

The most common acute toxicity is delayed wound healing with reoperation reported between 2.3% and 13.8% in the literature.[197] Bone fractures and neuropathy are reported, but the incidence does not appear to be increased by brachytherapy.[196] There are no trials to evaluate toxicity outcomes based on dose rate.

Brachytherapy has also been described as a boost for retroperitoneal sarcomas with mixed results. In a Princess Margaret Hospital (PMH) study, investigators initially reported EBRT plus brachytherapy to be well tolerated acutely except in the upper abdomen. In a subsequent PMH analysis with longer follow-up, EBRT plus brachytherapy was associated with increased toxicity with no difference in disease control compared to EBRT alone.[198]

TABLE 15-5 Recommended Brachytherapy Prescription Doses for Soft-Tissue Sarcoma

Modality	Dose		Dose Per Fraction or Dose Rate
	Monotherapy	Boost	
LDR	45-50 Gy	15-25 Gy	0.45-0.5 Gy/hr
PDR	45-50 Gy	15-25 Gy	0.45-0.5 Gy/hr
HDR	30-54 Gy	12-20 Gy	2-4 Gy/fraction

Modified from Holloway CL, Delaney TF, Alektiar KM, et al: American brachytherapy society (ABS) consensus statement for sarcoma brachytherapy. Brachytherapy 12:179–190, 2013.
Brachytherapy boost dose based on delivery of 45-50 Gy with EB.

Central Nervous System

Primary central nervous system (CNS) tumors continue to be one of the most aggressive and resistant of all human tumors. Despite the potential for higher tumor control through dose escalation the results have continued to disappoint. Whereas CNS brachytherapy at initial surgery is not practiced, it is reasonable to consider brachytherapy in treating recurrences in younger and high performance status patients when all EBRT options have been exhausted.

The most common form of CNS brachytherapy is the intraoperative placement of ^{125}I seeds along the walls of the resection cavity, held in place by various methods. Individual case series show reasonable level of LC with a tolerable level of radionecrosis. Another method uses an intracavitary balloon connected to a subcutaneous reservoir/port that is then filled with ^{125}I colloid for up to a week to deliver a therapeutic dose. The Brain Metastasis Study Group reported a Phase II study in which this device was used as a perioperative boost of 60 Gy with survival and recurrence similar to other published series of resection followed by EBRT.[199]

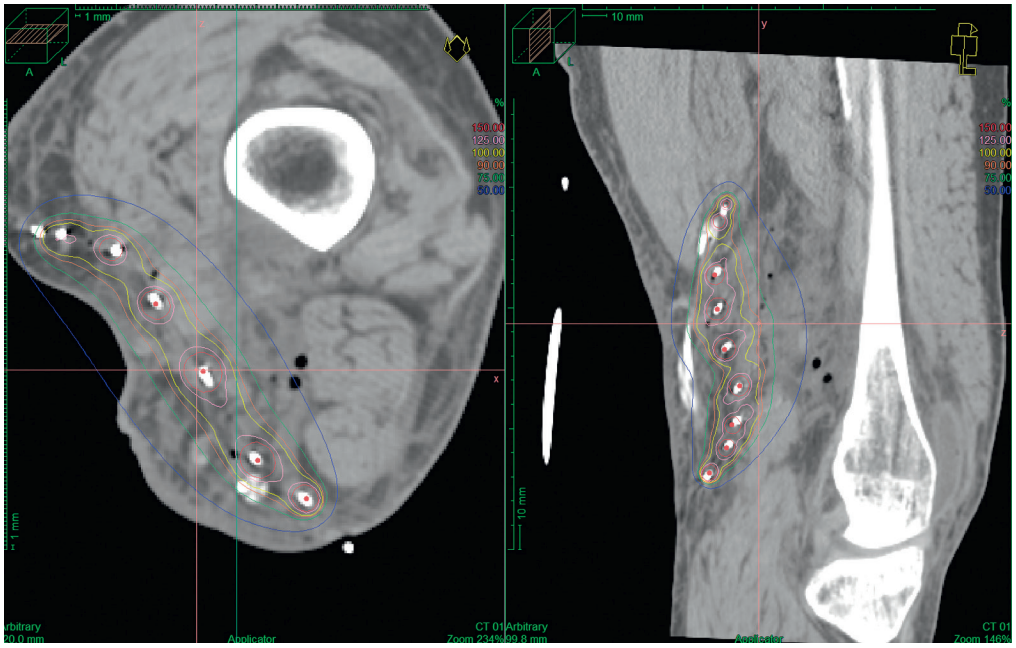

Figure 15-16 Single-plane implant for sarcoma brachytherapy delivery. The catheters are placed at the time of surgery.

Two prospective trials showed no statistically significant OS advantage for CNS brachytherapy. Brain Tumor Cooperative Group 87-01 trial randomized patients with newly diagnosed glioblastoma multiforme (GBM) to temporary ^{125}I brachytherapy as an addition to the regimen of EBRT and Carmustine (BCNU) chemotherapy; 270 patients were evaluated, 137 with EBRT alone and 133 EBRT with brachytherapy. The survival advantage of 10 weeks favored the addition of brachytherapy but did not reach statistical significance.[200] The University of Toronto randomization of an interstitial temporary ^{125}I boost after EBRT also showed no survival advantage.[201] Age, performance status, and the use of chemotherapy were associated with relative improved survival.

Recent attention has been turned to other CNS histologies, especially atypical meningioma in which small case series demonstrate the potential for brachytherapy in the recurrent setting when all external beam approaches have been exhausted and for which best resection can be attempted.[202]

Spinal CNS brachytherapy has been reported both as the use of permanent radioactive ^{125}I seeds placed in the region of the tumor and close margin at the dura at the time of partial of total vertebrectomy and reconstruction for various diseases.[199] An innovative approach deploys the temporary intraoperative use of a dural plaque coated with a beta-emitting foil such as Yittrium-90 (^{90}Y).[203]

Pediatrics

Brachytherapy is seldom considered a part of first-line therapy for children with cancer. However, the excellent use of this modality in the adult population combined with its inherent tissue-sparing abilities continues to stimulate pediatric radiation oncologists to develop innovative uses of brachytherapy as a part of modern multimodality care.

Case series for many solid tumor sites including Wilms tumor, neuroblastoma, hepatoblastoma, Ewing sarcoma, osteosarcoma, STS, rhabdomyosarcoma, retinoblastoma, and craniopharyngioma demonstrate the reasonableness of such considerations. Such series involve rare tumors, spread over many centers in different parts of the world with heterogeneous equipment and training. These case series demonstrate the reasonable use of ^{192}Ir HDR afterloading brachytherapy with computer graphics optimization, IORT with HDR brachytherapy, temporary ^{125}I-based extremity therapy, and sophisticated uses of ^{125}I eye plaques and even colloid. For consideration of the use of brachytherapy the patients would be referred to a pediatric cancer program that had the equipment and expertise. A comprehensive review of the applications and techniques in modern pediatric brachytherapy can be found in the Brachytherapy Applications and Techniques, ed 2.[204]

Ophthalmic

Ophthalmic plaques can used to deliver brachytherapy to the conjunctiva or the sclera. The choice of isotope used determines the type of applicator. Curved solid isotope applicators use Strontium-90 (^{90}Sr) with a fixed diameter applicator (typically 12 mm; see Figure 15-17) or Ruthenium-106 (^{106}Ru) in a range of diameters. These can be held in place for short applications or sutured directly to the sclera for longer applications. Alternatively customizable silicone or gold applicators can be loaded with seeds, usually ^{125}I, although the use of ^{103}Pd and ^{131}Cs seeds has also been investigated with promising dosimetric results.[205,206] Brachytherapy can be used for benign disorders such as pterygium and macular degeneration or for the treatment of primary malignant conjunctival tumors such as melanoma, squamous cell carcinoma, and lymphoma or for palliation of metastatic disease.[207]

Figure 15-17 Strontium applicator being held in position to deliver radiation to the sclera.

Before implant of anterior lesions, the eye is anesthetized using local anesthetic eye drops. The applicator is applied directly to the area of bare sclera, adjacent limbus, and affected cornea and either held in place by the operator for short applications or sutured to the sclera for longer applications. Following brachytherapy, the patient must wear an eye patch to prevent inadvertent damage to the eye. The use of natural spacers such as amniotic membrane has been described and may help to decrease pain during the procedure and reduce late toxicity.[208]

Following treatment, mild conjunctivitis is common, long-term sequelae are unusual, but the risks increase as fraction size and total dose increase. Scleral ulceration is the most common complication. Maculopathy may occur and is significantly associated with larger tumor size.[209] Retinal detachment is a rare late complication, with a reported rate of 1.48% up to 10 years after ^{106}Ru treatment of ocular melanoma[210] responding well to surgical management. Radiation-induced cataracts are rare, occurring following higher doses and responding well to surgery. Irradiation dose to the surgeon's fingers during implantation is low.[211]

Pterygium is a benign proliferation of the conjunctiva over the cornea. Locally applied ^{90}Sr decreases the rate of recurrence following surgery to as low as 0.5%,[212] using doses varying from 20 to 60 Gy in 1 to 6 fractions. Late scleral complications are decreased with fractionated treatment (4.5%

versus 1%). However, alternative treatments such as topical chemotherapy and conjunctival autografting are replacing ophthalmic plaque brachytherapy,[213,214] possibly because of ease of surgical administration.

^{90}Sr has also been used in the treatment of wet macular degeneration caused by neovascularization beneath the pigment of the retina. However, studies including brachytherapy for wet macular degeneration have not shown conclusive results with the potential toxicity of radiation retinopathy, thus this technique has been largely supplanted by the use of vascular endothelial growth factor inhibitors.[215] Brachytherapy may be of use in selected cases, particularly large areas.[216]

The Collaborative Ocular Melanoma Study (COMS) group conducted two randomized trials in North America, examining the use of ^{125}I for choroidal melanoma. When the use of ^{125}I brachytherapy was compared to enucleation for tumors of 3- to 8-mm depth there was no difference in survival and similar rates of toxicity.[217,218] Van Ginderdeuren et al demonstrated a 90% 15-year tumor control for sclera melanoma using a ^{90}Sr applicator using doses of 450 Gy to 800 Gy at the sclera.[219] There were a proportion of recurrences at the edge of the target volume, possibly because of the small applicator size. There was a 45% preservation of vision, which was generally dependent on tumor position rather than dose delivered.

Vascular

Endovascular brachytherapy in the treatment of peripheral vascular stenosis following angioplasty has fallen out of favor. A Cochrane meta-analysis of randomized control trials of percutaneous transluminal angioplasty (PTA) alone compared with PTA and brachytherapy in the femoropopliteal artery did not find sufficient evidence to support widespread use of endovascular brachytherapy.[220] Several trials comparing drug eluting stents versus brachytherapy for bare metal stent in-stent restenosis (ISR) of coronary vessels have shown brachytherapy to be associated with an increased incidence of target vessel failure.[221-223] In the TAXUS V-ISR trial, 396 patients with bare metal stent ISR were randomized to a stent eluting paclitaxel or beta source brachytherapy. At 24 months the freedom from clinical restenosis was worse for the brachytherapy cohort, but there were similar rates of death and myocardial infarction and target vessel thrombosis.[223] The randomized BetAce trial evaluating intracoronary brachytherapy for de novo lesions also failed to show benefit beyond 6 months with delayed and progressive restenosis.[224] Nonetheless, in the setting of multiple drug-eluting stent ISR failures for whom there is not a surgical bypass option then coronary vessel brachytherapy can be attempted to achieve suppression of refractory intimal hyperplasia. The BRAVO-II trial evaluated beta radiation for arterial-venous graft outflow stenosis in patients who undergo dialysis following angioplasty of a thrombosed graft. This trial closed early but did not show benefit to endovascular brachytherapy.[225]

SUMMARY AND FUTURE POSSIBILITIES

Brachytherapy is a fundamental part of any radiation oncology program. There are now more techniques and sources than ever before to use the unique physics and radiobiology of brachytherapy. Clinical research must continue to evaluate brachytherapy techniques allowing for more precise targeting of the volume of interest while minimizing dose to normal tissues. These further studies will also help guide dose and fractionation and define dose constraints and parameters.

Brachytherapy in the future will strive to deliver more personalized treatment through the use of image guidance and the ability to choose the best applicators and dose rate to fit the clinical scenario. Brachytherapy is particularly suited to subvolume dose escalation because of the ability to deliver a highly localized dose with rapid dose fall-off in the surrounding tissue. New biological and functional imaging modalities such as magnetic resonance spectroscopy (MRS) or positron emission tomography (PET) scanning could identify zones of aggressive cell repopulation that may allow dose escalation using brachytherapy.

The delivery systems for brachytherapy are also likely to evolve and improve in the future. The move from multiple catheter interstitial partial breast irradiation to the single-channel catheters is an example of this type of innovation. Delivery systems could be made more versatile with the capability to deliver different treatment modalities through the same applicator (e.g., brachytherapy and hyperthermia or chemotherapy). Brachytherapy delivery systems are not restricted to applicators. The use of injectable radioisotopes bound to delivery agents such as tagged antibodies or annealed spheres is likely to increase with future developments in antibody technology.

Future indications for brachytherapy are ever increasing, but it must be remembered that recommendations for the use of resource intense treatment and planning modalities, such as CT-guided implant placement, or MRI brachytherapy planning, may create treatment paradigms that are unsustainable in many healthcare systems around the world. When international guidelines are devised, emphasis should be placed on the use of available and accessible technology.

CHAPTER

16 Intensity-Modulated and Image-Guided Radiation Therapy

Benedick A. Fraass, Avraham Eisbruch, and Mary Feng

DEFINITIONS FOR CONFORMAL AND IMAGE-GUIDED THERAPY

Conformal therapy describes radiotherapy treatment that creates high-dose volume(s) that are shaped to closely "conform" to the desired target volumes and prescription doses while minimizing (as much as possible) the dose to critical normal tissues. As capabilities have improved, the definition of conformal therapy has expanded to incorporate the fact that high-quality conformal therapy is designed to conform to all the target dose requirements (both target volume shape(s) and the potentially complex dose distributions desired inside each target) while minimizing the normal tissue doses. Although these features are the general aim of any radiotherapy treatment, normally the term *conformal* is applied to treatment plans in which (1) the target volumes are defined in three dimensions using contours drawn on many slices from a computed tomography (CT) (or other) imaging study; (2) multiple beam directions are used to cross fire on the targets; (3) the individual beams are shaped or intensity modulated to create a dose distribution that conforms (in shape and dose) to the target volume shape(s) and desired dose levels; and (4) appropriate use is made of image guidance, accurate patient setup and immobilization, and management of motion and other changes to ensure accurate delivery of the planned dose distributions to the patient, so that deviations from the planned treatment of the patient are minimized. Figure 16-1 illustrates the conceptual difference between standard and conformal therapy: Figure 16-1, *A* shows a standard four-field box treatment for a given target volume that everyone would agree is a nonconformal approach, whereas Figure 16-1, *B* shows a conformal approach achieved with conformally shaped fields.

A number of different treatment planning techniques and various treatment delivery techniques are routinely used to perform clinical conformal therapy. Three-dimensional conformal radiotherapy (3DCRT) was the first conformal therapy technique developed, based on use of three-dimensional (3D) treatment planning and multiple cross-firing, carefully shaped fixed fields. A more recent planning method—inverse planning—involves creation of the radiotherapy plan using mathematical optimization techniques; often, this inverse planning technique is used to define intensity-modulated beams, which are radiation beams with a complex intensity distribution rather than the "flat," uniform intensity fields typically used for 3DCRT. The combination of inverse planning and intensity-modulated beams is called *intensity modulated radiation therapy* (IMRT). In recent years, the combination of IMRT delivery and optimization methods with arc therapy, volumetric modulated arc therapy (VMAT), has become an important method for the delivery of conformal therapy. All of these conformal therapy delivery methods are greatly improved by (and usually require) the use of image-guided radiation therapy (IGRT) techniques to accurately position and set up the patient, using integrated megavoltage or kilovoltage diagnostic imaging, cone beam CT, radiofrequency beacons or radiographic fiducials, and other image-guidance methods. Active consideration of the patient's respiratory (or other) motion in planning is described by four-dimensional (4D) imaging and 4D planning, and active motion management strategies are used during treatment to address the motion issues.

In general, there can be many different combinations of technologies used to develop and implement sophisticated conformal therapy. Conformal therapy is defined by the kinds of dose distributions that are planned and delivered to the patient, not by the specific technique(s) that are used. For example, one often performs conformal therapy by using IMRT, but the fact that IMRT is used does not necessarily imply that the treatment is conformal.

A SHORT HISTORY OF CONFORMAL AND IMAGE-GUIDED THERAPY

For many decades it has been known that delivering a high dose to the tumor is critical for control of the tumor and that the probability of complications increases with radiation dose and volume of organ irradiated. The basic concept of conformal therapy was elucidated quite early: "Treat the tumor to a high dose while minimizing the dose to normal tissues." However, it was not until the 1950s and 1960s that techniques recognizable as modern conformal therapy began to be developed.

One of the most important pioneers in "conformation therapy" was Shinji Takahashi, who described many of the important concepts of conformal therapy delivery and 3D treatment planning in a 1965 monograph.[1] Takahashi's innovations included early multileaf collimators, automated (mechanical) conformal beam shaping, dynamic conformal treatments, orthogonal light beams to identify the machine isocenter, and 3D tumor models based on early tomography.[1] Other notable work in this area was performed by Harold Perry and colleagues[2] in Detroit and by Proimos, Wright, and Trump at the Massachusetts Institute of Technology (MIT)–Lahey Clinic.[3-7] Another early approach to conformal therapy, known as the Tracking Cobalt Project,[8,9] was led by Green, Jennings, and others at the Royal Northern and Royal Free Hospitals in England. First reported in the late 1950s,[10] and summarized by Jennings, a series of mechanical, electrical, and finally, computer-controlled treatment machines were developed to track disease spread, particularly along lymph node chains. By 1980, the computer-controlled version of the tracking system was in clinical use,[11] although Brace summarized the major limitation to the delivery technique: "The major obstacle to the routine use of conformation therapy is treatment planning."[11] Finally, workers at the Joint Center for Radiation Therapy (JCRT) in Boston added computer control to a modern linear accelerator, so that the treatment table,

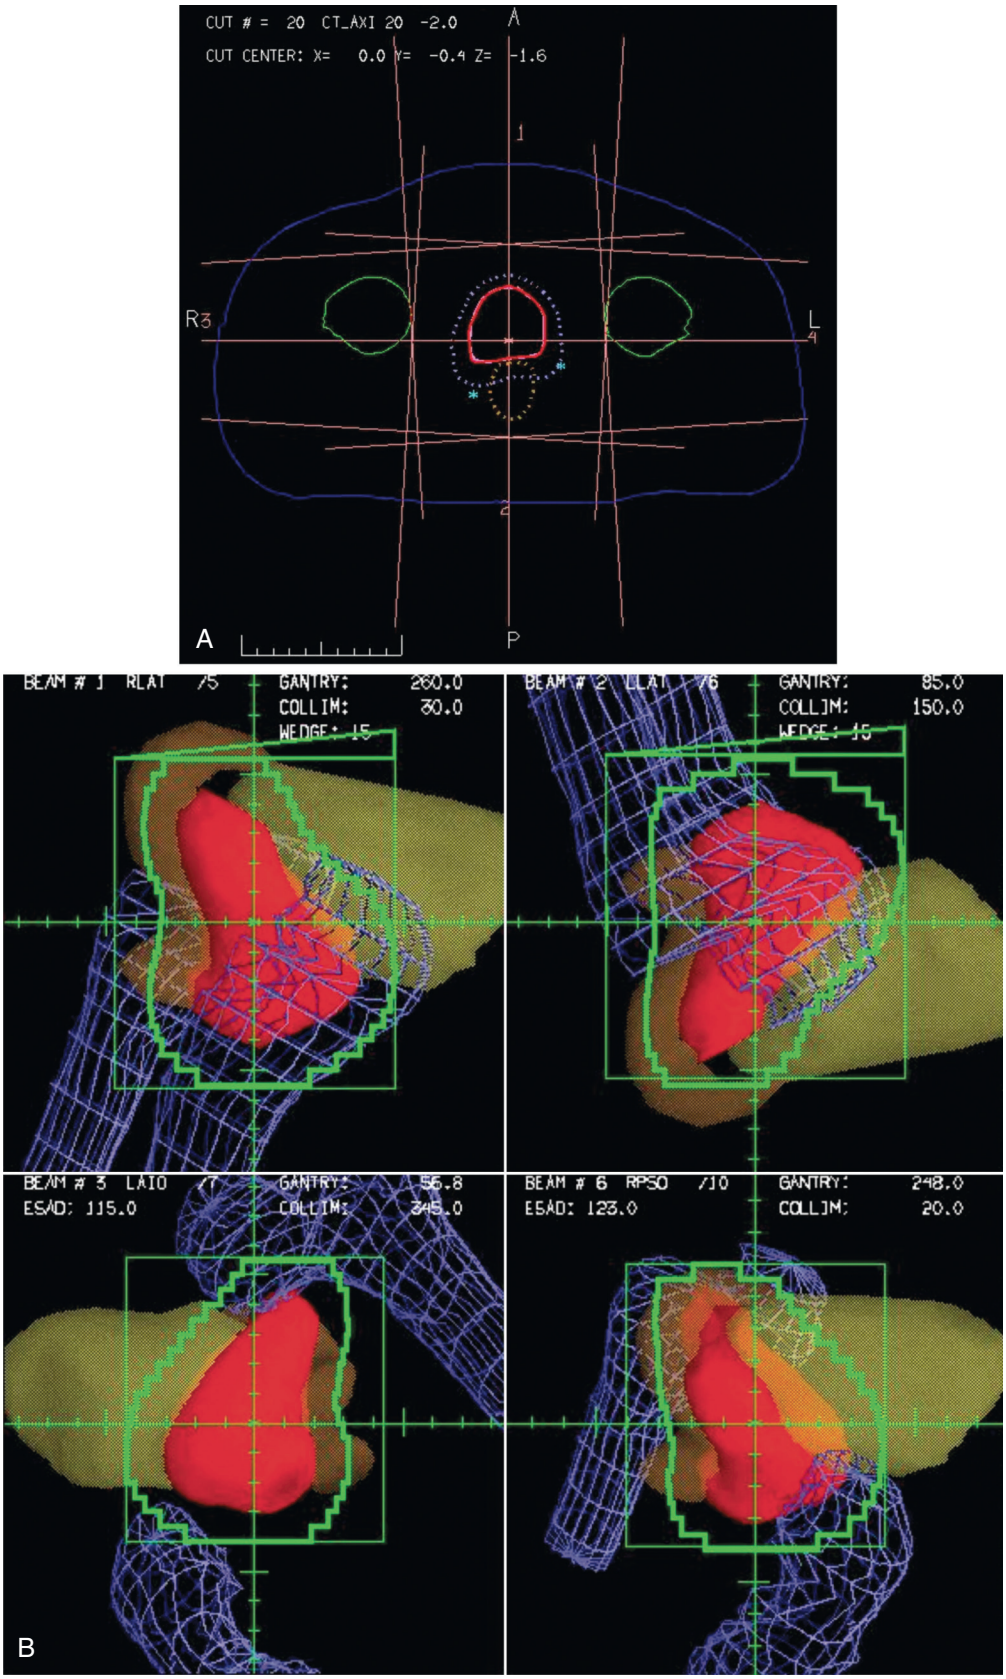

Figure 16-1 **A,** Four-field box treatment of the prostate. Contours shown include *blue* external contour, *red* prostate, *dotted* PTV, *yellow (dotted)* rectum, and *green* femoral heads. **B,** Beam's-eye view of a nonaxial four-field conformal plan for prostate treatment, where the *green* outlines show the conformally shaped MLC patterns for each field. *Red* is prostate, *blue* is femoral heads, *yellow* is bladder, and *brown* is rectum.

gantry, collimator, collimator jaws, dose rate, and other parameters could be controlled dynamically while the beam was in use. The JCRT achieved the delivery of what is now called "dynamic conformal therapy,"[12-15] which was a modern basis for computer-controlled conformal therapy.

As already described in the quote by Brace, treatment planning was one of the main limitations for the conformal delivery techniques that were developed during this time period. The introduction of CT in the early 1970s was a key to the development of the modern 3D planning that is crucial to conformal therapy because it made available a complete 3D description of the anatomy of each patient that could be the basis for planning. Early evaluation of the use of CT in treatment[16-18] quickly led to widespread use of CT-based planning (see Ling[19]) as well as new interest in the use of inhomogeneity-corrected dose calculations, which became possible because CT provided the necessary electron-density maps of the patient.[20] Other imaging data, including magnetic resonance imaging (MRI) and positron emission tomography (PET), also became available and began to be used for planning in the mid-1980s.[21]

With the widespread implementation of CT-based planning, it became possible to make use of continuing improvements in computer technology and new software developments to create fully 3D treatment planning systems that incorporated 3D graphics and the "beam's-eye view" (BEV), a 3D graphic reconstruction of the patient anatomy projected into the divergent geometry used by the x-rays in the radiation beam[22-26] (Figure 16-2). Using BEV displays to design field shaping[27] and evaluate coverage of tumor and sparing of normal tissues is perhaps one of the most effective concepts in the entire 3D planning paradigm. Routine clinical use of 3D radiation treatment planning (RTP) began in 1986,[28] and many academic centers began development and then use of 3D planning systems in their clinics.[29-32]

The development of 3D treatment planning systems helped drive the need for and design of more sophisticated treatment delivery systems because the 3D planning systems

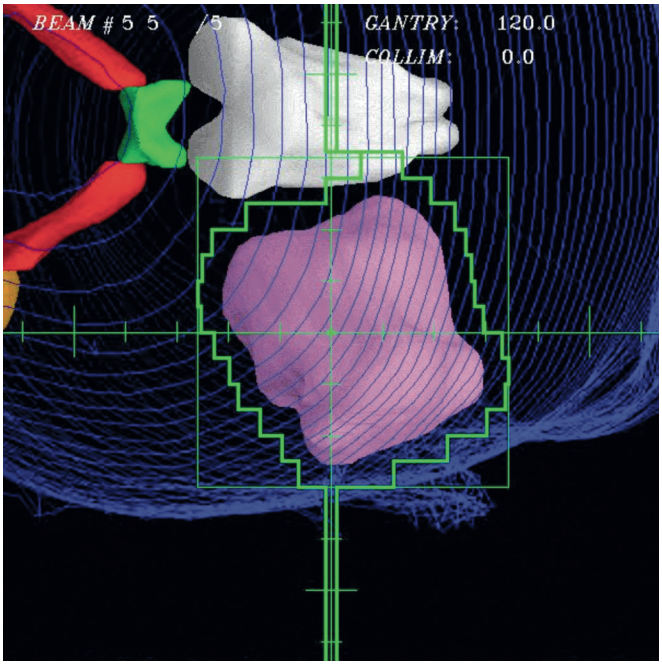

Figure 16-2 Beam's-eye view of a brain tumor showing a multileaf collimator shaped to the *violet* target volume. Normal tissues include brainstem *(white)*, chiasm *(green)*, and optic nerves *(red).*

demonstrated treatment improvements that would be possible to use clinically if more sophisticated machinery were available to make efficient delivery possible. The first treatment machine designed specifically to perform computer-controlled conformal radiotherapy (CCRT), the Scanditronix MM50 Racetrack Microtron, was developed during this same time period.[33-35] Among other unique features, this machine included a fully computerized control system and a computer-controlled multileaf collimator (MLC),[36] consisting of two sets of thin tungsten leaves that are used to shape the radiation field. Virtually all other radiation therapy machines have since also implemented computer control systems and MLC systems.[37-39]

The capabilities of computer control and MLC systems have made possible the delivery of complicated plans, including those that make use of modulated intensities (a beam with different intensities in different parts of the field). Intensity modulation created using multiple segments[40-45] or dynamic MLC motions[33,46,47] and computer plan optimization (inverse planning)[48-52] have been integrated and called *intensity modulated radiation therapy* (IMRT).[53] The basic concepts of IMRT were described in 1987 by Brahme[33,48,54] and a practical implementation was described by Bortfeld soon after.[55] The combination of the flexibility of computer-controlled IMRT delivery with sophisticated plan optimization techniques has made IMRT an extremely powerful tool that can be used to perform conformal therapy.

The initial commercial IMRT implementation by NOMOS in 1992[56] was a form of IMRT now called *serial tomotherapy*, in which patients were treated slice by slice (as with early CT scanners) by the machine rotating around the patient using a special multileaf collimator (MIMIC) that performed the intensity modulation. Within a few years, all major vendors had implemented MLC systems, with leaf widths varying from 1 cm to a few millimeters, that could perform IMRT using either dynamic motions of the MLC leaves ("DMLC") or a number of static segments (called "SMLC").[53] A more sophisticated implementation of tomotherapy based on helical delivery of IMRT, helical tomotherapy,[57] also became widely disseminated. In the last several years, a rotational MLC-based IMRT technique, originally described by Yu,[58] has been implemented and widely disseminated (VMAT).[59,60] Inverse planning has also developed substantially during this time. Though much of this optimization makes use of quadratic weighted sum cost functions and simple gradient-based search algorithms, there have also been developments of sophisticated cost functions[61] and the use of more biologically related costs that make use of normal tissue control probability (NTCP) models and equivalent uniform dose (EUD). Most inverse planning systems use the weighted sum cost functions, but there has been development of sophisticated multicriteria methods[62,63] that more directly take into account the numerous optimization goals involved in a typical clinical radiotherapy treatment plan and prioritize clinical tradeoffs.

One of the developments that made the conformal therapy revolution possible was the development of amorphous silicon flat panel imagers,[64] which allowed effective electronic portal imaging verification of the accuracy of these newly conformal fields. This technology then was further developed, first for kilovoltage (diagnostic quality) imaging and then to provide cone beam CT (CBCT) capability using kilovoltage imaging systems mounted directly on the treatment machine.[65] The availability of these high-quality CBCT or kilovoltage imaging modalities directly on the treatment machine led to the development of IGRT, in which diagnostic imaging is used to correct patient setup and positioning for treatment every day. IGRT processes have greatly increased the delivery accuracy that can be routinely achieved and have led to the possibility of much smaller margins for setup errors. This improved

confidence in targeting accuracy has made possible the development of stereotactic body radiation therapy (SBRT), which is now used routinely to give very high doses to well-localized targets in the liver, lung, and other sites using highly conformal treatment delivery performed with IGRT. The use of IMRT and the proper handling of patient motion, respiration, and other 4D issues have been pursued for many years and are still major threads of much current research and development.

ISSUES FOR CLINICAL USE

A number of important clinical features are crucial for planning and delivery of high-quality conformal therapy, and these issues should be carefully considered throughout the conformal therapy planning and delivery process.

- Conformal therapy attempts to carefully conform the dose to the target(s), so delineation of the target(s) and careful specification of the desired dose distribution(s) are crucial.
- Patient immobilization, localization, and motion are crucial, and setup accuracy and motion management must be considered throughout the process to minimize normal tissue that will be irradiated because needing to increase target margins will significantly decrease the advantages provided by conformal treatment.
- Improvement of the clinical results achieved by conformal therapy, compared with standard techniques, depends on choosing the correct tradeoffs between target coverage and normal tissue sparing, so these choices must be made carefully and appropriately.
- It is the quality and precision of the dose distribution that is achieved which is important. The techniques used for planning and delivery (e.g., DMLC IMRT, VMAT, 3D) are simply the means to achieve the desired dose distribution.
- The quality of the delivered dose distribution can be destroyed by motion, respiration, setup error, or involuntary motions during treatment, so use of motion management techniques to control motion (e.g., active breathing control, respiratory gating, tumor tracking) is essential for some clinical sites. The use of 4D CT for planning and IGRT for setup and motion analysis are all big contributors to the quality of the treatment.

PLANNING FOR CONFORMAL THERAPY

Treatment planning is one of the most critical parts of the conformal therapy process. In this description, we include all preparatory aspects of the planning process, including many activities that occur outside the therapy planning system (TPS). Many treatment delivery issues (e.g., setup accuracy, patient motion, portal and localization imaging) are briefly mentioned here and are more completely described later. Figure 16-3 shows a schematic of the basic components of the planning process for both forward (interactive) and inverse (i.e., IMRT optimization) planning.

Positioning and Immobilization

One of the basic ideas of conformal therapy is to minimize the dose to normal tissues while conforming the dose to the target, so it is of course crucial to accurately position and immobilize the patient for each procedure in the planning and delivery process. One of the first clinical decisions to be made for each patient includes what position to use for the patient's treatment and whether any positioning and immobilization devices or aids will be used.

Basic patient positioning, including location of the arms and legs and positioning of the patient (supine, prone, or in some other more unusual position), depends mainly on two issues: (1) patient comfort and stability and (2) the beam directions that will be used. In most cases, conformal therapy plans make use of three or more beams that cross fire on the target from a number of different angles arranged around the patient, so the patient is typically positioned with both arms up (if the target is somewhere in the torso) or arms down (head and neck and brain targets). For superficial targets, the target is typically positioned facing up to allow easy visualization of the target, but for most deep tumors, the cross-firing beam directions can be achieved with the patient in standard supine or prone positions, whichever is most stable and accurately set

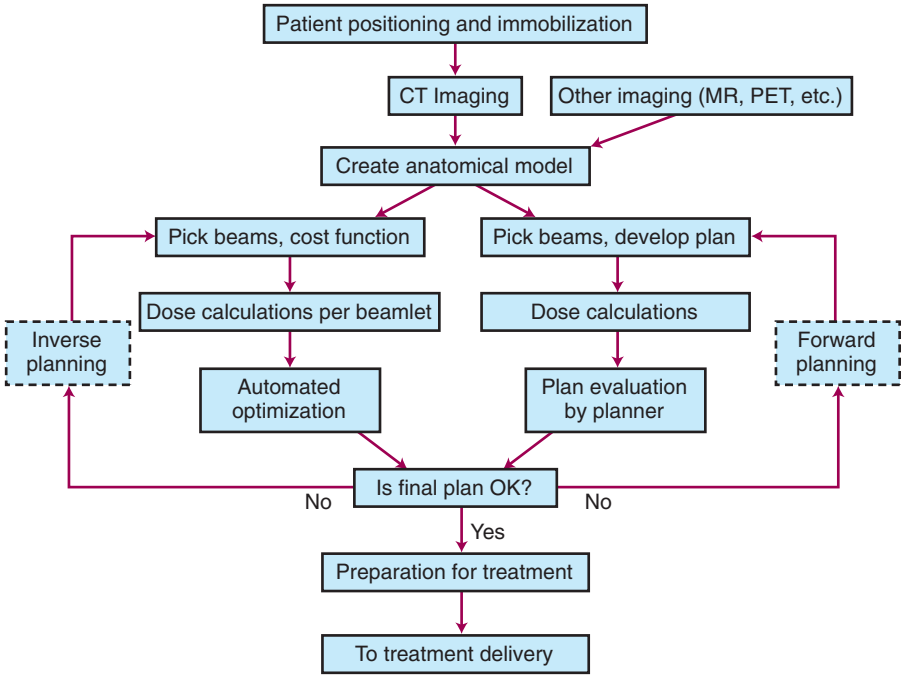

Figure 16-3 Schematic chart of the basic components of the planning process, shown for both forward and inverse planning.

up. There have been studies of the benefits of various positioning decisions (e.g., prone versus supine) for patients with prostate tumors[66]; there is some debate about the relative merits of the possible anatomic changes that occur for the prone versus the supine position, relative to other advantages and disadvantages for planning, daily setup, and respiratory motion-related stability.

The use of various types of so-called immobilization devices to help with patient positioning and immobilization for conformal therapy has run the entire gamut of possibilities, from the use of stereotactic head frames and other such devices that are physically attached to the patient's skull to other techniques that do not use any immobilization device. Early conformal therapy (1980s to 1990s) often incorporated a foam cradle device to help position the patient[67] though currently it is thought that more precision can be achieved without use of the cradle devices in many situations. In the end, each clinic should document the setup accuracy that is achieved with their chosen methods, for each clinical site, so that the planning and delivery process can take proper account of the expected systematic and random setup uncertainties. The use of in-room imaging systems (e.g., diagnostic and megavoltage CBCT) has provided more detailed information about setup accuracy and makes it possible to improve setup accuracy and minimize margins using IGRT setup.

Imaging for Planning: CT, CT Simulation, MRI, and Other Cross-Sectional Imaging

The development of x-ray CT in the 1970s and its application to radiotherapy planning[18] were absolutely crucial milestones in the development of conformal therapy techniques. Without the cross-sectional anatomic imaging provided by CT (or MRI), there was not enough anatomic knowledge about the tumor or normal anatomy to consider the use of highly conformal dose distributions. Once the detailed anatomic information provided by CT became available, it was clear that radiotherapy planning and treatment should make use of this new and detailed description of the patient to better spare normal tissues and more accurately deliver dose to the tumor. Conformal therapy is a logical response to the detailed information provided by CT.

Modern conformal therapy is always based on a 3D anatomic model of the patient, which is typically based on a CT scan of the involved region. Usually, a specific type of CT scan, the treatment planning scan or CT simulation, is obtained for use as the basis for treatment planning. Features of a basic treatment planning CT scan are listed in Box 16-1. One specific treatment planning CT scan procedure often used is called CT simulation. The CT simulation usually consists of a treatment planning CT scan plus the addition of the delineation of a reference point within the CT dataset (to be used for later planning or setup procedures), followed by marking this reference mark on the patient's skin. Sometimes CT simulation software on the CT scanner workstation is used to define the beams for the treatment plan, though this activity is really just simple treatment planning performed on the CT workstation.

Developments in CT and treatment delivery technology have made the consideration of motion during CT scanning (and radiotherapy treatment) an important topic. 4D CT describes various techniques for obtaining CT data correlated with patient respiratory phase information so that the changes associated with respiration (or other motion) are displayed. For certain clinical sites (e.g., lung, breast, upper abdomen), it is clear that consideration of respiratory motion is an important aspect of the initial imaging of the patient, so 4D CT is used to create an appropriate motion model of the patient for further planning and analysis. 4D CT,[68] respiratory gating,[69] active breathing control (ABC),[70,71] or other methods for motion management are often used for many treatment sites, though which combinations of techniques and methods are most efficient and appropriate is not yet clear.

BOX 16-1 Treatment Planning CT Scan Features

- Use a flat tabletop to mimic the treatment machine couch. Make use of couch coordinates or other documentation of exact positioning if possible.
- Use patient immobilization devices to position the patient in the same way as for treatment, including registration of the device with the couch top (if available).
- Scan extent should include completely any organs to be considered as organs at risk because planning typically requires delineation of entire organs to make use of biologic effect data. For example, treatment anywhere in the thorax would typically require scanning from the apex of the lung to below the diaphragm, so that the entire lung could be delineated.
- Modern CT scanners are efficient enough that 1- to 3-mm-thick slices can be obtained throughout the entire region of the scan, though use of thicker slices outside the target region is possible. This can amount to several hundred CT slices per study.
- Careful consideration must be given to the advantages and disadvantages of using contrast during the scans. Contrast can help identify organs but can also make accurate dose calculations difficult (because it distorts the apparent electron density of the tissue, affecting dose calculations).
- The treatment planning CT scan study is used for (1) target definition and delineation, (2) normal tissue delineation, (3) the overall anatomic model of the patient, (4) planning, (5) dose calculations based on electron density obtained from CT numbers, and (6) creation of digital reconstructed radiographs (DRRs) used to set up and verify patient position. Each of these uses may require some individualization of the CT scan protocol or use.
- The CT scan protocol should be defined for each clinical site, including slice thicknesses, scan extent (top and bottom), reconstruction window size, use of contrast, patient positioning and immobilization, patient breathing control or instructions, and so on.

CT provides anatomic and electron density information that is critical for most treatment planning, and it also provides a geometrically accurate base for planning. However, it provides only anatomic information, not the physiologic and functional information that would be helpful for planning, and it has only a limited amount of soft tissue contrast. MRI can provide complementary data, including excellent soft-tissue contrast and different kinds of physiologic information. In addition, functional magnetic resonance imaging (fMRI) studies can provide some of the functional information that to this point has been unavailable. Other kinds of imaging also contain complementary or new information. Positron emission tomography (PET) and single-photon emission computed tomography (SPECT) provide functional and physiologic information that can be quite important in helping define target volumes and regions that should be included or excluded from the radiation fields. Which modalities, scans, tracers, and analysis methods should be used for specific features is well beyond the scope of this work. However, to quantitatively make use of any additional imaging modality for treatment planning, one should incorporate a number of important procedures into the imaging process, as listed in Box 16-2.

BOX 16-2 Imaging for Treatment Planning (Not Including CT Imaging)

- Use a flat tabletop to mimic the radiotherapy Linac couch.
- Use patient immobilization devices to position the patient as you would for treatment.
- Ensure that the imaging protocol provides enough anatomic information to allow geometric registration of the new scan study with the base CT information.
- Imaging protocol parameters should be optimized to provide the anatomic, physiologic, or function data that are desired.
- The scan protocol should be defined for each clinical site and protocol, including slice thicknesses, scan extent (top and bottom), scan orientation (nonaxial slices are possible in most non-CT methods), reconstruction window size, use of contrast, patient positioning and immobilization, patient breathing control or instructions, and so on. For MRI, many additional scan technique parameters must be defined.
- CT scans should be performed in a manner that will allow accurate registration of other scan information (e.g., MRI, PET) with the CT scans.
- Motion management (consideration of how motion will be managed for CT scanning and for treatment) is an important part of the preparation for planning. It is appropriate to (1) control respiratory motion or (2) perform a 4D CT scan[68] for patients who demonstrate any significant motion in the target region. It may be necessary to perform a quick scan to evaluate motion before deciding on the final planning scan protocol and methodology.

To use more than one imaging dataset for planning, the additional datasets will have to be registered geometrically to the original (base) CT dataset (as described later). It is important during the imaging process (1) to position and align the patient similarly for each of the imaging studies because this makes the registration process more straightforward, and (2) to obtain all the information necessary so that the dataset registration and fusion process can be performed quickly and accurately. If the patient geometry is different between scans, deformable registration may be useful to "align" datasets, but the accuracy of that alignment is still being worked out for each registration method and situation.

Anatomy for Treatment Planning

Treatment planning is a computer simulation of the process of radiotherapy treatment, and it is based on creating a model of the patient inside the planning software, simulating radiation beams and the dose that those beams deliver to the patient. The definition of the virtual model of the patient, based on CT, MRI, and other types of imaging data, and how that anatomic model is used are crucial parts of the radiotherapy treatment planning process.

Three-Dimensional Anatomic Model

For conformal therapy planning, the representation of the patient used for treatment planning must be realistic and three dimensional. In general, the basic data used to define the anatomy come from a CT study, typically consisting of 50 to 200 CT scan slices. The anatomic model of the patient is based on this CT data and consists of a number of objects (structures) that delineate organs or other objects (e.g., target volumes) in 3D (or 4D; see Motion, Setup, and Four-Dimensional Anatomy). These structures can be defined by (1) a series of contours, (2) a 3D surface description, (3) a voxel-based description, or (4) a set of points distributed either randomly or on a grid. Methods used to delineate these structures are described in the section on Structure Delineation and Contouring.

The 3D anatomic structures are crucial to the planning process. The various target and normal tissue structures describe the areas to be irradiated or to be spared (respectively) so beams can be oriented and shaped. Graphic display of the 3D structures can also be used for geometric registration of the treatment planning anatomy to localize images obtained during simulation or treatment procedures. The external surface and any inhomogeneities are used for the dose calculation process. Most plan evaluation tools (e.g., dose-volume histograms [DVHs]) make use of these 3D structures for plan evaluation of the planned dose distribution.

Structure Delineation and Contouring

The delineation of the 3D anatomic objects (structures) used for planning and plan evaluation is one of the most important and time-consuming aspects of the entire conformal therapy process. It would be nice if all the anatomic structures could be automatically delineated once the CT data (and other imaging data) were obtained, but in general, this technology is still under investigation and development. Most anatomic structures are delineated by drawing contours on top of each of the CT (or other) images that are available. Because several hundred CT slices are often used, and there are many organs of interest that appear on each CT slice, there are many contours to be defined. Clever computer graphics drawing tools and techniques can make this easier, but defining the contours still requires much effort and care.

Accurately defining the structure contours is a critically important aspect of the conformal therapy process, and because it defines the target and normal structure extents for the entire process, any error or inaccuracy becomes a systematic error throughout the entire conformal therapy process. Errors in the process may come from sloppiness, from not knowing what is being visualized on the image on which contours are drawn, from limitations in the accuracy of the scan information (e.g., motion during the scan acquisition), interpolation of contours, and from many other problems. It is important that the 3D character of the objects being outlined is handled correctly: for example, sharp corners or spikes in a contour on just one slice are usually incorrect because such a structure will usually show related features on a number of images. To avoid this type of drawing problem, it is important to review all the contours serially or to visualize the 3D shape of the object, using coronal and sagittal planes, so that any unrealistic "spikes" can be identified and edited.

Target Volume Definition and Margins

To plan and deliver conformal therapy, it is essential to accurately define the volumes that must receive high radiation doses, the "target volumes." As described in detail in the International Commission on Radiological Units (ICRU) report ICRU-50,[72] three kinds of target volumes are typically defined, as summarized in Table 16-1.

The gross target volume (GTV) is typically delineated by drawing the imaged tumor on each of the imaging studies that are available. CT is used often, but for many sites, MR and PET can be useful. When multiple imaging studies are available, the GTV can be drawn on each study, and then, using dataset registration to geometrically align the different datasets (see "Multiple Imaging Modalities: Dataset Registration and Fusion" section), one can combine or transfer the different GTV contours onto a single dataset. How to combine the various GTVs defined is the subject of ongoing research;

TABLE 16-1 ICRU-50 Target Volume Definitions

Abbreviation	Name	Description
GTV	Gross tumor volume	Volume of macroscopic tumor that is visualized on imaging studies
CTV	Clinical target volume	Volume that should be treated to a high dose, typically incorporating both the GTV and volumes that are assumed to be at risk as a result of microscopic spread of the disease
PTV	Planning target volume	Volume that should be treated to ensure that the CTV is always treated, including considerations of systematic and random daily setup errors and inter- and intratreatment motion

however, typically, one will combine or take the union of all the defined GTVs to make sure that no gross tumor is missed within the defined GTV. Depending on the quality of the registration, additional margin is sometimes warranted for registration error.

The definition of the clinical target volume (CTV) is probably the most important thing that the physician does in the conformal therapy process, because the CTV defines the region that is supposed to be treated with the prescribed dose. The CTV typically combines the GTVs plus any volumes that may contain microscopic disease that could not be imaged. The CTV depends on knowledge of the patterns of disease spread and incorporates any other clinical knowledge of the disease or the specific risks for spread that apply to the individual patient. The CTV is usually created by combining two kinds of information: (1) often, an expansion of the GTV by some margin (0.5 to 1 cm, typically) is used to account for microscopic invasion, and (2) additional anatomic areas may be included in the CTV based on standard directions of spread for the particular tumor type. In the end, the goal is to outline all the areas that should receive the intended dose.

Whereas GTV and CTV definition are the job of the physician, definition of the planning target volume (PTV) is mainly the responsibility of the physicist and treatment planner because the goal of the PTV is to make sure that the CTV is adequately treated in the face of setup error, inter- and intrafraction motion, delineation errors, and other errors in the planning and delivery process. The definition of the PTV should be done with as much information as possible because the region between the CTV and PTV contours is all "normal tissue" and increasing the PTV margin will just cause more normal tissue to be irradiated. In a way, the physician is also involved in PTV definition by thoughtfully ordering appropriate patient or tumor immobilization for simulation and treatment. If a large PTV will not produce significant toxicity, and the prescribed dose will be low, then immobilization can be basic. If, however, each additional millimeter of PTV margin will clinically make a difference, then strict immobilization must be ordered.

Often, the PTV is designed by simply defining an isotropic margin (e.g., 1 cm), and the CTV is expanded by this margin to create the PTV (Figure 16-4). This expansion should be performed in three dimensions because expansion of contours only in the axial plane will lead to PTVs that are not correct in the third dimension. If the uncertainties are not isotropic but are larger in one direction than in the others (e.g., as a result of respiration), then the margin to be applied should be anisotropic.

There has been a great deal of work studying patient positioning, motion, and target volume delineation errors, and analysis of these issues has led to specific recommendations for the size of the margin (between the CTV and the PTV) that should be used for the PTV. As described in the "Consideration of Setup Error and Patient Motion" section, one reasonable method for deciding the PTV-CTV margin has been determined to be $(2.5 \times \Sigma) + (0.7 \times \sigma)$, where Σ is the standard deviation of the systematic error and σ is the standard deviation of the random errors for the population of patients treated in that particular site.[73] To apply this formula, it is important to have measured, for your institution and each clinical site, the two different standard deviations. As can be seen from the formula, the systematic errors in the process, such as incorrect contouring or use of a nonrepresentative CT scan for target delineation, are much more important issues than random day-to-day setup errors.

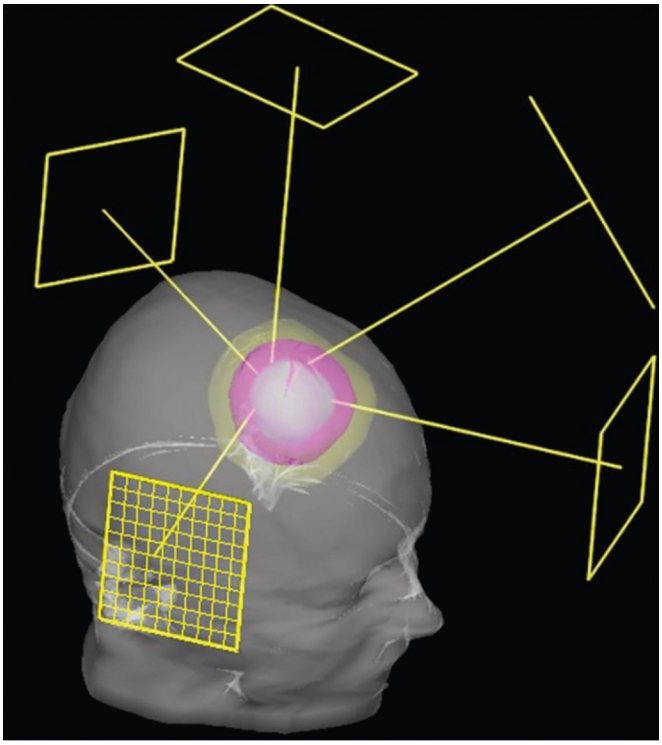

Figure 16-4 Noncoplanar IMRT plan for treating a brain tumor, with the ICRU-50 target volumes shown: gross tumor volume *(white)*, clinical target volume *(pink)*, and planning target volume *(yellow)*.

Further discussion of other types of target volumes, including the internal target volume (ITV), is included later in the section on motion.

For an individual patient, there can be multiple sets of GTVs, CTVs, and PTVs because there are often a CTV and PTV that correspond to each individual GTV. In the head and neck, where often a number of different nodal CTVs need to be treated, it can be important to develop an organized and clear naming convention for the various CTVs and PTVs.

Normal Tissues

Definition of *normal tissues* is also a critical task for conformal therapy because identifying the critical tissues will allow the treatment planner to avoid or at least minimize delivery of dose to those normal tissues. The planning tools used to avoid these structures can be simple graphic tools such as the BEV

display, which allows the planner to shape the radiation fields to avoid important structures, or it may involve detailed dosimetric and DVH analysis, as is often the case for IMRT planning.

To perform DVH or other dosimetric analysis, it is important that each organ to be analyzed be contoured completely because most current DVH data are characterized with respect to the whole organ's volume (either absolute volume or as a percentage of the whole organ). This has several implications:

1. The CT scans or other studies for a given site must image all the relevant normal tissues completely as well as the tumor. For example, a lung tumor CT scan should always include images from the neck down to below the bottom of the diaphragm, so that the complete volume of the relevant normal tissues can be identified (e.g., lung, heart, esophagus, spinal cord, rectum).
2. Contouring of normal structures must be done consistently if the DVH information is to be useful. Whole organs should always be contoured. For tubelike structures (e.g., spinal cord, rectum, esophagus) that can often extend out of the region of the tumor, it is important to have a defined protocol for how the structure will be defined, so that the superior and inferior extents of the contours for the structure are specified (e.g., the rectum during prostate planning). This is particularly important if relative volumes (e.g., <50% receiving >50 Gy) or mean doses of these normal structures will be used for plan construction and evaluation.

Multiple Imaging Modalities: Dataset Registration and Fusion

Although CT scans are the primary imaging modality used for radiotherapy planning, information from other types of imaging, particularly MRI and PET, can be useful for identifying disease or better identifying functional or anatomic areas that should be spared. Target volumes and normal structures can be identified on these additional imaging datasets, and that information can be incorporated into the treatment plan along with the contours and data from the CT scans. As described before, a CT scan set is typically taken to be the geometric basis for the treatment planning because the CT data are of high resolution, are geometrically accurate, describe the electron density information needed for inhomogeneity corrections, and are quickly obtained.

Several issues need to be solved to make quantitative use of the additional imaging information.

- For each imaging procedure, the patient should be positioned within the imaging device using the same position and immobilization and localization devices as for treatment. However, there are often positioning differences that must be taken into account.
- Even if the patient positioning is perfect, the coordinate system used in the new imaging device is usually different than the coordinate system used by the original CT scan. Therefore, a geometric registration of the new imaging information must be performed, to align the new images with the base imaging information. Otherwise, with different coordinates, one does not know how to map pixels in the new image dataset to the coordinates of the original image set.
- For many imaging modalities, for example, MRI, various kinds of distortion are possible. If the new image dataset has geometric distortions, then these must be corrected (or at least accounted for) before the imaging information can be transferred into the base coordinate system for use in planning.
- The resolution, slice thickness, and slice orientations of different imaging modalities can often be different than those of the original CT dataset, so any quantitative use of the new imaging data must also handle these kinds of differences.

To address these issues, the process of dataset (or image) registration is used to align the coordinates for the various imaging datasets so that information can be passed from one image set into a coordinate system to be used for treatment planning. The registration process finds the geometric transform between the new dataset's coordinate system and the base coordinate system (typically, the CT scan). If one considers only rigid body registration, the transform can consist of x, y, and z translations, or both translations and rotations, and it can include scaling as well (although typically, the scale of each dataset is known accurately and should not be modified).

Handling of deformable image registration is an important current research topic. These efforts work to develop methods for mapping deformations from one system to another, so the deformations resulting from imaging or patient motion (e.g., respiration) can be taken into account. Many different mathematical methods have been employed, including thin plate splines, B-splines, demons, and others.[74] However, the main current issue is that deformation is handled well for things that are imaged well, but there is no way to determine how to do the deformation mapping for tissues that are not well imaged. Most current algorithms do not take into account anatomic constraints and sliding organs (e.g., the diaphragm and lungs during respiration). Much work remains here.

To determine the best registration transform, an optimization algorithm is applied to the problem. The optimization process consists of choosing the metric to be optimized (some metric that describes the quality of the registration) and choosing an optimization search algorithm that will perform the search over possible transforms so that the optimal one can be found. The metric can be something as simple as the sum of the squares of the distances between predicted and actual point locations, if it is possible to define point-based landmarks on both imaging studies, or it can be image-based metrics such as the correlation between gray scale values of two CT scans, or mutual information that can be used to register different image studies (e.g., CT and MRI or PET). This is a rapidly developing area of research.

No matter what kind of registration algorithm is used, it is necessary to verify the registration and then to use the data from the various imaging studies. Verification typically consists of image-based or structure-based comparisons between the two datasets, with the goal of confirming that known structures from the two imaging studies accurately line up (Figure 16-5). The quality of the registration depends on what parts of the images are most important clinically and must be reviewed by the planner or physician because at this point, no quantitative measure accurately takes into account all the clinical knowledge of the case. Once the registration is verified, then contours or 3D structure definitions from one dataset can be transferred into the base coordinate system for planning. This combination of data from multiple imaging sources is sometimes called image fusion.

Motion, Setup, and Four-Dimensional Anatomy

So far, there has been little consideration of the fact that real patients breathe, move, are different from day to day, and change over time. Until recently, it was difficult to take such motions and localization differences into account within treatment planning, with the exception of defining appropriate PTV margins for the tumor. Fast helical CT scans, fast MRI, 4D-CT, and 4D-CBCT imaging using the treatment machine

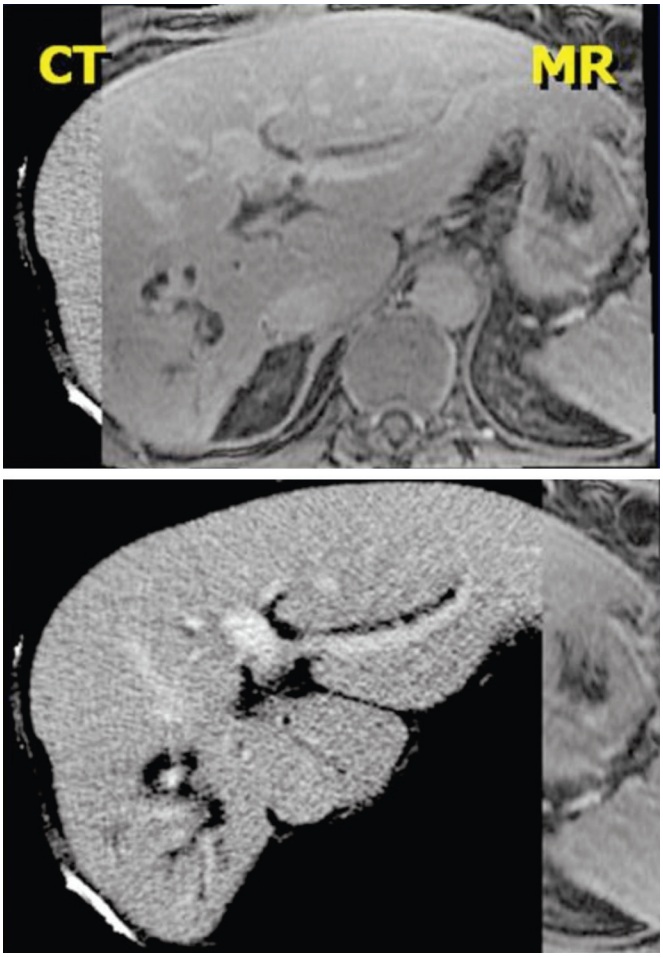

Figure 16-5 Split-screen comparisons of CT *(top)* and MR *(bottom)* image data to confirm the accuracy of the geometric registration of CT and MR scans of the liver.

have begun to provide detailed anatomic data as a function of time. These data have clearly demonstrated that a static anatomic description of the patient is not always appropriate and that treatment delivery schemes must also consider setup and motion effects if we are to achieve the optimal delivery of dose to the patient.

Several methods to handle motion and setup effects are in use or being investigated:

- As described in the section on Target Volume Definition and Margins, the standard way to handle motion and setup error is to determine the appropriate margin and then to expand the CTV by that margin to make a PTV that is the target for planning. If done correctly, the PTV ensures that the high-dose region always encompasses the CTV, even as the CTV moves around because of motion or setup error. The price, however, is that the larger the margin is, the more normal tissue is irradiated. Therefore, if the motion and setup error are taken more directly into account, this margin may be decreased, reducing the amount of normal tissue irradiated.
- One popular intermediate strategy for handling motion issues is to define the target volume extent at both ends of the respiration cycle. By combining those volumes, an *internal target volume (ITV)* is created that shows all the locations the target volume will move to during respiration, so it shows the envelope of volumes to be treated if the main goal is target coverage. As with the PTV margin, this ITV ensures coverage of the target, but increases the amount of normal tissue which is irradiated. Technically the ITV also includes the CTV, but in the era of 4D CT, "ITV" often is used interchangeably with the concept of the motion envelope of the GTV, and additional CTV margins are sometimes then added to the ITV after its creation.
- Stereotactic treatments and treatments using daily setup correction (IGRT) try to significantly reduce the daily setup variations by carefully reproducing the position of the patient each day.
- Using imaging with 4D CT, respiratory-correlated CBCT, and other such 4D methods, it is now possible to visualize the motions of the tumor (and normal tissue) with the CT data, and to create structure outlines that better approximate the clinical targets and structures to be avoided. This technology is currently undergoing rapid developments.
- With use of active breathing control (ABC) or patient-controlled respiratory methods,[75] it is possible to control the breathing of the patient with the goal of turning on the treatment beam only when the patient is in the correct breathing state. This method can help minimize respiration motion and allow smaller PTV margins.
- It is also possible to gate the radiation beam, turning it on only when the target structure is in the correct location, based either on external or internal markers or fiducials.
- Various radiographic and radiofrequency transponder markers are also used to help identify the position of the target. Transponders that identify their position 10 times per second allow real-time tracking of the target[76] and can help to dramatically reduce the PTV margin needed for treatment. This system is currently approved for use in the prostate, but is also being investigated in the lung and other sites.

This is a rapidly changing area with continuing technical progress expected.

Use of Functional Imaging Modalities

Standard CT and MRI techniques provide basically anatomic information, although some simple physiologic information is obtained from MR. However, PET, SPECT, and various fMRI imaging sequences can all lead to much more detailed knowledge of the physiologic and functional state of various tissues or organs. The details of these many different types of studies are well beyond the scope of this chapter. However, several features of any such use are similar: the patient must be positioned as close to the treatment position as possible, the imaging study must be carefully registered geometrically with the rest of the treatment planning imaging information, and the actual meaning of the imaging information should be known. Although many different imaging scans show some response in the image, it takes detailed clinical knowledge and trials to clearly define the clinical meaning of any imaging result, a crucial step before the imaging information is used clinically. The development and study of these functional and physiological imaging markers (imaging biomarkers) is a critical and fast-developing field.

Plan and Beam Definition

After the anatomic model of the patient has been established, the next major step in the planning process is to use the planning system to create a set of beams to be used for planning. This collection of beams, usually known as a "plan," can be created using standard protocols ("treat all prostates with a six field conformal plan") or designed based on the specific anatomy of the case. Basic decisions on beam technique are often made early in the planning process, using experience or

site-specific protocols. Typically, these decisions include picking the energy and number of beams, the basic orientations for the beams, and the type of beam shaping or intensity modulation to be used.

Beam Technique (Energy, Direction, and Type)

The first things to be decided as a treatment plan is generated are the number of beams to be used, their energy (and modality), and their direction. These choices are all interrelated, so typically this decision is based on standard experience or protocols. Although it is hard to summarize all of the useful ways to make this decision, there are a few standard rules that apply to most conformal planning.

- Avoid opposed beams. Simple nonconformal planning often used opposed beams (AP-PA and opposed laterals or obliques) to create a relatively uniform region of high dosage extending through the patient. For conformal planning, one typically wants to avoid pairs of opposed beams because one wants to conform the dose to the target. For IMRT plans, this is even more important because opposed beams can cause degenerate solutions for the optimization search, leading to the optimization bouncing between two fairly equivalent solutions for opposing beamlets.
- Typically, lower energies are used for relatively superficial targets or for beams that traverse less normal tissue on the way to the target, whereas beams that must penetrate a greater volume of tissue are typically of higher energy. Changing energies for individual beams often makes a relatively small difference in the dose distribution achieved, and this possible improvement should be balanced against the additional complexity of the plan if multiple photon energies are used.
- For sites in which one is attempting to make sure the dose in the buildup region is relatively high, lower energies are usually used because there is less skin sparing for these beams.
- The most conformal plans can be achieved by ensuring that there are beams arranged around the target in all three dimensions, so that the plan includes some nonaxial beams.
- There is a great deal of debate (still) over the best energy beams to use for plans that involve large inhomogeneities such as the lung.
- As one creates more complex IMRT plans that have many degrees of freedom available to be optimized, it is possible to achieve highly conformal plans. Typically, these plans include an odd number of fields, although the goal is just to make sure there are no opposing fields. There has been much discussion saying that IMRT plans can all be accomplished with 6 MV photons and that higher energies are not necessary, but there is little hard evidence to demonstrate that such a conclusion is correct. In addition, it is often said that IMRT plans can be achieved with only axial beams, but the use of noncoplanar beam arrangements will still result in at least slightly better plans (typically reducing somewhat the normal tissue dose for the same target conformality).
- Even when using IMRT or conformal arc therapy, beam selection is important because it could limit the degree of normal tissue sparing or target coverage. For example, if beams are placed so they shoot through the kidneys, no matter what cost function is used, kidney dose will be higher than if the beams are aimed outside of the kidneys. For arc therapy, if the arc is limited away from a particularly crucial organ, sparing will be improved.

Shaping with Blocks and Multileaf Collimator

Although beam directions are important, shaping the radiation field to conform to the shape of the target volume is one of the crucial and defining concepts for conformal therapy. The shaping can be accomplished equally well by focused blocks or with an MLC, as illustrated in Figure 16-6. The conformal shaping of focused blocks is in fact "more conformal" than the jagged shape created by an MLC, although the MLC has a number of other advantages that have led to its popularity.

The routine use of conformally shaped fields designed during treatment planning depends in large part on the availability of the BEV display in the planning system because this view of the target shows the projection of the shape of the targets from the point of view of the radiation beam, which is what is needed to design field shaping. The simplest method used to conformally shape the fields (with either blocks or MLC) is to create a uniform geometric margin around the projection of the targets in the BEV and to set the shape to that margin, as shown in Figure 16-7. This method, the basis of the simplest type of conformal therapy, is sometimes called *geometric conformation*, or BEV targeting. Shaping a block to a given contour is easy, but with an MLC it is more complicated. The most commonly used method for an MLC is the so-called equal area method (Figure 16-7).

Using a uniform geometric margin for the field shaping does not lead to the most conformal dose distribution. To truly conform the dose distribution to the target, one must optimize the shaping of each of the beams so that the dose distribution

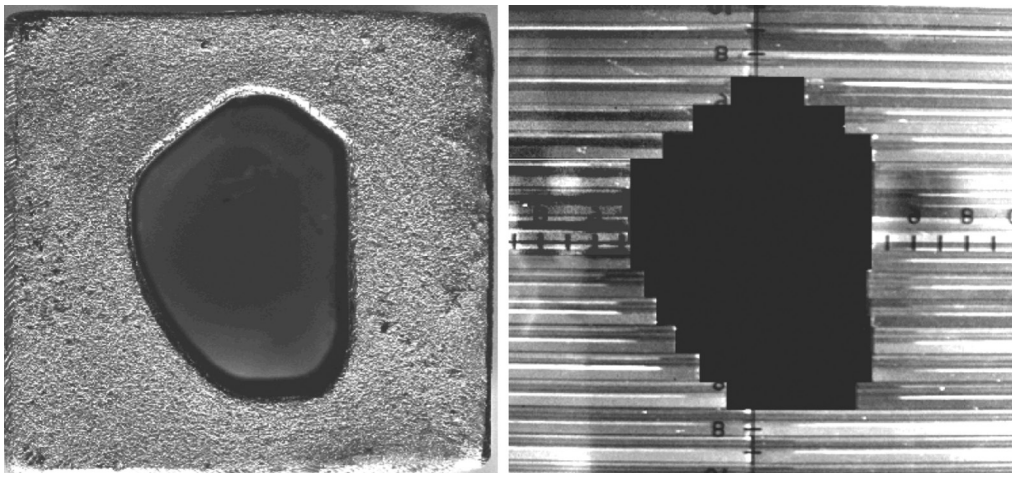

Figure 16-6 Shaped blocks and multileaf collimators can be used to shape the beam conformally.

is conformal. Figure 16-8 demonstrates the types of differences that occur when beam shapes are designed with a uniform margin and when the shapes are optimized to conform the dose to the target. Beam directions, the penumbra, and how the beams cross-fire on the target affect the margins required for individual beam shapes.

Collimator angle is one more thing that can directly affect the conformality of a plan, mainly when an MLC is used. The leaves from an MLC move in only one direction, so to minimize the "stair-step" or jagged edges caused by MLC leaves when shaped to an angled contour, one may use collimator rotation to cause the MLC leaves to best fit the shape of the target or normal tissue. By minimizing the jaggedness of the MLC edges, one can decrease the amount of penumbra in that particular region of the beam, thereby allowing the beam to do a better job making a sharp penumbra between a target and normal tissue. For example, for beams trying to make a sharp dose gradient between the prostate and the rectum, rotating the collimator to parallel the edge of the rectum can help make the edge sharper.

It is possible to create intensity-modulated beams using a limited number of MLC-shaped "segments" all from the same gantry angle. This "segmental" IMRT can be created using the normal interactive planning paradigm ("forward planning")[77] or the limited number of segments can be created by an inverse planning paradigm (see, e.g., "direct aperture optimization").[78] The use of a few segments to improve target homogeneity (e.g., in the treatment of breast cancer with tangential fields) is a logical extension of the concept of wedged tangents when 3D planning is available.

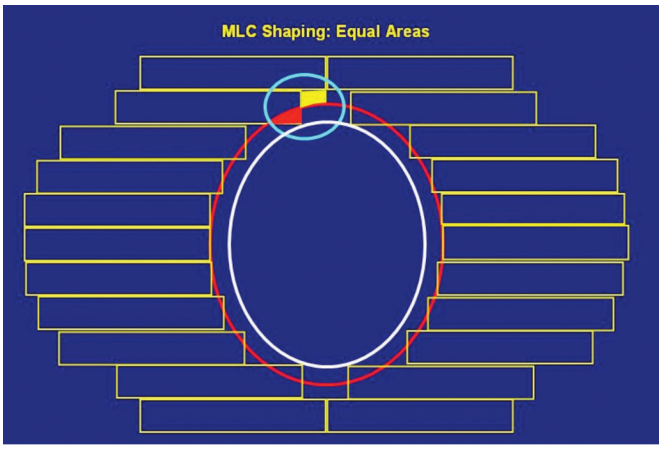

Figure 16-7 When using geometric conformal shaping for an MLC, the most common method is to create a contour at the desired margin *(red contour)* and then push the MLC leaves up to that contour so the areas overlapped and underlapped by each leaf are equal.

Other Beam Technique Decisions

There are numerous other decisions to be made when creating the plan.

- One must choose the intensity of each beam, typically called the *beam weight*. How this decision is made depends on the specific beam normalization methods used within the planning system. Because the beam weight or intensity is directly related to the number of monitor units (MUs) that will be delivered from each beam, it is essential that translation of beam weights into MUs be understood and carefully handled because errors in this step deliver the wrong dose to the entire field.
- For certain beam combinations, use of wedges in the field can help achieve a more uniform dose in the target volume. Standard two-dimensional (2D) planning makes routine use of pairs of fields known as "wedged pairs," where the wedges help compensate for the fields entering the patient at 90 degrees (or some other angle) to each other. For conformal planning in three dimensions, there is a broader range of combinations of fields for which wedges are useful. For example, a 3D cone has some number of fields placed around a cone, and each of the fields usually requires

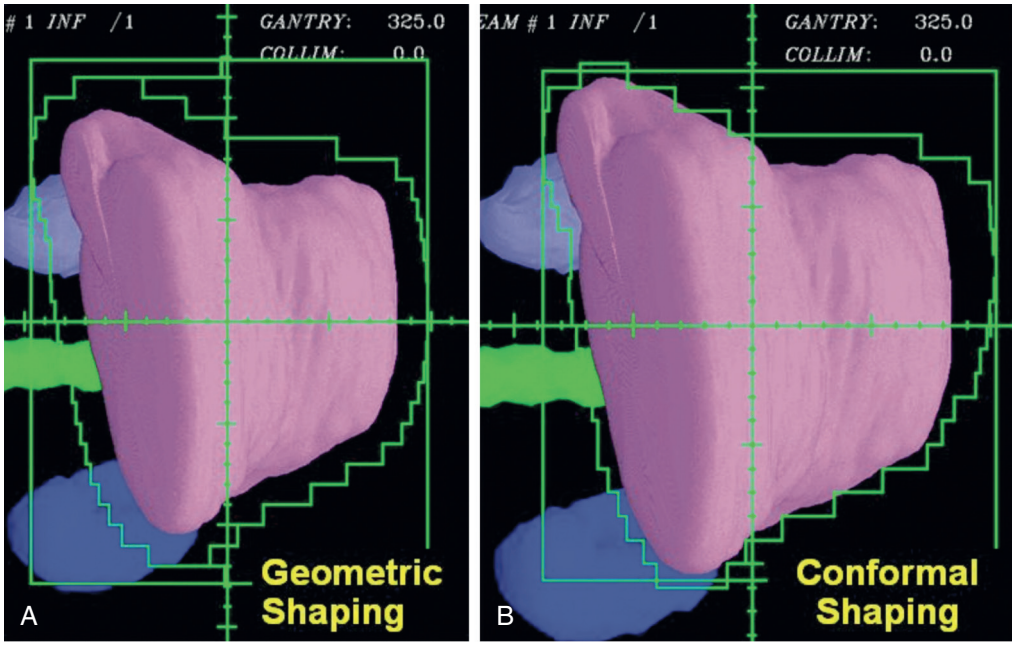

Figure 16-8 Beam's-eye view of conformal fields: uniform geometric margin *(left)* and conformal dose distribution *(right).* Using a uniform geometric margin typically does not achieve a dose distribution that is as conformal as possible. For this three-field pancreas treatment plan, the beam on the right had its shape optimized to make the dose distribution more conformal to the target.

a wedge to keep the target dose uniformity. This beam distribution is the 3D analog of the wedged pair.

- When the target is near the surface of the patient, it is often difficult to achieve the desired dose coverage of the target because of low doses in the entrance region of megavoltage photon beams. In this case, some amount of bolus can be added to the skin of the patient, for one or more beams, so that the photon beams can transit more material, therefore decreasing the skin sparing. This bolus description can be designed using the planning system, as long as care is taken in creating the physical bolus so that it actually matches the description that was put into the planning system.
- Most conformal treatment plans are isocentric, with the isocenter of the machine placed within the center of the target, and the beams rotating around the isocenter in the target. Other arrangements are possible, depending on the geometry of the normal anatomy and targets. For some situations, it is also possible to create pseudo-isocentric beams, which use 3D table motions to move the patient away from the head of the machine along the beam central axis, so that the plan is apparently isocentric but with a larger source-to-isocenter distance than the machine has. This technique can be used to create a larger range of table and gantry angles that can be used for treatment without the machine's head getting too close to the patient.[79]

Intensity Modulated Radiation Therapy

Soon after conformal therapy began to be used clinically in the late 1980s, Brahme,[54] Bortfeld,[55] and others introduced the idea of modulating the intensity across each radiation beam, assisted by computer-based optimization algorithms to help determine the intensities required of the different parts of the beam. This combination of beams with modulated intensities and the use of optimization (inverse planning) is commonly called IMRT, and is now a commonly used method for the creation of highly conformal treatment.

Intensity modulated fields can be achieved in a number of different ways. There is a continuum of situations ranging from a flat field to multiple shaped segments to a beamlet-type description (beamlets refer to dividing the beam cross-section into numerous "beamlets," which each have an independent intensity or fluence). The intensity modulation is created by either a series of SMLC segments or a dynamic DMLC sequence. For plan optimization strategies, there is a similar range from simple (forward) iterative planning to optimized (inverse) planning that is driven completely by a mathematical cost function. Typically, the most complex intensity distribution (IMRT) is generated with inverse planning, but it is also possible to perform optimization for flat field conformal therapy.[80,81]

Beam design for IMRT depends on the type of planning to be used (forward or inverse) and the photon energies and beam arrangement expected. It should consider the tradeoff between the planning goals chosen and the complexity of the plan that will be allowed. If simple multiple segments are planned, then the individual segments may be created by the planner, whereas for more complex IMRT planned with "beamlets," the beamlet size (1×1 cm, 0.5×0.5 cm, etc.) to be used for planning will be chosen by the planner (or by the planning system).

Dose Calculations

Once the initial treatment plan is designed, the next step is typically to perform a dose calculation, so that the planner and physician can evaluate the dose distribution expected from the plan. Currently, because biologic effects are not well documented and understood in general, the physical dose distribution is the main characteristic that is used (1) to choose between plans, (2) to choose what dose to deliver to the patient, and (3) to evaluate the quality of various plans proposed by the planner.

Three-Dimensional Dose Calculations

Treatment planning dose calculations have been performed on one (or more) 2D slices (or contours) of the patient since the 1940s. Often, these calculations were performed by hand, from table or chart look-ups, using a single traced contour of the external shape of the patient on a single axial slice of the patient at the center of the treatment fields. Even if performed on a number of slices, these dose distributions were in principle 2D and did not give a complete description of the dose to be delivered to the patient.

Continuing increases in computer capabilities and improved treatment planning and dose calculation algorithm developments resulted in availability of 3D dose calculations in the 3D planning systems that became available in the late 1980s. Since that time, most planning systems have implemented 3D calculation algorithms that (1) calculate the dose throughout a 3D volume of points, (2) calculate the dose with algorithms that take 3D scatter into account, (3) have algorithms that take the 3D effects of inhomogeneities into account, (4) use a 3D description of the anatomy, (5) fully take into account 3D beam divergence, and so on. Because the calculation of dose with high resolution using an accurate and realistic dose calculation algorithm still takes a significant amount of time, every dose calculation algorithm and implementation makes tradeoff choices between accuracy, speed, computer resources needed, resolution, features, and effects that are correctly modeled, and other factors. Determination of the appropriate mix of approximation, compromise, and robustness needed for particular kinds of clinical planning dose calculations is an important responsibility of the radiation oncology physicist.

To accurately perform planning for conformal therapy, accurate and 3D dose calculations must be performed. An accurate 3D anatomic model is required; the dose must be determined throughout the volume encompassing the targets and the critical normal tissues; and the calculations should be done at high resolution if one wants to know how conformal the plan actually is. This is particularly critical for small organs in which toxicity is driven by max dose, such as the chiasm and optic nerves. It is critical that all limitations in the calculations be understood and the effects of those limitations should be considered in any clinical decisions that are based on the results of the calculations.

Algorithms

Many different types of calculation algorithms have been developed for photon and electron beams, and new improvements or implementations are continually becoming available. It is beyond the scope of this text to describe any algorithms in detail. Algorithms ranging from simple table look-ups based on measured data to Monte Carlo simulations that require many hours of calculation time on fast calculation servers all have their place, and different algorithms can be the appropriate choice for different specific situations. Table 16-2 summarizes some of the advantages and disadvantages of each class of photon algorithm. If there is a choice between different algorithms for use with conformal planning, the choice should be made with careful consideration of the potential limitations of the chosen algorithm. The radiation oncology physicist should carefully commission the algorithm

TABLE 16-2 Advantages and Disadvantages of Each Class of Dose Calculation Algorithms for Photon Therapy

Algorithm Class	Description	Limitations	References
Matrix, data based	Based on measured data; often used for situations with specific field size capabilities (e.g., stereotactic applicator systems, very small field techniques). Very fast.	Only usable for specific measured situations—mainly radiosurgery applicators	82
Analytic beam models	Algebraic formulas model different aspects of the dose distribution. Very useful for fast 2D calculation models; limited in ability to model all the features in 3D dose distributions. Very fast.	Does not accurately model shaped beam scatter, patient contour changes, inhomogeneities	83-85
Scatter integration	The most used class of models from the 1970s until the last few years. Includes the well-known TAR-SAR (tissue-air ratio–scatter-air ratio) integration method developed by Cunningham.[70] 2D integration of scatter around the field handles most field-dependent scatter well but does not handle 3D inhomogeneities. Pencil beam models, often used for IMRT calculations, fall into this class. Fast.	OK for field shaping, 3D CRT, except for inhomogeneities	86,87
3D integration	Convolution/superposition algorithms are the most popular of the 3D integration models. These algorithms calculate, for every point inside the 3D calculation grid, the scatter contribution from each voxel. To be done completely, this involves a seven-dimensional integration over all voxels, all primary dose deposition points, and energies, although many implementations compromise to speed up the calculations. Based on a dose-spread kernel typically calculated once by Monte Carlo and then used for all calculations.	In principle, should get most photon-related effects correct, though inhomogeneities can still be a problem if energy spectrum and other issues are compromised	88,89
Monte Carlo	This method tracks dose deposition for millions of particle histories, using the basic physics interactions to determine what happens in each history. This algorithm has the best potential for accurate results but is costly in terms of calculation time and needs accurate simulation of the behavior and scattering, which occurs in the head of the machine. Slower, but easily parallelizable.	Most reliable if it includes good simulations of particle behavior in head of machine	90,91

for clinical use by comparison with appropriately measured data for the local machines to demonstrate the adequacy and limitations of the algorithm for clinical use.[92]

Other Dose Calculation Issues: Grids, Resolution, Inhomogeneities, and Other Issues

Aside from the inherent capabilities and limitations of the dose calculation algorithm that is used, many other user-controlled factors, as well as implementation decisions by the algorithm developer, affect the final accuracy of the doses predicted by the calculations that are performed for a plan. Unfortunately, it is not possible to address all these issues with a few simple guidelines.

Every step of the treatment planning, dose calculation, and plan evaluation process involves decisions about how much time, effort, and precision to spend defining or reviewing each aspect of the planning, and the accuracy of the final product depends on all those individual decisions. If one chooses to calculate the dose on a dose calculation grid with spacing $0.5 \times 0.5 \times 0.5$ cm, it will clearly be difficult to evaluate the dose 2 mm from the target with a significant degree of confidence, given that dose gradients at the edge of a beam can be approximately 10% per millimeter. Highly conformal therapy will require that dose calculations be performed with high-resolution grids (perhaps 2 to 3 mm), leading to large numbers of points that need to be calculated, thus leading to longer calculation times and computer resource requirements. Similarly, if truly conformal therapy is going to be performed in lung tumors, where inhomogeneities are significant, an advanced calculation algorithm that can accurately predict the dose in inhomogeneities should be used if one wants to understand the real dosimetric situation in the patient. For IMRT plans, there are further dose calculation-related issues (discussed later).

Plan Evaluation Tools

After the dose distribution from the plan has been calculated, the next step in the process is to evaluate the plan and the predicted dose distribution. Typically, the dose distribution is evaluated by looking at isodose curves on individual CT (or MR) slices through the plan, looking at isodose surfaces (3D displays of the isodose information), as well as using DVH analysis of the dose delivered to individual organs. If the capability and appropriate data are available, it is also possible to use biologic modeling results such as NTCP, tumor control probability (TCP), and EUD to help with the plan evaluation. If simultaneous integrated boosts are being used, or treatment is hypofractionated, it is important to keep in mind that biologic corrections must be performed to ensure safe doses to critical structures. For example, 50 Gy in 2 Gy fractions may be acceptable for the spinal cord, but 50 Gy in 2.5 Gy fractions may not be.

Dose Display

The most commonly used type of display of the dose distribution for a plan consists of displaying contour lines of constant dose, or "isodose lines," on top of the anatomic information that was used for the plan. These kinds of displays have been used for many years—first with only the contours of the patient (obtained by hand measurement using solder wire or other techniques) and then later displaying the isodose lines on top of the CT scan. For conformal planning, not only axial

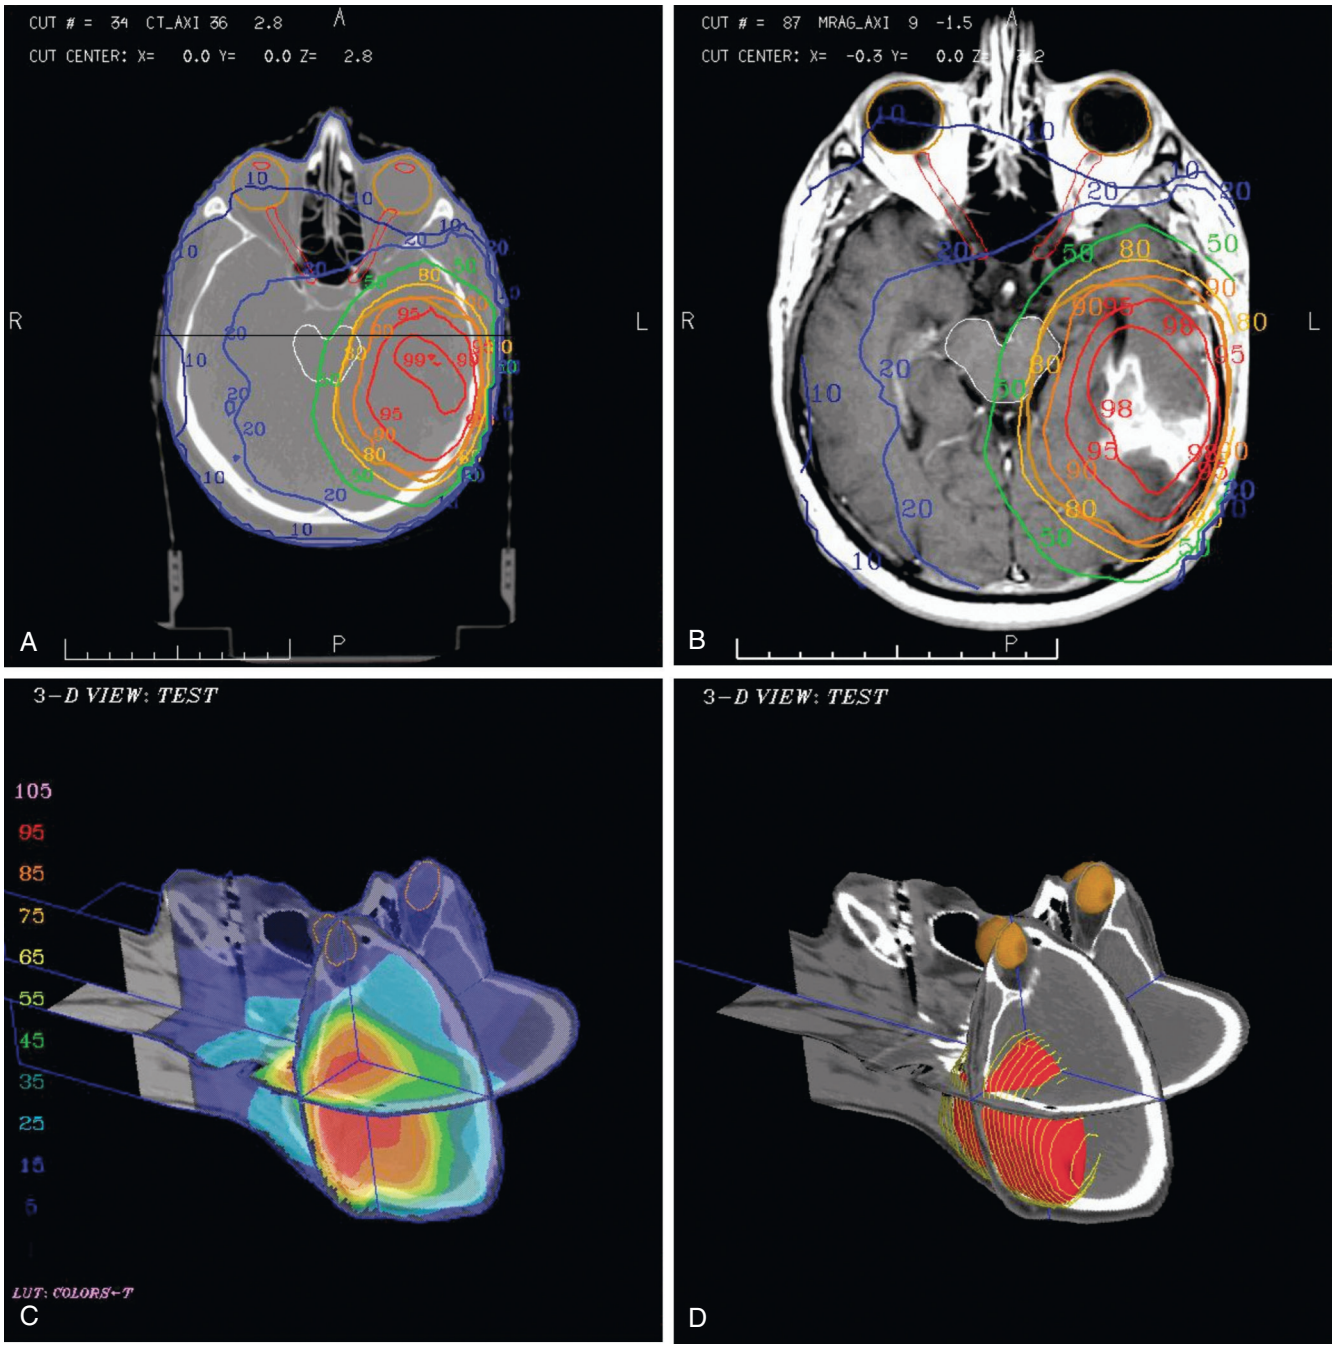

Figure 16-9 Dose display for a conformal brain plan. **A,** Axial CT with isodose lines. **B,** Axial MRI with isodose lines. **C,** Three-dimensional axonometric view with dose colorwash. **D,** Target volume *(red contour)* and isodose surface *(yellow contour)*.

cuts should be used for the isodose lines but also coronal and sagittal CT images because display of isodose lines on multiple orthogonal cuts can give the planner a more 3D sense of the coverage of the target volume. 3D graphics techniques can be used to put the images and dose lines in 3D perspective, as shown in Figure 16-9. A variation of the isodose line display is the colorwash display, in which the dose level calculated for each pixel of the image is used to assign a color value (see Figure 16-9, C).

Any image that is part of the anatomic model of the patient should, in principle, be usable for dose calculation and dose display (though this is not always permitted by some TPS systems). If MRI, PET, or other image datasets have been registered with the basic anatomy, then the PET or MR images can also be the backdrops for the dose display. By comparing the location of the isodose lines with the contours of the targets and critical normal tissues, the planner and physician can evaluate the quality of the dose distribution that is obtained for this particular beam arrangement and decide whether the plan is adequate or whether further modification of the plan is necessary.

The goal of conformal therapy is typically to conform the shape of the high-dose region to the target in three dimensions, so display of the 3D dose distribution shape may be a help when evaluating the conformality of the plan. The 3D analog of an isodose line, called an *isodose surface* or sometimes

a "dose cloud," is typically displayed in a 3D perspective graphic image (see Figure 16-9, *D*).

The dose displayed in isodose curves or surfaces, or any other dose display, can be shown in a number of ways. The most common mode used for conformal therapy is the relative dose distribution, where all the dose display is normalized to the dose value at the isocenter or center of the target. With this kind of relative dose normalization, typical conformal therapy plans would have the 95% isodose surface surrounding the target, with the shape of the 95% surface (or isodose lines) conforming to the target. One could, however, equally well display the dose in absolute terms so that the high-dose region demonstrated the desired total dose for the plan (e.g., 60 Gy) or the desired dose per fraction (e.g., 2 Gy/fraction). It is of course essential that the output of the plan that is used for treatment preparation should be carefully understood and documented, so that there is no confusion between the different ways the dose can be displayed.

Dose-Volume Histograms

Review and evaluation of the dose throughout the patient in three dimensions can be a complex and time-consuming process, and it is also difficult to give specific guidelines for normal tissue or tumor responses with respect to that complex data. It has become standard to evaluate the dose received by the target volumes and normal tissues using DVHs. To form a DVH for any 3D object, one looks at the dose value for each voxel in the object and forms a histogram, counting the number of voxels that receive each different dose level. Because the volume of each voxel is known, the volume of the organ receiving each dose level is known. See the review by Kessler[93] for more detail.

Both the volume (vertical) and dose (horizontal) axes can be displayed in absolute terms (as cubic centimeters [cc] or Gray [Gy]) or in relative terms (% volume or % dose), depending on how the planner wants to analyze the results. DVHs are displayed in three different forms: direct, cumulative, and differential.

- The direct histogram is the generic form of any histogram, displaying the volume of the organ that receives dose within each dose bin (1% or 0.5 to 1 Gy is a typical dose bin width). The direct DVH is most useful for display of the dose-to-target volumes, because one can easily visualize the minimum dose, the maximum dose, and the dose most representative of the dose to the entire target volume (Figure 16-10, *B*).
- The DVH display most commonly used in radiotherapy is the cumulative DVH, a plot that shows the volume receiving at least a given dose value. The cumulative DVH is an integration of the direct histogram, so it always begins at 100% (100% of the organ receives at least 0 dose), and ends at the maximum dose (see Figure 16-10, *A*). Figure 16-10, *A* illustrates a desirable cumulative DVH for a target (PTV, which has a uniform target dose with no underdosing or overdosing of the target). Figure 16-10, *A* also shows two normal tissue DVHs: normal brain, which has some volume of the organ receiving a high dose, and chiasm, with a smaller volume of organ receiving high dose, even though the mean dose of the two DVHs is about the same. Whether a normal tissue DVH shaped like the example normal brain DVH is better than one shaped like the example chiasm DVH is only known once reliable clinical data are obtained for the two situations.
- The third type of DVH used for radiotherapy analysis is the differential DVH. This type is necessary to appropriately compare DVHs formed with different dose bin sizes because the volume contained in any dose bin changes as the dose bin size changes. The differential DVH plots $(1/D_{bin}) * DV/DD$, so different differential DVHs can be compared even if their dose bin sizes are different.

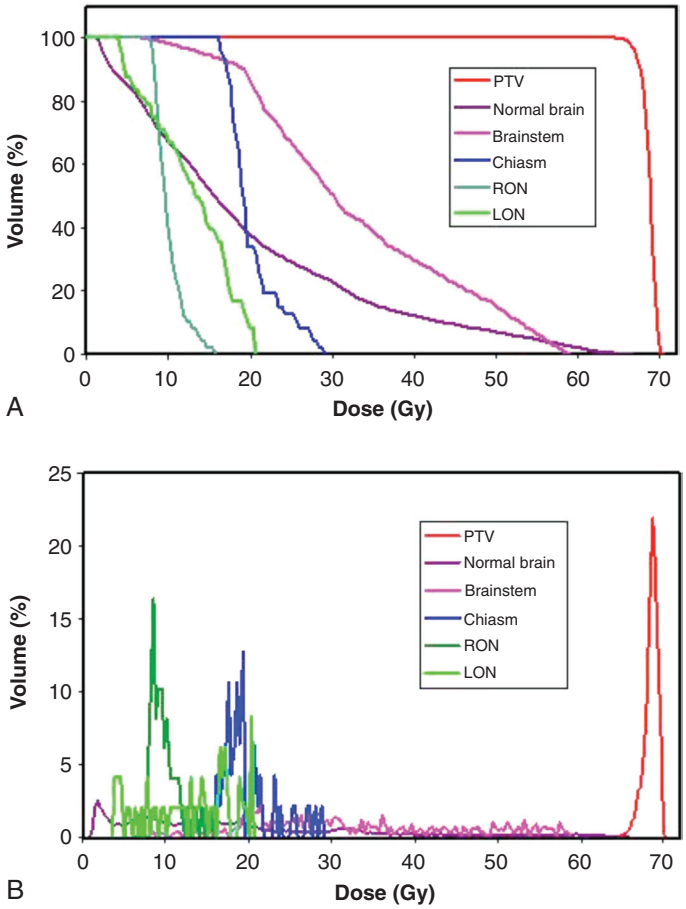

Figure 16-10 DVH displays for a brain treatment plan. **A,** Cumulative DVHs. **B,** Direct DVHs. *LON,* Left optic nerve; *RON,* Right optic nerve.

DVH analysis is an important part of conformal therapy planning, but DVHs of target and normal structures do not tell the entire story. The DVH of an organ summarizes the dose to that organ, but it does not give any information about the geometric distribution of the different doses within the organ. If the DVH for a PTV shows cold and hot spots, it is not possible to tell if either the hot spots or the cold spots are in the center of the PTV or along the edges. Whenever the location of some dosimetric feature may make a difference, it is important to review the dose distribution using dose display tools.

Minimum, Maximum, and Other Quantitative Metrics

DVHs are only one kind of dosimetric analysis that can be used for conformal planning, and many other kinds of analysis are possible. For example, simple dosimetric metrics are often used to help make planning decisions. The maximum dose allowed within a target volume, or inside critical organs, is often specified in conformal therapy protocols. Particularly for IMRT conformal plans, the maximum dose may be a fairly difficult metric to use clinically because it may depend strongly on the dose calculation grid spacing used and on details of the dose calculation algorithm implementation. A volume-based maximum dose criterion (e.g., the maximum dose to 1 cc of

the object) is typically less sensitive to algorithmic details. Similarly, the minimum dose to the PTV is subject to the same algorithm-related limitations and may be of limited value, particularly for IMRT planning. Another common dose metric is the mean dose to a structure, often used to describe target doses and for certain volume-effect organs such as the lung and liver, where the NTCP generally scales with the mean dose to the normal tissue.[94]

Use of Equivalent Uniform Dose and "Biologic Models"

To this point, all the treatment plan analysis has been based directly on the dose distribution. In reality, of course, it is the biologic effects that are important, especially the probability of controlling the tumor and of causing acute or late complications in normal tissues. Analyzing the dose distribution is in many ways a surrogate for the analysis that is really needed, the biologic effect analysis. It is expected that there will be major and continuing improvements in biologic effect knowledge and modeling over the coming years, and as these improvements happen, they should be integrated into use for treatment planning. At the moment, however, the only biologically related parameters that are commonly used in treatment planning are the NTCP, the TCP, and the EUD. This section discusses each briefly.

The most commonly used "biologically related" parameter used in treatment planning is the NTCP. The term *NTCP* actually has several meanings: (1) The NTCP is a probability that can be determined clinically for an organ; (2) there are NTCP models that attempt to model how the probability of a particular complication changes as a function of dose, volume of the organ irradiated, and potentially other factors; and (3) the NTCP is used as the value of the complication probability that has been determined by an NTCP model for a particular situation. It is important to make sure that it is clear how to differentiate between the real clinical NTCP, an NTCP model, or the particular expected value of the NTCP for a situation.

There are many kinds of models that have been developed for the NTCP, and these models have been applied to specific complications for many different organs. Discussion of these different models is beyond the scope of this work, so here we briefly describe only the most well-known model, the Lyman NTCP model. John Lyman developed the three-parameter "Lyman" model early in the 1980s.[95,96] This power law model is a phenomenological model that characterizes complications using three parameters: the TD_{50} for uniform irradiation, the slope of the dose sensitivity (n), and the volume parameter (m):

$$NTCP = (1/(2\pi)^{1/2}) \times \int_{-\infty}^{t} \exp(t^2/2)dt \qquad \text{(Eq. 1)}$$

where

$$t = [D - TD_{50}(\upsilon)]/[m \times TD_{50}(\upsilon)] \qquad \text{(Eq. 2)}$$

$$\upsilon = V/V_{ref} \qquad \text{(Eq. 3)}$$

$$TD_{50}(\upsilon) = TD_{50}(1) \times \upsilon^{-n} \qquad \text{(Eq. 4)}$$

To use this model for a real clinical DVH, one typically uses the Kutcher-Burman DVH reduction method[97] to convert the clinical DVH curve into a DVH with a single dose and volume, which are then used inside Equation 1. Together, these techniques are called the LKB (Lyman-Kutcher-Burman) model.

When developing this model, Lyman made no claim that it was a real biologic model; he simply developed the simplest model that agreed with some of the most basic behavior of NTCPs, at least as characterized at that time. The model has been used extensively, either as a way to characterize complication data or for plan evaluation and comparison. An important starting point for study of NTCPs of various organs was published by Emami,[98] who summarized a tabulation of then-current knowledge of clinical complication expectations (based on a physician working group) using Lyman NTCP model parameters. Recently, the Quantec Project evaluated complication data and parameterizations for many clinical sites, performing a review of the published data using site-specific groups of experts with the goal of providing updated complication modeling information.[99] The Lyman model has proven to be a useful way to parameterize clinical NTCP data and has been used as part of dose escalation studies based on treating patients with a specific isocomplication level (for liver[100] and lung[101]).

One of the most important things that can be done to improve conformal therapy planning is to perform clinical studies that (1) document, for each normal organ, the distribution of doses and volumes of various organs that are irradiated, (2) include careful patient follow-up, and (3) are analyzed to find the dose-volume-complication relationship for each organ. The dose-volume-complication relationship for each organ (and each complication) is unique and must be determined clinically. Once these results are known for all normal tissues, we will know better how to optimize treatment plans.

Just as the dose-volume-effect relationship is important to know for normal tissues, it is also important to know for the tumor. The tumor control probability (TCP) is the subject of clinical studies and modeling and is a way of comparing expected tumor responses with planned dose distributions. A number of different models exist, including the Niemierko-Goitein[102] and Nahum[103] TCP models. Most of these models use various basic assumptions about tumor cell density and distribution, the statistical interactions between dose and tumor cell survival, the incorporation of population-based statistics for tumor heterogeneity, and may also consider effects that depend on tumor stage, hypoxia, and other issues. Tumor cell biology and predicting local tumor control are complicated subjects that are well beyond the abilities of current models. TCP modeling is used in a reasonably limited way because it is known that the predictions are of limited accuracy.

The EUD is often regarded (at least partially) as a biologically related parameter that is often used for treatment plan evaluation and optimization. The EUD was originally described by Niemierko[104] by using a biologically and statistically influenced method to derive a dose parameter that was related to the effects one would expect on the tumor. The EUD has been generalized further[105,106] to be useful for normal tissues and targets. Because the EUD is in principle a generalized mean of the dose distribution according to a specific weighting method, one may use the parameters to represent the sensitivity of the tumor to underdosing in a small region or the effect of hot spots in the tumor. Because the concept of the EUD is relatively new, numerous publications and analyses continue to explore and expand the characterization of tumor and normal tissue responses using various EUD representations.

FORWARD PLANNING

Since computerized treatment planning began (in the late 1950s) until the last decade, nearly all planning has made use of the basic paradigm that is currently called "forward" planning, using the following process:

1. Define the anatomy. Use contours on multiple axial cuts through the patient (e.g., CT scans or manual contours) to define the external surface, targets, and important normal structures. Also include PTV margins.

2. Create the plan. Create a beam arrangement, choosing beam energies, locations, directions and shapes, weights, and addition modifiers if necessary (e.g., wedges, compensators).
3. Calculate the dose. Calculate the dose distribution that results from that beam arrangement, on 2D slices or through the full 3D volume.
4. Evaluate. Evaluate the dose distribution, usually by looking at isodose line displays relative to the anatomy and (in recent years) by calculating DVHs for the normal tissues and targets.
5. Optimize the plan iteratively. If the plan is not adequate, or if the planner wishes to try to improve the plan, then the planner will iteratively modify the plan technique in an attempt to improve the plan result. Each iteration involves modifying the plan, performing a new dose calculation, and reevaluating the plan. Consultation with the treating physician is helpful for input on which clinical tradeoffs to accept.
6. Complete the plan. Once the plan is judged acceptable (or complete) by the planner and physician, the iterative optimization stops, and the plan is prepared for use. This involves calculation of MU for treatment, calculation of digital reconstructed radiographs (DRRs) to be used for patient localization, and transfer of the plan to the treatment delivery system.

Iterative forward planning is driven by the treatment planner and usually relies a great deal on the visual dosimetric evaluation performed by the planner or physician.

Setting Planning Goals

Creation of a high-quality conformal plan using forward planning depends crucially on the planning goals set by the physician. A typical set of conformal therapy planning goals may include the following:

- Usually, the plan is normalized to the dose at the isocenter of the plan.
- The plan will typically make the 95% isodose line (for example) conform to the PTV (target volume) shape, so the minimum dose to the PTV will be 95% of the plan normalization point dose. For IMRT plans, sometimes the coverage goals can be more restrictive (e.g., 99% of the PTV receiving 99% of the plan normalization point dose, but this should be done carefully because it also can escalate hot spots as minimum coverage is escalated).
- The dose uniformity inside the PTV should be specified (e.g., ±5%), which will determine the maximum dose allowed in the PTV (in this example, 105%).
- Keep the maximum dose to the spinal cord less than some limit (typically, 45 to 50 Gy).
- Minimize the dose to all normal tissues.
- Prescribe the target dose—either prescribe the dose to the plan normalization point and accept ±5% uniformity throughout the target, or prescribe the minimum dose to the target volume, and accept that the dose in the target may be as much as 10% (for example) higher.
- If normal tissue responses are known, specify reasonable normal tissue limits for the planner. For example, one can specify that the mean dose to the normal lung stay below some given value because it is known that mean dose can be used to predict the chances that pneumonitis will develop.

The physician should also specify any other constraints or evaluation expectations that will be used for final plan evaluation. One of the primary causes of additional planning iterations and frustrated planners is a physician who chooses to use some plan evaluation criterion or rule that was not described to the planner as a goal or expectation.

Beam Arrangements

Beam arrangements useful for conformal therapy planning are site specific and depend on the geometry of the target volumes and normal tissues. Virtually all conformal plans have at least three beam directions, and seven, nine, or many more beam directions are sometimes used (e.g., conformal stereotactic radiosurgery). Plans with more than seven beam directions are relatively uncommon when forward conformal planning is used, simply the result of the complexity involved in designing and determining the correct beam orientations, shapes, and weights interactively when there are so many different beams to consider. Nonopposing beam directions are useful, as are beams that separate the target from the most critical normal tissues (increasing the distance between the target and normal tissues when viewed in BEV display). It is useful to have beams not in the axial plane because they can help improve the conformality of the plan in all three dimensions.

Iterative Planning

Shaping beams is an important part of the iterative planning process. Typically, a BEV margin of 6 to 7 mm is a good starting point for conformal beam shaping, but the shape of each field will then need to be modified to improve the conformality of the calculated dose distribution, as discussed previously. This is the part of the iterative forward planning process that is most time-consuming, potentially, because in principle one needs to optimize the location of each leaf of the MLC for each beam, and there 50 to 100 involved MLC leaves in each field. The changes in shape that are needed are somewhat predictable, though, because larger MLC margins are needed in regions where there are no other beams (e.g., the superior and inferior aspects of the PTV for a plan with axial-only fields), whereas the margins can be much smaller if there are other beams that are transiting from an orthogonal direction. In the end, however, many iterations of the shapes may be necessary to get reasonably close to the optimal shaping. This is the part of forward planning that is often time-limited by clinical needs, and it could potentially be significantly improved by the application of computerized optimization methods to perform this shaping automatically.[81] Beam weights, use of wedges, and collimator angle rotation followed by revised beam shaping can also be part of the iterative planning process.

Plan Evaluation for Forward Planning

Evaluations of plans resulting from forward planning are typically based on isodose line display and DVH plots for target (PTV) and normal tissues. The physician evaluates the plan using these tools and decides if the plan is adequate for clinical use, as well as whether the plan has the potential to be improved through plan technique changes, or by the physician modifying the dosimetric planning goals that were specified initially for the planning. In forward planning, most clinical tradeoff decisions are made in a qualitative way by inspection of the displayed dose distribution and the DVHs.

INVERSE PLANNING

Rather than trying plans and seeing what kind of dose distribution can be achieved, as in forward planning, the basic concept of inverse planning is to decide up front what the dose distribution should look like and to then "invert" the problem to solve for the beams (and beam intensities) that will give the desired doses. This inverse problem, which is the inverse of the CT back-projection process, would be wonderful except

for two small problems: (1) Because there are no negative radiation intensities, it is not possible to invert the problem, and (2) planners probably do not know what the best "achievable" dose distribution would be to use as a goal. Planners do know that the goal of full dose to the target and zero dose to the normal tissues is not possible.

To get around these problems, inverse planning makes use of computerized optimization techniques to search for the best plan among all possible candidate plans, using an objective or cost function to drive the optimization toward the plan that is "optimal." This kind of inverse planning or plan optimization process could in principle be performed for any kind of radiotherapy plan. In practice, however, the plan needs to have many adjustable (optimizable) parameters so there is enough flexibility in the plan to allow the optimization search to find a good solution to the planning problem. This is the reason that up to this point, most inverse planning and optimization efforts have been applied to IMRT plans created with many separate beamlets or intensity "bixels" per beam because there are a large number of degrees of freedom in the plan that make it possible for the optimization process to work effectively.

A typical inverse planning process can be summarized as follows:

1. Define the anatomy. The planner and physician must define (contour) all the target and normal tissue structures of interest. Whereas in forward planning one is not "forced" to delineate all important structures, in inverse planning one must define all anatomic objects that are to be considered by the optimization to prevent unplanned dose from being deposited in unintended regions. One must also define how calculation points are to be distributed throughout the involved objects.
2. Create the plan. Define the beam energies and directions, determine the largest extent of the beam shape, and divide the beams into beamlets.
3. Calculate the dose per beamlet. For each relevant dose point, calculate the dose per unit fluence from each beamlet. This "D_{ij}," or "influence," matrix tells how much dose each point receives as the intensity in an individual beamlet is changed by the optimization search algorithm.
4. Prepare the optimization algorithm parameters. One must define the cost function (and possibly the optimization search algorithm if more than one is available) to be used for the inverse plan. The cost (or objective) function definition is crucial because it will be used to direct the optimization search and to drive the solution toward the desired dose distribution. The cost function is defined individually, at least for each planning protocol, and perhaps for each patient, and is likely to be the most crucial decision involved in determining what kind of plan will result from the optimization process.
5. Iterative plan optimization. Inverse planning uses the optimization search algorithm, driven by the evaluation of the chosen cost function, to perform iterative plan optimization, with the search algorithm determining how the plans are modified, and the cost function serving as the judge of plan quality. In most current inverse planning, only the beamlet intensities are varied, so to recalculate the change in the plan dose distribution and cost function, one only needs to resum the dose contributions from the changed beamlets, a calculation that can be performed quickly. The optimization search will continue until predefined stopping criteria are achieved.
6. Plan evaluation and reoptimization. Once the optimization process is complete, the physician and planner must evaluate the plan, dose distribution, cost function results and metrics, and any other relevant information, to decide if the plan is acceptable. If it is not, then the plan optimization process must be rerun; however, it is necessary to make changes in the cost function to drive the plan toward a different result, because running the optimization again using the same cost function should result in approximately the same plan result as the first time.
7. Plan completion. Once the plan is judged acceptable (or complete) by the planner and physician, the plan is prepared for use. For a beamlet-optimized IMRT plan, this completion step includes leaf sequencing, which is the preparation of the MLC leaf trajectories (DMLC delivery) or MLC segment shapes (SMLC delivery) that will create the desired beamlet distribution. Leaf sequencing issues are described in more detail later. Other preparation steps include calculation of MU for treatment (usually included in leaf sequencing for IMRT), calculation of DRRs to be used for patient localization, and transfer of the plan to the treatment delivery system.

Comparison of this process for inverse planning with the previously described forward planning process (see Forward Planning) shows that only a couple of steps are really different; most of the planning process is approximately the same. However, for inverse planning, most interactions aimed at improving the plan must be made by modifying the cost function used for the optimization, a much more indirect type of control on the plan parameters than one has when modifying a beam shape while doing forward planning.

Goals for Inverse Planning

As with forward planning, it is critical for the physician and planner to decide the overall goals for the inverse plan and to prioritize the various clinical issues. Goals for inverse planned IMRT may include the following:

- The dose to the target volumes should be specified: typically, this is the minimum dose, the mean dose, or the dose to a specific point inside the targets.
- Often, the dose distribution is defined in absolute terms (i.e., a plan will specify either the total dose [for the course of treatment, e.g., 60 Gy] or the dose/fraction [e.g., 2 Gy/fraction]). Relative dose can also be used, but given the use of IMRT, the dose to any defined reference point can be variable, so the relative dose mode of treatment planning is somewhat less useful than it is for flat field conformal therapy. In addition, if one wants to use a biological model or other such evaluation or analysis tools, then the absolute dose mode of planning is much more useful than the relative dose mode.
- The dose uniformity inside the PTVs should be specified (e.g., ±5%). Many current inverse planning systems may have a hard time achieving the ±5% uniformity in the target volume that is commonly used for conformal treatments, but this is not caused by using IMRT per se but rather by the kinds of cost functions used within those planning systems.[107]
- Keep the absolute maximum dose to the spinal cord to less than 50 Gy. Note that for many (but not all; see previous discussion) cost functions, there are tails on the DVH of many structures that may allow higher doses to a small volume of the organ.
- Minimize the dose to all normal tissues.
- If normal tissue responses are known, specify reasonable normal tissue limits for the planner. For example, one can specify that the mean dose to the normal lung stay below some specified value because it is known that mean dose can be used to predict pneumonitis.

The physician should also define and specify any other constraints or evaluation expectations that will be used for the

cost function because there is no other way to specify to the optimization method what it should do or should not do.

Beam Arrangements for Inverse Planned Intensity-Modulated Radiation Therapy

The rules usually applied to beam arrangements for forward planned conformal therapy also apply to inverse planned IMRT beams in general. The beam arrangements that are most useful still depend on the site to be treated and on the geometry of the target volumes and normal tissues. Virtually all IMRT plans have at least three different beams, and many beam directions are sometimes used. Another type of IMRT called volumetric modulated arc therapy (VMAT, discussed later) uses rotational beams. In much of the early IMRT literature, it was common to find plans with seven or nine axial beams, with beam directions evenly distributed about the patient. This number of beams allowed enough flexibility for the optimization to achieve an adequate plan, even if the beam directions were not tuned with respect to the anatomy. However, as IMRT planning has progressed, the use of nonaxial and geometrically optimized beam directions has become more popular. Even with a strict cost function, the best way to minimize dose in a normal tissue is not to place beams that enter through this structure. Contrary to some early IMRT literature, it is still useful to use beams from outside the axial plane because they help to improve conformality. However, with IMRT, it is often only obvious that the nonaxial beams are useful when considering low-priority normal tissues because the IMRT optimization can typically achieve all of the higher-priority goals without use of nonaxial beams. One feature of most IMRT plans still remains the same: typically, one avoids the use of opposed beams because opposing beams tend to lead to degenerate solutions that can cause difficulties for some optimization search algorithms, preventing them from reaching the optimal solution.

Optimization Method

The most important issue affecting the quality of the final IMRT plan is typically the type of cost function used and, in particular, how the different parts of the cost function are defined for each relevant organ or other anatomic object. In some systems, there is limited flexibility in the type of cost function available because the cost function is limited to a simple method (often, a quadratic function of dose) to allow the gradient descent-based optimization search method to easily calculate the derivative of the cost function for each variable. However, other cost function methods can be quite general, allowing the use of dose, dose-volume, biologic model, or other types of costlets that can be combined into an overall cost function.[61] In any event, it is the relationship of the different costlets (individual pieces of the cost function) that determines how important the various parts of the plan evaluation are, so by changing one or more parameters in a costlet or costlets, one can drive the solution of the plan toward a different type of solution. Learning how to modify the cost function to modify the kind of solution achieved for the plan is one of the most important aspects of inverse planning and may take a significant amount of effort to master.

Regardless of the type of inverse planning system or cost function used for inverse planning, one of the easiest ways to choose the appropriate cost function parameters for the plan is to first make sure that the clinical goals for the plan have been prioritized. Then, one constructs the cost function using the highest weights (or power or importance) for the high-priority issues and decreasing weights for the lower-priority issues. How this works in detail is specific for each type of inverse planning system, search method, and clinical site, but the general concept holds true for most inverse planning methods.

A number of different types of search algorithms are used for IMRT optimization, and these different methods can have specific characteristics that are useful to know. Many current inverse planning systems, however, make use of only one search method, so many planners will not be able to choose different methods for specific patients or plans. Many inverse planning systems use gradient descent-based search methods because they are fast, but this forces their cost functions to be limited to easily differentiable functions, typically quadratic dose penalties that take the form $w_i(D - D_i)$,[2] where w_i is the weight of the penalty and D_i is the dosimetric goal for the i^{th} object. This type of cost function tends to lead to tails on the DVHs because a small volume of the object can go higher than the desired dose without causing too much of a penalty. Another common concern about gradient-descent algorithms is the possibility of local minima in the cost function. For simple cost functions this is not a problem, but use of many costlets or complex functions can potentially lead to local minima that may trap the optimization search at a solution that is not the "global" minimum (the optimal solution). To avoid the possibility of being trapped in such local minima, stochastic search algorithms such as simulated annealing[52] and others can be used. These algorithms can perform a global search that is more certain to achieve the global minimum of the cost function, but they often are quite slow and can also be sensitive to the search parameters used (as in fact are all of the search algorithms).

Plan Evaluation for Inverse Planning

If we knew exactly how to define the cost function so that it correctly summarized all of the physician's goals and desires for the treatment plan, then if the optimization method worked correctly and achieved the global minimum, we would know that the best plan had been found, and that would complete the plan evaluation. However, this is not the case at the current time. Most clinical inverse planning is still limited by many things; therefore, many IMRT plans still involve some "forward" iterative plan optimization. Often when an inverse plan is performed and the plan is evaluated by the physician or planner, the cost function is modified, and then the plan is reoptimized as the planner or physician attempts to push the plan toward some goal that he or she believes is a better clinical result than what the inverse plan gave on the first attempt. As cost functions and search methods become more sophisticated, we can expect that this iterative forward planning use of inverse planning technology will become less necessary.

This problem demonstrates that there are some important issues for plan evaluation. The biggest problem to resolve is that the cost function determines what the search method will choose as the optimal plan, but the physician evaluation of the plan may not be consistent with what the cost function is telling the optimization to do. Whenever this happens, the physician will find the "optimized" plan to be less beneficial than desired and will often attempt to make modifications in the cost function and then reoptimize the plan, perhaps many times, to achieve what was desired. A second complication is the fact that the metrics that physicians use to evaluate plans are often not the same kinds of metrics used by the cost functions, causing another mismatch between physician and cost function. Methods that use clinically relevant metrics as part of the cost function may help decrease this problem somewhat. A third problem with IMRT plan evaluation is that most planners and physicians still have a difficult time knowing what is actually achievable with a given plan, beam

arrangement, and anatomic situation, so even when an acceptable plan is achieved they are not sure whether they might be able to achieve a "better" plan by changing something. New methods are needed to help give the planner and physician tools that can show them the kinds of changes that may be possible, so they can better know when the optimal plan is achieved. Defining several levels of priorities can help minimize the number of iterations of a plan, particularly if multiple tradeoffs are being made between targets and normal tissues. For example, one can set a nonnegotiable limit and a negotiable one which can be exceeded if beneficial for a competing structure.

One final plan evaluation issue involves the many compromises and approximations that are involved in current inverse planning and IMRT processes. Because of the huge number of calculations involved in a single iteration of the optimization method, and the large number of iterations that are necessary to optimize a given plan for some search methods, it is essential to make compromises in the dose calculation method, the evaluation of the cost function, and other parts of the process, and to limit the resolution of dose calculation points used within the calculation. In addition, as described in more detail in the next section, various compromises in the plan must be made when converting the ideal intensities of the beamlets into a deliverable set of MLC segments (SMLC) or trajectories (DMLC), and these compromises will generally degrade the quality of the plan that is delivered to the patient. As any plan is evaluated, one must also keep in mind the further degradation that will occur. The limited resolution used for dose calculations can often lead to changes in apparent conformality or target coverage if a new dose calculation (with different resolution or calculation grid placement) is used. More discussion about plan degradation caused by MLC sequencing is included in the section on conformal therapy delivery.

Plan Preparation

After a plan has been approved by the physician for clinical use, it must be prepared for treatment delivery and transfer to the delivery system. These preparations include the following:

- Documentation of plan approval. Documentation of the physician's approval of the plan for treatment should be clearly performed (e.g., signature on the treatment plan output, or electronic signature in the electronic chart). Other approvals (e.g., quality assurance approval for IMRT treatments) may also be required.
- Preparation of treatment instructions. Creating a treatment plan for the patient usually involves determining the treatment beams to be used, but often does not consider other parts of the treatment delivery process, including patient setup and localization imaging, the treatment delivery methods to be used (e.g., automated delivery of all the beams, or manual delivery). For complex or automated treatments, creation of a complete treatment delivery script may be required. A graphic treatment delivery simulator can be quite useful.[108]
- Calculation of MUs may be required for non-IMRT fields, although some treatment planning systems also provide the MUs for the plan. In any event, an independent check of the MUs required for treatment should always be part of the process.
- Quality assurance (QA) checks for IMRT and other complex plans. Before delivery of a complex plan to the patient, it is often appropriate to perform various QA checks on the treatment plan delivery, to assure that the treatment will work correctly and accurately. These kinds of QA checks are routine for IMRT treatments to confirm the correct dosimetric delivery of the complex beam intensity patterns that IMRT uses, and for stereotactic radiosurgery treatments to verify that the geometric accuracy of the treatment delivery is adequate because large single doses are often delivered for these treatments.
- Hard copy plan output. Once a plan is finalized, it is important to create a hard copy (or electronic) output describing the treatment plan, to be used in the patient's chart.
- Calculation of DRRs. The creation of DRRs is an important part of the plan preparation process because these DRRs will be used for localization checks of the patient position while one is performing the setup of the patient.
- Plan transfer. Transfer of the plan information into the paper or electronic treatment chart and the treatment delivery system is an important part of the process. For manual transfer methods, one of the biggest potential problems is the large probability of transcription errors as the various parameters for each field are transferred from the planning system to the delivery system or chart. For electronic transfers of the plan information to a computer-based delivery system, the errors that happen are typically not random transcription errors, but systematic errors are more likely. The difference between the manual and electronic methods and their most likely errors means that the QA procedures for the two methods should be carefully defined to be appropriate for the method in use.
- If IMRT beams are used, then rather than calculation of MUs, "leaf sequencing" is performed for each beam to convert the planned IMRT intensity pattern into either multiple fixed MLC segments (SMLC) or dynamic trajectories of each leaf pair if the DMLC method is used.

MLC Leaf Sequencing

To convert an IMRT intensity pattern into a delivery prescription that will create the desired pattern of intensities, a leaf sequencing algorithm is used. Many different leaf sequencing algorithms exist, and all have advantages and disadvantages. Any leaf sequencing algorithm is really an optimization procedure that attempts to find the best way to create the desired intensity pattern while still adhering to all the constraints or limitations of the MLC and machine that are to deliver the IMRT intensity pattern. There are always compromises in the final result achieved by any of these algorithms, so one always knows that the plan has been changed (usually degraded) by those compromises. It is thus important to verify that the final "deliverable" plan is still acceptable. Many IMRT systems use a second-dose calculation, based on the actual delivery sequence, to check that the plan is still within acceptable limits even after the compromises.

Several different methods of IMRT delivery make use of MLC systems (Figure 16-11). Segmental MLC (SMLC) uses a set of fixed MLC segment shapes to deliver the intensity pattern with the beam off as the MLC moves from one shape to the next. Many algorithms have been developed for this kind of MLC sequencing.[45,109] Dynamic MLC (DMLV) uses MLC leaves that move on a trajectory that is defined so that the desired intensity pattern is created. Typically, a "sliding window" algorithm is used to derive the trajectories required.[47]

Volumetric Modulated Arc

VMAT is a relatively new IMRT method that combines rotational (or arc) delivery and MLC-based IMRT.[59,60] VMAT makes use of the same fundamental methods (intensity modulation, inverse planning) as IMRT, but is different in the constraints that the rotational IMRT delivery places onto the plan optimization strategies that are used. Typically, completely

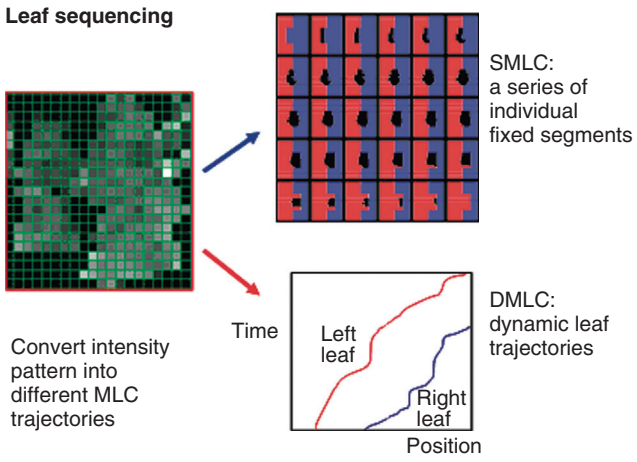

Figure 16-11 Segmental multileaf collimator (SMLC) and dynamic multileaf collimator (DMLC) leaf sequencing.

different optimization strategies are used for VMAT planning because the strategy must be tuned differently to make it possible for the optimization to reach a high quality plan, given the constraints on MLC motion during the arc rotation of the gantry. Given the type of rotational delivery used, the dose distributions achieved with VMAT are different than fixed field IMRT, often spreading more low dose regions over the volume of the patient. The tradeoffs and differences between IMRT and VMAT plans have been the subject of many studies and are still the subject of ongoing work. One important advantage of current VMAT delivery techniques is that often the VMAT delivery for a single arc, or even for a multiple arc plan, can be much faster than that for fixed field IMRT delivery. This decrease in delivery time can sometimes be a significant advantage that may overshadow some of the dosimetric constraints of the VMAT plan optimization and can be particularly useful when particularly uncomfortable immobilization is being used (e.g., head and neck cancer) or targets are spread out in large multiple-split fields (e.g., anal cancer).

CONFORMAL THERAPY DELIVERY

Careful, efficient, and accurate treatment delivery is just as important as sophisticated treatment planning if the patient is to receive the benefits typically ascribed to conformal therapy.

Patient Setup and Localization: Transitioning to Image-Guided Radiation Therapy

One of the most crucial aspects of patient treatment involves the setup and localization of the patient for each treatment fraction. For many years, this process has typically involved lining the patient up to laser lines using skin marks defining lateral and anteroposterior (AP) projections of the plan isocenter. To verify correct patient positioning, lateral and AP localization films were obtained (typically, once per week) to confirm the correct placement of the isocenter inside the patient. The "orthogonal pair" films were compared by eye with the expected location (shown by simulator film, DRR, or BEV display from treatment planning) to document the accuracy of the setup. Use of a calibrated gradicule in the accelerator head when making the megavoltage images[110] was helpful in making the comparison somewhat quantitative.

In the last decade, many new developments have dramatically changed the setup and localization process for many patients, a set of much more quantitative and automated setup procedures that are known as IGRT. The development and implementation of electronic portal imaging devices (EPIDs)[111] for megavoltage imaging, diagnostic x-ray imagers,[108] and megavoltage or diagnostic cone beam CT (CBCT) scanning[65] using accelerator-based systems have revolutionized the setup and localization process. If the new digital imaging capabilities are integrated with the computer-control system of the treatment accelerator, it is possible to perform relatively automated patient setup with accuracy much improved over the old manual method.[112] As this technology is disseminated, it is clear that use of IGRT methods for patient setup, on a daily basis, will lead to significantly improved accuracy for routine patient setup.

Tools for Image Guidance

A number of new tools are now available for patient positioning and localization and are mentioned here as tools for image guidance.

MV Imaging

Megavoltage imaging was the initial development that made IGRT possible because it made routine use of imaging (on a daily basis) practical. After early development of an ion-chamber based portal imager (or electronic portal imaging device, EPID),[113] amorphous silicon (a-Si) EPIDs were developed[114] and quickly became the standard EPID device for most accelerator systems.

KV Imaging

The a-Si technology developed for the megavoltage EPID has also been optimized for kV imaging[115] and is now widely available on many newer treatment machines. The large and high resolution a-Si flat panel imagers have allowed high-quality diagnostic imaging systems to be installed on many accelerators, thus making both kV imaging and cone beam CT imaging possible. The availability of high quality kV imaging has also made many x-ray fiducial markers[116] much easier to use.

CBCT

Cone beam CT has revolutionized the amount of pretreatment localization information available for use in image guidance.[117] Most CBCT is created with a kV x-ray tube and a-Si flat panel imager that are mounted on the accelerator system orthogonal to the megavoltage radiation beam, and typically create a volumetric CT image in about 1 minute of accelerator time. The usual process involves acquiring a CBCT image set, registering those images with the treatment planning CT performed during CT simulation at the beginning of the treatment course, and then determining the shift required to place the patient in exactly the same position (and configuration) as originally planned.

RF Beacons

In place of x-ray fiducials, small RF transponders ("beacons")[76] can be implanted in the patient (just like fiducials), and the position of those beacons can be electronically determined by the system in real time (typically happens about 10 times a second). This kind of system allows real-time monitoring of the position of the target during therapy, with the opportunity to stop the irradiation if the target beacons move outside a predetermined tolerance.

MR Devices

A number of new devices using MRI have also been developed for IGRT treatment. A number of centers have installed

either an MR or CT system on rails, in the treatment room, so that a patient may be scanned in the treatment position and then directly moved underneath the accelerator for their treatment.[118,119] A startup company has developed a novel device (ViewRay), that incorporates a rotational gantry system mounted with 3 Cobalt-60 sources (evenly distributed around the ring), each with its own MLC system, all installed with a 0.3 T permanent magnet system for MRI imaging.[120] This system allows treatment with concurrent MR imaging. Several types of MR-Linac systems are currently also being developed, each with the goal of delivering sophisticated photon treatment using 6 MV photons while at the same time performing 1.5 T MR imaging.[121-123]

Video Surface Imaging

Another type of imaging currently being used for IGRT patient setup and monitoring uses video cameras and various methods for projecting information onto the patient's skin so that the 3D shape of the patient surface can be determined in real time, so that it can be compared to the expected model of the patient surface as a way of identifying positional or motion differences between the current patient surface and the model. Though this technology has been studied for many years, current technological improvements have helped bring these devices into the commercial and clinical mainstream.[124]

The IGRT Process

Although IGRT can be used to describe any use of any image guidance technique to help set up or position the patient for treatment, or to monitor the position, motion, or field localization during treatment delivery, the true IGRT process is integrated into many parts of the overall radiation planning and delivery process. The main parts of this integrated process are briefly summarized here:

CT-simulation imaging: obtain the imaging data that will be used for planning and as the model used when matching the treatment imaging

Delineation of the target and normal structures. Used for planning, but also for comparison to the treatment day imaging results.

Determination of the appropriate margins to use for the planning target volume (PTV) or other normal structure limits (PRV, planning organ at risk volume). Each institute must document the setup accuracy achieved, so these margins can be designed appropriately.

Setup and image guidance instructions must be transmitted to the treatment machine for use daily along with the treatment plan information.

Daily, the patient is set up and then imaged. The imaging information is then compared to the model (planned) image set, and the two sets of images are registered (or "matched"). If the patient's position (or pose) do not match precisely, then the shifts (or rotations) needed to move the patient so their position agrees with the planned position are determined from the registration process, and the patient can then be moved to the correct position. The region of interest for matching can be an actual visible tumor, surrogate soft tissue or bony anatomy for the tumor, or an avoidance structure if there is a steep dose fall off between acceptable and unacceptable dose to a particular structure (e.g., spinal cord, bowel, etc.). Documentation that the shifts of the patient are made correctly should be performed, though sometimes this is not done. The patient is then treated.

IGRT information can also be used during treatment to monitor the patient's position, pose, breathing state, and any other factor that might indicate the treatment should be stopped and positioning corrected. Some real-time imaging systems are equipped with triggers that can automatically stop the irradiation if necessary.

Review and analysis of the daily IGRT results are critical to the accuracy of the guidance procedure. This review includes both peer review of the imaging registration procedures as well as more technical review of the daily results so that trends (e.g., drift, or systematic deviations) can be separated from the more typical random variations. It is this kind of analysis that will determine the specific margins that are appropriate for target volumes for a given type of patient in each particular clinic.

Manual and Computer-Controlled Treatment

The treatment delivery process used for modern conformal therapy has also changed. For many years, the standard treatment process involved two or more therapists carrying the paper treatment chart into the treatment room, setting up the patient (as described using lasers and skin marks), and then positioning the accelerator manually for each treatment field using the accelerator hand pendant controls. The therapists would exit the room to allow the treatment of each field, which was controlled by the treatment machine console in the control room. Although some machines were equipped with computer-based "record and verify" systems[125,126] that would confirm the parameters to be used for each field, many of these systems were of limited sophistication. Most parameters used for patient treatment were set by hand and susceptible to various random errors.

Since the 1990s, integrated computer-controlled systems have entered widespread use for control of the treatment process, usually tied to a treatment plan or information system database that contains all the treatment plan information. To varying degrees, the progression through the setup process and treatment delivery is often automated, controlled via the machine's system. However, much remains to be done to optimize the efficiency, safety, and accuracy of the computer-controlled treatment delivery process. There has been some published work on the treatment delivery process,[108,127-129] but too often a treatment process taken directly from the old manual techniques is implemented with the computer-controlled system, without implementing modifications that would improve the accuracy, safety, or efficiency of the computer-controlled treatments. The more recent introduction of the wide variety of image-guided delivery methods also leads to the need for further improvements in the workflow of the process, and additional effort to optimize the process is required. Much work is needed in this area.

The use of IMRT treatment delivery has also caused a dramatic change in various aspects of the delivery process. With simple nonconformal fields, it was common to outline the shape of each treatment field on the patient's skin and to confirm at treatment that the shape and placement of each radiation field agreed with the shape drawn on the skin. This limited large errors but certainly was not a highly accurate positioning check. With modern IMRT treatment fields, understanding the fluence pattern that will be delivered requires computer-generated images, and there is no intuitive way to check the field shape, position, or intensity pattern directly on the patient, so more sophisticated QA checks or procedures are necessary. With modern EPID systems, so-called portal dose measurements (intensity or "dose" measured with the EPID) can be compared with that which is expected and used as a QA check that can potentially identify both geometric and dosimetric differences between the desired and delivered dose distributions.[130,131] It is also possible to reconstruct the

delivered intensity distribution by analysis of MLC trajectory information.[132] The further development of quantitative online delivery QA checks along with their integration into the treatment delivery process is an area of significant ongoing experience that is expected to lead to much more sophisticated delivery systems.

Electronic Medical Records, the Patient Treatment Chart, and Treatment Management Systems

As computer systems have increased the sophistication of planning, treatment delivery, and treatment verification and QA, the need for more sophisticated treatment documentation has also grown. Computer-controlled treatment plans and IMRT require the use of electronic patient treatment charts because there is just too much technical information to allow sole use of a paper treatment chart. The trend toward the use of electronic medical records (EMRs) to replace paper patient charts is certainly mirrored throughout the healthcare system as all major medical systems convert their paper-based record systems to electronic EMRs.

It is incumbent on all users of EMR systems to carefully implement and use the new technology. It is not appropriate to just convert all the old paper-based documentation practices into electronic forms because some standard paper-based methods just do not work well in the electronic world. For example, writing notes in a chart in pencil to show what should happen in some number of future treatments cannot be easily mimicked in an electronic system.

Some analysis of the needs for electronic treatment charts has been published,[129] but the ongoing transition from paper to electronic charts should be evaluated and performed with care. Complex IMRT-based prescriptions and plans probably require new methods that were not supportable in a paper-based chart, and users of highly sophisticated conformal therapy will have to develop their own migration from paper to electronic prescriptions and treatment charts.

In radiation oncology, the transition to EMR use has involved more of a migration than just replacement of the paper chart with an electronic one. The early computer-based record and verify systems that were originally developed in the 70s[125,126] have morphed into complete treatment management systems (TMS) that can support all of the electronic medical record needs of stand-alone radiation therapy centers, while also needing to work along with the larger hospital EMR systems in hospital settings. The TMS is a major component of the hardware/software that is needed to run a radiation oncology department, and it is quite complex, extending from general patient care all the way into the treatment delivery arena. Although early efforts to develop such integrated systems have been published,[39,108,127-129] there is relatively little current literature to help users of the systems (this means most radiation therapy professionals) to understand commissioning, optimization of use, and ways to improve workflow through the planning/delivery process through more effective use of the TMS. More work in this area is needed.

Consideration of Setup Error and Patient Motion Management

As the field of radiation therapy has made the transition from four-field boxes and AP-PA fields to sophisticated conformal therapy based on 3D treatment planning and IMRT, it has become more obvious that considerations of daily setup uncertainties and errors and patient and organ motion during treatment are important considerations that should affect both treatment planning and treatment delivery methods. During multiple fraction treatment, all of the following effects should be considered:

- Daily setup variations
- Changes in patient anatomy and target shape over time
- Patient movement and organ motion during treatment

For many years, the ICRU-50 concept of the PTV[72] has been the response to these issues. However, the desire to perform precise conformal therapy has led many institutions to study these issues in more detail and to measure the associated uncertainties.

The importance of correcting the systematic setup uncertainty, if possible, has also led many institutions to convert their positioning verification procedure from the use of weekly port films, with position correction if a large-enough error is seen, to a more sophisticated offline or online repositioning scheme.

It is now quite routine to use the sophisticated setup, localization, and imaging strategies of IGRT (described previously). Use of daily IGRT setup correction based on imaging (megavoltage imaging, kilovoltage imaging using an integrated kilovoltage tube and imager, or kilovoltage or megavoltage CBCT) is a significantly more accurate method for daily patient positioning than the methods used previously, although these IGRT techniques require more effort. Even relatively straightforward daily imaging techniques using EPID imaging and automated repositioning of the treatment table demonstrate large improvements in setup accuracy (e.g., improvement in Σ [the systematic setup uncertainty] from >8 mm to 2.3 mm for liver patients).[133] It is also possible to apply "decision rule" protocols[134,135] in an offline manner: verification imaging is performed several days in a row, and only after the systematic error in the setup is determined is a correction made.

Daily IGRT also provides detailed information about the stability of patients and their positioning, and can make possible adaptive treatment changes that can allow individualization of the margins and setup techniques used for individual patients. This is a rapidly developing area, and promises improvements in patient treatment precision, as well as in improving our ability to image[136] and respond to changes in the patient, tumor, or normal tissue behavior through the course of therapy.

In the last decade, major progress has been made in taking account of motion and patient respiration throughout the patient imaging, planning, and delivery process. 4D CT[137,138] is now regularly available in many clinics, giving the physician and planner the ability to visualize, at least to a limited degree, the motion which occurs as a result of respiration or other such internal motions. Planning strategies that take into account respiratory motion have been described,[139] including the definition of an ITV, which describes the extra margin required to keep the CTV in the high-dose region of the dose distribution. Respiration management systems[71,140] are routinely used to minimize respiratory motion, leading to a significant decrease in the additional margins, which need to be left to keep the target in the high-dose volume in the face of motion as a result of respiration. Using deep inspiration breath hold (DIBH) methods for patients with left-sided breast cancers has helped significantly decrease cardiac dose from the usual tangent-like fields used for those patients.[141,142] Finally, real-time monitoring of motion in the target can be accomplished with radiofrequency beacons, video surface imaging, and other real-time methods that can give direct information about motion during treatment.

CLINICAL CONSIDERATIONS

To this point, the technical process of conformal therapy planning and delivery has been described. This final section

describes some of the clinical considerations involved in the application of conformal therapy techniques and provides a brief summary of some clinical results of IMRT treatments.

Immobilization and Setup Uncertainties

Patient positioning and immobilization should be reproducible and comfortable enough to be maintained for the duration of the treatment, whether it is 5 or 50 minutes. Because position reproducibility and PTV (or planning organ at risk, PRV) margin are necessarily linked, careful consideration must be given to both. For example, if a target intended for high doses is near a critical structure like the spinal cord, a small PTV margin is desired; thus, careful immobilization is required, even if less comfortable. Without nearby critical structures, immobilization can be less restrictive.

PTV margins also vary per site, depending on specific immobilization devices or techniques. The clinically measured range of motion and setup uncertainties for each clinical site should be known, as those uncertainties will determine the margins required for the PTVs and PRVs (if used) during treatment planning. Additional margin information can be obtained from the literature, as margins for a sample of patient populations using commercial, widely available immobilization systems have been determined and published; for example, the setup error standard deviation when using a commercial thermoplastic mask for head and neck immobilization has been determined to be 3 to 4 mm if patient-specific information is obtained and daily patient repositioning protocols using portal imaging are enacted.[143] Although weekly verification is considered the standard method for conventional radiation therapy and 3D radiation therapy, daily imaging of the skeletal anatomy or implanted fiducial markers using an EPID has reduced systematic and random variations.

Systematic setup error can be established from imaging during the first three to five treatments[72] and can then be corrected, leaving only the random deviation to be accounted for by adequate PTV margins. Daily patient imaging and correction of setup deviations can reduce it even further, making it possible to minimize the PTV margin, thereby increasing the sparing of adjacent noninvolved tissue.

Considerations of patient setup and immobilization approaches are complex. For example, in prostate cancer, the prone patient position can improve the separation between the prostate and the rectum compared with the supine position, thus potentially improving sparing of the rectum. However, prone positioning also can increase breathing-related motion of the prostate,[143,144] which may increase the required margin in the superior-inferior dimension, actually increasing the length of rectum within or close to the PTV. In breast cancer, prone positioning is gaining popularity for patients with large or pendulous breasts. However, with prone positioning, the heart can fall closer to the chest wall and potentially into the tangential fields for a left-sided breast cancer.[145] Thus, careful evaluation of how immobilization position impacts not only target, but also normal tissue geometry, is crucial.

Patient and Organ Motion

Individual measurements of motion and setup uncertainties, and their corrections, are especially important in sites where breathing or internal motion is significant, such as the thorax and abdomen. Techniques for dealing with this motion can be separated into two basic categories: eliminating motion or including motion in planning and delivery. Methods to eliminate motion include forced or voluntary breath hold. With these methods, assessment of tumor position can be performed using cone-beam CT or orthogonal imaging of implanted fiducials or the chest wall, and setup variation can be reduced to just a few mm.[133,146] Methods to confirm position of external surrogates[147] are popular and user friendly, but rely on the assumption that there is a consistent relationship between external surrogates and specific internal anatomy, which is not always the case.[148] Not all patients can tolerate breath-hold treatments, and they also increase time on the treatment machine and patient discomfort. Thus, methods to include motion in planning and delivery are important to avoid treating a PTV that is too small and risking a marginal tumor failure, or treating one too large and risking increased toxicity. Most free-breathing motion management strategies start with a 4D CT, to understand the trajectory of tumor motion, which can be quite complex and variable.[143] The apparent tumor (if identifiable without optimal intravenous contrast-enhancement) is contoured on all phases to include the GTV with motion envelope. Then, a clinical target volume margin is added to include regions of microscopic spread, and finally, a margin must still be added for setup uncertainty before arriving at the final PTV. This workflow is most commonly used for lung tumors. If the tumor is only apparent on breath-hold contrast-enhanced CT or MRI, the GTV is still contoured, and a motion envelope for asymmetrical expansions can be created by studying the motion of an internal surrogate in close proximity to the tumor, ideally implanted fiducials. Adding margins for microscopic spread (if appropriate) and setup uncertainty would also follow. This is most useful for liver tumors.

Although most of the focus is on motion of targets, it is important to keep in mind that normal tissues also move, often differently. This can happen during as well as between treatments. During respiration, even different abdominal organs have varying amplitudes of motion.[149] Additionally, the shape of and relationship between organs can change, most notably for the stomach, but for other organs such as the colon, duodenum, gall bladder, and bladder as well.[150] Thus, a PRV margin and patient instructions on empty versus full stomach and bladder can be helpful to avoid inadvertently high doses to nearby organs.

Both breath-hold and free-breathing techniques can be used with treatment gating or tracking. With gating, the beam is only on through a prespecified range of positions, within the ITV and PTV margin employed.[151] With tracking, the radiation beam follows the motion of the tumor.[152] Selection of gating versus tracking is a complex choice, with considerations including practical (which technology is available in a particular center) and theoretical (considerations of duty cycle, margins, etc.).[153]

Determining the Targets

The dosimetric advantages of IMRT must be balanced with potential pitfalls related to the production of tight dose distributions around targets contoured on the CT scan. The most important issues are the reliability and reproducibility of outlining the targets that typically rely on a single planning scan performed before the start of treatment, and the error of image registration if supplemental imaging, like an MRI, is used. The GTV is contoured on the treatment planning CT scan using clinical and radiologic information. In many cases, contrast-enhanced CT combined with clinical information derived from physical examination is the main modality used for the delineation of the targets. For some sites, CT is not the best imaging modality for the definition of the extent of the macroscopic tumor, and ancillary studies such as MRI or fluorodeoxyglucose (FDG)-PET may add important information. MRI can be limited by its sensitivity to artifacts, long examination time, and cost. FDG-PET is often limited by a lack of

specificity regarding tumor versus inflammation, and by uncertainties in interpretation, which may be subjective and differ depending on the observer's experience. PET-defined target volumes can also depend substantially on the standardized uptake value (SUV) chosen to contour the PET scan. The best added information from these studies is derived following their registration either with diagnostic CT or with the planning CT scans. Rigid body geometric registration of multiple scan types can now be performed in many cases using commercially available software, whereas registration of nonrigid structures is the subject of ongoing research, with less than satisfactory commercial products available today.[154-157] Careful review of the registration is necessary to evaluate its quality and any potential need to add additional margin for registration errors.

Future improvements in the anatomic and metabolic imaging of tumors are expected to decrease the uncertainties in contouring the GTV while determining the volume to receive high radiation dose. However, the definition and contouring of the tissue volumes at risk of harboring subclinical disease (CTVs) depend on clinical judgment alone. It is not surprising that large interobserver differences have been noted in outlining these volumes.[158-162] The uncertainties in outlining the target volumes raise concerns about the potential of highly conformal radiotherapy to miss disease while striving to spare organs adjacent to the targets. Efforts to define the volumes at risk for subclinical disease for each tumor site have been made for head and neck cancer,[163,164] breast cancer,[165,166] and cancer at other sites.[167-170] They constitute the initial steps in this direction. Clinical validation, based on data regarding the sites of locoregional tumor recurrence and their relationships to the targets, is necessary. To date, relevant data are scant. They suggest that when target outlining is performed by experienced investigators, the large majority of the locoregional tumor recurrences are in-field, and only few marginal failures are observed.[171,172] Until more data are available, target outlining should be done in a conservative manner. Target volume definition requires thorough knowledge and understanding by the radiation oncologist of the anatomy and the locoregional tumor spread pattern. Recently, atlas-based automatic segmentation has become a reality within several planning systems. Validation studies are encouraging, but even these contours require careful examination and cannot completely replace dedicated physician time and expertise.[173-175]

An outline of imaging studies required for each tumor site and other considerations for determining the targets, normal tissues, and image guidance requirements are described next.

Head and Neck Cancer

Most head and neck target volumes are defined using CT information. However, MRI is a necessary adjunct to CT for tumors close to the base of skull (i.e., nasopharyngeal and paranasal sinus cancer), where it provides better details of tumor extension and the parapharyngeal and retropharyngeal spaces, compared with CT.[176] FDG-PET, in most cases, defines smaller primary targets compared with CT, and the volumes depicted by each modality do not completely overlap.[177] Relying on FDG-PET may result in changes in the outlining of the GTVs compared with outlining based on CT, at least in some patients. Whether FDG-PET is more accurate than CT in delineating the primary tumor GTV has not yet been established, because of the paucity of data correlating the imaged extent of the gross tumor and its size in pathologic specimens following resection. Current data from series involving imaging followed with surgical validation suggest slightly more accurate definition of the gross tumor by FDG-PET compared with CT. Until more data are available, the most prudent practice seems to be outlining the GTV as the composite of the lesions observed on CT and PET, as FDG-PET has poor sensitivity for microscopic disease. In cases of recurrent cancer, where extensive scars from previous surgeries confound the CT-based delineation of the tumor, FDG-PET has a clear advantage[178] and should be used as the primary modality for the delineation of the GTV.

The CTVs for head and neck cancer include subclinical disease in the vicinity of the primary tumor and lymph node groups at risk of subclinical disease. Outlining the CTVs requires knowledge of the natural history and pattern of failure of each tumor site. Suggestions for the selection and delineation of the targets have been published, and atlases detail the recommended delineation of various lymph nodal groups.[163,164] Although PET has been useful for definition of the GTV, it cannot be used to justify omitting radiotherapy to established, standard CTV volumes based on patterns of nodal spread. Perhaps more so than in any other disease site, the radiation oncologist and dosimetrist or physicist treatment planner must make the most clinically rational tradeoffs between target coverage and normal tissue sparing. Because these tradeoffs are complicated and depend on balancing the likelihood of cure and likelihood of toxicity, they require individual consideration for each patient.

The PTVs for head and neck treatments, as with all other sites, depend on IGRT strategies, as discussed previously. For tumors near the base of skull, where accuracy is particularly important to avoid overdosing the optic chiasm and optic nerves, CBCT is particularly useful to assure alignment, particularly when minor rotations can cause clinically significant dosimetric differences that could translate to major toxicities. In this case, alignment should be biased toward the most critical structure.

Lung Cancer

In lung cancer, the primary lesion should be contoured on the CT scan using window/level settings for pulmonary visualization (i.e., a pulmonary window), with mediastinal settings to aid in defining borders near the mediastinum or chest wall. FDG-PET can be helpful when a PET avid but anatomically indistinct tumor is present. In particular, PET can differentiate atelectasis from tumor, preventing unnecessary inclusion of noninvolved lung tissue in the GTV.[179] On the other hand, PET is certainly not perfect, and there is still controversy regarding proper thresholding of imaging to most closely approximate the actual tumor size.[180,181] Unfortunately, appropriate radiographic-pathologic correlation studies are still lacking. Additionally, because 4D-PET is still not widely available, most PET images depict an "average" intensity of a moving target and may overestimate the true tumor size.

The CTV for non–small cell lung cancer is typically an approximate 5 mm uniform expansion of the GTV allowing for direct microscopic spread, although some advocate for customized margins based on exact tumor histology.[182,183] Elective nodal radiation has fallen out of favor because recurrences in nodal basins are quite rare compared with recurrences in the primary tumor and the elective irradiation significantly increases dose to normal tissues.

Because respiratory motion can significantly affect the dose distribution, lung target volumes often require use of an internal target volume-like margin (from ICRU-62[184]) for respiratory motion of the target, depending on whether measures to reduce the motion are used (e.g., ABC or gating). In the absence of such measures, large variability in tumor motion is observed among patients, on average 1 cm in different directions, with high variability. Methods to minimize respiratory motion,

such as abdominal compression and coached breathing, may minimize but not eliminate motion. In the end, the PTV for a lung tumor is typically comprised of radiographically apparent tumor, motion envelope, CTV margin for microscopic spread, and PTV margin for setup variation. The PTV margin is preferably small because of the extreme sensitivity of the lungs. Thus, reproducibility of setup is crucial. Advanced image-guided systems, including CBCT and tomotherapy, can visualize the tumor and organs at risk in three dimensions before treatment and allow for online correction. Imaging of internal fiducials placed within the tumor may also be used when CBCT is not available.[185]

Brain Cancer

For brain tumors, multiple sequences of MRI, with and without contrast, are typically crucial for both GTV and CTV delineation. Registration of these images to a planning CT is usually quite straightforward, compared with areas of the body that may deform. Still, careful review of the registration is necessary, with particular attention focused on the optic chiasm or other sensitive normal structures, especially for tumors in close proximity to those structures. If a preoperative MRI is fused with a postoperative planning CT, clinical judgment must be used to determine how much of the normal brain parenchyma to include because it often falls into the tumor bed.

Immobilization typically consists of a thermoplastic mask, and with a typical accuracy of as little as 3 mm, helpful for tumors near the chiasm or brainstem. Still, for those cases, daily imaging with not only orthogonal images but with CBCT is advised to minimize both systematic and random error of setup in that critical region.

Gastrointestinal Cancer

Contrast-enhanced CT is crucial for many sites including pancreas and liver cancers. MRI is usually necessary for identification of hepatocellular carcinoma, although liver metastases are usually well-seen on a high-quality CT with delayed imaging. Radiographic data must be supplemented with physical examination and endoscopy reports for rectal cancer, and PET scan and endoscopy reports for esophageal cancer. Many site-specific atlases have been developed to aid in consistency in delineation of target volumes.

Target definition must take into account significant respiratory-related organ motion for upper abdominal tumors, which can be up to 25 mm.[148,149] Without methods to reduce respiratory movement, the large margins required to accommodate this motion can markedly increase the volumes of small bowel and duodenum receiving target doses and limit the ability to escalate tumor dose. With tightly defined target volumes, the volume of small bowel and duodenum irradiated are reduced, producing improved toxicity and potentially allowing higher radiation doses in certain sites.[186,187]

Image guidance has traditionally consisted of orthogonal imaging, but for mobile tumors, the relationship with bony surrogates is changing and unpredictable. Thus, confirmation of soft-tissue location with CBCT may be necessary, either by aligning the tumor itself, or if not visible, implanted fiducials or a nearby surrogate landmark. Historically, tumor control for pancreatic cancer has been poor and toxicity rates high. Likely contributors to the problem included poor tumor definition because of inadequate imaging, poor accounting for tumor and organ-at-risk (OAR) motion, lack of highly-conformal treatment techniques, and poor image-guidance. Thus, with advances in these, there is hope that tumor control and toxicity will both improve.

Prostate Cancer

Gross disease within the prostate gland cannot be defined accurately using conventional imaging, so routine practice is to treat the entire prostate as the CTV. Research in magnetic resonance spectroscopy (MRS) suggests that it may be used to identify aggressive tumor foci within the prostate using the choline-to-citrate ratio, which is higher in tumor cells compared with prostatic cells.[188-190] Other sequences may also be useful to identify nodules of high Gleason grade for additional boosting, although lower grade tumors are not consistently detected, confirming the need to treat the entire gland with radiation. Still, if confirmed, MRS imaging may be used to define the high grade GTV, or the boost volume, within the prostate, with the hypothesis that high radiation doses may prevent failures in these nodules.[191,192] In any case, MRI is extremely helpful for prostate contouring. The prostate's superior margins at the base of the bladder and its inferior margin (apex) are better defined on MRI compared with CT. MRI is also better at defining the rectal and bladder boundaries and the penile bulb. Target delineation for the post-prostatectomy setting is aided by a contouring atlas.[168]

The size of the PTV depends on image-guidance strategy. Implanted gold fiducials, which can be visualized with standard orthogonal imaging, or electromagnetic transponders, can help allow for a reduction in PTV margin to 5 mm, although this must be closely monitored for both translations and rotations.[193] Daily imaging with tomotherapy or CBCT can also reduce required margins.[194] Recently transponders have been integrated into a gating system and linked to MLC tracking for the first time.[195]

Gynecologic Cancer

Accurate target delineation is vital in the conformal radiation treatment of cervical cancer. MRI defines gross abdominal disease better than CT and is strongly recommended in defining the tumor volume, which may be further aided by FDG-PET.[196] Fusion of the T2-weighted MRI images to the simulation planning CT scan is advised when possible. To assist in delineating targets, the RTOG consensus panel has proposed guidelines.[170] Because of substantial organ motion, tumor regression, and deformation associated in patients with cervical cancer, margins of 1.5 to 2 cm around the CTV are recommended for the primary PTV with a PTV margin of 7 mm around the nodal CTV. Whether IMRT can be useful in the treatment of an intact cervix, replacing brachytherapy or, more likely, serving to augment GTV doses after brachytherapy, is not yet known. Brachytherapy remains the standard of care. If IMRT is considered for the intact cervix, daily soft-tissue image-guided verification is required to avoid the risk of geographic miss.

Breast Cancer

Typically, the whole breast is considered the clinical target volume, with an additional lumpectomy cavity volume designated for a boost in most cases after breast-conserving surgery. The lumpectomy cavity is outlined on CT, with the assistance of surgical clips, as the CTV, and a margin is often assigned as the PTV, for breathing motion and setup uncertainties. When regional lymph nodes require irradiation, treatment complexity is higher, and heart doses in left-sided breast cancer therapy may be substantial. For the outlining of the lymphatic CTVs, particularly the supraclavicular lymphatics, in addition to other relevant structures, including the heart, anatomic guidelines, and atlases have been published.[165,197,198]

Accelerated partial breast irradiation (APBI) is increasingly being used to treat early-stage breast cancer patients, as

elsewhere (outside of the lumpectomy cavity) breast failures are rare. The optimal margin of tissue requiring radiation after lumpectomy in patients treated with APBI remains somewhat controversial. However, contemporary radiographic and pathologic data suggest that a margin of 10 mm around the tumor bed appears adequate to cover any disease remaining in the breast after lumpectomy in most (>90%) of patients, provided the final margins are negative.[199]

Noninvolved Normal Tissue

Forward planned 3DCRT allows intuitive decisions by the planner regarding beam apertures and directions, but such decisions cannot be made in inverse planned IMRT. This requires that all targets and organs at risk be determined and outlined in the planning CT for use in the inverse planning. Many normal tissue atlases have recently been published to standardize delineation, and thus aid in consistent dose reduction to critical organs.[165,197,200-202] In addition, inverse planning typically requires the definition of "non-specified tissue." This information is usually obtained by subtracting all targets and specified organs at risk from the external contour of the patient in the CT dataset. It allows limits on the maximum doses delivered outside the targets and the organs at risk, which is necessary to reduce unexpected damage to soft tissue, nerves, blood vessels, and so on. This is particularly important when a new technique is being implemented. For example, in the early days of IMRT, alopecia and dermatitis of the posterior low scalp were an unanticipated result of using multiple beams without dose limits on the nonspecified normal tissue of the scalp. With the resurgence of arc therapy and development of new techniques, it is particularly important to carefully set dose limits on normal tissues, often requiring contouring of structures which had traditionally been spared by avoiding beams entering through these regions.

Treatment Goals and Rationale for Highly Conformal Radiotherapy

Data from many disease sites suggests that target dose escalation improves local control. At the same time, we are learning more about the dose-response curves for toxicity after irradiation of organs at risk. Additionally, as the number of normal tissues with avoidable toxicity increases, often treatment planning becomes similar to avoiding mines in a battlefield. In many situations, this absolutely could not be accomplished without IMRT, newer modes of arc therapy, and potentially proton therapy.[72] However, this must be balanced against the increased time and cost required, for each situation. The clinical considerations for several sites are described here.

Head and Neck Cancer

Delivery of the prescribed dose to the targets in advanced head and neck cancer is often limited by the dose to the spinal cord and brainstem, especially in advanced nasopharyngeal cancer, posterior pharyngeal wall cancer, and thyroid cancer. Also, irradiation of gross disease in the posterior neck may be suboptimal because of dosimetric deficiencies due to the off-cord photon and posterior neck electron beams if 2D or simple 3D treatment planning is used. By making possible concave dose distributions, IMRT can overcome these deficiencies and potentially improve tumor control rates. Dose escalation to the GTVs[203] or to hypoxic subvolumes within the GTV[204] using IMRT has been proposed.

Sparing of the parotid glands, in an effort to reduce xerostomia, has been a major goal of earlier 3DCRT[205] and subsequent IMRT studies.[206,207] Randomized studies of IMRT versus 2D radiation therapy in nasopharyngeal cancers demonstrated improvement in salivary production and in observer- and patient-reported xerostomia.[208-210] Sparing the contralateral submandibular gland in cases where contralateral level IB is not a target has been proposed, suggesting a mean dose of less than 39 Gy as a goal.[211] However, IMRT cannot substantially preserve the function of the submandibular glands in some cases because these glands lie anterior to the subdigastric nodes that are important targets in both sides of the neck, and this poses a limitation on reducing xerostomia even by IMRT. Similarly, reducing the doses to the noninvolved oral cavity, striving to spare the minor salivary glands and to reduce mucositis, is an important planning goal. Additional objectives, depending on the clinical scenario and balance between adequately treating targets and sparing normal tissues, include reducing doses to the optic pathways, inner ears, swallowing structures, skin, and carotid arteries.[212-215]

Brain Cancer

Dose escalation trials attempting to increase the currently poor local control of high-grade gliomas have been conducted at the University of Michigan.[171,216,217] These trials used 3DCRT or IMRT, more recently with concurrent temozolomide, delivering a high dose to the GTV while keeping a constant dose to the CTV and limiting the doses to the optic pathways and noninvolved brain to minimize the risk of brain necrosis and visual decline. IMRT may be superior to 3DCRT for tumors that are close to the optic nerves or chiasm, or for irregularly shaped tumors, particularly if dose is escalated.

Lung Cancer

Facing low local tumor control, the goals of conformal irradiation are to improve target irradiation while reducing lung volumes receiving a high dose. Using 3DCRT, trials of dose escalation have been conducted using various constraints on uninvolved lung doses, such as the mean dose, the lung volume receiving more than 20 Gy (V_{20}), and a fixed low normal tissue complication probability. Using similar dose constraints, IMRT has been used to treat lung cancer. However, substantial geometric uncertainties about beamlet doses in lung tissue may influence the accuracy of imaging, treatment planning, and delivery. To improve the optimization of IMRT beam direction, the role of ventilation perfusion scans is being explored so that well-ventilated lung may be more appropriately spared.[218] Additionally, because of a completely different pattern of dose distribution with IMRT as compared with 3D and 2D, some are concerned that traditional models to predict pneumonitis may not completely apply, and that restrictions on even low doses such as 5 and 10 Gy (V5 and V10) are necessary, as treatment of high volumes of lung tissue to even low doses has been associated with fatal toxicity, and concurrent chemotherapy may increase this risk.[219-221] Other potential reasons to use IMRT for lung cancer would depend on geometry, specifically proximity of the tumor to organs at risk including spinal cord, heart, and brachial plexus.

Breast Cancer

IMRT can potentially produce more homogeneous doses to the intact breast compared with lateral tangential beams. In randomized trials, this has translated into reduced rates of moist desquamation, improved quality of life, and improved cosmesis compared with 2D radiotherapy.[222,223] An active area of research is how much IMRT would add to excellent 3D

conformal planning for these endpoints, and which patients would be most likely to benefit. IMRT potentially also could aid in reduction of dose to the heart, particularly for left-sided breast cancers, although because of anatomical variation, even treatment plans for right-sided breast cancers can deliver considerable dose to the heart.

The use of hypofractionated partial breast irradiation is a recent strategy for the treatment of early-stage breast cancer. The main advantages of this technique include shortened overall treatment time, and better access and compliance. This accelerated hypofractionated irradiation regimen to the lumpectomy site takes into account the pattern of breast relapse that predominates in the original tumor quadrant and assumes that good cosmetic outcome may be achieved if high fraction doses are delivered to limited breast volumes using highly conformal therapy. Recent reports call this into question, with poor cosmesis observed.[224-227] Therefore, this approach should not be taken outside the context of a clinical trial.

Prostate Cancer

Dose escalation to the prostate and limiting the doses to the rectum and bladder to reduce the gastrointestinal and genitourinary toxicities of therapy have been the major goals of 3DCRT and IMRT, particularly given the benefit for dose escalation seen in four randomized trials.[228-231] IMRT potentially can help create sharper dose-gradients and allow for safer dose escalation. Indeed, a subgroup analysis of the high-dose arm of RTOG 0126 suggested that patients treated with IMRT had lower rates of acute (15% versus 10%, $p = 0.04$) and late (22% versus 15%, $p = 0.04$) grade 2 or higher genitourinary or gastrointestinal toxicity, likely related to improved dosimetry.[232] Efforts have also been made to reduce the doses to the penile bulb and the pudendal arteries to possibly minimize the rates of treatment-related erectile dysfunction, although conclusive dose-volume-toxicity relationships have not been validated.[233,234] In patients with high-risk of prostate cancer, when IMRT is used to treat the pelvic nodes along with the prostate and seminal vesicles, IMRT is helpful to reduce dose to the small bowel and bladder, in addition to the rectum.

Gastrointestinal Cancer

Pancreatic cancer has high rates of local and distant failure despite aggressive surgical resection. Traditionally, large volumes, including the primary tumor and potentially involved nodal basins, have been treated with radiotherapy, with concurrent moderately active chemotherapy. IMRT is helpful to minimize dose to large volumes of bowel and kidneys. Recently, many groups have advocated delivering escalated doses of radiotherapy to smaller volumes (only the gross tumor with PTV margin) with more potent chemotherapy (full dose gemcitabine), relying on the chemotherapy to sterilize microscopic disease. With dose-escalated radiotherapy, the sharp dose gradients achievable with IMRT are crucial to protect the adjacent duodenum. In both cases, IMRT improves sparing of the gastrointestinal structures including the duodenum, stomach, small bowel, colon, and liver, in addition to the kidneys.

IMRT is also crucial for treatment of anal cancer. Traditionally, patients have required treatment breaks because of severe perineal and inguinal desquamation. RTOG 0529 demonstrated that IMRT for anal cancer is feasible across institutions and resulted in lower dermatologic, gastrointestinal, and hematological toxicities compared with historic controls.[187] Additionally, with less than optimal local control of advanced tumors, dose escalation may also have a role in this disease.

Gynecologic Cancer

Most current studies of IMRT for gynecologic cancer aim at reducing the volume of small bowel irradiated during postoperative treatment. Escalating the dose to the GTV using IMRT as a replacement for brachytherapy has been proposed, but it is unlikely that escalated external beam doses can match the extremely high doses delivered safely by brachytherapy.[170] In recent years, there has been growing interest in the potential for IMRT to reduce dose to marrow-producing regions of bone to reduce hematologic toxicity. Recently, an analysis of RTOG 0418, a study of postoperative IMRT for gynecologic cancer, suggested that the volume of marrow receiving 40+ Gy and the median bone marrow dose correlated with higher rates of grade 2+ toxicity in patients receiving concurrent weekly cisplatin chemotherapy, thus justifying the use of IMRT for this purpose. Efforts to incorporate functional bone marrow sparing into treatment planning are under way.[235,236]

Pediatric Tumors

The rationale for highly conformal radiotherapy in pediatric tumors is to limit the high-dose volumes in growing and critical organs, especially the cochlea, brain parenchyma, brainstem, bowel, and bones. Although IMRT may achieve this goal better than 3D radiation therapy in some cases, it increases the volumes receiving low-dose radiation and the potential for future radiation-related cancers. This should be an important consideration, particularly since follow up of patients who received this type of dose-distribution is limited, and second malignancies can appear 10 to 20 years or more later. Only when an obvious benefit is expected should IMRT rather than simpler techniques be used in children. For example, in medulloblastoma, IMRT can reduce the dose delivered to the cochlea when a posterior fossa boost is planned with IMRT compared with parallel-opposed beams, but similar benefit may often be gained by the use of 3DCRT.[237] This requires thoughtful decision making from the physician and dosimetry-physics team.

Target and Organ Prescription: Dose Considerations

Standard 2D radiotherapy has typically been delivered in two or three phases. For a typical head and neck example, in the first phase radiation is delivered to all targets, including nodal and high-risk volumes. After a dose that is likely to eradicate subclinical disease is delivered (typically, 46 to 50 Gy), additional irradiation is delivered only to the high-risk targets, to a total of approximately 70 Gy. In this scheme, all of the targets receive the same daily dose of 1.8 to 2 Gy. In contrast, with IMRT, the most commonly used strategy is a single treatment plan with a simultaneous integrated boost (SIB) technique. High-risk targets receive both a higher total dose and a higher daily dose compared with the lower-risk targets, and compared with critical normal structures whose total maximal dose is limited to total doses that are lower than the prescribed target doses. Smaller daily doses reduce the biologic effect of the doses delivered to the critical organs (described by the normalized total dose [NTD]), so the SIB technique creates the situation in which the maximum critical organ doses usually allowed in standard radiotherapy become much more conservative when used with the SIB IMRT technique, if they are treated with lower doses per fraction. Conversely, doses above 2 Gy per fraction should be used with caution because this would deliver a higher biologic dose to normal tissues (e.g., mandible) adjacent to these targets. In addition, the maximum doses specified in IMRT or 3DCRT are delivered to smaller (or

much smaller) organ volumes compared with conventional radiotherapy. IMRT or highly conformal 3DCRT treatments may be safer than corresponding standard radiotherapy treatments even if nominal maximum critical organ doses are similar. On the other hand, higher-than-standard total target doses, delivered inadvertently as a result of nonuniform dose distributions typical of many IMRT plans, or resulting from intentional GTV dose escalation in an effort to increase tumor control rates, are associated with increased daily doses, causing a further increase of the NTD to the tumor. This has the potential to increase toxicity related to tissue embedded within the target. Such toxicity may only be apparent long after therapy and its prevalence is not yet known. Dose escalation relying on the ability of IMRT to restrict the high-dose volume to the GTVs should be conducted only within careful clinical trials. For clinical situations in which the range between the dose intended for microscopic and gross disease is large, two IMRT plans are generated to avoid both low (<1.5 Gy per fraction) or high (>2.5 Gy per fraction) daily doses, which would risk increased tumor recurrence and late toxicity rates, respectively. Consecutive IMRT plans are commonly used for prostate and sarcoma treatments.

When Should the Use of Highly Conformal Radiotherapy/Intensity-Modulated Radiation Therapy Be Considered?

Planning, delivery, and QA of 3DCRT/IMRT are more complex, costly, and work-intensive compared with these factors for previous technologies. The use of 3DCRT/IMRT is justified if it offers apparent clinical advantages. The advantage in the dose distributions achieved by IMRT compared with 3D radiation therapy is mainly in the ability to form concave, horseshoe-like dose distributions. Such distributions are desirable in cases in which the target partly encircles a critical involved structure whose tolerance is less than the desired target dose. This includes cases of head and neck cancers in which the targets are arranged anterior and lateral to the spinal cord and are bounded laterally by the major salivary glands; in prostate cancer, in which the prostate abuts the anterior rectal wall and sometimes extends slightly laterally as well, particularly in the postoperative setting; in lung cancer, in which the target (usually, the mediastinal lymph nodes) may lay close to the esophagus, or the primary tumor may be in close proximity to the spinal cord, brachial plexus, or heart; in gynecologic cancer, in which the lymph node targets are arranged lateral to and posterior to the small bowel; in left-sided breast cancer, in which the target is concave and anterior to part of the lung and heart; in brain tumors near the optic pathways; in medulloblastoma, in which the posterior fossa partly surrounds the inner ear; and in others. IMRT may also be indicated in cases in which minimizing the extent of the tissues receiving a high dose (at the expense of higher volumes receiving low doses) is likely to be beneficial, such as retreatment of recurrent cancer. On the other hand, it is less likely that a dosimetric benefit will be gained from IMRT in cases in which tumors are remote from sensitive tissues or are adjacent to a sensitive tissue but do not (partly) surround it, compared with simpler conformal techniques. Even when dosimetric differences between 3DCRT and IMRT are small, like in prostate cancer, where the anterior wall of the rectum can protrude somewhat into the posterior prostatic target, these differences still may be translated into a clinically meaningful benefit in reducing rectal complications by IMRT compared with 3DCRT.

Patient-related issues include the ability to tolerate treatment times that are longer than those required for less complex treatments, although more rapid methods, such as VMAT, are reducing this problem. Poor immobilization and breathing-related motion increase uncertainties regarding the accurate positions of the targets and adjacent normal tissue in the chest and abdomen and, to a lesser degree, in the pelvis. Daily changes in the shapes of organs such as the rectum and bladder may affect their spatial relationships with the prostate target. Because of the tight dose distributions produced by 3DCRT and IMRT, these uncertainties require the use of techniques that minimize, or take into account, target and OAR internal motion in most sites apart from the brain and head and neck. An additional concern is tumor shrinkage during therapy, which may also change the shape and relative position of adjacent organs. Whether these changes over the course of treatment require modifications of the treatment plans in most patients is the subject of current investigations.[238-240]

The high flexibility in creating desired dose distributions by IMRT or other highly conformal techniques provides the ability to deliver high doses to part of tumors judged to be at higher risk than other parts, as identified by functional imaging. Clinical accomplishment of this concept, termed "dose sculpting," or "dose painting" depends on the verification of the reproducibility and reliability of innovative imaging of tumor physiology and early tumor response prediction.

IMRT treatment plans are often characterized by nonhomogeneous dose distributions in the targets that produce "hot spots," receiving substantially more than the prescribed dose. It is imperative that these hot spots are confined to the GTVs, but as with SBRT, these high dose regions may be associated with higher tumor control. Still, the potential for increased local toxicity as a result of "hot spots" is not yet clear and may depend on the site irradiated; high doses delivered to the nasopharynx may be well tolerated, as attested by the common use of an intracavitary boost with radioactive sources for nasopharyngeal cancer, but may not be well tolerated by the mucosa in other sites in the head and neck. In any case, heterogeneous dose distributions by IMRT are not a necessity. By strictly limiting maximum doses, homogeneous dose distributions can be created, as for use in breast cancer. The decision of whether to deliver homogeneous dose belongs to the physician and planner, who can force more homogeneity by limiting maximum doses allowed by the optimization cost function.

Potentially Negative Aspects of Intensity-Modulated Radiation Therapy

Several potential negative aspects of IMRT exist, for which there is as yet no clinical validation. Although IMRT reduces the tissue volumes receiving high doses, larger tissue volumes receive low doses compared with standard radiation therapy or 3DCRT. This is primarily a result of the use of many beams, many MUs, and leakage through the MLC leaves. This characteristic may increase the risk of radiation therapy–related second malignancies because the risk of radiation therapy–related mutations and carcinogenesis increases at intermediate rather than at high doses and is also related to volume of irradiated tissues. This risk is especially relevant for young patients. As the risk of radiation therapy–related cancers increases over time, usually beyond 5 to 10 years after therapy, clinical data are not available at this time.

Another theoretical concern is the loss of biologic effect of radiation therapy when treatment delivery time is prolonged. Prolonged treatment delivery time is characteristic of some IMRT delivery techniques. There are differences in IMRT delivery modes that make a difference in this respect. For example, tomotherapy delivers sequential treatment throughout the target volumes, so that the exposure time of each tumor cell to daily radiation is short. In contrast, other systems irradiate all the targets simultaneously over a relatively prolonged daily

treatment time. Whether the prolonged fraction delivery time translates into a clinical difference is not known.

A last caution for clinics starting to implement IMRT and other highly conformal techniques is definition of all normal tissues of interest because with inverse planning, beam selection alone cannot limit dose to organs at risk, as often done in 3D planning. For example, if small bowel is not specifically contoured for abdominal or pelvic cases, with dose limits specified in optimization, dose may be the same if not higher with IMRT as compared with 3D, wasting the potential to reduce dose.

Future Efforts

To further improve the technical clinical contribution of IMRT to cancer therapy, additional steps need to be taken. They include better understanding of tumor and organ motion and changes during each treatment fraction and during the total course of therapy, and an improved ability to image the anatomic extent and metabolic activity of tumors. Detailed knowledge of the clinical dose-volume-response relationships for all tissues involved in irradiation, to be gained from careful clinical studies and analyses, will help lead to improved treatments using the tools provided by conformal therapy and IMRT planning and delivery.

CONCLUSION

Conformal therapy describes a general strategy for conforming the dose distribution to the desired target volume(s) while minimizing the dose to all normal tissues. Many different techniques can be used to accomplish this, ranging from multiple flat conformally shaped fields (3D conformal) to complex intensity modulated (IMRT) or VMAT plans. The key to high-quality conformal therapy is the accuracy and precision with which targets and normal tissues are defined, the treatment plan(s) are optimized, and the treatments are delivered using image-guidance methods (IGRT), so any technical improvement that enhances any of those capabilities will potentially improve the outcome of the therapy. Though conformal therapy has now been studied and used for as long as 20 years, the most important remaining task continues to be the clinical study of normal tissue complications and tumor control as a function of dose, volume, fractionation, and other factors, so radiation oncologists have the basic clinical data necessary to further improve the optimization of conformal therapy treatment.

CHAPTER

17 Intraoperative Irradiation

Brian G. Czito, Felipe A. Calvo, Michael G. Haddock, Manisha Palta, and Christopher G. Willett

Intraoperative radiation therapy (IORT) is the delivery of radiation at the time of surgery. The rationale is straightforward: increasing doses of radiation therapy enhance local tumor control. In many clinical situations, the dose delivered by external-beam radiation techniques is limited by tolerance of surrounding normal tissues. To overcome this, intraoperative irradiation has been employed as a technique facilitating tumor dose escalation. Recent Phase III trials have explored IORT, testing noninferiority or equivalence in patients with early breast cancer.[1,2]

This chapter reviews the rationale and treatment strategies of intraoperative electron irradiation (IOERT), intraoperative high-dose-rate brachytherapy (HDR-IORT), as well as orthovoltage techniques with surgery. These strategies frequently integrate external beam irradiation (EBRT) and chemotherapy.

HISTORY

The use of IORT was first employed almost 100 years ago.[3] The contemporary approach to IORT was initiated in the 1960s by Abe et al in Japan. These investigators advocated resection (where possible) with large, single dose radiation therapy (25 to 40 Gy using Cobalt-60).[4] In the mid- to late 1970s, many institutions in the United States had adopted IORT as a treatment approach, primarily as a radiation boost component, using linear accelerator-based electron treatment in the operating room, including Howard University, Massachusetts General Hospital (MGH), Mayo Clinic, and the National Cancer Institute (NCI). Presently, there are about 90 centers in at least 16 countries worldwide with active IORT programs.[5]

RATIONALE

IORT has the potential to improve local control and the therapeutic ratio in many tumor sites by reducing the volume of the irradiation "boost" field by direct tumor/tumor bed visualization and conformal treatment, exclusion of part or all of dose-limiting normal structures by operative mobilization, direct shielding, or varying electron beam energy, and allowing the delivery of high dose irradiation by the preceding methods.

Although early investigators studied this modality separately in the treatment of resected and unresectable malignancies, current approaches frequently employ this technique in combination with fractionated EBRT (with or without concomitant chemotherapy) and resection. The rationale is that EBRT fields encompass the primary tumor and surrounding tissues harboring potential microscopic disease. In contrast to a large single fraction of irradiation, fractionated radiation (EBRT) is radiobiologically advantageous in promoting tumor control while minimizing late normal tissue injury.

Shrinking field techniques permit dose escalation. This approach is used in many malignancies, including head and neck cancers, breast cancer, and cervical cancer with excellent local control and acceptable morbidity to dose limiting normal tissues. These "boost" fields can be delivered in a multitude of ways, including interstitial and intracavitary techniques as well as superficial electrons. For selected intraabdominal, pelvic, thoracic, and other malignancies, IORT is a technique for localized dose escalation while optimizing normal tissue protection.

BIOLOGY OF IORT

When EBRT is fractionated there is a preferential therapeutic advantage for normal tissues relative to tumor as defined by the 4R's of classical radiobiology (normal tissue repair, tumor reoxygenation, cell-cycle redistribution, and normal tissue repopulation). With a single large fraction of radiation therapy, these advantages are lost. In addition, large doses per fraction may result in increased risk of late effects. There is evidence that small vessel injury caused by large doses per fraction may contribute to late effects, and ischemic complications are dose dependent.[6] Furthermore, tumor response to single and fractionated radiation therapy depends on the percentage of hypoxic cells within a tumor. This differential sensitivity between hypoxic and well-oxygenated cells increases with increasing dose.

Using alpha/beta calculations (α/β), biologically equivalent doses to a fractionated EBRT course using 2 Gy per fraction for varying IORT doses have been estimated (Table 17-1). As shown, there are disadvantages from a late effects standpoint with IORT; however, many of these disadvantages are mitigated by exclusion of nontarget tissues from the radiation field by direct inspection, mobilization, and shielding.[7] When combined with EBRT and resection, IORT doses of 10 to 20 Gy provide local control for most solid tumors, especially in the setting of microscopic residual disease. When combined with EBRT and surgery, there is little reason to exceed IORT doses of 10 to 20 Gy. Late normal tissue complications are often the limiting sequelae of IORT administration, and careful planning and administration with techniques designed to reduce dose to nontarget tissues is of paramount importance. Experimental animal data and clinical studies have documented the tolerance of normal tissues to IOERT, EBRT, or both modalities combined, with detailed description of incidence and characteristics of reported observations and toxic events expected in the clinical practice scenario.[8]

LOCAL CONTROL: AN IMPORTANT ENDPOINT

For any treatment, a patient is incurable if local control of the tumor is not achieved. If conventional treatment methods of EBRT, chemotherapy, and surgery provided high local control rates, IORT as a component of treatment would be unnecessary. Single-dose irradiation with precise radiotherapy techniques has also emerged as a valid alternative in patients with metastatic disease[9] or as a potentially cost-effective technique for patients with tumors in early stages and with a favorable prognosis[10] tumors. Although local control rates are satisfactory in many tumor sites using conventional techniques, local failure is problematic in other sites, including abdominal and

TABLE 17-1 Estimated Biologically Equivalent EBRT Doses (2 Gy per Day) of Varying IORT Doses

IORT Dose	10 Gy	15 Gy	20 Gy
Normal tissue (acute) ($\alpha/\beta = 7$)	20 Gy	37 Gy	60 Gy
Tumor ($\alpha/\beta = 10$)	17 Gy	31 Gy	50 Gy
Normal tissue (late) ($\alpha/\beta = 2$)	30 Gy	65 Gy	120 Gy

pelvic malignancies. Treatment of these areas employing standard EBRT techniques is limited by normal tissue tolerance. Examples of such sites are discussed herein.

Pancreatic Cancer

EBRT with 5-fluorouracil (5-FU) based chemotherapy employed in the treatment of unresectable pancreatic cancer results in a doubling of median survival compared to surgical bypass/stenting alone (3 to 6 months versus 9 to 13 months) and an increase in 2-year survival from between 0% to 5% and 10% to 20%.[11] Unfortunately, these techniques result in poor local control rates (20% to 30%). The use of IORT has been evaluated in patients with both resectable and unresectable pancreatic cancer patients.

Retroperitoneal Sarcoma

When surgery is used as the primary treatment modality for retroperitoneal sarcomas, local failure has been reported to range from 40% to 90%. Despite the addition of EBRT to surgery, local failure rates are 40% to 80%. This is in contrast to extremity sarcomas where local control rates approach 90%. Because of the limited tolerance of surrounding normal tissue (small intestine, stomach, liver, kidney, spinal cord), EBRT doses are limited. A randomized NCI trial evaluating IORT in retroperitoneal sarcomas demonstrated that patients receiving IORT with EBRT experienced significantly improved local control and less small bowel toxicity versus patients treated with EBRT alone (80% in-field relapse; discussed later).[12]

Colon and Rectal Cancer

In patients with locally advanced (T4) or locally recurrent colon and rectal cancers, local control is difficult to achieve, despite multimodality therapy. Studies from Princess Margaret Hospital and Mayo Clinic report local failure rates of 90% or greater in evaluable patients treated with EBRT with or without systemic therapy.[13,14] In patients who are radiation naive, the optimal approach in locally advanced patients is preoperative EBRT combined with 5-FU-based chemotherapy followed by resection. Despite this, local recurrence occurs in 30% to 70% of patients.[15]

Cervical Cancer

For patients with cervical cancer, paraaortic nodal metastases are common. Despite the presence of these "distant" metastases, approximately 15% to 20% of patients are cured by radical radiotherapy techniques employing EBRT doses of 55 to 60 Gy. However, high complication rates have been reported with these doses and techniques.[16,17] As in rectal cancer, patients with recurrent cervical cancer in the pelvis or paraaortic region have a poor long-term prognosis with five-year overall survival (OS) rates ranging from 5% to 30%. These patients have often been previously irradiated and retreatment with meaningful doses of EBRT is usually not feasible given normal tissue tolerance. When patients have paraaortic or locally recurrent disease, administration of IORT is a feasible method to escalate dose and enhance local control.

Oligorecurrences: Miscellaneous Intraabdominal Sites

Active follow-up of patients with cancer initially treated for cure has identified new entities including oligometastatic or oligorecurrent disease still amenable to salvage treatment by combining surgical and radiotherapy components. Recent analyses of patient cohorts including varying cancer primaries and histological subtypes have reported local control rates of greater than 80% and 5-year survivals of 35% in patients with extrapelvic, oligotopic disease.[18] In the case of intrapelvic gynecological oligorecurrences, salvage therapy with extended surgery and IOERT has demonstrated a 10-year locoregional control of 58%, with improved results if EBRT treatment was integrated into this approach.[19]

LOCAL CONTROL: RADIATION DOSE, COMPLICATIONS, SHRINKING FIELD TECHNIQUES, AND DISTANT METASTASES

Influence of Dose

In both animal and human models, the probability of local control of a tumor by radiation is generally proportional to the total dose administered. The dose of radiation to control a tumor locally depends on several factors, including tumor type, clonogen number, and tumor microenvironment. Thus, a given radiation dose may be able to control a small tumor with high probability and acceptable morbidity; however, that same dose may be insufficient against disease of larger volume. Clinical experience has generated a body of data correlating local control by tumor type and radiation dose. Figure 17-1 summarizes in vivo data for a variety of irradiated human tumors of varying sizes and types.[20]

The studies of Fletcher examined local control probability as a function of radiation dose for patients undergoing treatment for breast carcinoma and squamous cell carcinoma of the upper aerodigestive tract (eTable 17-1). For patients with breast cancer, control of subclinical disease was approximately 60% to 70% with 30 to 35 Gy, 85% with 40 Gy, and 95% with 45 to 50 Gy. For larger/palpable tumors, EBRT doses of 46 Gy, 59 Gy, and 76 to 90 Gy result in a local control probability of 20%, 35% to 50%, and 70% to 80%, respectively.[21-24] Dose response data is summarized for patients with squamous cell carcinomas of the upper aerodigestive tract in eTable 17-2. These data suggest that marked improvements in local control can be achieved by escalating radiation doses.

Dose versus Complications

The chief limitation of EBRT to control macroscopic disease in the abdomen and pelvis is normal tissue tolerance. Normal organs such as stomach, small bowel, and kidney have tolerance levels well below the radiation doses required to eradicate most abdominal and pelvic malignancies. Exceeding these, EBRT doses results in prohibitive risk of late normal tissue damage (see eTable 17-2). Because of this, "conventional" tolerable doses of EBRT from 45 to 55 Gy using 1.8 to 2 Gy per fraction are not curative in most abdominal and pelvic malignancies, with resultant local persistence/local recurrence of disease common in patients treated with

eTABLE 17-1 Tumor Control Probability Correlated with Irradiation Dose and Volume of Cancer

Dose (Gy)	Tumor Control Probability
SQUAMOUS CELL CARCINOMA: UPPER AERODIGESTIVE TRACT	
50*	>90% subclinical ~60% T1 lesions of nasopharynx ~50% 1-cm to 3-cm neck nodes
60*	~90% T1 lesions of pharynx and larynx ~50% T3 and T4 lesions of tonsillar fossa ~90% 1-cm to 3-cm neck nodes ~70% 3-cm to 5-cm neck nodes
70*	~90% T2 lesions of tonsillar fossa and supraglottic larynx ~80% T3 and T4 lesions of tonsillar fossa
ADENOCARCINOMA OF THE BREAST	
50*	>90% subclinical
60*	90% clinically positive axillary nodes, 2.5-3 cm
70*	65% 2-3 cm primary
70-80 (8-9 wk)	30% >5 cm primary
80-90 (8-10 wk)	56% >5 cm primary
80-100 (10-12 wk)	75% 5-15 cm primary

radiation therapy alone. This often results in tumor-related morbidity and mortality such as bowel obstruction and perforation, ureteral obstruction, and neuropathy.

Although local control is enhanced with increasing doses of radiation, tumor dose response curves with EBRT closely resemble normal tissue complication curves. Therefore, efforts to improve local control through escalating EBRT doses may also result in treatment-related complications (Figure 17-2). In an R1 (microscopic residual) resection, EBRT doses of 60 Gy or higher using conventional fractionation schemes are necessary to achieve a high probability of local control. In an R2 (gross residual) resection, even higher doses are usually required. Such doses exceed normal tissue tolerance (see eTable 17-2).

Because of the risks associated with dose escalation beyond normal tissue tolerance, an attractive alternative in patients with locally advanced malignancies is to deliver moderate doses of EBRT (i.e., at or below accepted tolerance of surrounding normal tissue). A typical course would range from 45 to 50 Gy at 1.8 to 2 Gy per fraction, followed by surgical exploration. After resection, IORT would be performed, avoiding or minimizing irradiation of surrounding organs by shielding or mobilization. With this approach, an increase in local control with decreased risk of normal tissue complications (relative to an EBRT-only approach) can be achieved (see Figure 17-2—local control curve shifts to left with IORT; complication curve shifts to right with increasing EBRT doses).

Shrinking-Field (Boost) Techniques

The concept of shrinking-field irradiation, otherwise known as administering "boost" treatments, has been used for decades by radiation oncologists. This strategy entails treating larger fields encompassing the primary/recurrent tumor along with local-regional lymph node basins and other tissues at risk for subclinical disease. These larger fields receive a dose sufficient to control microscopic disease yet respect normal organ tolerance (often 45 to 50 Gy using 1.8 to 2 Gy per fraction). Fields are then reduced to encompass gross disease with smaller margins, excluding dose-limiting normal tissues. An additional 20 to 35 Gy may then be administered to these fields using either EBRT or brachytherapy techniques, bringing the cumulative dose to 65 to 80 Gy. These approaches are employed in many tumor sites including gynecologic and head and neck cancers with excellent long-term outcomes and local control with relatively low and acceptable morbidity levels. The concept of administering IORT in conjunction with EBRT is a logical application of this approach.

Local Control and Development of Distant Metastases

Preclinical data suggests that the incidence of distant metastases is related to both tumor size as well as the development of locally recurrent disease in multiple spontaneous tumor systems.[25-27] In fibrosarcoma and squamous cell carcinoma cell lines in rodent models, Ramsay et al reported increased rates of distant metastases in tumors measuring 6 mm versus 12 mm in size, as well as primary versus recurrent tumors.[25] Additionally, Suit et al showed that in mouse mammary tumors treated with single-dose irradiation, increasing rates of local failure were associated with increasing rates of distant metastases.[27] Specifically, the incidence of metastatic disease was 31% (16 of 52) of mice with local control, 50% (9 of 18) in those with local relapse salvaged by resection, and 80% (12 of 15) in mice with local relapse in whom salvage was not attempted. Similar high rates of metastases associated with local failure have been observed in human malignancies including cervix,[28] prostate,[29] head and neck,[30] and breast[31] cancers. These and other data suggest that metastases may arise from locally recurrent disease.

PATIENT SELECTION AND EVALUATION

Patient Selection Criteria

Candidates for IORT should be evaluated by the treating surgeon and radiation oncologist in the multidisciplinary setting. This allows for joint decisions regarding the appropriateness of IORT and whether further studies that may influence IORT and EBRT planning are appropriate. Additionally, joint decisions can be made defining the optimal sequencing

of surgery/IORT and EBRT. Informed consent should be obtained from both specialties, specifically with regard to potential risks, benefits, and side effects of proposed treatments. Criteria for the appropriate selection of patients for IORT generally include:

1. Surgery alone will result in a high probability of incomplete resection (microscopic or gross residual disease) and resultant high probability of failure within the tumor bed. Potential candidates must be appropriate for surgical attempts at gross total resection. IORT administration should be performed at the time of a planned operation.
2. There is no evidence of distant metastases. Rare exceptions include resectable single-organ metastasis, slow progression of systemic disease, excellent chemotherapy options, and patients with oligometastatic disease with slow systemic progression and high probability of symptomatic local failure.
3. EBRT doses required for high probability of local control following subtotal or no resection exceed normal tissue tolerance (Total doses required for eradication in this setting: 60 to 70 Gy for microscopic disease and 70 to 90 Gy for gross disease at 1.8 to 2 Gy per fraction)
4. Surgical displacement or shielding of dose-limiting structures or organs can be accomplished during IORT administration, allowing for acceptable risks of immediate and late effects. Theoretically, EBRT in conjunction with IORT should result in an improved therapeutic ratio between disease eradication and normal tissue complications.

Patient Evaluation

Pretreatment patient evaluation in patients eligible for IORT should include a thorough history and physical examination, with attention to palpable disease and its relationship to anatomically immobile normal structures. Examples include pelvic disease and its relationship to the pelvic sidewall, presacral space, prostate, or vagina. Computed tomography (CT), magnetic resonance imaging (MRI), and endoscopic ultrasound may aid in identifying adherence to structures (e.g., bony pelvis, large vessels) that may be surgically unresectable for cure. Examination under anesthesia may be helpful in some situations including locally advanced gynecologic and rectal cancers. Routine blood counts including complete blood count (CBC), liver function tests, renal function tests, and tumor-specific serum test (e.g., carcinoembryonic antigen, CA19-9) should be obtained where appropriate. Patients should be evaluated clinically and radiographically for evidence of distant spread. Positron emission tomography (PET), preferably in conjunction with CT, may facilitate defining local disease extent as well as unsuspected distant metastases. Evaluation of distant metastases is particularly important in the recurrent setting where concurrent distant failure is common. Biopsy confirmation of disease should usually be obtained before proceeding with resection.

SEQUENCING AND DOSE OF EBRT AND IORT

Sequencing of EBRT, IORT, and Surgery

For patients with localized malignancy, the goal of curative oncologic surgery is an R0 (margin-negative) resection. Because of the locally advanced and infiltrative nature of many primary tumors (including colorectal, gynecologic, and upper gastrointestinal [GI] malignancies, sarcomas, etc.) and locally recurrent malignancies, surgery may be compromised with close margins or microscopic/gross residual. For patients with locally advanced tumors, preoperative EBRT to doses of 45 to 50 Gy using 1.8 to 2 Gy fractions (with or without chemotherapy) followed by laparotomy, resection, and IORT offers theoretical and clinical advantages over resection and IORT followed by EBRT. These are listed as follows:

1. By postponing surgical resection until after preoperative therapy is completed, patients with disease that is rapidly progressive may avoid an unnecessary surgical procedure with associated morbidity.
2. Preoperative therapy may allow for tumor downstaging and facilitate resection with curative intent.
3. Preoperative therapy may reduce the risk of tumor seeding/dissemination at resection.
4. Preoperative therapy allows delivery of treatment to disease with an intact vasculature, potentially improving the delivery of chemotherapy and improving oxygen delivery for EBRT.
5. The morbidity and delayed recovery time associated with extensive surgical procedures may prevent the timely delivery of postoperative therapy in a high percentage of patients.[32,33]

The role of preoperative versus postoperative therapy has been evaluated in rectal cancer. A large German randomized trial demonstrated that patients undergoing neoadjuvant irradiation and chemotherapy experienced significantly improved local control and less toxicity than patients receiving postoperative irradiation and chemotherapy.[34]

Radiation Dose and Technique

Techniques combining EBRT and IORT have been fairly uniform in the United States and Europe. In previously untreated patients, EBRT doses of 45 to 54 Gy have been employed delivering 1.8 to 2 Gy per fraction, 5 days per week, over a period of 5 to 6 weeks. Because of the anatomical location of pelvic and abdominal malignancies, high-energy (>10 MV) photons delivered via linear accelerators using multifield, shaped techniques are required. CT-, PET-, or MRI-based treatment planning permit accurate definition of the target volume. For extrapelvic, unresected or residual disease following resection, radiation doses of 40 to 45 Gy delivered at 1.8 to 2 Gy per fraction with a 3- to 5-cm margin accounting for microscopic extension and target mobility are sometimes used. Treatments are generally delivered through multifield techniques aided by three-dimensional (3D) or IMRT-based treatment planning. Reduced-field or "boost" techniques are often used to bring the total dose to 45 to 54 Gy as dictated by tolerance of surrounding normal tissue (see previous discussion). Concurrent chemotherapy administration during EBRT varies by tumor site; for patients with gastrointestinal malignancies, concurrent 5-FU–based regimens (plus cisplatin or mitomycin C) are frequently implemented, and for patients with gynecologic cancers, concurrent cisplatin is frequently given. In carefully selected patients who have received prior irradiation, low-dose preoperative EBRT doses of 20 to 30 Gy at 1.5 to 1.8 Gy per fraction (often with concurrent chemotherapy) may be employed.

Dose of IORT

IORT dose should be based on extent of residual disease at resection, the amount of EBRT delivered previously, and the type and volume of normal tissue irradiated. For patients who have received preoperative doses of 45 to 54 Gy (1.8 to 2 Gy per fraction, 5 days per week), IORT doses usually range from 10 to 20 Gy. For patients with microscopic residual or close margins, doses of 10 to 12.5 Gy are often administered. Patients with gross residual disease require higher doses and 15 to 20 Gy is usually administered. In previously irradiated

patients, in whom additional EBRT is feasible (20 to 30 Gy), the dose of IORT generally ranges between 15 Gy and 20 Gy. In patients in whom no or very limited EBRT is planned, IORT doses from 25 to 30 Gy have been administered; however, doses in this range should be judiciously employed given the risk of normal tissue damage, specifically peripheral nerve injury.

The biological effectiveness of single-dose IORT in early responding tissues (tumor) relative to an equivalent total dose of fractionated EBRT has been estimated to be 1.5 to 2.5 times the IORT dose delivered (Table 17-1).[7,35,36] Therefore, the effective tumor dose (when "normalized" to fractionated EBRT doses) of IORT treatment added to 45 to 50 Gy given by EBRT are as follows: 10 Gy IORT dose, 60 to 80 Gy; 15 Gy IORT dose, 75 to 87.5 Gy; 20 Gy IORT dose, 85 to 100 Gy. These figures are not intended to be exact but represent educated estimates.

Technical Aspects

The technical aspects of IORT administration are beyond the scope of this chapter and have been discussed in other publications (see reference list). In brief, the implementation of IORT-based treatment is a multidisciplinary effort including one or multiple surgeons, radiation oncologist, anesthesiologist, operating room nurse, radiation physicist/dosimetrist, and therapist. In its broadest sense, IORT may be administered with either electrons (IOERT) or HDR photon afterloading techniques (HDR-IORT). Each method has potential advantages and disadvantages, which are summarized later.

IORT DOSE-LIMITING STRUCTURES AND TOLERANCE

The development of normal tissue late effects increases with increasing radiation dose as well as dose delivered per fraction. Therefore, the incidence of late normal tissue effects in patients receiving IORT plus EBRT would be higher than those receiving EBRT alone.[37] However, in this context the severe morbidity and mortality associated with locally recurrent tumor is often overlooked. As an example, when EBRT alone is used as the primary treatment modality for locally advanced rectal cancer, more than 90% of patients experience local persistence or local recurrence of disease with associated symptomatology. These symptoms include severe pelvic pain and neuropathy, which are difficult to manage clinically and the vast majority of patients experience disease-related death within two to three years. An argument can be made that the tumor-related morbidity/mortality approaches 100% in these patients.[38]

IORT tolerance for intact or surgically manipulated organs or structures in animals (primarily canines) is seen in Table 17-2. Much of this information has been derived from studies from the NCI[39-44] and Colorado State University (CSU).[45-47]

Several dose-sensitive structures have been studied in humans receiving IORT, including the ureter and peripheral nerve. These are discussed next.

Ureter

Clinical studies of the effect of IOERT on the ureters of patients with cancer have been undertaken at the Mayo Clinic. Doses

TABLE 17-2 Normal Tissue Tolerance to Intraoperative Electron Irradiation in Animals (Usually Dogs)

Tissue	Maximum Tolerated Dose (Gy)	Tissue Effect	Dose (Gy)
INTACT STRUCTURE			
Aorta, vena cava	50	Fibrosis of wall (patency up to 50 Gy)	≥30

Bladder	30	Healing but contraction	≥30
Bronchial stump	>40	Absence of air leak	>40

of 10 Gy administered intraoperatively resulted in a 50% incidence of ureteral obstruction, increasing to 70% with doses from 15 to 25 Gy. This high complication rate relative to canine models may be as a result of age-related factors, surgical manipulation, EBRT, or tumor bed effects.[48]

In an update of this experience, investigators from the Mayo Clinic reported on 146 patients with locally advanced malignancies receiving IORT to one or both ureters of doses between 7.5 Gy and 30 Gy. They reported the risk of obstruction following IOERT is significant and increases with time and IORT dose. The rates of clinically apparent type 1 obstruction (obstruction from any cause) after IOERT at 2, 5, and 10 years were 47%, 63%, and 79%, respectively. The rates of clinically apparent type 2 obstruction (obstruction occurring at least 1 month after IOERT, excluding obstruction caused by tumor or abscess and patients with stents) at 2, 5, and 10 years were 27%, 47%, and 70%, respectively. Multivariate analysis revealed that the presence of obstruction before IOERT was associated with an increased risk of clinically apparent type 1 obstruction ($p < 0.001$). Increasing IOERT dose was associated with an increased risk of clinically apparent type 2 obstruction ($p < 0.04$). Obstruction rates in ureters not receiving IOERT at 2, 5, and 10 years were 19%, 19%, and 51%, respectively, suggesting an underlying risk. However, obstruction risk for ureters not receiving IOERT was also high, which suggests an underlying risk of ureteral injury from other causes (EBRT, surgical manipulation of ureters).[49]

Peripheral Nerve

Peripheral nerve is the principal dose-limiting normal tissue for IORT in the pelvis and retroperitoneum. Data regarding peripheral nerve tolerance and neuropathy comes from canine models as well as clinical analyses from patients treated intraoperatively.[40,43,45,48,50-60] Peripheral nerve is often situated adjacent to or directly involved by tumor in the abdomen and pelvis. Because of this, the relative surgical "immobility" of peripheral nerves and inability to shield the nerve from the IORT field, nerve tissue will often receive full dose EBRT and IORT.

The mechanism of neuropathy following IORT is poorly understood. Peripheral nerve tolerance depends on the volume of nerve irradiated and total dose delivered. In animal models, histomorphologic findings following IORT have demonstrated decreased central nerve fiber density, particularly in large nerve fibers receiving >20 Gy. Electron microscopy analysis has demonstrated increased microtubule density and neurofilament accumulation within axons without associated myelin changes, suggesting possible hypoxic injury related to vascular changes.[60]

A Spanish study evaluated 45 patients with primary or locally recurrent extremity soft-tissue sarcoma undergoing resection with IOERT (10 to 20 Gy). Nine patients received IOERT alone secondary to prior EBRT or patient refusal. Five patients developed neurotoxicity at a median of 13 months; 4 of 5 showed objective weakness or sensory loss. Most patients developing neuropathy received IOERT doses greater than 15 Gy.[61]

An analysis from the Mayo Clinic evaluated peripheral nerve tolerance in 51 patients undergoing IOERT for primary or recurrent pelvic malignancies. Patients received EBRT (median dose 50.4 Gy), maximal resection where possible, and IOERT boost from 10 to 25 Gy using 9 MeV to 18 MeV electrons. Sixteen patients (32%) experienced grades 1 to 3 peripheral neuropathy as manifested by pelvic/extremity pain, leg weakness, numbness, or tingling. Pain was severe (grade 3) in 3/51 patients (6%)[48] (eTable 17-3).

A follow-up study from the Mayo Clinic evaluated 178 patients with locally advanced colorectal cancer receiving IOERT. This study suggested a relationship between increasing doses of IOERT and the incidence of clinically significant neuropathy (Table 17-3). In patients with primary and locally recurrent colorectal cancer, the incidence of severe (grade 3) neuropathy was approximately 5%, and the incidence of any neuropathy was approximately one third. This is consistent with canine studies suggesting increasing IOERT doses are related to the incidence of clinical and electrophysiologic neuropathy.[51,52]

TABLE 17-3 Colorectal IOERT, Mayo Clinic IOERT Dose versus Neuropathy

Disease Presentation	IOERT Dose versus Grade 2 or 3 Neuropathy ≤12.5 Gy	≥15 Gy	*p*
Primary[52*]	1/29 (3%)	6/28 (21%)	0.03
Recurrent, no prior EBRT[51†]	2/29 (7%)	19/101 (19%)	0.12

EBRT, *External beam irradiation;* IOERT, *intraoperative electron irradiation.*
**57 IOERT fields in 55 evaluable patients. Incidence of grade 3 neuropathy by dose: ≤12.5 Gy, 0 of 9; 15 Gy or 17.5 Gy, 1 of 19, or 5%; ≥20 Gy, 2 of 9, or 22%.*
†130 IOERT fields in 123 patients.

A more recent Mayo Clinic analysis of 607 patients with locally recurrent colorectal cancer receiving IORT reported an incidence of grades 1 to 3 neuropathy of 15% (grade 1, 5%; grade 2, 7%; grade 3, 3%). A dose-related increase in grades 2 and 3 neuropathy was seen in patients receiving ≥15 Gy compared to ≤12.5 Gy.[53]

Conclusions

All patients considered for IORT should undergo thorough pretreatment informed consent, including a discussion regarding neuropathy-related side effects. It should also be remembered that uncontrolled tumor frequently causes symptoms related to neural impingement, and in fact many potential IORT candidates present with neuropathic symptoms related caused by primary or recurrent disease. Based on human and animal data evaluating IORT induced neuropathy, IORT doses are generally limited to 10 to 20 Gy when a full course of EBRT is administered (45 to 54 Gy using 1.8 to 2 Gy per fraction). Doses exceeding 20 Gy in the intraoperative setting should be used with caution, and our general policy regarding such is to administer higher doses only in the setting of limited EBRT options (i.e., prior EBRT treatment).

IORT RESULTS FOR SELECTED DISEASE SITES

A summary of IORT results and future possibilities in selected disease site (pancreas, breast, colorectal, gynecologic cancers, and retroperitoneal/pelvic sarcomas) are now presented. For a more detailed discussion, the reader is referred to dedicated chapters on each site in an IORT text.[64]

Pancreas Cancer: EBRT and IORT

Given local failure rates of 50% to 80%, the use of IORT in the setting of pancreatic cancer is rational. Available data in patients receiving IORT after pancreaticoduodenectomy

demonstrates an improvement in local control; however, a clear survival benefit has not been demonstrated. Series of patients with locally advanced pancreatic cancer suggest local control and pain relief, with select studies demonstrating an OS benefit.

IORT in Resected Disease

In the United States, initial feasibility of IORT in conjunction with surgery was demonstrated at the NCI. Thereafter, the NCI reported a series evaluating 24 further patients randomized to receive IORT (20 Gy) versus EBRT. After excluding 7 perioperative deaths, an improvement in local control (67% versus 0%) and median survival (median OS 18 versus 12 months, $p = 0.01$) was seen in the patients who received IORT.[65]

Further data on IORT at the time of surgery are limited to single and multiinstitutional retrospective series (Table 17-4A). The largest of the single institution series evaluated 127 patients treated with surgery and IORT compared to a cohort of 26 patients who underwent surgery alone. No additional operative morbidity or mortality was seen with the addition of IORT; however, for patients with Stage I/II disease IORT resulted in lower rates of local failure and significantly longer time to local failure, time to failure, and OS compared to surgery alone. These data suggest possible local control benefit with the use of IORT after resection in select patients.[63]

These data are corroborated by two multiinstitutional series. A Japanese series evaluated 210 patients undergoing surgery and IORT with and without EBRT. Median IORT and EBRT doses were 25 Gy and 45 Gy, respectively. Seventy-one percent of patients experienced disease relapse with local failure occurring in 15% of patients. Median and 2-year OS were 19.1 months and 42%, respectively. The combination of IORT and chemotherapy resulted in improved survival compared to IORT alone. The authors concluded that IORT yields excellent local control rates for pancreatic cancer with a low incidence of toxicity, and IORT combined with chemotherapy confers a survival benefit compared to IORT alone.[62]

A European multiinstitutional series evaluated 270 patients treated at five institutions between 1985 and 2006.[69] Neoadjuvant EBRT or concurrent chemoradiation (CRT) was delivered in 24% of cases and median IORT dose was 15 Gy (range 7.5 to 25 Gy). Significantly better local control was seen in patients undergoing preoperative radiation therapy (RT) with a median time to local relapse not reached and median OS of 30 months compared to 22 months with postoperative EBRT or CRT and 13 months with IORT alone. The authors concluded preoperative EBRT increases the effect of IORT in terms of local control and survival, with favorable long-term local control rates.[69] Compared to historical controls, these low rates of local failure and reasonable median survival reflect the possible benefit of IORT in patients with resected pancreatic cancer.

IORT in Locally Unresectable Disease

The role of IORT has been more clearly defined in the treatment of patients with locally unresectable pancreatic cancer. Many studies have documented both safety and pain control with IORT, resulting in complete pain resolution in 75% to 90% of cases.[72] Table 17-4B shows outcomes of select series using IORT in locally unresectable pancreatic cancer patients.

A study from Mayo Clinic evaluated 159 patients with locally unresectable pancreatic cancer who underwent exploratory laparotomy; 122 had postoperative EBRT alone or plus concurrent 5-FU and 37 received an IOERT boost followed by EBRT alone or plus 5-FU. One-year local control (LC) with the combination of EBRT and IORT was 82% compared to 48% with EBRT alone (2-year LC was 66 versus 20%, $p = 0.0005$).

Despite a benefit in LC, there was no difference in median or long-term survival between the groups because of the high incidence of liver or peritoneal relapse in both groups (>50%).[73]

A Japanese study evaluated the use of IORT in the treatment of 115 patients with locally unresectable pancreatic cancer. Patients received either a combination of EBRT and IORT, EBRT alone, or IORT alone. In the subgroup of patients with a CA19-9 <1000, the combination of EBRT and IORT produced superior survival compared to EBRT alone.[74]

Investigators at MGH initially published early results of the use of IORT (15 to 20 Gy) in patients with locally unresectable pancreatic cancer.[80] Updated publication of 194 consecutive MGH patients with locally unresectable cancer demonstrated a median survival of 12 months and long-term survival in 6 patients. Patients treated with a smaller diameter applicator, a surrogate for smaller tumor size, had superior survival rates and the only long-term survivors were within the smaller applicator diameter cohort. On multivariate analysis small applicator size, low comorbidity index, and receipt of chemotherapy predicted improved OS.[76,77]

Two retrospective studies from the Thomas Jefferson University Hospital (TJUH) evaluated the use of IORT in patients with locally unresectable primary disease. In the initial TJUH series, 49 patients were treated with IORT and perioperative chemotherapy followed by concurrent CRT. Median survival was 16 months with a 4 year OS of 7%.[78] In a follow up series from TJUH, 105 patients received multimodality therapy including surgery, chemotherapy, and radiation therapy. Patients were subdivided into three groups: IORT via electrons (IOERT), IORT with Iodine 125 implant, and no IORT. Median OS in the group receiving IOERT was 18 months with 2-year LC of 70%.[79] The median and long-term survival results from these IORT series are significantly longer than outcomes seen in other studies evaluating patients with locally advanced pancreatic cancer treated with conventional combined modality approaches.

Future Possibilities

Although slight gains in survival may be achieved by improving LC in patients with pancreatic cancer, the high rate of distant metastases limits significant improvements in long-term survival by IORT approaches. Given the high incidence of failure in the peritoneal cavity and liver, pilot studies are evaluating novel combinations of systemic agents in the treatment of this disease, including "targeted" agents as well as novel combinations of more traditional chemotherapeutics.

Breast Cancer

IORT Alone

Randomized trials have demonstrated equivalent disease-free survival (DFS) and OS in selected patients with breast cancer undergoing either mastectomy or breast-conserving surgery followed by EBRT.[81] Local recurrences frequently occur at or adjacent to the original tumor bed following breast-conserving surgery. There is increasing interest in the use of IORT as a supplement to or alternative to EBRT in selected cases in both Europe and the United States.[82-92]

Phase III Trials

The Italian ELIOT trial of 1305 patients was a randomized Phase III trial comparing 21 Gy IOERT versus standard EBRT whole-breast/boost therapy.[83] IOERT was delivered with a mobile linear accelerator (the NOVAC 7) while shielding the thoracic wall with a lead plate. Women aged 48 to 75 years with early breast cancer, a maximum tumor diameter of up to 2.5 cm, and suitable for breast-conserving surgery were randomly assigned to the two treatment arms. This was an equivalence trial with a primary endpoint of ipsilateral breast tumor recurrence (IBTR). After a median follow-up of 5.8 years, 35 patients in the IOERT group and 4 patients in the EBRT group had experienced an IBTR ($p < 0.0001$). The 5-year outcomes for the IOERT compared to EBRT arms included an IBTR rate of 4.4% compared to 0.4% (hazard ratio 9·3 [95% confidence interval, 3.3 to 26.3]) and 5-year OS of 96.8% compared with 96.9%. Significantly fewer skin side effects occurred in women in the IOERT than in the EBRT arms ($p = 0.0002$). The authors concluded the rate of IBTR was significantly greater with IOERT than with EBRT, and OS did not differ between groups, while improved selection of patients could reduce the rate of IBTR with IOERT.[93]

An approach of targeted IORT using the INTRABEAM system (TARGIT) implements a 50 kV x-ray generator mounted on a flexible floor stand with a set of spherical applicators ranging from 1.5 cm to 5 cm in diameter (eFigure 17-1) Radiotherapy is delivered to the tumor bed by placing the applicator within the tumor cavity and conforming the adjacent breast tissues around the applicator before treatment. A potential disadvantage of this approach is that low-energy x-rays could potentially lead to underdosing of residual tumor cells removed from the tumor cavity.

In an international phase III TARGIT-A trial, patients were randomized to IORT alone (n = 1721) or a typical course of EBRT (n = 1730). If resected patients were at high risk of local recurrence in other quadrants (extensive intraductal component, extensive lymphovascular invasion, nodal metastases, etc.) then EBRT could be delivered postoperatively. Supplemental EBRT after TARGIT was necessary in 15.2% of patients who received TARGIT. Median follow-up for 3451 patients was nearly 2.5 years and 1222 had median follow-up of 5 years. The 5-year risk for local recurrence in the conserved breast was 3.3% for TARGIT versus 1.3% for EBRT (p = 0.042). Overall, breast cancer mortality was similar between groups (2.6% for TARGIT versus 1.9% for EBRT; p = 0.56), but there were significantly fewer deaths related to breast cancer with TARGIT (1.4% versus 3.5%; p = 0.0086), attributable to fewer deaths from cardiovascular causes and other cancers. Overall mortality was 3.9% for TARGIT versus 5.3% for EBRT (p = 0.099). Wound-related complications were similar but grade 3 or 4 skin complications were significantly reduced with TARGIT (4 of 1720 versus 13 of 1731, p = 0.029). The authors concluded TARGIT concurrent with lumpectomy within a risk-adapted approach should be considered as an option for carefully selected, eligible patients with breast cancer as an alternative to postoperative EBRT.[94] Late toxicity data was available in 305 patients with significantly fewer telangiectasias in the IORT arm.[95]

In summary, randomized trials to date show that IORT alone may result in slightly higher rates of ipsilateral breast cancer recurrence when compared to adjuvant EBRT techniques and that careful patient selection when using this approach is warranted.

Phase II Trials

Extensive Phase II data from single or multiinstitutional IORT alone series is also available. Series design and outcomes can be found on the Expert Consult website.[85,88,96,97]

IORT Plus EBRT

In the Medical College of Ohio and Centre Regional de Lutte Contre le Cancer (France) combined series, 72 patients with early stage breast cancer underwent lumpectomy with axillary lymph node dissection followed by 10 to 15 Gy IOERT using 6 MeV to 20 MeV electrons. Patients later received EBRT doses of 45 to 50 Gy at 1.8 to 2 Gy per fraction. No significant complications were observed and cosmetic results were described as excellent. Eight of 72 patients developed minor palpable fibrosis at the lumpectomy site. At a minimum two-year follow-up in all patients, no patients had experienced local relapse.[90]

The University of Salzburg investigators used IOERT combined with EBRT in 351 consecutive patients from October 1998 to April 2002 and reported their results in the initial 170 patients treated through December 2000.[91] LC results were compared to patients treated with EBRT alone. At the time of publication, 3-year LC with an IOERT compared to EBRT boost was 100% to ~97%.

The University of Heidelberg reported a preliminary experience in 155 patients with breast cancer using a 20 Gy orthovoltage IORT boost followed by EBRT in women with T1-T2 breast cancers. The 5-year local relapse-free survival was 98.5% at a median follow up of 34 months. Grade 3 fibrosis of the tumor bed was found in 5% of patients at 3 years.[92]

A European pooled analysis by Sedlmayer et al evaluated 1200 patients with limited breast cancer resection plus IOERT (median dose 9.7 Gy, range 5 to 17 Gy) followed by whole-breast EBRT using standard fractionation. Patients undergoing immediate secondary mastectomy as a result of extensive margin involvement were excluded. At median follow up of 59.6 months, local tumor control was 99.3%. The authors concluded IOERT boost during breast-conservation therapy results in optimal dose delivery and outstanding LC rates.[98,99] The most recent update of this experience with long-term follow-up (72.4 months median follow-up) reported a 99.2% local tumor control with an annual in-breast recurrence rate of 0.64%, 0.34%, 0.21%, and 0.16% in patients younger than 40 years, 40 to 49 years, 50 to 59 years, and older than 60 years, respectively.[100]

Early results of the TARGIT trial using IORT as boost therapy reported 183 patients treated with the INTRABEAM system of 5 Gy or 7.5 Gy followed by EBRT. At a median follow up of 16 months, actuarial 2-year LC was 99% with serious complications (including fistula, wound dehiscence, and ulceration) occurring in 11% of patients.[87] In summary, the available data suggest that IORT used as a boost technique with EBRT results in low rates of ipsilateral breast tumor recurrence.

Future Possibilities

Multiple Phase II or III trials evaluating adjuvant IORT continue to actively accrue patients in the United States, Europe, United Kingdom, and Australia. These trials use varying IORT techniques including 50 kV photons as well as low-energy electrons. Identification of patients appropriate for breast IORT remains an area of investigation. Long-term results from these and other trials will be necessary to demonstrate ultimate local recurrence, late effect, and survival data with these approaches.

Retroperitoneal and Pelvic Soft-Tissue Sarcomas

NCI Randomized Phase III Trial

The NCI conducted a randomized Phase III trial in patients undergoing surgical resection of primary retroperitoneal sarcoma. All patients underwent gross total resection, although most had microscopically involved margins. Patients were randomized to receive 20 Gy IOERT followed by 35 to 40 Gy of EBRT postoperatively versus postoperative EBRT alone to a dose of 50 to 55 Gy. Patients receiving IOERT were treated with concurrent misonidazole given 15 to 30 minutes pretreatment. EBRT treatments were delivered over 4 to 5 weeks at 1.5 to 1.8 Gy per fraction in both arms; however, patients receiving EBRT only received an additional 15 Gy using similar fractionation by reduced fields. The incidence of in-field local-regional recurrence was significantly lower among patients receiving IOERT compared to patients receiving EBRT only (3/15 versus 16/20, $p < 0.001$). Patients receiving IOERT experienced fewer episodes of radiation enteritis than EBRT alone patients (2/15 versus 10/20, $p < 0.05$); however, radiation-related peripheral neuropathy was more frequent in patients receiving IOERT (9/15 versus 1/20, $p < 0.01$).[12]

Mayo Clinic Experience

Investigators at Mayo Clinic Rochester reported on 87 patients with primary or recurrent retroperitoneal or intrapelvic sarcomas receiving IOERT as a component of treatment.[101]

eFigure 17-1 The INTRABEAM system for IORT of breast cancer. This consists of a 50-kV x-ray generator mounted on a flexible floor stand and a set of applicators ranging from 1.5 to 5 cm in diameter.
Figure used with permission-PENDING.

A preliminary report from the Italian Collaborative Breast IOERT Group described a multicenter trial comparing IOERT alone following lumpectomy to conventional fraction EBRT in tumors less than 3 cm with negative margins. IORT patients received a single 21-Gy fraction using 6 MeV to 9 MeV electrons. Of 314 evaluable patients, no local recurrence was detected in either treatment group at a median follow-up of 31 months, although a significant difference in the incidence of grades 1 to 2 late toxicity was seen in favor of the IORT group (3% versus 63%).[84]

A systematic review of seven published IORT alone series in early breast cancer suggested that short-term LC, DFS, and OS were similar to reported EBRT series. Local recurrence rates ranged from 0% to 29% with IORT. However, many of these small, single institution studies had short follow-up (median, 2 years).[85]

Veronesi et al reported on 237 patients with primary tumors ≤2 cm undergoing wide excision with either sentinel lymph node biopsy or axillary lymph node dissection. Patients received IOERT using 3 MeV to 9 MeV electrons with doses of 17 to 21 Gy (>90% received 21 Gy as the prescribed dose). At a median follow-up of 19 months, the rate of posttreatment complications was low, with 1.7% developing breast fibrosis. A follow-up report from this group of 574 patients revealed 3 patients with local recurrence and 3 additional patients with ipsilateral recurrence in other quadrants at median follow-up of 20 months.[88] A similar report by Veronesi et al of 1822 patients treated with the ELIOT strategy, but outside of a randomized trial, showed that after a mean follow-up of 36 months, the incidence of local recurrence was 2.3% and new primary ipsilateral carcinomas was 1.3%.[96]

Another report of long-term side effects and cosmetic results has been analyzed in 119 patients selected randomly selected from 1200 cases. After a median follow-up of 71 months, grade 2 fibrosis was observed in 31.9% of patients and grade 3 in 5.9% of patients. Physicians and patients scored cosmesis as excellent or good in 84% and 77% of cases, respectively.[97]

The addition of boost treatment following lumpectomy and conventional EBRT has been shown to reduce local recurrence rates by 50% in all age groups versus EBRT alone.[89] Potential advantages of an IORT boost compared to EBRT boost are as follows: more precise delivery of irradiation to the tumor bed, skin sparing with avoidance of associated late cosmetic sequelae, and a smaller boost area with a more homogeneous dose distribution.

Seventy-seven patients received EBRT (53 preoperatively, 12 postoperatively, and 12 both) to a median dose of 48 Gy, usually through a shrinking field technique. Fifteen patients (17%) had gross residual disease following resection, 56 (64%) microscopic residual, and 16 (18%) either negative margins or no residual disease. Median IOERT dose was 15 Gy (range 9 to 30 Gy). Five-year OS was 47%. Patients with tumors >10 cm experienced a significantly worse survival compared to smaller lesions (5-year OS 28% versus 60%, $p = 0.01$) and patients with gross residual disease following resection experienced worse 5-year survival versus gross totally resected patients (37 versus 52%, $p = 0.08$). Five-year LC rates in patients with gross, microscopic and no residual tumor were 37%, 57%, and 100%, respectively. Factors influencing 5-year LC and survival for patients with primary disease are shown in Table 17-5 and eTable 17-4. Patients with R0 or R1 resection experienced significantly improved LC and those with tumors greater than 10 cm were less likely to be long-term survivors.[101]

A further update of the Mayo Clinic reported on 226 IORT patients (52% primary) treated from 1981 to 2008.[102] Most (63%) had high-grade tumors and 36 (16%) had received prior EBRT. In previously unirradiated patients, EBRT was delivered preoperatively in 70% of patients, postoperatively in 10%, and both in 10%. R0 and R1 resection was achieved in 39% and 50% of patients, respectively. Median IORT dose was 12.5 Gy. Five-year OS was 50% (R0 resection, 52%; R1, 55%; R2, 28%). For the entire population, 5-year local failure was 29% (R0, 18%; R1, 31%; R2, 61%), with distant metastases developing in 42% of patients. Central failure in the IORT field occurred in only 10% of patients. The authors concluded that: (1) patients with retroperitoneal sarcoma undergoing gross total resection experience improved LC relative to subtotal resection when treated with combined modality treatment including IORT; (2) improved outcomes were seen in patients with primary versus recurrent disease; and (3) the high rates of distant relapse suggest more effective systemic therapy is needed for patients with high-grade disease.

Massachusetts General Hospital Experience

Investigators from MGH described 37 patients with primary or recurrent retroperitoneal sarcoma who underwent EBRT (median dose, 45 Gy) and resection. Twenty patients received IOERT (10 to 20 Gy). In twenty-nine (78%) patients receiving gross total resection and IOERT, 5-year survival and LC rates were 74% and 83%, respectively. In comparison, 13 patients undergoing gross total resection without IOERT had 5-year survival and LC rates of 30% and 61%, respectively. Four patients receiving IOERT experienced significant complications including neuropathy, hydronephrosis, and fistula formation.[103]

A subsequent report from MGH described 103 patients with primary retroperitoneal sarcoma, 62 of who underwent gross total resection. In this group, patients with high-grade disease or involved margins received EBRT with or without IOERT, particularly when a localized area of close margin of residual tumor was identified. This study again demonstrated a trend for IORT to further improve survival versus EBRT alone with significant increased time to both local and distant relapse. In patients who were completely resected, a trend toward improved survival with IOERT was seen compared to EBRT alone (5-year OS of 77% versus 45%, $p = 0.13$).[104]

Pooled European Analysis

A pooled European analysis described 122 curatively approached patients (81 recurrent) with retroperitoneal sarcoma undergoing maximum resection plus IOERT (median dose 15 Gy). Most received adjuvant EBRT. Five-year OS, DFS, LC, and freedom from metastatic disease rates were 64%, 28%, 40%, and 50%, respectively. Five-year LC within the IOERT field was 72%. In patients receiving IOERT, EBRT, and R0 resection, 5- and 10-year OS were 80% and 5- and 10-year LC were 100%. Only 5% of patients experienced an in IOERT-field relapse after R0 resection, 23% after R1 resection, and 75% after R2 resection. Late complications ≥grade 2 were seen in 21% of patients. The authors concluded that in selected patients, IOERT resulted in excellent LC and survival with accepted morbidity.[105]

Conclusions and Future Possibilities

IORT combined with EBRT and resection offers an effective means of improving LC in patients with primary and recurrent retroperitoneal sarcomas, as demonstrated in a randomized trial from the NCI as well as multiple U.S. and European single-institution studies.[101-108] A randomized NCI trial showed an 80% tumor bed relapse rate with adjuvant EBRT alone, likely as a result of an inability to deliver effective EBRT doses given normal tissue constraints. Because these results are similar to reports of resection alone, the use of adjuvant EBRT without IORT following marginal resection could be questioned. A more practical approach would be to administer preoperative EBRT following confirmation of diagnosis by thin-needle biopsy. This would be followed by resection at an institution with IORT capabilities.

Even with improved LC rates, locoregional and distant failure remains common modes of failure, emphasizing the need for improved therapies. Pilot studies are evaluating dose escalated EBRT using IMRT techniques in combination with IORT, as well as the role of concomitant radiochemotherapy with preoperative EBRT, IORT, and maintenance chemotherapy for resectable moderate- and high-grade retroperitoneal and pelvic sarcomas.[109] An Italian Sarcoma Group Phase II study is evaluating preoperative EBRT with high-dose continuous infusion ifosfamide, using IOERT or postoperative EBRT for radiation dose escalation following maximal resection.

Gynecologic Cancers

Patients with locally advanced or locally recurrent gynecologic cancers often have involvement of the pelvic sidewall, pelvic lymph nodes, or paraaortic nodes. The use of radical resection and IORT with or without EBRT or chemotherapy may benefit patients when compared with EBRT alone.

A Mayo Clinic analysis described 148 patients with primary (23 patients) or recurrent (125 patients) gynecologic

malignancies treated with IOERT-containing regimens.[110-112] Preoperative or postoperative EBRT was delivered in 113 patients; 85 (57%) had received prior EBRT. The 5-year OS for all patients was 27%, and the 5-year local failure rate was 40% (Table 17-6).[111,112] On subset analysis, patients with R0 or R1 resection ($N = 115$) had improved 5-year OS compared to patients with R2 resection (31% versus 13%, $p = 0.01$); patients with uterine or ovarian primary origin had better survival than those with cervical or vaginal primaries (5-year OS 41% versus 18%, $p = 0.002$); patients with no prior EBRT had better 5-year OS than those with prior EBRT (35 versus 15%, $p = 0.01$). The rate of distant metastases at 5 years was 49% (R0 resection, 63%; R1/R2, 41%; $p = 0.04$). Fewer metastases were seen in patients treated with MVAC (methotrexate, vinblastine, doxorubicin, cisplatin) chemotherapy in a prior analysis.[110]

Cervical Cancer: Primary Locally Advanced Disease

IOERT containing regimens for locally advanced primary cervical cancers have been reported by several investigators. A Mayo Clinic analysis[113] of 13 patients with locally advanced cervical cancer treated with preoperative EBRT followed by resection and IOERT (median 12.5 Gy) and adjuvant chemotherapy in 77% reported a 29% 3-year survival and pelvic control in 69%. Spanish investigators treated 31 patients with primary locally advanced cervical cancer with 45 Gy EBRT in 1.8 Gy fractions followed by resection and 12 Gy IOERT. Survival at 10 years was 58% and LC was observed in 93%.[114]

A study from Xian Jiaotong University in China reported on 78 patients with stage IIb squamous cell carcinoma of the cervix who received IOERT during hysterectomy and selected lymphadenectomy. A comparison group of 89 patients was treated contemporaneously with standard therapy without surgery. IOERT-treated patients received 20 Gy EBRT at 2 Gy per fraction followed by 1 to 2 intracavitary brachytherapy HDR treatments with Ir-192, receiving 7 Gy per fraction to point A, followed by surgery and IOERT using 12 MeV electrons with doses of 18 to 20 Gy. Patients treated with standard therapy received 30 Gy EBRT whole pelvis and 20 Gy split pelvis, all in 2 Gy fractions, followed by 5 to 6 HDR insertions with Ir-192 delivering a dose of 35 to 40 Gy to point A. The 5-year OS, DFS, and LC in the IOERT patients were 89%, 87%, and 96%, respectively, versus 73%, 67%, and 73% in the standard therapy group ($p < 0.05$). Ten-year OS and LC were 85% and 94%, respectively, in the patients who underwent IOERT compared to 55% and 65%, respectively, in patients who underwent standard therapy. The patients who underwent IOERT had fewer rectal and bladder complications.[115]

Italian investigators reported the results of a Phase II trial containing IOERT as part of the multimodality regimen in patients with stage IIA bulky-IVA cervical cancer.[116] Forty-two patients were treated with 50.4 Gy EBRT in 1.8 Gy fractions with concomitant cisplatin and 5-FU followed by radical hysterectomy and IOERT (11 Gy median; range, 10 to 15 Gy). Seven patients were not resected because of refusal (1), progression (3), unresectability (2), and hemorrhage (1). For the 35 patients with radical hysterectomy and IOERT, the 5-year OS and DFS were 49% and 46%, respectively. Crude pelvic control was observed in 63% and control within the IOERT fields was 89%.[116]

Cervical Cancer: Recurrent Disease

Treatment of patients with recurrent cervical cancer is challenging, especially in those treated with high-dose radiotherapy for primary disease. There are several reports in the literature of curative attempt regimens including surgery and IOERT with or without EBRT. Stanford investigators evaluated 17 patients with recurrent cervical cancer treated with orthovoltage IORT (median 11.5 Gy). LC, distant metastasis-free survival, and disease-specific survival (DSS) rates at 5 years were 45%, 60%, and 46%, respectively.[117] A University of Washington series included 22 patients with recurrent cervical cancer. IOERT doses ranged from 14 to 27.8 Gy and 12 patients had R2 resections, with R1 or close R0 in 10 patients. LC at 5 years was 48% and DSS was 48%. Peripheral neuropathy was observed in 32%.[118]

Spanish investigators reported on 36 patients with recurrent cervical cancer treated with IOERT (median, 15 Gy).[114] Previously unirradiated patients were generally treated with preoperative EBRT to 45 Gy at 1.8 Gy per fraction with concurrent cisplatin and 5-FU. Previously irradiated patients underwent immediate resection or neoadjuvant chemotherapy if unresectable. Ten-year LC rate (within the IOERT field) was 47%, control in pelvic and paraaortic region was 42%, and 10-year survival was observed in 14%. Factors adversely influencing LC included involved parametrial margins, gross residual disease, and pelvic lymph node involvement. Patients with two or more risk factors had a 10-year LC rate of 0%, and there were no 10-year survivors with R2 resection. Six of 36 (17%) patients experienced nerve pain that resolved after a few months. All failures within the IOERT field occurred concomitant with relapse in the pelvis or distant metastases.[114]

Contrary to the relatively favorable results reported in most series, a French multiinstitutional analysis found relatively poor survival and LC with IORT. Seventy patients were treated in seven institutions with IORT alone (40 patients) or IORT with EBRT (30 patients) in addition to surgery. The pelvic sidewall was involved in 80% of cases and resection was macroscopically complete in only 47% of patients. IORT doses ranged from 10 to 30 Gy with a median of 18 Gy in patients with R0-R1 resections and 19 Gy in patients with R2 resections. LC was observed in only 21% and 5-year survival was 8%.[119]

A Mayo Clinic series included 73 patients with recurrent cervical cancer treated with IOERT to a median dose of 17.5 Gy. EBRT (median, 45 Gy) was included as part of the treatment in 66% of patients and 48% received perioperative chemotherapy. The median OS was 17 months with 25% survival observed at 3 years. The 3-year cumulative incidences of central relapse, locoregional relapse, and distant relapse were 23%, 39%, and 44%, respectively. On multivariate analysis, central control and locoregional control were associated with pelvic exenteration and use of EBRT. R2 resection was associated with a higher risk of distant metastases and poorer cause-specific survival (CSS). High-tumor grade and relapse within 6 months of primary diagnosis were associated with poor cause-specific survival and no patients treated within 6 months of primary diagnosis survived 3 years. Some degree of peripheral neuropathy was observed in 19% of patients.[113]

Endometrial Cancer: Recurrent Disease

Mayo Clinic investigators reported on 25 patients treated with IOERT for recurrence of endometrioid endometrial cancer.[120] Most patients (21/25, 84%) had involvement of the pelvic sidewall and the remaining 4 patients had paraaortic with and without upper abdominal involvement. EBRT was delivered to 21 patients (84%) to a median dose of 45 Gy (range, 9 to 50.7 Gy). EBRT was given preoperatively in 81% of cases. The median IOERT dose was 15 Gy (range, 10 to 25 Gy). The surgical resection was R0 with close margins in 7 (28%) patients, R1 in 11 (44%) patients, and R2 in 7 (28%) patients. The 5-year OS was 47% and median survival was 57 months. Survival was associated with resection margins with 5-year OS of 71%, 40%, and 0% in R0, R1, and R2 patients, respectively. Central relapse within the IOERT field was observed in 4 patients (16%), local relapse with control in IOERT field in 2 patients (8%), and distant relapse in 6 patients (24%). Peripheral neuropathy was observed in 8 patients (32%).[120]

Uterine Sarcoma

Mayo Clinic investigators reported on the use of IOERT as component of therapy in 16 patients with primary (3) or recurrent uterine sarcoma, including 9 patients with leiomyosarcoma, 4 with stromal sarcoma, and 3 with carcinosarcoma. All were treated with perioperative EBRT (median, 50.4 Gy; range, 20 to 62.5 Gy) and 6 (38%) received perioperative chemotherapy. Surgical resection was classified as R0 in 8 (50%) patients, R1 in 2 (12.5%) patients, and R2 in 6 (37.5%) patients. The median IOERT dose was 12.5 Gy with a range of 10 to 20 Gy. The 5-year OS was 43% and CSS was 47%. There were no central relapses within the IOERT field and only 1 local relapse (6%). Nine patients (56%) relapsed in distant sites. Peripheral neuropathy was observed in 3 patients (19%).[121]

Ovarian Cancer

Although the primary pattern of relapse of ovarian cancer is peritoneal, a subset of ovarian cancer patients experience isolated locoregional relapse. There are several reports on the use of IOERT in selected patients with ovarian cancer. A Chinese series included 25 patients with primary ovarian cancer and 20 with isolated local relapse. Intraperitoneal chemotherapy was delivered to 33 patients (73%) and intravenous chemotherapy to 7 (16%) patients. No EBRT was used. The IOERT dose was 18 to 20 Gy in 43 patients and 10 Gy in the remaining 2 patients. Five-year survival was observed in 64% in the primary group and 60% in the recurrent group. In the primary group 8 patients (32%) relapsed locally and 3 (12%) distantly. In the recurrent group there were 6 local relapses (30%) and 2 distant relapses (10%). The rate of central relapse within the IOERT field was 9% for the entire group. Five patients (11%) experienced peripheral neuropathy.[122]

Stanford investigators reported on 22 patients with recurrent ovarian cancer who received orthovoltage IORT as a component therapy.[123] The median IORT dose was 12 Gy (range, 9 to 14 Gy) and treated sites included pelvis, paraaortic nodes, inguinal nodes, and the porta hepatis. Nine patients received whole abdominal EBRT, 5 locoregional EBRT, and 6 chemotherapy. The median survival was 26 months, 5-year OS was 22%, and DFS 18%. Locoregional control was 68% at 22 months and 55% of patients experienced distant relapse. There were no long-term peripheral neuropathies.[123]

A Mayo Clinic analysis described 20 patients with recurrent ovarian cancer treated with IOERT as a component of therapy.[124] Thirteen patients (70%) had epithelial ovarian carcinomas and the remaining histologies were granulosa cell tumor, malignant teratoma, adenosarcoma, stromal tumor, and squamous cell carcinoma. The site of recurrence was pelvis in 14 patients, paraaortic nodes in 6, and inguinal nodes in 1. Sixteen patients received a median EBRT dose of 50 Gy (range, 20 to 54.3 Gy). Surgical resection was classified as R0 in 9 patients, R1 in 11, and R2 in 1. The median IOERT dose was 12.5 Gy (range, 10 to 22.5 Gy). Median survival was 30 months with 49% 5-year OS. Central control within the IOERT field was observed in 76% with all central relapses occurring in patients with R1 resections. Distant relapse was observed in 9 patients (45%). Three patients experience grades 1 to 2 peripheral neuropathy.[124]

Future Possibilities

Because of the high incidence of distant metastases observed in patients with gynecologic cancer with microscopic and gross residual disease following resection, evaluation of newer systemic and maintenance regimens is indicated. Investigation of newer chemotherapeutic and targeted biologic agents may hold promise in improving distant metastases rates and ultimate survival in these malignancies.

Colorectal Cancer: Primary and Recurrent Disease

Primary Locally Advanced Cancers

Locally advanced colorectal cancers are tumors that cannot be resected without microscopic or gross residual secondary to tumor adherence to adjacent structures. In selected patients, the optimal approach is to administer preoperative chemoradiation in efforts to "downstage" disease and facilitate surgical resection. At the time of resection, if clinical suspicion for involved margins is high, the use of IORT may be appropriate.

In an MGH series, 64 patients with locally advanced primary rectal cancer underwent preoperative irradiation (with or without 5-FU) followed by resection and IOERT. Patients undergoing R0 resection had a 5-year LC and DSS of 91% and 63%, respectively. Patients with R1 resection experienced 5-year LC and DSS of 65% and 47%, respectively, and patients with R2 resection, 57% and 14%, respectively (Table 17-7).[125]

A Mayo Clinic Rochester report described 56 patients with primary locally advanced colorectal cancer undergoing EBRT

†Three-year actuarial DF of 43%, 38%, and 66%, respectively, for complete resection, microresidual, and gross residual.

(45 to 55 Gy, usually with concurrent 5-FU administration) followed by resection and IOERT (10 to 20 Gy). Five-year OS for all patients was 46%. Patients with R0 or R1 resection had an improved OS relative to patients with R2 resection (5-year OS of 59% versus 21%, $p = 0.0005$). Failure within the IOERT field occurred in 4 of 16 patients (25%) with R2 resection versus 2 of 39 (5%) with R0 or R1 resection ($p = 0.01$)[52] (see Table 17-7).

An update from Mayo Clinic Rochester analyzed 146 patients with locally unresectable primary colorectal cancers who received IOERT in addition to preoperative or postoperative combined modality therapy. Median survival was 44 months with 5-year OS of 52%. Three-year local and distant relapse rates were 10% and 43%, respectively. Patients receiving preoperative combined modality therapy appeared to have a survival advantage versus those receiving postoperative therapy (median survival 76 months versus 26 months, 5-year OS of 55% versus 38%, $p = 0.02$).[53]

Madrid investigators from the General University Hospital Gregorio Marañon described 558 patients with T3-T4 rectal cancer, 281 of which received preoperative combined modality therapy plus IOERT and 277 who received postoperative chemoradiotherapy without IOERT. Patients receiving preoperative therapy plus IOERT (despite higher stage disease at presentation) had a significant improvement in pelvic control (92% versus 84%, $p = 0.03$), DFS (65% versus 56%, $p = 0.05$), and OS (68% versus 58%, $p = 0.016$).[55] In a recent and selected update of the postchemoradiation plus IORT presacral boost experience, 335 patients treated from 1995 to 2011 (median follow-up 52.2 months) showed 5-year LC, in-field and out-field control rates of 94.4%, 97.0%, and 93.4%, respectively. In multivariate analysis, nonsphincter-preserving surgery and grade 3 histology were associated with increased risk of presacral relapse.[56]

A pooled European analysis of 651 patients treated with IOERT from four major centers showed that 5-year OS was 67% with 5-year LC of 88% in patients with locally advanced rectal cancer.[57] Positive circumferential margins were a strong predictor for both OS and local relapse, and the addition of preoperative CRT appeared to improve 5-year OS (70% versus 64%, $p < 0.05$). An update of the pooled European analysis in 605 patients demonstrated that chemoradiotherapy led to more downstaging and complete remissions compared to radiotherapy alone.[58] Local recurrence, distant metastasis, and OS rates were 12%, 29%, and 67%, respectively. Risk factors for local recurrence included lack of downstaging with preoperative therapy, lymph node involvement, margin involvement, and lack of postoperative chemotherapy. The authors concluded that oncological results following multimodality therapy including IORT showed promising outcomes and the addition of adjuvant chemotherapy could potentially improve local recurrence rates.

The feasibility of IOERT at the time of laparoscopic resection of locally advanced rectal cancer, after preoperative chemoradiation, has been reported by the Gregorio Marañon Hospital team. In a group of 125 patients, laparoscopic resection plus IOERT had significantly less blood loss and shorter hospital stay. Oncological and toxicity results were similar.[59]

Locally Recurrent Colorectal Cancer

Patients developing local recurrence following curative resection of primary colon or rectal cancer are treated with palliative intent at most institutions. Local recurrence from rectosigmoid cancer often causes pelvic pain due to nerve involvement in the presacral space or pelvic sidewall. The likelihood of margin negative resection is low. Patients undergoing surgery alone for pelvic recurrence from rectal cancer have reported 5-year survival rates of 0%.[126]

When IOERT is combined with EBRT with or without chemotherapy and surgical salvage, 5-year OS in the range of 20% to 30% has been achieved.[51,126-130] In an MGH analysis of 41 patients with locally recurrent rectosigmoid cancer undergoing IOERT, patients with gross residual disease experienced 5-year LC and DFS of 21% and 7%, respectively, versus 47% and 21% with clear or microscopically positive margins.[127] Eindhoven investigators described a series of 147 patients with locally recurrent colorectal cancer receiving IOERT. Median OS was 28 months with 5-year OS, DFS, metastases-free survival, and LC rates of 32%, 34%, 50%, and 54%, respectively. R0 resection was associated with improved disease outcomes. Patients treated with IOERT alone had worse outcomes vs those who were reirradiated or treated with full dose preoperative EBRT.[128]

The potential of extended resection in combination with IOERT and EBRT has been analyzed at the University Hospital Gregorio Marañon. In a 16-year experience an adaptive surgical approach based on extent of recurrence extension was systematically combined with IOERT: 60 patients underwent extended surgery (43% multiorgan, 28% bone, 38% soft-tissue resection) and 22 had nonextended resection. With a median follow-up time of 36 months, locoregional control was 44% at 5-years and OS was 43%. On multivariate analysis, positive margins, EBRT at the time of rescue, lack of tumor fragmentation, and lack of lymph node metastasis were significant factors associated with locoregional relapse.[131]

A Mayo Clinic Rochester report described the outcome of 106 patients undergoing palliative resection of locally recurrent, nonmetastatic rectal cancer. Forty-two patients received IOERT as a component of treatment (most 15 to 20 Gy) and 41 EBRT (most ≥45 Gy). Patients with R2 resection had a significantly worse outcome versus R1 resection (5-year OS of 9% versus 33%, $p = 0.03$). Patients who underwent IOERT compared to those that did not had 5-year OS of 19% versus 7% ($p = 0.0006$).[126]

An updated Mayo Clinic analysis described 175 patients with locally recurrent colorectal cancer (123 no prior EBRT, 52 prior EBRT) undergoing IOERT. Five-year OS in previously unirradiated patients was 20% versus 12% in previously irradiated patients. Three-year LC rate in previously unirradiated patients was 75% versus 51% in those previously irradiated. Three-year distant metastases rates were 64% and 71%, respectively.[132]

An even more recent Mayo Clinic analysis described 607 patients with recurrent colorectal cancer who received IOERT as a component of treatment. Five-year OS was 30%. In patients undergoing R0 resection, 5-year OS was 46%. Prior in-field radiation was associated with an increased risk of local relapse (3-year local relapse of 39% versus 20%, $p < 0.0001$) but not with survival. On multivariate analysis, complete resection, no prior chemotherapy, and treatment after 1996 were associated with improved survival. Three-year local and distant relapse rates were 27% and 55%, respectively.[54]

Systematic reviews and meta-analysis are available to evaluate results of IORT in colorectal cancer. From 1965 to 2011, 14 prospective and 15 retrospective studies were identified meeting methodological quality and design (3003 patients involved: 1792 primary locally advanced category). When comparative studies were evaluated, a significant effect favoring improved LC ($p = 0.003$), DFS ($p = 0.009$), and OS ($p = 0.001$) was noted with no increase in total urologic or anastomotic complications, although increased wound complications were observed after IORT ($p = 0.049$). Heterogeneity in methodology and reporting practice warrant caution in the interpretation of these results.[133]

Future Possibilities

Based on the preceding and other data, it appears improved LC and survival may be achieved when IORT is combined with preoperative chemoradiation for locally advanced or locally recurrent colorectal cancer. Many patients will develop distant metastases; relapse within the IORT and EBRT fields is common if gross total resection is not obtained. Based on the proven survival benefit of concurrent 5-FU–based regimens with EBRT in colorectal and other gastrointestinal malignancies, 5-FU–based chemotherapy should be administered concurrent with EBRT. Although adjuvant 5-FU with leucovorin has previously been shown to improve survival in patients with advanced stage colorectal cancer, the addition of newer therapies (oxaliplatin, capecitabine, irinotecan, bevacizumab, cetuximab, panitumumab) has demonstrated further survival benefit in patients with stage IV cancer. These agents have been evaluated as adjuvant therapy in patients with stages II and III cancer (see Colon and Rectal Cancer, Chapters 50 and 51). Given the high rate of subsequent distant metastases in patients with locally advanced and recurrent colorectal cancer, significant improvement in long-term survival will likely be achieved through further improvements in systemic agents.

CONCLUSIONS AND FUTURE POSSIBILITIES

Conclusions

IORT is the delivery of radiation at the time of operation. This can be accomplished using different techniques including IOERT, HDR-IORT, and orthovoltage. IORT is usually given in combination with EBRT with or without chemotherapy and surgical resection. IORT allows exclusion of part or all dose-limiting sensitive structures, thereby increasing the effective dose to the tumor bed (and therefore LC) without significantly increasing normal tissue morbidity.

Despite optimal therapy with non-IORT approaches, high rates of local relapse occur in patients with retroperitoneal sarcoma, pancreatic cancer, colorectal cancer, gynecologic cancer, and other malignancies. The addition of IORT to conventional treatment methods has improved LC as well as survival in many disease sites in both the primary and recurrent disease settings. In view of newer, lower cost treatment devices, the use of IORT in clinical practice will likely continue to grow, with increasing integration into the treatment of "nonconventional" malignancies. Cancer sites in which IORT has been explored and found to be feasible include renal cancer,[134] prostate cancer,[135] extremity sarcomas,[136] and pediatric cancers.[137]

IORT: Technical Considerations

Many limitations and perceived drawbacks of IORT in past decades were the result of inefficiencies associated with nondedicated facilities. Patients were often transported from the operating suite to the radiation oncology department where they were treated with nondedicated linear accelerators. These inconveniences have been overcome with dedicated IOERT, HDR-IORT, or orthovoltage facilities. Presently, dedicated IORT suites within or adjacent to the operating room exist at many institutions in the United States, Europe, and Far East. These facilities simplify treatment by avoiding transportation and sterility problems. A major limiting factor is the expense associated with outfitting a dedicated room (e.g., retrofitting an operating room with proper shielding, purchase of a linear accelerator dedicated for use in the operating room, construction of a separate IORT suite adjacent to the operating room, etc.). However, newer technologies have lowered these costs. Contemporary options include mobile IOERT units (Mobetron, Liac) as well as mobile HDR-IORT.[138] The Mobetron is a mobile, self-shielded compact linear accelerator with C-arm design that generates electron energies of 4 MeV to 12 MeV (Intraop Medical, Inc., Santa Clara, CA, Figure 17-3). This can be transported in and out of the operating theater. HDR-IORT units are remote afterloading devices that use an Ir-192 source (Figures 17-4, 17-5). In contrast to the Mobetron, HDR-IORT requires room shielding, which may be achieved by retrofitting an existing room or construction of a smaller shielded room adjacent to the operating suite. In either situation, patients are monitored by camera during radiation administration. After completion, the HDR-IORT unit can be transported to the radiation oncology department for outpatient HDR appropriate malignancies, including gynecologic and prostate malignancies. Mobile IOERT devices used in Europe include the Liac machine. The INTRABEAM system for breast cancer IORT consists of a 50-kV x-ray generator mounted on a flexible floor stand and a set of spherical applicators ranging from 1.5 cm to 5 cm in diameter (see eFigure 17-1).

Treatment planning systems specifically designed for IOERT are now commercially available (Radiance). Initial clinical testing demonstrated feasibility and multispecialist agreement for simulation of different cancer sites and anatomic locations, including breast cancer, locally advanced rectal cancer, retroperitoneal sarcoma, and isolated recurrence of rectal and ovarian cancer.[139] Research opportunities in IORT are a multidisciplinary endeaver that spans knowledge ranging from radiation beam adaptive development to advanced molecular biology for biopredictability of outcomes. Technical innovation requires further improvements in quality assurance and

Figure 17-3 The mobile electron-beam radiation device (MOBETRON) (seen here in the operating room) allows use in an existing operating room with little or no additional shielding required.

Courtesy Varian Medical Systems.

clinical practice. The incorporation of treatment planning systems for IORT use will help decision-making processes and its registration will facilitate normalization of medical and surgical practice in IORT programs. Opportunities in radiation beam modulation, delivery, dosimetry and planning, infrastructure, and treatment factors are recognized and expected to be developed over the next decade.[140]

A detailed description of the relative advantages and disadvantages of IOERT and HDR-IORT has been discussed elsewhere and is beyond the scope of this chapter[36] (eTables 17-5 and 17-6). In summary, treatment or procedure times

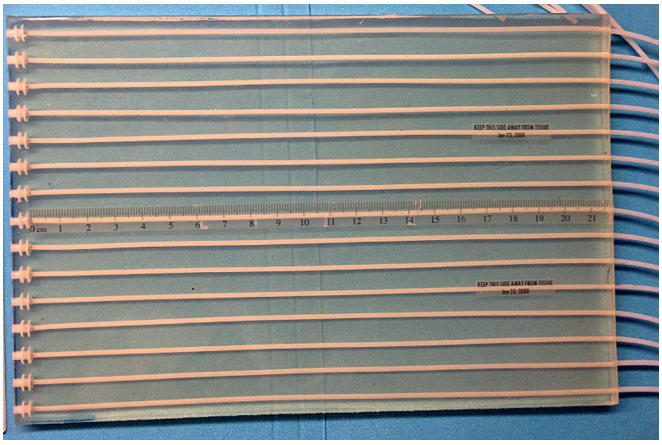

Figure 17-5 Harrison-Anderson-Mick (HAM) applicator used to guide Ir-192 source during HDR-IORT.

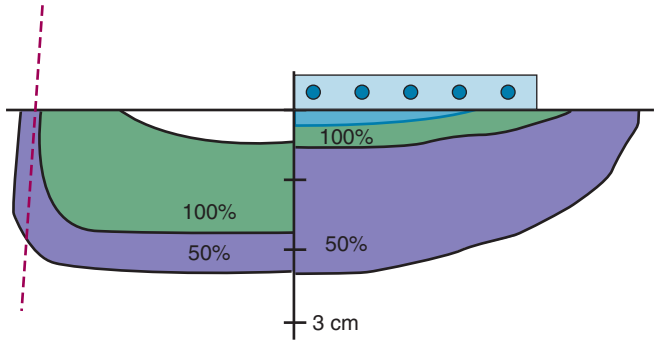

Figure 17-6 Dose distribution characteristics of IOERT *(left)* and in HDR-IORT *(right).* Note IOERT is utilizing 6 MeV electrons; HDR-IORT is utilizing 1 cm surface applicator with dose prescribed to 0.5-cm depth.

are generally shorter with IOERT compared to HDR-IORT. Additionally, IOERT allows variation of electron energies and therefore treatment of both superficial and deeper-seated targets, whereas HDR-IORT is appropriate only for targets ≤0.5 cm in thickness (Figure 17-6). The flexible Harrison-Anderson-Mick (HAM) applicator used in HDR-IORT may allow more conformal treatment along curved body surfaces (e.g., large pelvic sidewall fields, lateral abdominal wall, and thoracic cage) that may prove difficult with rigid IOERT applicators (Figure 17-5). Separate, matching fields may be required to treat larger target areas with IOERT-based applicators. A comprehensive IORT program would ideally have IOERT, HDR-IORT, as well as perioperative brachytherapy available to treat all disease sites and situations. These modalities should be viewed as complementary and not competitive.

Future Possibilities

Although there is a large body of data supporting the use of IORT in various malignancies, there is a relative paucity of Phase III randomized trials. This is at least in part because of the limited number of IORT facilities in any given country as well as relative rarity of diseases commonly treated with IORT. Completion of Phase II/III trials will likely require cooperation among multiple institutions and countries. Future treatment approaches should include "standard" courses of EBRT with or without concurrent chemotherapy and surgical resection with the integration of novel radiation sensitizers, protectors, and targeted biologic agents with IORT.[141]

eTABLE 17-5 Relative Advantages and Disadvantages of IOERT versus HDR-IORT Brachytherapy after Gross Total or Near-Total Resection (Maximum Tumor Thickness ≤0.5 cm)

IOERT Potential Advantage If Technically Feasible	Potential Disadvantages of IOERT	Potential Solution to Disadvantage
Better dose homogeneity	Surface dose <90% with 6 ± 9 MeV	Add bolus over tumor bed to improve surface dose; use HDR-IORT
Faster treatment time		
Less shielding required in OR	Unable to include area at risk in single field within either abdomen or pelvis	Use abutting IOERT fields (difficult in pelvis): use HDR-IORT
Can treat full thickness of organ or structure at risk with relative homogeneity (e.g., aorta or vena cava, bladder sidewall)	Area at risk is technically inaccessible because of location	Use HDR-IORT; surgically displace small bowel or stomach with vascularized flap (omentum, muscle) and give postoperative EBRT boost or perioperative brachytherapy

eTABLE 17-6 Potential Differences between IOERT and HDR-IORT

	IOERT	HDR-IORT
Actual treatment time	2-4 min	5-30 min
Total procedure lime	30-45 min	45-120 min
Treatment sites	Accessible locations	All areas where depth at risk is ≤5 cm from surface of applicator
Surface dose	Lower (75%-93%)	Higher (150%-200%)
Dose at depth (2 cm)	Higher (70%-100%)	Lower (30%)
Dosimetric homogeneity (surface to depth)	<10% variation	>100% variation

CHAPTER

18 Total Body Irradiation

Christopher Andrew Barker and Joachim Yahalom

Total body irradiation (TBI) is a radiotherapy technique that has been applied to treat various benign and malignant diseases over the past century. The technique has evolved in parallel with an increase in the knowledge of the biologic response to ionizing radiation and improvements in radiation dosimetry and treatment delivery. TBI remains an important component of hematopoietic stem cell transplant (HSCT), with the goal of eradicating residual malignant cells or modulating the immune system of the transplant recipient. In the context of HSCT, TBI is advantageous because biologic effects can be exerted uniformly, without the sparing of "sanctuary" sites such as the nervous system or tests or interference from metabolic or resistance processes.

HISTORY OF TOTAL BODY IRRADIATION

Only a decade after Roentgen described the "x ray," German biophysical engineer Friedrich J. Dessauer[1,2] first described a "new technique of radiotherapy" that involved homogenous irradiation of the entire body. In his initial report describing the technique in 1905, he proposed irradiating a supine patient using three simultaneously active, low-voltage roentgen-ray sources (Figure 18-1). In 1907, Aladár Elfer,[3] a medical professor in Hungary, reported his experience using a TBI technique that spared the head in three patients with leukemia. Although there is a paucity of data regarding the early use of the technique, some have speculated that untoward hematologic toxicity probably limited its application.[4]

Early success using TBI to treat hematopoietic and lymphoid malignant tumors in Europe (there named the Teschendorf method) prompted development of the technique in the United States.[5-7] Arthur C. Heublein, in collaboration with Gioacchino Failla, is credited with the development of the first TBI unit in North America, located at Memorial Hospital in New York City. In the United States, the technique became known as Heublein therapy.[8] A specially constructed treatment ward was designed to treat four patients at extended distance (5 to 7 m) simultaneously at an exposure rate of 0.7 roentgen (R)/hour, for about 20 hours/day, typically over 1 to 2 weeks, using a 185-kV x-ray tube at 3 mA, with a 2-mm copper filter. The goal was to deliver 25% of the erythema dose (750 R).

Remarkably, in Heublein's initial report, no hematopoietic toxicity was noted with this treatment schedule. Seven of 12 patients (58%) with advanced lymphomas and leukemias and 2 of 8 patients (25%) with metastatic breast, melanoma, and kidney cancers were noted to demonstrate some form of improvement after treatment.[9,10] A later report of the experience with 270 patients with cancer from Memorial Hospital treated with TBI between 1931 and 1940 confirmed that the technique was more successful in patients with hematopoietic and lymphoid cancers compared with those with carcinomas or sarcomas, for whom it was ineffective. The authors emphasized that the technique was safe if doses were prescribed cautiously. They did not recommend exposures greater than 300 R and noted hematopoietic and gastrointestinal toxicity with exposures as low as 50 to 100 R.[8]

In the early 1940s, World War II prompted an initiative to develop nuclear weapons, known as the Manhattan Project. Part of this endeavor sponsored research into the human biologic response to ionizing radiation, including TBI. The military's interest in TBI was primarily to help understand human tolerance for radiation exposure during occupational duties and warfare and to develop radiation biodosimetric assays. Several research studies coordinated through the Manhattan Project were initiated in patients with advanced cancers,[11-13] as well as patients with benign diseases.[13] For example, studies of dose escalation, radiation biologic dosimetry, and cognitive and psychomotor function were carried out at the M. D. Anderson Hospital for Cancer Research.[14] A detailed report of 30 patients treated at the maximum exposure level (200 R) in the initial study concluded that side effects primarily consisted of nausea, vomiting, and myelosuppression, and that intervention was necessary in 10% of patients treated with this dose of TBI.[15] At Baylor University College of Medicine, studies using 25 R to 250 R of TBI with 250 kV to 2 MV photons were performed to find a biologic dosimeter, as well as to study acute effects of radiotherapy.[16] The Sloan-Kettering Institute for Cancer Research also participated in similar studies of at least 20 patients, although the results were never published. The military conducted similar studies at the Naval Hospital in Bethesda, Maryland, and reported palliation of patients with radiosensitive diseases treated with fractionated TBI.[17] The most recent research study of TBI sponsored by the U.S. Department of Defense was conducted at the University of Cincinnati. It focused on identifying biochemical markers in the urine that predicted response to TBI. Later, studies of the neuropsychiatric effects of TBI were initiated. Ultimately, only results regarding the palliation of advanced cancers were reported.[18] Patients with advanced metastatic radioresistant malignant tumors, for whom chemotherapy was unavailable, were often treated with TBI in the absence of any clear anticipated benefit. Patients treated with TBI in this manner were included in research studies, often without consenting to participate. The ethics of this practice was called into question by a report written in 1995 by the U.S. Department of Energy's Advisory Committee on Human Radiation Experiments,[19] which may have contributed to the public's general uneasiness regarding radiation.[20]

TBI was not only used in malignant diseases, but it was also considered the critical immunomodulator in the first successful solid organ transplant. In 1959, a kidney was successfully transplanted between dizygotic twins after TBI at exposures of up to 450 R (given to the recipient).[21] Around the same time in France, successful kidney transplants after TBI were being reported.[22,23] Of the first seven patients who underwent kidney transplant following TBI or pharmacologic immunomodulation worldwide between 1959 and 1962, the two who did not experience kidney failure were treated with TBI alone (without chemical immunosuppression) before transplant, and each survived for more than 20 years after transplant.[21-23] However, successful preclinical studies with pharmacologic therapy prompted the use of chemical immunosuppressants (corticosteroids, 6-mercaptopurine, and azathioprine) for solid organ transplantation after 1963.[24]

With an increased understanding of the human response to TBI and a rapidly growing body of preclinical in vivo studies

of TBI, therapeutic protocols were developed to maximize benefit in patients with malignant diseases. In 1957, Nobel laureate E. Donnall Thomas[25,26] first reported the use of bone marrow infusion in humans following whole body irradiation or chemotherapy, and less than 1 year later he published his experience in using TBI with exposures up to 600 R followed by bone marrow transplantation. In the series of the first five patients with leukemia treated with TBI, who then received intravenous infusion of normal donor marrow, Thomas et al[26] noted the difficulty of acute myelosuppression and resultant hemorrhage and infection during the period leading up to engraftment. The report also commented that low dose rates (delivery over 2 to 3 days) appeared preferable to higher dose rates, for metabolic and immunologic reasons. In addition, patients receiving 200 R to 300 R fared better than those receiving 400 R to 600 R. The problem of delivering an adequately homogenous dose was raised, and suggestions about using higher-energy photons were proposed. Thomas et al[27] later reported on syngeneic bone marrow transplantation in two children after 850 R to 1140 R was delivered in a single fraction over 22 to 25 hours, using cobalt-60 (^{60}Co) sources. The authors concluded that 1000 R of TBI did not produce "troublesome" acute radiation sickness, did produce remission of leukemia, but did not cure the disease. The first report of successful cure of a patient with leukemia with allogeneic transplantation after TBI was reported in 1969. The technique involved opposed ^{60}Co sources, which operated at 5.8 R/minute, to a total exposure of 1620 R, calculated to be 954 rad at midline. With appropriate supportive care, no major acute radiation sickness was noted, but the patient died of overwhelming cytomegalovirus infection, without evidence of leukemia.[28]

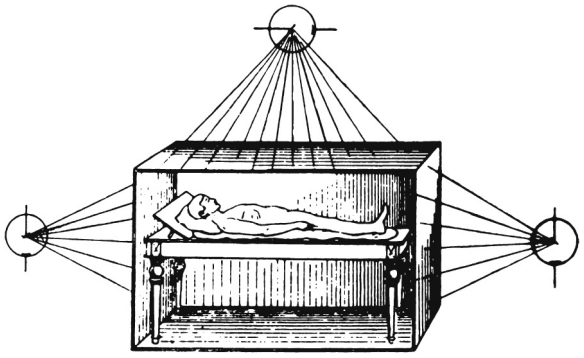

Figure 18-1 Diagram demonstrating the total body irradiation technique proposed by Dessauer in 1905.
Reprinted from Wetterer J editor: Handbuch der Röntgentherapie nebst Anhang. In Die radium therapie, Leipzig, 1908, Otto Nemnich.

Over the next several years, techniques of combining chemotherapy and TBI were developed and refined, with promising results.[29,30] Success in the treatment of advanced leukemias and severe aplastic anemia was achieved. Departure from the use of TBI alone was primarily fostered by the development of more effective cytotoxic chemotherapeutics and immunologic therapies, which when combined with TBI, yielded fewer leukemic recurrences.[29] Although the use of TBI without HSCT has largely been abandoned, primarily for fear of inducing secondary malignant tumors and limiting later therapeutic options, some question the validity of this fear and still contend that low dose TBI (1.5Gy to 2 Gy in 10 to 20 fractions over several weeks) is a viable option for initial therapy in advanced indolent lymphomas.[31] Figure 18-2 demonstrates how the use of TBI during HSCT has changed over a recent 15-year period.[32]

HEMATOPOIETIC STEM CELL TRANSPLANT

HSCT has evolved into a highly complex clinical discipline, firmly rooted in immune system and cancer biology, the details of which are beyond the scope of this chapter. When HSCT was initially performed (see History of Total Body Irradiation section), bone marrow was extracted from the donor and infused intravenously into the recipient. Later, peripheral blood stem cells, instead of bone marrow, were collected from the donor as an alternative to bone marrow grafting. For this reason, bone marrow transplants are now more appropriately termed *hematopoietic stem cell transplants* because the critical component of the graft is the hematopoietic stem cell (HSC), independent of the source. The peripheral blood stem cells

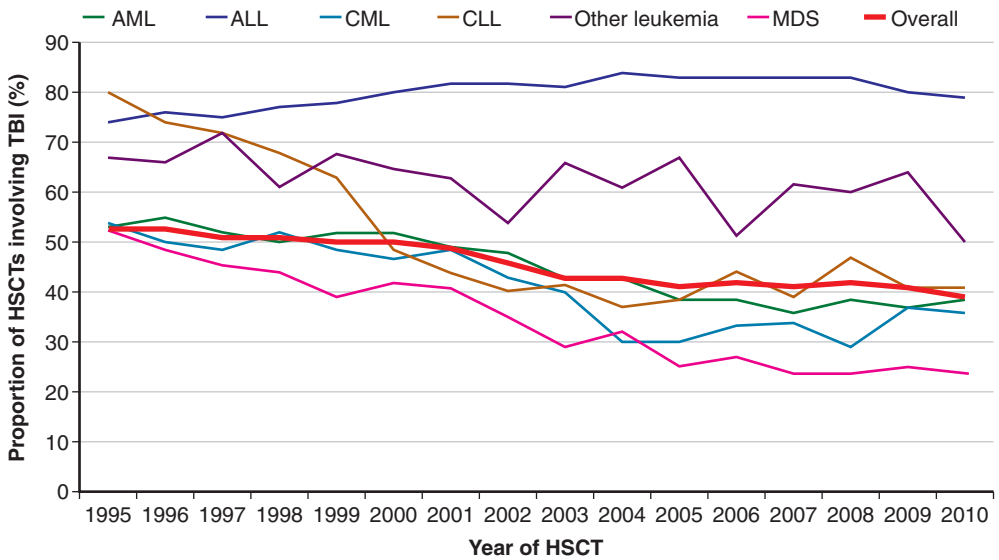

Figure 18-2 Temporal trends in the five diseases most frequently involving TBI as part of allogeneic HSCT, and overall. *ALL*, Acute lymphoblastic leukemia; *AML*, acute myelogenous leukemia; *CLL*, chronic lymphocytic leukemia; *CML*, chronic myelogenous leukemia; *HSCT*, hematopoetic stem cell transplant; *MDS*, myelodysplastic syndrome.
Data from Hong S, Barker CA, Klein JP, et al: Trends in utilization of total body irradiation (TBI) prior to hematopoietic cell transplantation (HCT), worldwide. Biol Blood Marrow Transplant 18(2 Supplement 2):S336–S337, 2012.

are often "mobilized" from the donor using hematopoietic growth-stimulating factors and are removed from the donor by apheresis. In addition, recent success using HSCs derived from human umbilical cord blood has been described. Depending on the source of HSCs, various postcollection processing measures (e.g., cell selection and depletion) may be undertaken to optimize the outcome of the transplant.

When transplant occurs between different individuals, the hematopoietic graft is said to be an *allogeneic graft.* This is in contradistinction to reinfusion of native HSCs back into the donor in an *autologous transplant,* more appropriately termed an *autoplant,* because nothing is being transferred between different individuals.[33] A rare but alternative situation is when an organ from a genetically identical twin of a patient is transplanted *(syngeneic transplant).* Of these three methods of HSCT, autologous and syngeneic transplantations are generally associated with less risk because issues related to immunocompatibility are minimized. Allogeneic transplantations require the "matching" of donor and recipient and are typically carried out through identification of human leukocyte antigen (HLA) compatibility. The donor may be related to the recipient or may be identified through registries of volunteers, such as the National Marrow Donor Program.

Before undergoing HSCT, most patients will require intensive antineoplastic or immunomodulatory therapy, often referred to as *conditioning,* in preparation for HSCT. Conditioning can involve cytotoxic chemotherapy, immunomodulators, antibody therapy, or radiation therapy. The nature of the conditioning regimen can be referred to as of high or reduced intensity or as myeloablative, submyeloablative, or nonmyeloablative, to carry out conventional or mini-(ature) transplants.[33] Although agreed-on formal definitions of these regimens do not exist,[34] the goal of high-intensity/myeloablative/conventional transplant is to completely eliminate the recipient's native HSC compartment, which necessitates HSCT (autologous or allogeneic) for survival. High-intensity, myeloablative, and conventional transplants may or may not involve TBI to high doses (>5 Gy in a single fraction, >8 Gy in multiple fractions). Reduced-intensity, nonmyeloablative, minitransplant conditioning regimens are often used for older patients or those with medical problems, for whom a high-intensity, myeloablative, and conventional transplant would cause excessive morbidity or mortality and may or may not involve TBI to lower doses. During and immediately after conditioning, the transplant recipient is at significant risk for infections and other hematologic complications. For this reason, the supportive care of HSCT recipients is complex and should only be undertaken in specialized facilities. Nonetheless, some groups have developed reduced-intensity and myeloablative HSCT regimens, including TBI, which have been safely undertaken on an outpatient basis.[35,36]

After undergoing conditioning and HSCT, the major challenges are related to engraftment, the permanent reconstitution of the recipient's hematopoietic system, and prevention of graft rejection and associated postengraftment complications. The former process can be facilitated through the use of hematopoietic growth-stimulating factors, and the latter can be mitigated with chemical and biologic immunomodulators. Once the graft has successfully taken, the recipient is at risk of developing graft-versus-host disease (GVHD), in which engrafted HSCs recognize the host's native, non-HSC tissues as foreign and attack them. Specific organs at risk are the skin, gastrointestinal tract, and liver. The risk of GVHD is only present in patients undergoing allogeneic HSCT. Moreover, it has been recognized that part of the beneficial effect of transplant is the graft-versus-tumor (GVT) effect, a fundamental component of the therapeutic effect of HSCT, which can occur in autologous or allogeneic transplants.

According to data summarized by the Worldwide Network for Blood and Marrow Transplantation in 2006, the diseases most commonly treated with HSCT are lymphoproliferative disorders (54.5%, most often multiple myeloma [MM], non-Hodgkin lymphoma [NHL], and Hodgkin lymphoma [HL]), leukemias (33.8%, most often acute myelogenous leukemia [AML], acute lymphocytic leukemia [ALL], myelodysplastic syndrome [MDS], chronic myeloid leukemia [CML], and chronic lymphocytic leukemia [CLL]), solid tumors (5.8%), and nonmalignant disorders (5.1%).[37] The 2014 National Comprehensive Cancer Network (NCCN) guidelines for therapy indicate that allogeneic or autologous HSCT may be a treatment option for testicular cancer, AML, MM, MDS, CML, HL, and NHL, depending on the clinical situation. HSCT with or without TBI-based conditioning has also been described in the treatment of solid tumors, including breast cancer, germ cell tumors, renal cell carcinoma, melanoma, neuroblastoma, and other pediatric cancers. Detailed discussion of these diseases and their management is beyond the scope of this chapter, and the reader is referred to other chapters in this text and other reviews.[38-41] The role of TBI in nonmalignant diseases will be discussed in subsequent sections of this chapter.

RADIOBIOLOGY

Experimental radiobiologists have described much of what is known regarding the fundamental biologic effects of TBI, and clinicians have applied these principles to optimize the therapeutic benefit for patients. The essential rationale for TBI in the context of HSCT is to eradicate malignant or dysfunctional cells or modulate immune system function. Therefore, the critical radiobiologic in vitro data related to efficacy of treatment deal with normal and malignant hematopoietic cells.

Preclinical studies have helped define some of the fundamental radiobiologic properties of the normal lymphocytes. The D_0 (see Chapter 5) of normal lymphocytes has been reported to be 0.5 Gy to 1.4 Gy,[42-45] depending on the in vitro or in vivo model used to calculate this parameter. This D_0 suggests that normal lymphocyte cells are sensitive to ionizing radiation. A small shoulder on the radiation cell survival curve has been noted,[46,47] suggesting little repair between fractions of radiation. Clinical data have revealed similar findings in patients undergoing hyperfractionated TBI, with lymphocyte survival demonstrating an effective D_0 of 3.8 Gy, according to one study.[48] Other radiobiologic phenomena have been ill defined in other normal hematopoietic cells. Radiobiologically relevant levels of hypoxia are unlikely in the hematopoietic compartment. Repopulation is not likely to influence hematopoietic cell survival, given the short duration of most TBI regimens (1 to 5 days), although given the variable life span of leukocytes (days to years), it may be of some relevance. Redistribution would appear to be of significance, given the time scale for TBI; however, this has been difficult to assess.[49]

The radiobiology of malignant hematopoietic cells has been described. The D_0 of leukemic cells generally ranges from 0.8 Gy to 1.5 Gy; however, compared with normal hematopoietic cells, a wider range of radiosensitivities have been described.[50,51] Many have cited the technical nuances and variations in assay technique for this great range.[49,52] Similar to normal hematopoietic cells, their malignant counterparts are thought to demonstrate little sublethal damage repair,[53-57] although split-dose-rate and low-dose-rate experiments have demonstrated the capacity of leukemic cells to repair radiation-induced damage.[58-64] Generally, leukemic cells are thought to have a cell survival curve with a minimal shoulder or no shoulder, although this varies across cell types and cell lines.[47,61-63,65] For example, Cosset et al[52,66] summarized preclinical and clinical findings, concluding that AML demonstrates

little repair, whereas CML does demonstrate repair; ALL, myeloma, and lymphomas have not been well studied but appear to demonstrate a wide range of repair capacity.

Similar to normal hematopoietic cells, reoxygenation is unlikely to be radiobiologically relevant to malignant hematopoietic cells during TBI. Redistribution and repopulation, however, may be relevant but have not been systematically studied. Recent molecular studies suggest a significant effect of TBI on peripheral blood mononuclear cell immune-related gene expression in patients.[67]

In vivo preclinical research laid the foundation for the first successful HSCT in humans. Studies in rats,[68] dogs,[69] and nonhuman primates[70] demonstrated that reconstitution of the hematopoietic system was possible after TBI with supralethal doses of radiation. Later work in animals revealed that delivering TBI in several fractions required a higher total dose relative to the biologically isoeffective dose given in a single fraction.[71,72] Another model demonstrated no significant difference in the effect of a low-dose-rate (0.04 Gy/minute), single-fraction of TBI compared with a hyperfractionated course of TBI given three times a day to the same total dose.[73]

Although the hematopoietic system is the target of TBI, normal tissues effectively limit the dose that can be safely delivered. The sparing of normal tissues with fractionated TBI was proposed by Peters et al[53,54] and was subsequently supported by preclinical data in mice[74,75] and dogs[76] that showed that less lung injury occurred with fractionated TBI regimens.

IMMEDIATE TOXICITY AND MANAGEMENT IN TOTAL BODY IRRADIATION

Although a good deal of what has been learned about the acute in vivo biologic effects of TBI has been derived from laboratory-based animal studies, whole-body irradiation also has been studied in people exposed during accidental or wartime nuclear events.[77,78] These large-scale studies are valuable because they deal with apparently normal subjects; however, the retrospective nature limits the quality of the data. The reader is referred to several excellent reviews of acute and fatal radiation syndromes (gastrointestinal, hematopoietic, and cerebrovascular syndromes) that can be caused by TBI in an uncontrolled setting.[79-81]

Acute side effects of therapeutic TBI can be difficult to distinguish from other HSCT-related morbidities. However, Chaillet et al[82] conducted an informative prospective clinical study of the symptoms and signs that occur in patients after TBI, before the initiation of any other HSCT-related therapy. Thirty-one patients, 4.5 to 55 years of age, were treated using parallel-opposed anteroposterior 18-MV photons from a linear accelerator. Shielding was used to limit the lung dose to 8 Gy. A total dose of 10 Gy was given as a "single dose" as six discrete fractions of 1.6 Gy each given over 15 minutes, with a 30-minute break between fractions, for a mean dose rate of 0.04 Gy/minute and an instantaneous dose rate of 0.11 Gy/minute to 0.12 Gy/minute. Symptoms and signs were assessed regularly during the 4-hour TBI and for 20 hours after the completion of TBI. Antiemetics, but no chemotherapy or steroids, were given before the start of TBI. Table 18-1 displays the symptoms and signs experienced by patients during the 4 hours of TBI and within 24 hours of starting TBI. Fever was a common finding, and a maximum of 40.8° C (105.4° F) was noted in one patient. Tachycardia frequently paralleled febrile episodes; a maximum rate of 130 beats/minute was noted. Drowsiness was noted only in patients who received sedating antiemetics. Parotid gland pain was common, and bilateral parotid swelling was noted in 29% of patients. Marked lacrimation was noted in 6% of patients, whereas 16% of patients experienced ocular dryness. Two patients experienced mild conjunctival edema. Hypertension was noted only during TBI. The results of a similar study conducted by Buchali et al[83] of patients who were treated with a fractionated course of TBI delivered mostly to a total dose of 12 Gy using 2 Gy per

TABLE 18-1 Signs and Symptoms in Patients after Single-Dose or Fractionated TBI

	Single-Fraction TBI		Fractionated TBI
Symptom/Sign	Percentage of Patients Experiencing during TBI	Percentage of Patients Experiencing after TBI	Percentage of Patients Experiencing during 3 Days of TBI

fraction, twice daily, 8 hours apart, with lung doses limited to 10 Gy, are also summarized in Table 18-1.

A prospective clinical study showed that fractionation of TBI can reduce acute nausea, vomiting, mucositis, diarrhea, and parotitis, although the differences were not statistically significant. Late cutaneous eruptions were more common in patients undergoing fractionated TBI, although the numbers were not statistically significant. The same study, which randomized patients to either high- or low-dose rate TBI, revealed no differences in the acute toxicities mentioned when comparing dose rate.[84] Another randomized controlled trial (RCT) reported that fractionating TBI revealed "no apparent difference in acute toxicity" compared with single-fraction TBI, with both regimens being "well-tolerated."[85]

Older studies cite nausea and vomiting as frequent side effects of TBI. These symptoms have been substantially lessened with the advent of more effective antiemetics, such as the 5-hydroxytryptamine (serotonin) receptor-3 (5-HT3) antagonists. Several small but high-quality controlled clinical studies support the prophylactic use of 5-HT3 antagonists to reduce nausea and vomiting during TBI[86-90]; they are summarized in eTable 18-1. The use of corticosteroids in conjunction with 5-HT3 antagonists is supported by a trial listed in eTable 18-1. However, given the toxicity associated with this approach, consensus regarding routine administration in conjunction with TBI is lacking.[91-93] Of note, less nausea and vomiting have been noted in myeloablative conditioning regimens involving TBI compared with those that use chemotherapy alone, even with modern antiemetics.[94]

Oral mucositis is a side effect of TBI in up to 75% of patients undergoing myeloablative TBI, causing mouth pain and odynophagia and necessitating intensive supportive care such as total parenteral nutrition and opioid analgesics.[95] In one study, intensive dental hygiene conferred a reduction in the rate of moderate and severe mucositis, although the authors thought the rate to be clinically insignificant.[96] Topical oral agents, such as chlorhexidine digluconate and neutral calcium phosphate in conjunction with topical fluoride treatments can decrease pain duration and severity of oral mucositis, as well as pain and need for opioid analgesics.[97-99] Similarly, prophylactic oral sucralfate and clarithromycin have reduced moderate and severe oral mucositis rates.[100,101] One study showed that when given prophylactically, amifostine limited the duration of mucositis, with an associated decrease in the rate of moderate and severe infections, with no effect on HSCT outcome.[102] Low-level laser (650 nm) therapy has been reported to reduce the incidence of oral mucositis in a RCT.[103]

In one study, researchers noted that short-term intravenous recombinant granulocyte-macrophage colony–stimulating factor decreased rates of moderate to severe mucositis,[104] but in another study, no effect was found when this agent was delivered topically.[105] Recently, Spielberger et al[106] reported the results of a trial of the recombinant human keratinocyte growth factor palifermin, given before and after conditioning with 12 Gy of fractionated TBI. Palifermin reduced the rate and duration of moderate and severe mucositis by 35% and 3 days, respectively, and decreased mouth and throat pain, as reflected in reduced morphine usage and decreased need for total parenteral nutrition (by 24%). This study dealt only with patients undergoing autologous HSCT; however, in the setting of TBI for allogeneic HSCT, palifermin may also confer a protective effect on the mucosa, although studies suggesting this have been small and inadequately designed.[107]

Skin erythema may also be noted toward the end of a course of TBI; desquamation is rare. Hyperpigmentation may be noted in the long term. Alopecia typically occurs 7 to 14 days after TBI, and hair typically returns 3 to 6 months after treatment.[108] Changes in the color or texture of regrown hair have been noted. Of note, myeloablative conditioning regimens using chemotherapy alone have produced a significantly higher incidence of permanent alopecia.[109]

LATER TOXICITY AND ITS MANAGEMENT IN TOTAL BODY IRRADIATION

Hematopoietic Toxicity

As previously mentioned (see Radiobiology section), the hematopoietic system is particularly sensitive to TBI, and lymphopenia is often seen with doses of 0.5 Gy and can be seen with doses of 0.3 Gy. Lymphopenia is typically followed by neutropenia, thrombocytopenia, and finally anemia. Soon after a TBI dose of 4 Gy to 6 Gy has been given, lymphocytosis can be seen, but it typically is followed by neutropenia within 1 week. Three to 4 weeks after TBI, neutrophils fall to their minimum[110] (Figure 18-3). Regeneration of the HSC compartment depends on the total dose used because higher doses cause more rapid myelosuppression of greater duration. Administration of hematopoietic growth factors after TBI have the theoretical potential to alter hematopoietic system reconstitution, although reports in the setting of allogeneic HSCT have demonstrated an increased risk of GVHD and compromised survival,[111] and therefore, routine use is controversial.[112,113] Of note, hematopoietic growth factors have only been used in the period following TBI, given the concerns raised by a trial in lung cancer, where growth factors increased pulmonary toxicity and thrombocytopenia when given concurrently with chemoradiation therapy.[114]

Oral Toxicity

As noted before, the salivary glands frequently are affected by TBI. Although acute parotitis is typically self-limited and can be managed with antiinflammatory medicines, long-term salivary gland dysfunction can result in xerostomia, which may lead to dental caries. In a study of children who underwent allogeneic HSCT, the risk of developing impaired salivary function was 22% in those who received TBI as part of conditioning versus 1% in those who did not.[115] Salivary flow can improve up to 1 year after the completion of TBI.[116] Fractionated TBI was shown to reduce salivary dysfunction by 54% in one study.[117]

eTABLE 18-1 Randomized Controlled Trials of Prophylactic Antiemetics in Patients Undergoing TBI

Author	No. Patients	Total TBI Dose/ No. Fractions	Experimental Antiemetic	Control of Antiemetic	Outcome
Tiley et al.[86]	20	10.5 Gy/1	8 mg oral ondansetron at start of TBI + standard (metoclopramide, dexamethasone, lorazepam)	Placebo + standard (metoclopramide, dexamethasone, lorazepam)	Significantly fewer emetic events with ondansetron (60% vs. 10%, $p < 0.03$) during TBI
Spitzer et al.[87]	20	13.2 Gy/11 (in 4 days)	8 mg oral ondansetron 1.5 hr before TBI tid	Placebo	Significantly more patients had two or fewer episodes of emesis with ondansetron (60% vs. 10%, $p < 0.03$): significantly longer time to first emetic episode ($p < 0.005$) and significantly fewer episodes of emesis during the first 24 hours and over the entire study period ($p < 0.05$) with ondansetron
Prentice et al.[88]	30	7.5 Gy/1	3 mg IV granisetron 1 hr before TBI	Metoclopramide, dexamethasone, and lorazepam 1 hr before TBI	Significantly higher rates of complete control of emesis within first 24 hr with granisetron (53% vs. 13%, $p = 0.02$) and significantly longer duration of emesis control ($p < 0.005$) with granisetron
Okamoto et al.[89]	58	74% of patients received TBI: 6-12 Gy/1-6	40 μg/kg IV granisetron twice daily 30 min before TBI	Various	Significantly higher rates of complete control of emesis within the first 24 hr with granisetron (92% vs. 44%, $p < 0.01$) and throughout the duration of HSCT (68% vs. 0%, $p < 0.001$) with granisetron in patients receiving TBI
Matsuoka et al.[90]	50	64% of patients received TBI: 12 Gy/4-6	4 mg IV dexamethasone + 40 μg/kg granisetron bid 30 min before treatment	40 μg/kg IV granisetron twice daily 30 min before treatment	Significantly higher (100% vs. 63%. $p = 0.02$) rates of complete emesis control within the first 24 hr with dexamethasone in patients receiving TBI; insomnia, headache, flushing, and hyperglycemia were more common in patients with corticosteroid

TBI, *Total body irradiation.*

Myeloablative conditioning regimens with and without TBI have been associated with abnormalities in tooth development in children.[117-119] In one series, myeloablative conditioning regimens using chemotherapy alone were associated with significantly higher rates of tooth developmental abnormalities than those involving TBI, although rates of salivary gland dysfunction were highest among the patients treated with single-fraction TBI.[120] Because of the increased risk of oral pathology associated with TBI, careful pretransplant evaluation by a dental specialist is recommended to minimize the risk of serious morbidity.[121] Pilocarpine has been noted to help relieve symptoms of xerostomia in patients treated with TBI.[122]

Pulmonary Toxicity

The major dose-limiting toxicity of TBI is pneumonopathy (restrictive or obstructive lung disease), which can manifest early as pneumonitis or later as pulmonary fibrosis. In the setting of HSCT, radiation pneumonopathy can be difficult to distinguish from other causes of lung pathology; moreover, lung damage is likely multifactorial, with the risk of acute lung complications estimated to be 30% to 60%, depending on factors such as infection, conditioning regimen, GVHD, age, and diagnosis.[123] Likewise, late pneumonopathy occurs in 10% to 26% of patients and is associated with underlying lung dysfunction, type of conditioning regimen, acute and chronic GVHD and prophylaxis, donor and recipient age and immunocompatibility, stage of disease, and genetic predisposition.[124] TBI is a risk factor for idiopathic pneumonia syndrome,[125] as well as for diffuse alveolar hemorrhage.[126] Although rates of pneumonopathy in patients receiving TBI vary widely (10% to 84%),[127] some series have reported pneumonitis in up to 20% of patients undergoing HSCT who never received TBI.[128] In the modern era, with appropriate TBI techniques, the risk of pneumonopathy in patients treated with TBI may not be increased at all.[129] Nevertheless, the significance of the problem is clear, given that mortality related to interstitial pneumonitis in patients treated with TBI can be 60% to 80%.[128,130,131]

Several TBI-specific factors (e.g., total dose, fractionation, dose rate, and use of lung shielding) have been shown to have a significant bearing on the development of pulmonary complications. The total dose used during TBI has frequently been cited as a major factor influencing lung complications.[127,132,133] In two prospective RCTs using 12 Gy versus 15.75 Gy, higher rates of mortality were noted within the first 6 months in patients treated with 15.75 Gy, although pulmonary complications were not specifically cited as the cause of excess deaths.[134-137] In a retrospective dosimetric study, a mean lung dose of more than 9.4 Gy was found to be an independent predictor for lethal pulmonary complications in patients receiving TBI to a total dose of 10 Gy in three daily fractions, at 0.055 Gy/minute using parallel opposed lateral fields.[138] Two RCTs have demonstrated that fractionated TBI can reduce pneumonitis compared with single-fraction TBI, although only one study showed differences that were statistically significant.[85,139,140] A retrospective study found no difference in pneumonitis rates when comparing a single fraction of 6 Gy and three daily fractions of 3.33 Gy, suggesting that total doses of less than 10 Gy may not require fractionation to prevent toxicity, although no randomized data support this.[141] The necessity of hyperfractionation to prevent lung toxicity is unclear: A comparison of two prospective single-arm trials at the same institution revealed that conventional fractionation given with anteroposterior fields and lung blocks to a total dose of 12 Gy in daily three-Gy fractions may not be any different than hyperfractionated TBI given twice daily with 1.7 Gy per fraction to a total dose of 10.2 Gy over 3 days, using parallel opposed lateral fields and no blocks.[142] An RCT suggested that the angiotensin-converting enzyme inhibitor, captopril, may mitigate pulmonary toxicity associated with TBI.[143]

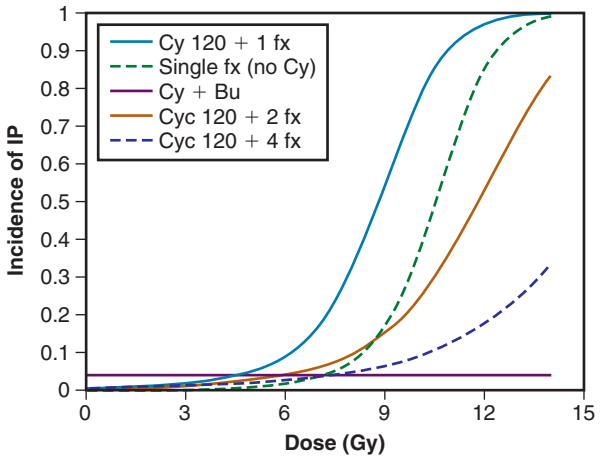

Figure 18-4 Incidence of pneumonitis based on dose-response model accounting for TBI fractionation, as well as chemotherapy effects. *Bu*, Busulfan; *Cy and Cyc*, cyclophosphamide; *fx*, fraction(s). *Data from Sampath S, Schultheiss TE, Wong J: Dose response and factors related to interstitial pneumonitis after bone marrow transplant. Int J Radiat Oncol Biol Phys 63(3):876–884, 2005; Figure 2, © 2005, Elsevier, with permission from Elsevier.*

Sampath et al[144] reviewed 26 studies involving 1096 patients to create a dose-response model for predicting the risk of pneumonitis from TBI while taking other factors into consideration. Although unable to estimate the risk of pneumonitis for hyperfractionated regimens, they were able to determine the effect of fractionation, cyclophosphamide, and busulfan on the risk of developing pneumonitis, in a dose-response model, as seen in Figure 18-4.

Pneumonitis rates were not significantly different in a trial that randomized patients to high- or low-dose-rate TBI.[84] However, there is an abundance of retrospective clinical data suggesting that lowering the dose rate (<0.025 to 0.09 Gy/minute) does decrease the likelihood of pulmonary complications,[127,133,137,145,146] especially if TBI is delivered as a single fraction.[147] If TBI is fractionated, some report that a low dose rate (<0.069 Gy/minute) is not necessary,[131] whereas others found a beneficial effect.[148,149] Studies of patients receiving fractionated TBI with lung shielding have demonstrated a reduction in pneumonopathy[150,151]; however, one RCT found no difference in pneumonopathy rates if the shielding allowed a lung dose of either 6 Gy or 8 Gy in a single fraction.[152]

Pulmonary function tests (PFTs), such as spirometry and diffusion capacity, are often helpful in the assessment of patients with pulmonary symptoms or radiographic abnormalities. Studies of PFTs in patients treated with HSCT have demonstrated a deleterious effect on spirometry and diffusion capacity, which often resolves in the absence of other complicating factors[153-155] and is related to the TBI dose.[156] A retrospective study found that lung shielding had a small but significantly beneficial effect on PFTs 1 year after HSCT, especially in patients with abnormal function before HSCT.[157] In one study, busulfan and not TBI, was associated with a negative effect on PFTs.[158] There is no evidence that obtaining PFTs improve pulmonary outcome after HSCT in adulthood, and for this reason they are not recommended.[159] However, some groups recommend baseline PFTs as part of long-term follow-up care for children treated with TBI.[160] Counseling regarding smoking cessation is of critical importance for all patients, especially those who are at increased risk of developing lung injury. In the event of acute pneumonitis, high-dose

steroids (30 mg to 60 mg of prednisone/day) typically alleviate symptoms within 24 to 48 hours.

Cardiovascular Toxicity

Cardiovascular toxicity in adults as a result of HSCT is relatively rare, given the stringent selection criteria for patients treated with this aggressive therapeutic modality. Nevertheless, in adult patients who survived autologous or allogeneic HSCT, cardiac events were responsible for 2.4% and 3% of deaths, respectively; this represents a greater than expected occurrence.[161,162] Most of the recent literature has identified no association between TBI and the development of cardiovascular disease in adults.[163,164] In several detailed prospective analyses using plasma cardiac troponin and brain natriuretic peptide levels, electrocardiography and echocardiography revealed no evidence of cardiac dysfunction in previously healthy individuals treated with TBI.[165,166] However, a prospective study of children who underwent allogeneic HSCT found a 12% and 26% cumulative incidence of abnormalities in ejection fraction (<30%) on echocardiography before HSCT and 5 years after HSCT, respectively. This study revealed that TBI was associated with abnormalities in cardiac function on univariate analysis but not multivariate analysis; the 5-year cumulative incidence of cardiac abnormality was 26% or 2% in children treated with TBI, with or without prior anthracycline therapy, respectively.[167] Recent data from large studies of survivors of childhood cancer suggest that the risk of cardiac mortality is significantly elevated for children who receive heart doses of 5 Gy, although it should be noted that anthracycline doses of more than 360 mg/m^2 similarly increased the risk.[168] Importantly, the rate of death from recurrence or progression of cancer exceeds the rate of death from cardiac disease by approximately a factor of 7.[169] The reason for excess late cardiovascular toxicity in TBI in children is probably because of the association of TBI with the premature development of cardiovascular disease risk factors (e.g., hypertension, dyslipidemia, diabetes) that result in deleterious consequences rather than direct radiation cardiotoxicity.[170-172] Therefore it is prudent to screen patients who have undergone HSCT for cardiovascular disease risk factors, whether treatment involved TBI, to minimize late morbidity and mortality.

Hepatic Toxicity

Hepatotoxicity from TBI manifests primarily as venoocclusive disease (VOD), also known as sinusoidal obstructive syndrome (SOS), of the liver. This clinicopathologic phenomenon was first described in 1977 by Shulman et al,[173] who noted the onset of weight gain from ascites, painful hepatomegaly, and jaundice from centrilobular liver acinus necrosis 1 to 4 weeks after HSCT. Up to 70% of patients who undergo HSCT can be affected by VOD. TBI, along with many other risk factors, has been implicated in the development of VOD.[174] An RCT and a meta-analysis found that patients treated with busulfan instead of TBI were significantly more likely to develop VOD.[175,176] Two RCTs have concluded that fractionated TBI reduces the incidence of VOD compared with single-dose TBI.[139,140] Another RCT found no difference in the rate of VOD when the dose rate was either 0.06 Gy/minute or 0.15 Gy/minute,[84] although a retrospective study of single-dose TBI found that dose rates of 0.07 Gy/minute were associated with less VOD than dose rates of 0.18 Gy/minute to 1.2 Gy/minute.[177] A TBI dose greater than 13.2 Gy has been reported to be associated with higher rates of VOD on univariate analysis,[178] although a dose greater than 12 Gy was not associated with VOD in another retrospective study.[179] Lawton et al[180] reported a nonstatistically significant 10% decrease in the rate of fatal VOD in patients treated with TBI as part of HSCT when a 10% attenuation liver block was employed. Ursodeoxycholic acid was effective in preventing VOD in an RCT of patients undergoing TBI followed by HSCT,[181] although another RCT did not support this finding.[182] Reduced-intensity conditioning regimens may also prevent VOD. Treatment of VOD can include the fibrinolytic antithrombotic agent defibrotide; decompressing the sinusoids by a transjugular intrahepatic portosystemic shunt and liver transplantation is another, more invasive, option for the management of severe disease.[183]

Visual Toxicity

Cataracts are one of the most common complications of TBI. Patients may present with painless vision loss and may be noted to have opacification of the lens on examination. In one series of patients treated with TBI in one or two fractions, severe visual impairment was noted in about half of patients.[184] This problem has been noted to arise in a large proportion of patients treated with TBI, depending on the total dose, use of fractionation, and the dose rate. When considering risk factors associated with HSCT, steroid use,[185-187] prior cranial irradiation,[188,189] and the development of GVHD[187] have been shown to predispose to cataractogenesis, whereas heparin use appears to be protective.[190]

Delivering TBI in a single fraction is the single biggest risk factor for developing a cataract after HSCT.[190-195] High-dose-rate (>0.035 Gy/minute to 0.048 Gy/minute) TBI also appears to increase the risk of cataract formation.[188,190,193,196] A prospective study that randomized patients to high- or low-dose rate TBI found that the incidence of cataract 5 years after treatment was 12% and 34% in the low- and high-dose rate arms, respectively, with 13% and 39% of the cataracts, respectively, occurring in patients who received fractionated or single-dose TBI.[197] Kal[198] and van Kempen-Harteveld[199] recently reviewed the subject of TBI-induced cataracts and concluded that a biologically equivalent dose of 40 Gy yields a 10% chance of developing cataracts, using linear-quadratic modeling that included corrections for dose rate, with an α/β of 0.65 for late effects on the lens. On the basis of this, they suggest considering lens shielding for single-fraction TBI regimens,[198] although this is controversial in the setting of malignant disease.[199] Given the frequency of cataracts occurring after TBI, patients should be monitored for the development of this complication.[200] Management of cataracts that impair vision or degrade quality of life may involve phacoemulsification and extraction; recent data suggest that these procedures are safe, with an adverse event rate of 0.1% for experienced surgeons,[201] and effective, with a 90% chance of 20/40 vision postoperatively.[202]

Renal Toxicity

Kidney dysfunction occurs in approximately 17% of survivors of HSCT[203] and can manifest in a number of ways, with the most to least frequent syndromes being idiopathic chronic kidney disease, nephrotic syndrome, thrombotic microangiopathy (thrombotic thrombocytopenic purpura and hemolytic uremic syndrome), and acute renal failure.[204] The syndrome most associated with TBI is thrombotic microangiopathy, which can manifest as nephritis, hypertension, proteinuria, or anemia 6 to 12 months after HSCT. HSCT-related risk factors for nephropathy can include GVHD, infections with cytomegalovirus or BK virus, nephrotoxic medications such as cytotoxic chemotherapeutic agents (cytarabine, cyclophosphamide, ifosfamide, cisplatin, retinoic acid, carmustine, actinomycin D, melphalan), antibiotics (acyclovir, ganciclovir, foscarnet, vancomycin, amphotericin, aminoglycosides), and

immunosuppressants (cyclosporine, tacrolimus, methotrexate). The larger and more contemporary studies of chronic kidney disease after HSCT have not demonstrated an association with TBI.[205-209]

Total dose has been implicated as the most important factor in predicting renal morbidity from TBI; a retrospective study found that GVHD and high-dose TBI (13.5 Gy) were associated with elevated serum creatinine levels.[210] A prospective evaluation of renal function using radioisotopes found that early nephropathy was associated with age of younger than 40 years, use of kidney blocks (possibly related to nephrotoxic contrast media given during simulation), and nephrotoxic drug use, whereas late nephropathy was associated with nephrotoxic drug use but not TBI dose.[211] The benefit of kidney shielding has been assessed in two retrospective studies, both of which demonstrated significant improvement in long-term kidney function, with no evidence of dysfunction when the hyperfractionated dose was limited to 9.8 Gy to 10 Gy.[212,213] Two recent dose-effect modeling studies have demonstrated that nephropathy is unlikely after a biologically equivalent total dose of 16 Gy (calculated using a linear quadratic model, with corrections for dose rate and an α/β of 2.5 Gy) and that fractionating TBI and delivery of a low dose rate (<0.10 Gy/minute) prevent kidney dysfunction.[198,214] Monitoring blood chemistry and counts, as well as blood pressure and urine studies, is advised given the prevalence of kidney disease after HSCT.

Although no therapies have been proven to treat HSCT-related nephropathy, medication therapies (antihypertensives, corticosteroids), plasma exchange, hemodialysis, and renal transplant are possible options for management.[204] The angiotensin-converting enzyme inhibitor captopril prevents chronic nephropathy in patients with diabetes[215] and may reduce the risk of radiation nephropathy from TBI in preclinical studies.[216,217] A small RCT in which captopril was given to mitigate chronic renal failure in patients undergoing 12 Gy of fractionated TBI (with a kidney dose of 9.8 Gy) before HSCT revealed less nephropathy; however, the results were not statistically significant.[218]

Endocrine Toxicity

Hypothyroidism is the most common endocrinopathy after HSCT.[219] Most cases are overt and primary in nature, but subclinical and autoimmune thyroid dysfunction have also been noted. Hypothyroidism has been reported in up to 90% of patients after TBI delivered with a single dose of 10 Gy[220] and in up to 15% of patients treated with hyperfractionated TBI to 15 Gy.[221] These findings demonstrate the benefit of fractionation in avoiding this complication. One of the largest studies with a lengthy follow-up of children treated with or without TBI before HSCT revealed that TBI was not a risk factor for developing hypothyroidism when compared with equivalent conditioning with busulfan. In this study, the risk of hypothyroidism was higher in children undergoing HSCT before 10 years of age, and the risk continued to increase until 28 years after HSCT.[222] A recent study demonstrated that reduced-intensity conditioning with lower doses of radiation during TBI was not associated with lower rates of hypothyroidism,[223] suggesting that there is no dose threshold effect. Nevertheless, this complication should be monitored with assessment of thyroid hormones and can be easily managed with thyroid hormone replacement and monitoring.

Gonadal and reproductive endocrine functions can be altered by HSCT and TBI, as reviewed by Chemaitilly and Sklar.[219] In males, Leydig cell function is typically preserved, given the dose of radiation delivered during full-dose TBI.[224] However, in patients who have received prior testicular radiation or who will have a testicular boost during conditioning, Leydig cell function may be threatened. Germ cells are typically thought to be exquisitely sensitive to radiation. A recent study demonstrated that fertility is significantly reduced among boys treated with a radiation dose of more than 7.5 Gy to the gonads, although it should be kept in mind that other antineoplastics, such as alkylating agents, also profoundly reduce fertility.[225] Although there have been case reports of men being treated with TBI and later having children, most men are rendered sterile by HSCT with full-dose TBI; most will experience azoospermia with reduced-dose TBI, but some may also be rendered sterile. With this in mind, male patients should be counseled regarding gamete cryopreservation before initiation of therapy. Likewise, postpubertal women are likely to experience ovarian failure as a result of intensive conditioning, including TBI, and should be counseled about this before treatment. However, about half of prepubertal girls who are treated with fractionated TBI will experience normal reproductive development.[226] As reviewed by Schmidt et al,[227] several fertility-preserving options may be available to women who wish to bear children after HSCT. In a longitudinal prospective study, TBI was reported to be associated with worse sexual functioning among men (but not women) who underwent HSCT.[228]

Hypothalamic-pituitary function appears to be unaffected by TBI of adults to doses of 12 Gy.[229] However, if additional brain radiotherapy is delivered, this complication could be encountered. Growth dysfunction may be caused by TBI through a variety of mechanisms, including growth hormone deficiency and skeletal dysplasia; other factors, including GVHD, liver dysfunction, and busulfan-based conditioning, may also contribute. Younger patients are more likely to be affected by growth impairment. In addition, children treated with single-fraction TBI (as opposed to fractionated TBI) are more likely to experience growth impairment.[230] Growth hormone replacement therapy has been recommended to correct this deficiency,[231] although RCTs have not shown proven benefit[232] and treatment is associated with significant toxicities.

Bone Toxicity

Bone health is another concern after HSCT. Although TBI has been shown to be a risk factor for avascular necrosis of bone,[233] a prospective study found no association between bone metabolism and conditioning with TBI; corticosteroid use is probably the major factor in HSCT causing bone health problems.[234] Monitoring bone health with growth assessments, biochemical hormone assessments, and dual-energy x-ray absorptiometry (DEXA) scans is appropriate, and consideration of counseling, weight-bearing exercise, and use of calcium and vitamin D supplementation or antiresorptive agents (bisphosphonates) should be given in patients with evidence of abnormalities.

Nervous System Toxicity

Mild to moderate neurocognitive impairment has been noted in up to 60% of adults undergoing HSCT with TBI.[235] However, these findings have not been consistent, and several studies have documented no impairment at all.[236,237] As recently confirmed in a prospective multicenter study,[238] TBI-based conditioning (compared with non–TBI-based conditioning) has not been associated with neurocognitive impairment in adults who received full-dose[239] or reduced-intensity conditioning.[240] Children treated with TBI may experience mild neuropsychologic effects.[241] The effects are more prominent in young children,[242] especially those younger than 3 years of age.[243] Similar to adults, no difference in neurocognitive function has been

associated with TBI and non–TBI-based conditioning regimens in older children.[244] However, in young children, TBI-based regimens appear to exert more of a negative effect than non–TBI-based regimens.[245] The magnitude of the deficit has been described as statistically, but not clinically, significant (i.e., a deficit of 3 points in IQ) in recent investigations.[246]

Beyond generally mild cognitive effects of TBI on the nervous system, other types of toxicity are rare. Myelopathy is uncommon, but it has been reported to occur with TBI in conjunction with involved radiation therapy fields, even at cumulative doses considered to be "tolerable" (e.g., 45 Gy).[247] Similarly, severe and fatal neurologic toxicity was reported in a series of children treated with TBI and was generally associated with prior whole-brain radiotherapy to 18 Gy; therefore the cumulative radiation dose in this approach must be considered carefully.[248] Other neurologic toxicity has not been associated with TBI in adults[249] or children.[250]

Risk of Secondary Malignant Tumors

Beyond organ-specific toxicities, the risk of developing secondary malignant neoplasms is increased in patients who have undergone HSCT. Typically, three groups of secondary malignant neoplasms after HSCT are described, and they follow a distinct pattern of development[251] (Figure 18-5): myelodysplastic disease (MDS) and acute myelogenous leukemia (AML), posttransplant lymphoproliferative disorder (PTLD), and solid tumors.[252] There are multiple risk factors that may predispose a patient to the development of a secondary malignant tumor after HSCT, including, but not limited to, genetic aberrations, therapy given before HSCT, conditioning regimen, graft source and processing, posttransplantation immunosuppression, and GVHD[38]; only the association of TBI with secondary malignant neoplasms will be discussed here.

Secondary MDS or AML after HSCT has been reported to occur at rates between 1.1% at 20 months and 24.3% at 43 months. The World Health Organization classifies secondary MDS and AML as alkylating-agent or radiation-related disease, typically occurring 4 to 7 years after treatment, or topoisomerase-II inhibitor–related disease, typically occurring 6 months to 5 years after treatment.[253] Several studies have attempted to quantify the risk of developing secondary MDS or AML after undergoing TBI, with conflicting results. Studies from research groups from Minnesota,[254] Newcastle,[255] the City of Hope,[256] and France[257] have demonstrated no increase in rates of MDS or AML after myeloablative HSCT using TBI. Other studies from Nebraska,[258] the European Group for Bone Marrow Transplantation (EBMT),[259] Paris,[260] Barcelona,[261] and France[262] have found weak associations of borderline or no statistical significance. One study found an association of secondary MDS or AML with TBI on multivariate analysis when TBI was used with etoposide and cyclophosphamide.[263] A recent, detailed study of this subject found that among 4000 patients treated with autologous HSCT for lymphoma, 57 developed MDS or AML, with a cumulative incidence rate of 3.7%, 7 years after HSCT. A case-control analysis revealed a weak association of TBI and the subsequent development of MDS or AML that was not statistically significant. In a small subgroup analysis, a TBI dose of 13.2 Gy was associated with MDS or AML, but the authors cautioned that this group of patients may have shared other non–TBI-related factors that could have contributed to leukemogenesis. Older age also appeared to increase the risk.[264] The dose threshold effect was not supported by a more recent study that found no differences in the rate of MDS or AML after TBI, whether 12 Gy or 14 Gy of TBI was given.[265]

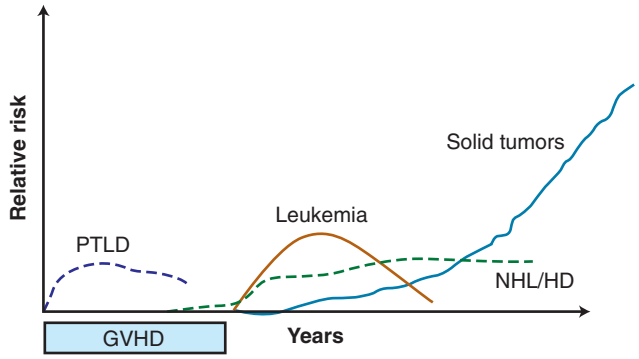

Figure 18-5 Relative risk and chronology of second malignant tumors after allogeneic hematopoietic stem cell transplant (HSCT). *GVHD*, Graft-versus-host disease; *HD*, Hodgkin disease; *NHL*, non-Hodgkin lymphoma.
Data from Ades L, Guardiola P, Socie G: Second malignancies after allogeneic hematopoietic stem cell transplantation. New insight and current problems. Blood Rev 16(2):135–146, 2002; Figure 1, © 2005, Elsevier, with permission from Elsevier.

The association of TBI with the subsequent development of a PTLD has been described in several studies. Because it is thought to result from immune system dysfunction, PTLD occurs primarily in patients following allogeneic, not autologous, HSCT. The cumulative incidence of PTLD at 12 years varied by the number of risk factors the patient had and ranged from 0.2% to 8.1%.[266] Small early studies from Seattle[252] and the Center for International Blood and Marrow Transplant Research (CIBMTR)[267] suggested an association between TBI use during HSCT and subsequent development of a PTLD. However, later research from Minnesota,[254] Vancouver,[268] and Nebraska[269] suggested no association between TBI and PTLD. A follow-up study from the CIBMTR, the largest and most comprehensive study available, involving 26,000 patients who underwent allogeneic HSCT over a 30-year period, clearly demonstrated no association between PTLD and TBI, in contrast to their previous findings.[266]

The risk of solid tumors after HSCT involving TBI has been studied extensively.[270-280] The largest and most recently updated analysis from the CIMBTR suggests that among patients who undergo allogeneic HSCT, the cumulative incidence of developing a solid malignant tumor (including carcinomas in situ that are not of the skin) is 1%, 2.2%, and 3.3% at 10, 15, and 20 years after transplant, respectively, based on the competing risk analysis method.[281] The number of secondary solid tumors was double what would have been expected in this population; significantly higher rates of oral cavity and pharyngeal, liver, central nervous system, thyroid, bone, and soft-tissue cancers and melanomas were observed. TBI was found to be a risk factor for developing a secondary solid tumor, with the risk increased in those who survived more than 5 years from the HSCT and in those younger than 30 years old at the time of HSCT. Although a previous study found that TBI doses of less than 10 Gy were associated with fewer secondary solid tumors,[270] this dose association was not maintained in the subsequent analysis.[281] There was no difference in the rate of secondary solid tumors in patients treated with fractionated or single-dose TBI. There was no increased risk of squamous cell carcinomas in patients treated with TBI and no increased risk of secondary solid tumors in patients treated with TBI after age 30. Chronic GVHD and male sex were associated with the development of secondary solid tumors and squamous cell carcinoma, respectively.[281]

Given the increased risk of secondary malignant neoplasms after TBI, careful surveillance of long-term survivors is a desirable (but not yet proven effective) strategy for minimizing secondary morbidity and mortality. Guidelines published by

the American Cancer Society,[282] the National Comprehensive Cancer Network (NCCN; www.nccn.org), and the Children's Oncology Group[160] provide important references regarding assessing patients at higher risk of developing a secondary solid tumor.

PHYSICAL PRINCIPLES OF TOTAL BODY IRRADIATION

Although irradiating the entire body may seem like a simple exercise, TBI is a highly specialized technique fraught with unique challenges. Nevertheless, the physical aspects of TBI have not changed significantly over the last three decades. The American Association of Physicists in Medicine (AAPM) Report 17, Task Group 29, "The Physical Aspects of Total and Half Body Photon Irradiation," is still considered the authoritative reference for methodology and recommendations regarding the physical aspects of TBI.[283] More recently, the American College of Radiology created a practice guideline for TBI treatment delivery.[284] The reader is referred to these resources and others[285] for detailed information on this subject.

As with all radiotherapeutic techniques, TBI requires meticulous attention to the details of patient measurement, set-up, dosimetry, and quality assurance. Among institutions that perform TBI, most have a dedicated and specially trained team of physicians, dosimetrists, physicists, and therapists who participate in successful implementation because the technique is quite different than typical external beam radiation therapy. Backup systems are essential given the critical time- and situation-dependent nature of HSCT. Readers intending to develop a TBI program are encouraged to contact and learn from centers that have experience with the technique.

Comparison of Techniques of Total Body Irradiation

A report from 1980 highlighted several approaches that have been explored in TBI.[286] The common factor in the different ways of delivering TBI is the goal, which is to deliver the prescribed dose of ionizing radiation to the entire body in a uniform manner (±10% of the prescription dose). An opposed-parallel anterior-posterior (AP/PA) horizontal field setup was developed at Memorial Sloan-Kettering Cancer Center (MSKCC) many years ago.[287] In this technique, the patient is positioned upright several meters from the source with the support of a custom-designed stand. In this technique, high-energy photons are used to increase dose homogeneity although high-energy photons will reduce the dose in superficial structures (skin and subcutaneous tissues), and therefore a beam spoiler is used to increase the surface dose. The beam spoilers are affixed to the stand, which can also accommodate blocks for shielding, imaging equipment for field and patient position verification, and placement of dosimeters (Figure 18-6). When using shielding, compensatory electron boosts can be delivered to superficial tissues such as those of the chest wall (Figure 18-7).

An alternative to the AP/PA field arrangement is a lateral field arrangement, pioneered by Khan.[288] In this approach, the patient is able to recline in a comfortable position during treatment, typically with the knees drawn toward the chest and the arms by the side. As with the AP/PA technique, the patient is typically positioned several meters from the radiation source and the arms can provide shielding to the lungs from the lateral beams. However, as the lateral body thickness is quite disparate over the head-to-toe length of a patient, compensators (usually fixed to the gantry head) will often be required to reduce the dose to the head, neck, and legs. Positioning with this technique is critical; therefore performing and confirming several measurements as well as determining symmetry using in-room light fields and lasers are essential.

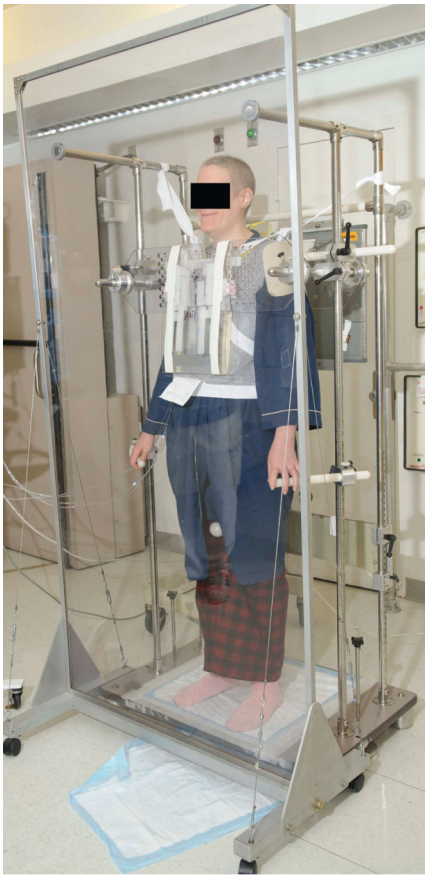

Figure 18-6 Patient in position for total body irradiation using anteroposterior beam arrangement, with lung blocks in place.

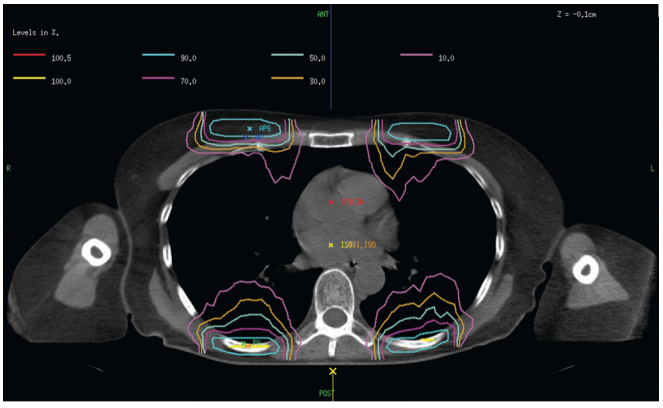

Figure 18-7 CT axial section demonstrating electron-boost dose distribution.

Although the AP/PA and lateral field arrangements are the most commonly employed TBI techniques, other methods exist. Children undergoing TBI may require conscious sedation during radiation therapy, making the previously described techniques impossible. In this situation, TBI can be delivered with the child lying on or near the floor with the gantry pointed down. The child's smaller body size often will facilitate this arrangement; however, in larger children it may be necessary to match two fields. An alternative would be

translating the patient or radiation source during treatment.[287] Logistic considerations largely prohibit this type of approach.

In recent years, several novel approaches to delivering radiation therapy to the entire body have been described. One of these approaches involves rotational intensity-modulated radiation therapy (delivered by a TomoTherapy unit). This approach appears dosimetrically advantageous because it could allow targeting and radiation dose escalation in the bone marrow, and for this reason, it is often referred to as total marrow irradiation (TMI).[289] Early phase clinical trials suggest the technique is tolerable.[290,291] However, sparing the circulating hematopoietic cells from radiation therapy might defeat the purpose of delivering radiation to the entire body. Another approach of delivering systemic radiation therapy is using radionuclides conjugated to monoclonal antibodies, commonly referred to as radioimmunotherapy, instead of external beam radiotherapy. The feasibility of this concept has been demonstrated by several groups, with encouraging results in allogeneic[292,293] and autologous HSCT.[286,287] The uncertainty in biodistribution and clearance of this form of radiotherapy is the major drawback.

Because there are no clinical data to suggest that one technique is advantageous over others, dosimetric benefits have largely dominated the choice of which TBI method to use. Because the AP/PA TBI technique is employed most frequently and is preferred under most conditions, the remaining discussion will focus on its application.

Simulation and Planning for AP/PA Total Body Irradiation

Patients undergoing TBI should be simulated in the treatment position, which is often most easily reproduced in the treatment room. For AP/PA TBI, height must be measured to ensure that the field will adequately encompass the entire patient; exceptionally tall patients might need to sit on the seat of the treatment stand. Other measurements of the AP thickness at the suprasternal notch, chest, abdomen, and pelvis are performed for dosimetric calculations.

While the patient is in the treatment position, radiographs of the thoracic cavity can be obtained to create lung shielding or other blocks. Careful attention should be paid to the size of the blocks so that they are produced in a manner proportional to the treatment field size and distance from the source; this often requires a magnification correction factor. For example, lung shielding is typically designed so that block edges are 1 cm to 2 cm from the bony thoracic periphery, diaphragm, and vertebral bodies. When shielding is used, some institutions choose to perform compensatory electron boosts matched to the blocks. In these situations, computed tomography (CT) can be helpful for planning purposes (Figure 18-7), although the obvious limitation is that CT cannot be performed when the patient is in the treatment position. Alternative imaging modalities (e.g., ultrasound) performed in the treatment position may be helpful in specific situations (e.g., chest wall boosts in patients with large, pendulous breasts).

Beam Energy, Angling, and Production

A wide variety of beam energies have been used for TBI. Most radiation oncology departments now use linear accelerators to generate ionizing radiation, although it should be noted that ^{60}Co generators, which typically produce lower-energy photons than linear accelerators, were the source for many of the early clinical studies. As noted previously, higher beam energies will achieve a more uniform dose distribution but may provide doses lower than desired to superficial structures, so beam spoilers may be needed. The thickness of the patient along the beam axis is the dominant factor dictating the choice of beam energy; typically, lateral field arrangements require higher beam energies than AP/PA field arrangements; however, this ultimately depends on patient size, beam spoilers, and source-axis distance. The source-axis distance can be up to 5 meters; it will often depend on the size of the treatment room relative to the size of the radiation field (dictated primarily by the size of the patient) and may restrict the application of some specific geometric approaches.

The central axis of the beam should be incident at the umbilicus; this usually requires around 5 degrees of gantry angling. The collimator is usually opened to its maximum size (40 × 40 cm) and is rotated to 45 degrees, maximizing the height of the field. The total dose can be prescribed to any anatomic point, but it is often prescribed in the midplane of the pelvis or at the umbilicus.

Compensation

As higher beam energies will reduce the dose delivered to the superficial structures, beam spoilers are often used. Typically an acrylic screen 1 cm to 2 cm thick is used to produce electrons that should increase the surface dose to at least 90% of the prescribed dose. If required, shielding is affixed to the plastic holder on the beam spoiler and placed using reference marks on the patient. For example, at MSKCC, a half-value layer block is employed for lung shielding. Electronic portal imaging can be used to confirm accurate placement of shields. Electron boost fields matched to the lung shields can also be set up using reference marks on the patient.

Calibration and Quality Assurance

Several groups recommend calibrating the treatment delivery unit for TBI using a dosimeter in a large water tank at the distance that will be used for treatment, in the treatment stand, if possible. Given the extended distance, large field size, and compensators used in this technique, a significant amount of scatter radiation will be produced and must be accounted for during calibration. For this reason, the typical percent depth dose (PDD) or tissue maximum ratio (TMR) measurements used for external beam radiation therapy should not be used for TBI; these measurements must be made specifically for the TBI setup. Moreover, variations in dose based on patient size and dose heterogeneity throughout the body should be anticipated and verified during the calibration process. In vivo dosimetry should be performed at several locations (i.e., along the central beam axis, under shielding blocks, and at distal extremities) to verify accurate dose delivery. Regular quality assurance checks should be undertaken according to AAPM guidelines.

ROLE OF TOTAL BODY IRRADIATION IN CONTEMPORARY HSCT

The role of TBI in HSCT has been refined over the last several decades. High-level evidence guides some of the rationale for using TBI, and in some situations, institutional and practitioner preference dictates the use of the technique. Major questions that have been answered deal with the necessity of using TBI during HSCT, as well as questions regarding dose, fractionation, shielding, and boosting.

Necessity of Using Total Body Irradiation in HSCT Conditioning

Although the earliest studies of HSCT for malignant hematopoietic diseases involved both chemotherapy and

radiotherapy (see History of Total Body Irradiation), in the 1970s several regimens using only chemotherapy (without TBI) were developed, largely for logistic reasons, because facilities adequate for performing TBI were not widely available.[294] Soon thereafter, the availability of conditioning regimens for HSCT *without* TBI (primarily involving busulfan and cyclophosphamide)[295] gave rise to several important clinical studies that investigated the necessity of TBI in HSCT in various hematopoietic diseases.

Acute Myelogenous Leukemia

There have been two RCTs comparing TBI-based conditioning regimens with non–TBI-based conditioning regimens for AML. In 1987, the Groupe d'Etude des Greffes de Moelle Osseuse (GEGMO) initiated a prospective multicenter RCT to evaluate whether TBI could be replaced by busulfan, in an effort to limit toxicity in allogeneic HSCT.[296] A similar single-institution study was initiated at the University of Minnesota, for patients receiving autologous HSCT, but accrual was poor and the study was terminated early.[297] As noted in eTable 18-2, superior rates of overall survival, disease-free survival, and fewer relapses were noted with the TBI conditioning regimen in both trials, with only the French trial demonstrating a statistically significant difference.[296,298] An updated analysis of three trials of allogeneic HSCT for AML that randomized patients to conditioning with or without TBI found marginally significant improvements in overall survival and disease-free survival rates. In patients treated with TBI, the estimated 10-year survival rate was 63%, and in those not treated with TBI, the rate was 51% ($p = 0.068$); patients treated with TBI had a 10-year disease-free survival rate of 57%, and untreated patients had a rate of 47% ($p = 0.051$). On multivariate analysis, TBI was associated with significantly less hair loss and no difference in the rates of GVHD, cataracts, avascular necrosis, or pulmonary complications.[299] A retrospective analysis by the CIBMTR revealed that TBI-based conditioning yielded fewer relapses (especially in extramedullary and central nervous system sites) and less hepatic VOD than busulfan-based conditioning.[300] This topic continues to generate controversy, with recent retrospective analyses of registry data demonstrating no difference in TBI and non-TBI, intravenous busulfan-based conditioning,[301] and other similarly designed observational studies suggesting improved outcomes with non–TBI based regimens.[302,303]

Chronic Myelogenous Leukemia

Two RCTs have compared the efficacy and toxicity of allogeneic HSCT in patients with CML, preceded by conditioning with either TBI with cyclophosphamide or busulfan with cyclophosphamide[305-307] (see eTable 18-2). Both studies showed no significant difference in rates of overall survival, event-free survival, or transplant-related mortality. The French study found more relapses in patients treated with TBI (especially fractionated TBI), but this was not seen in the study from Seattle, which used fractionated TBI exclusively. The Seattle trial did show significantly longer episodes of fever, more blood cultures revealing bacteria or fungi, more hospitalizations in the 100 days after transplantation, and a higher incidence of grades 2 to 4 GVHD in patients treated with TBI. An updated, combined analysis of three studies that randomized patients with CML to different conditioning regimens before allogeneic HSCT confirmed no significant difference in rates of survival (65% and 63%) and disease-free survival (52% and 42%) for patients treated with busulfan and cyclophosphamide or cyclophosphamide and TBI, respectively. There were no differences in the 5-year cumulative incidence of chronic GVHD (37% and 39%). However, cataracts were more common among patients treated with TBI.[299] Retrospective data also suggest that busulfan-cyclophosphamide–conditioning regimens before allogeneic HSCT for CML may be favored because of lower relapse rates,[308] although higher rates of GVHD, hepatotoxicity, and hemorrhagic cystitis have been reported with chemotherapy alone.[309]

Acute Lymphoid Leukemia

The Pediatric Blood and Marrow Transplant Consortium conducted the only RCT comparing the effect of preallogeneic HSCT conditioning using busulfan or TBI, in children with ALL. A central nervous system boost of 6 Gy was given to patients with a history of prior central nervous system disease but no prior central nervous system irradiation if randomized to TBI; if randomized to busulfan, patients with a history of central nervous system disease received 18 Gy of central nervous system radiation therapy before receiving busulfan. The study showed no difference in overall survival rates; however, longer event-free survival times were noted for patients treated with TBI. Patients 6 years old or younger, as well as those in their first complete remission, appeared to experience the most benefit from the TBI regimen.[310] A retrospective study by Davies[311] using the CIBMTR data of 627 children with ALL who underwent HSCT after conditioning with cyclophosphamide and TBI (CY/TBI) or busulfan and cyclophosphamide (Bu/CY) found that the risk of relapse was not significantly different in the two cohorts. However, the risk of treatment-related mortality was significantly greater in the Bu/CY group. The use of CY/TBI was associated with superior rates of overall survival and leukemia-free survival. Based on these data, the authors concluded that less treatment-related mortality in the CY/TBI group led to greater rates of overall survival and leukemia-free survival. A multivariate analysis of adults with ALL who underwent HSCT preceded by conditioning with fractionated TBI to 12 Gy (lung dose of 9 Gy) or busulfan found that shorter times of event-free survival and disease relapse were more likely among patients who did not receive TBI on multivariate analysis. There were no differences in the rates of transplant-related mortality, hepatic VOD, or GVHD.[312]

Multiple Myeloma

The Intergroup Francophone du Myelome conducted a trial (9502) that randomized 399 patients with newly diagnosed multiple myeloma to high-dose therapy in preparation for autologous HSCT, after three cycles of vincristine-Adriamycin-dexamethasone chemotherapy. High-dose therapy consisted of melphalan 200 mg/m^2 (HDM200) or melphalan 140 mg/m^2 and 8 Gy of TBI delivered in four daily fractions without lung shielding (HDM140). Overall survival rates were longer in the HDM200 group ($p = 0.05$); however, event-free survival rates were not different in the two groups. The authors speculated that the improved overall survival rate was attributed to the better salvage regimens available after initial therapy with HDM200 and suggested that the standard conditioning regimen for autologous HSCT for MM should be without TBI.[313]

Mixed Diseases

Two prospective trials of conditioning have been carried out in groups of patients with leukemias and lymphomas. Because these trials included a heterogeneous group of diseases, results should be interpreted with caution. Nevertheless, in 1988, the Nordic Bone Marrow Transplantation Group initiated a

eTABLE 18-2 Randomized Controlled Trials Comparing HSCT Conditioning Regimens with and without TBI

Disease	Author (Group)	No. Patients	Type of Transplant	TBI-Based Conditioning	Non-TBI–Based Conditioning	Total TBI Dose Number and Frequency of Fractions Dose Rate	Technique

multicenter RCT of 167 patients (27 children and 140 adults); 68 patients had AML, 38 had ALL, 57 had CML, and 4 had lymphoma before allogeneic HSCT.[175] With 7 years of follow-up, the authors found a survival benefit in the TBI group among patients with "advanced" disease, with less toxicity compared with busulfan regimens; no differences were identified in the subset analysis of the different diseases that were treated.[109] The Southwest Oncology Group's RCT (SWOG 8612) also investigated the role of TBI before allogeneic HSCT for ALL ($n = 48$), AML ($n = 40$), and CML ($n = 34$) patients who were not in their first remission. This regimen substituted etoposide for cyclophosphamide in the TBI group only, making a meaningful comparison difficult. Although rates of overall survival and disease-free survival appeared to be superior for "good-risk" patients in the TBI group, the differences were not statistically significant.[314]

In the setting of allogeneic HSCT, a meta-analysis of the RCTs by Hartman and colleagues[176] summarized how TBI influences the outcome of conditioning regimens before allogeneic HSCT. As illustrated in Figure 18-8, overall survival and disease-free survival rates are slightly better with TBI-based regimens, although the results were not statistically significant. As shown in Figures 18-9 and 18-10, rates of GVHD were roughly equivalent, whereas hepatic VOD was clearly more common with busulfan-based regimens. The occurrence of interstitial pneumonitis also appeared similar in both groups. Another recent meta-analysis of 18 prospective and retrospective studies comparing TBI-based conditioning regimens with those not involving TBI (busulfan-based regimens) found that TBI improved disease-free survival rates in AML and ALL but not in CML. Growth and development problems, interstitial pneumonitis, and cataracts were more common with TBI-based regimens, but transplant-related mortality, VOD, and hemorrhagic cystitis were more common with busulfan-based regimens.[315]

There is much less data regarding the role of TBI before autologous HSCT. A non–TBI-based conditioning regimen is preferred for MM; however, no other trials have randomized

patients to a TBI or non-TBI conditioning regimen before autologous HSCT, and therefore, institutional preference primarily dictates choice of the technique in these situations.

Dose of Total Body Irradiation

The appropriate radiation dose to use during conditioning with TBI has been investigated by several groups. In 1985, researchers in Seattle conducted an RCT of two TBI regimens

as part of the HSCT for AML. Seventy-one patients were randomized to receive 12 Gy in six daily fractions (2 Gy/fraction/day) or 15.75 Gy in seven daily fractions (2.25 Gy/fraction/day). TBI was delivered using opposed ^{60}Co sources, at 0.06 Gy/min to 0.07 Gy/minute. The use of shielding was not described. Higher-dose TBI (15.75 Gy) was associated with higher rates of mortality in patients who did not relapse, although the authors note that this was limited to the first 6 months after transplant and to higher rates of grades 2 to 4 acute GVHD ($p = 0.02$). Patients receiving higher-dose TBI were less likely to receive adequate immunosuppression. Nonetheless, patients treated with lower-dose TBI (12 Gy) appeared to be more likely to relapse, although this finding was only marginally significant ($p < 0.06$).[134] A report of the long-term results (minimum follow-up of 7.5 years) of the trial revealed no difference in overall survival rates between the two TBI groups.[136]

In a similar trial, also from Seattle, 116 patients with CML were randomized to receive either 12 Gy or 15.75 Gy, as described previously. Higher-dose TBI (15.75 Gy) was associated with a superior relapse-free survival rate and with more grades 2 to 4 acute GVHD, although this was not statistically significant ($p = 0.15$). Initially, survival rates appeared to be superior in patients receiving lower-dose TBI (12 Gy). However, further follow-up revealed no significant difference in survival rates. Similar to the experience with AML, the authors concluded that higher-dose TBI was associated with greater relapse-free survival but at the cost of more acute GVHD, which likely led to transplant-related mortality that offset the survival benefit.[135]

Retrospective data suggest a benefit to higher-dose (>12 Gy) TBI in certain clinical scenarios. The highest doses of TBI reported in the literature are 20 Gy before autologous HSCT,[316] but at least one study has reported lower relapse rates and less transplant-related mortality in a subset of patients with ALL who received a TBI dose of more than 13 Gy.[317] Although modeling studies suggest that higher biologically effective doses are associated with lower relapse rates and longer overall survival times,[318] the finding of excess toxicity with higher doses in clinical dose-escalation studies does warrant caution.[319-322] For these reasons, fractionated TBI doses used before myeloablative HSCT typically range between 12 Gy and 15 Gy.

Reduced-intensity conditioning regimens have been used more often over the last decade for patients who might not be able to tolerate a myeloablative HSCT (because of advanced age or comorbidities) but could benefit from the graft-versus-tumor effects of allogeneic HSCT. A recent RCT suggested that reduced-intensity conditioning regimens (with TBI to 8 Gy in four fractions and fludarabine) offer fewer side effects than standard conditioning (with TBI to 12 Gy in six6 fractions and cyclophosphamide), but no difference in disease control or survival.[323] The role of TBI as part of reduced-intensity regimens is ill defined; however, a recent RCT compared reduced-intensity condition with busulfan or TBI (2 Gy in one fraction) and found inferior disease control, but lower nonrelapse mortality with TBI, and no difference in overall or progression-free survival.[324] Likewise, the optimal dose of TBI as part of reduced-intensity autologous HSCT has not been defined in an RCT. Several notable studies of allogeneic HSCT have employed TBI doses of 2 Gy to 8 Gy, often in conjunction with chemotherapy.[325-340] eTable 18-3, lists some representative allogeneic HSCT regimens using low-dose TBI.

Fractionation and the Total Body Irradiation Dose Rate

Laboratory-based radiobiologic data (see Radiobiology section) and clinical observations prompted trials investigating fractionation and dose-rate delivery in TBI. Thomas and et al were the first to conduct an RCT of single-dose or fractionated TBI in patients with AML. In this study, 53 patients with AML were randomized to receive TBI in a single 10 Gy dose or in a dose of 12 Gy in six daily fractions after receiving cyclophosphamide. TBI was delivered using opposed ^{60}Co sources, at a rate of 80 R/minute in air at midpoint (~0.06 Gy/minute). Disease-free survival times were significantly longer in the patients who were treated with fractionated TBI. There was no apparent difference in acute toxicity in the two treatment groups.[85] A follow-up report from the same institution described similar results using a slightly lower dose of single-fraction TBI (9.2 Gy using opposed ^{60}Co sources at 0.04 Gy/minute). Among the patients randomized, those who received fractionated TBI survived significantly longer than those receiving single-fraction TBI. Patients receiving single-fraction TBI experienced twice as many leukemic recurrences compared with those receiving fractionated TBI, although this was not statistically significant ($p = 0.09$). VOD of the liver was significantly more common in patients receiving single-fraction TBI ($p = 002$).[139]

Ozsahin et al[84] conducted a study investigating the effect of dose rate in patients undergoing single-dose or fractionated TBI as part of autologous or allogeneic HSCT for a variety of hematologic and lymphoid cancers. One-hundred fifty-seven patients receiving single-dose or multiple-fraction TBI were randomized to a low dose rate (0.06 Gy/minute or 0.03 Gy/minute, respectively) or a high dose rate (0.15 Gy/minute or 0.06 Gy/minute, respectively). Radiotherapy was delivered with ^{60}Co or 6-MV photons. Single-dose TBI was delivered to a total dose of 10 Gy with the lung dose limited to 8 Gy. Fractionated TBI was delivered to a total dose of 12 Gy in six fractions over 3 days, with the lung dose limited to 9 Gy. A variety of chemotherapies were used. The authors found no significant differences in rates of overall survival or relapse-free survival, pneumonitis, VOD, or GVHD. Cataracts were significantly more common among patients receiving single-fraction, high-dose-rate TBI. In a follow-up report, with a median follow-up time of 50 months, TBI in a single fraction or at a high dose rate was associated with the development of cataracts.[197]

Girinsky et al[140] conducted an RCT of 160 patients older than 15 years who were undergoing autologous or allogeneic HSCT for a variety of hematologic and lymphoid cancers. Patients were treated with a single fraction of TBI (STBI) with 10 Gy over 4 hours (average dose rate of 0.045 Gy/minute; instantaneous dose rate of 0.125 Gy/minute) or with hyperfractionated TBI (HTBI) with 14.85 Gy in 11 fractions over 5 days at a dose rate of 0.25 Gy/minute. A linear accelerator was used to deliver 18-MV photons with lung shielding; patients receiving STBI received a lung dose of 8 Gy, and patients undergoing HTBI received a lung dose of 9 Gy. After TBI, cyclophosphamide or melphalan was given, followed by HSCT. With a median follow-up of 8 years in 147 assessable patients, rates of overall survival and cause-specific survival were higher in the HTBI group; however, the differences were not statistically significant. A multivariate analysis that controlled for prognostic variables revealed greater cause-specific survival rates but not greater overall survival rates in patients treated with HTBI ($p = 0.04$). There was no significant difference in the rates of lethal pneumonitis, hepatic VOD, GVHD, graft failure, infection, or organ failure. However, the rate of hepatic VOD was significantly higher in the STBI group.

The necessity of hyperfractionation versus conventional daily fractionation has never been tested in a prospective trial. Investigators from the M. D. Anderson Cancer Center compared the outcome of patients in different prospective HSCT protocols and found that fewer patients in the conventionally fractionated group had recurrences of disease. These results

eTABLE 18-3 Representative TBI-Based Reduced-Intensity Conditioning Regimens for Allogeneic HSCT

Disease	Author (Group)	No. Patients	Total TBI Dose Number and Frequency of Fractions Dose Rate	Additional Conditioning Therapy	Technique	Type of Transplant
AML	Hegenbart (multicenter)[312]	122	2 Gy 1 0.07 to 0.20 Gy/min	84% received Flu 90 in 3 days, then TBI	Dual opposed ^{60}Co sources or linear accelerator Geometry not described Blocks not described	Allogeneic marrow (5%) and peripheral blood (95%)

MM	Badros (Arkansas)[326]	31	2.5 Gy 2 given bid; dose rate not reported	TBI and Mel 100, then Flu 60 in 2 days	Not described	Allogeneic peripheral blood

AML, *Acute myelogenous leukemia;* ATG, *antithymocyte globulin;* Bu, *busulfan;* Clad, *cladribine;* CLL, *chronic lymphoid leukemia;* CML, *chronic myelogenous leukemia;* Cy, *cyclophosphamide;* Flu, *fludarabine;* MDS, *myelodysplastic syndrome;* Mel, *melphalan;* MM, *multiple myeloma;* MPD, *myeloproliferative disorder;* TBI, *total body irradiation.*

All drug doses are given in mg/kg unless otherwise stated.

should be interpreted with caution because this study was not randomized and other factors not related to TBI may have influenced the results.[142] Investigators in Seattle have conducted phase I/II studies of twice- and thrice-daily hyperfractionation protocols that did not suggest a significant benefit with hyperfractionation versus conventional fractionation when they were compared with historical results.[315,321]

Organ Shielding During Total Body Irradiation

The necessity of shielding to prevent normal tissue toxicity has been investigated in several studies; because pneumonopathy has been considered the dose-limiting toxicity of TBI, the studies have primarily been concerned with lung shielding. Labar et al[150] conducted a trial in 64 patients with AML, ALL, and CML who were undergoing TBI and cyclophosphamide conditioning. Patients were treated with 12 Gy of TBI in three fractions given once daily and were randomized to TBI with or without lung shielding after stratifying by age group (<20, 21 to 30, 31 to 40, >40 years), sex, underlying disease, GVHD prophylaxis, and donor-recipient sex combination. TBI was delivered using a ^{60}Co source, and blocks were used to limit the estimated lung dose to 9 Gy in the group of patients treated with lung shields. There was no difference in rates of leukemia-free survival or relapse. Although interstitial pneumonitis was more common in the group of patients treated without lung blocks (12%) compared with those treated with lung blocks (4%), this difference was not statistically significant.

Girinsky et al[152] conducted a similar study in a group of 85 patients with various lymphoid or hematopoietic cancers. Each patient received TBI with a dose of 10 Gy given in a single fraction over 4 hours (average dose rate of 0.04 Gy/minute; instantaneous dose rate of 0.125 Gy/minute). Patients were randomly assigned to receive a 6 Gy or 8 Gy lung dose. The authors observed no differences in rates of overall survival or lung complications. However, chronic GVHD and infections were significantly less common in the low lung dose group. Interestingly, there were significantly more leukemia relapses in the low lung dose group. The authors speculated that the additional lung shielding may have fostered survival of leukemic cells, which led to higher rates of relapse.

Retrospective data support the benefit of shielding. Weshler et al[151] reported a series of 44 consecutive patients who received 12 Gy of TBI; the first 23 patients were treated with opposed lateral fields and had no lung shielding in place, whereas the subsequent 21 patients had half-value layer transmission blocking after 6 Gy. Pneumonitis occurred in 26% of patients without lung shielding, whereas no pneumonitis was noted in those who had lung shielding. Investigators from Wisconsin have demonstrated sparing of renal and hepatic dysfunction with shielding.[180,212]

Boosting in Total Body Irradiation

There is scant high-level evidence for integrating a boost into the radiotherapy plan involving TBI. The EBMT conducted an RCT to assess the benefit of splenic boosting before allogeneic HSCT in patients with CML in their first complete remission. Two-hundred twenty-nine participants were enrolled and stratified based on age (25 years) and T-cell depletion. Patients were randomized to receive a 10-Gy boost to the spleen (given in one, two, or three fractions) within 14 days of HSCT. Overall, there was no difference in the groups. However, in subgroup analysis, it was determined that patients who did not undergo T-cell depletion and who had more than 3% circulating basophils before transplant demonstrated a statistically significant improvement in overall survival rates.[341] At MSKCC, the testes of males with leukemia undergoing myeloablative HSCT are boosted with 4 Gy in one fraction, based on the results of a retrospective series that revealed significantly lower rates of testicular relapse with this treatment strategy.[342] These findings have never been validated in a prospective study, but other institutions have incorporated the findings in their radiotherapy strategies, as discussed by Quaranta et al.[343] In other situations, investigators have reported success in delivering an involved field boost to the central nervous system (in leukemia)[344] or bulky nodal disease (in lymphoma),[345] although the efficacy of these approaches has never been validated in prospective trials.

Total Body Irradiation in Nonmalignant Diseases

Because radiotherapy is most commonly employed in the treatment of malignant diseases dealt with in other sections of this book, special attention will be paid to the role of TBI as part of HSCT for nonmalignant diseases. Although there are reports of using TBI as part of conditioning before HSCT for nonmalignant-acquired diseases such as severe aplastic anemia, paroxysmal nocturnal hemoglobinuria, systemic amyloidosis, and the acquired immunodeficiency syndrome caused by the human immunodeficiency virus, in general TBI is avoided in these situations.

Although no RCT data exist to support the use of TBI in the conditioning regimen of patients undergoing autologous HSCT for autoimmune conditions, several pilot studies have prompted the execution of phase III studies incorporating TBI. The basis for the role of TBI lies in preclinical studies of a rat model of autoimmune arthritis treated with pseudo-autologous HSCT. When the highest tolerable doses of TBI, cyclophosphamide, or busulfan were given, TBI was the most effective single conditioning agent.[346] Saccardi et al[347] summarized the results of phase I and II trials carried out by the EBMT using HSCT for multiple sclerosis (MS), which revealed stabilization or improvement of neurologic symptoms in 63% of patients, who generally had severe or progressive disease. Collectively, TBI was part of the conditioning regimen in 16 of the 178 patients. Statistical analysis revealed that busulfan, and not TBI, was associated with transplant-related mortality. Interestingly, Nash et al[348] studied 26 patients in a pilot study using high-dose myeloablative conditioning before autologous HSCT, including 8 Gy of TBI, and found that the 3-year progression-free survival rate was 73%, with a 91% overall survival rate, with minimal toxicity. Concerns about the use of TBI in HSCT for MS were brought up by Samijin et al[349] as well as Burt et al,[350] who speculated that radiotherapy may have contributed to axonal injury or caused dysfunction of neural precursor cells, although direct evidence of this was lacking. For these reasons, the ongoing RCT to compare autologous HSCT (ASCT) with mitoxantrone drug therapy for severe MS will not involve TBI (www.astims.org/). Similar concerns regarding the toxicity of radiotherapy in patients with inflammatory bowel disease have prompted investigators to omit TBI from ongoing RCTs of autologous HSCT in Crohn disease.[351]

As in studies of MS and Crohn disease, autologous HSCT has been explored recently for patients with systemic sclerosis (SSc, scleroderma) in several pilot studies. Binks et al[352] reported the results of a phase I/II trial of autologous HSCT for poor-prognosis systemic sclerosis, using a variety of conditioning regimens, some of which included TBI. In their initial report, two of nine patients who received 8 Gy of TBI died of interstitial pneumonitis 1 and 3 months after TBI. This prompted investigators to minimize the TBI dose during further investigations of HSCT in this disease.[353] After two of

the first eight patients in a study by Nash et al[354] died of pneumonitis, these investigators shielded the lungs with five half-value layers after patients received the first 2-Gy fraction. With shielding in place, no further TBI-related pulmonary mortality has occurred; however, two patients developed myelodysplastic syndrome and a former smoker was diagnosed with stage 1 lung cancer.[355] Autologous HSCT for systemic sclerosis is currently being studied in two RCTs; in the United States, the Scleroderma Cyclophosphamide or Transplantation (SCOT) trial, NCT00114530, will incorporate 8 Gy of TBI, whereas in the Autologous Stem Cell Transplantation International Scleroderma (ASTIS) trial in Europe (www.astistrial.com), TBI will not be used.

Several inherited diseases have been successfully treated with HSCT using TBI for conditioning; however, this approach is not desirable for children, who frequently need HSCT at a young age. HSCT for thalassemia has been carried out in several Italian centers and generally does not involve TBI. However, reduced-intensity regimens involving low doses of TBI have been used in a few small series of patients undergoing HSCT for thalassemia and sickle cell disease with favorable results.[356,357] Immunodeficiency syndromes are often treated with HSCT, but TBI is not commonly employed during conditioning, probably because these syndromes are commonly caused by impaired DNA damage repair by nonhomologous end-joining. Phagocytic disorders have been treated with HSCT using myeloablative doses of TBI.[358] HSCT is considered the only curative therapy for osteopetrosis, and the first successful case involved TBI.[359] Likewise, hundreds of patients have been successfully treated for lysosomal or peroxisomal storage diseases (i.e., mucopolysaccharidoses, mucolipidoses, leukodystrophies, glycoprotein and other disorders) with HSCT, often using TBI, although this approach is undesirable in younger children.[360-362] Recent studies have focused on non–TBI-based approaches in these diseases.[363] Fanconi anemia is a disease commonly treated with allogeneic HSCT. In favorable patients with an HLA-matched sibling donor, TBI can usually be avoided. However, in patients with evidence of MDS or AML, use of TBI should be considered. TBI is typically delivered in a single fraction, given the underlying defects in DNA repair and cell-cycle checkpoint regulation in patients with Fanconi anemia. Prospective dose-escalation studies have found no benefit of doses beyond 4.5 Gy.[364]

CHAPTER

19 Charged Particle Radiotherapy

William P. Levin and Thomas F. DeLaney

Interest in the use of charged particle radiotherapy derives from the superior dose distributions that can be achieved with these particles compared with those produced by standard photon therapy techniques, as well as the potential for higher biological effect in the tumor with heavier charged particles. Charged particles deposit energy in tissue through multiple interactions with electrons in the atoms of cells, although a small fraction of energy is also transferred to tissue through collisions with the nuclei of atoms. The energy loss per unit path length is initially relatively small and constant until near the end of the range where the residual energy is lost over a short distance, resulting in a steep rise in the absorbed dose (energy absorbed per unit mass). This portion of the particle track, where energy is rapidly lost over a short distance, is known as the *Bragg peak* (Figure 19-1).

The initial low-dose region in the depth-dose curve, before the Bragg peak, is referred to as the plateau of the dose distribution and delivers about 30% of the Bragg peak maximum dose. The Bragg peak is too narrow for practical clinical applications. For the irradiation of most tumors, the beam energy is modulated to achieve a uniform dose over a significant volume. This has traditionally been accomplished by superimposing several Bragg peaks of descending energies (ranges) and weights to create a region of uniform dose over the depth of the target; these extended regions of uniform dose are called *spread-out Bragg peaks* (SOBP; see Figure 19-1 and Techniques of Proton Delivery section). Although the SOBP beam modulation does increase the entrance dose, the proton dose distribution is still characterized by a lower-dose region in normal tissue proximal to the tumor, a uniform high-dose region in the tumor, and zero dose beyond the tumor. The protons are distributed laterally through the target volumes by a passive scattering foil, collimated with brass apertures, and contoured distally with customized range compensators to compensate for proton range differences from variable proton absorption by tissues of different radiologic density.

Increasingly, charged particle therapy is being delivered by raster scanning a pencil beam of charged particles through the deepest slab of the target volume, then reducing the energy of the particle beam and repeating the process iteratively through the target volume. The pencil beam scanning technique delivers lower proximal dose than the traditional SOBP modulation with passive scattering, can eliminate the need for machining customized apertures and range compensators, and provides greater flexibility in dose delivery including dose painting and intensity modulation.

Charged particles are generally characterized as having either high or low linear energy transfer (LET), which is the rate of energy loss by the particle in tissue. The LET influences the biologic impact of the energy deposited in tissue. X and gamma photons, protons, and helium ions are considered to be forms of low LET radiation. Heavier charged particles (e.g., neon ions, carbon ions) are considered to be forms of high LET radiation. There is an initial increase in the relative biologic effectiveness (RBE) with an increase in LET.[1] Carbon ions have an RBE of about 3, whereas the recommended RBE of protons is 1.1.[2] Higher-LET radiation is less influenced by tissue oxygenation and less sensitive to variations in the cell cycle and DNA repair. For particle radiation, the Gray equivalent dose is calculated by multiplying the physical dose administered by the RBE for that particle; the recommended nomenclature for expressing the dose is Gy(RBE) = physical dose in Gy × RBE.[3]

DEVELOPMENT OF PROTON BEAM RADIOTHERAPY

The vast majority of patients receiving charged particle therapy have been treated with protons. As of December 2012, more than 78,000 patients had received part or all of their radiotherapy by proton beams.[4] Table 19-1 lists currently operational proton beam treatment facilities worldwide. Multiple sites are scheduled to begin using proton beam therapy over the next several years.

In 1946, Robert Wilson proposed that proton beams would provide superior dose distributions over photons and should be considered for clinical radiotherapy.[5] Initially, patients were being treated at facilities designed and constructed for basic high-energy physics research, and this often meant that treatment delivery was cumbersome. The proton beams were limited to a fixed horizontal position, which meant that the patient had to be moved to align the tumor on the trajectory of the beam. This technique was in contrast to the isocentric capabilities of the modern linear accelerator, which rotates around a point in space and can effectively target any site in the body. In addition, for many of the proton machines, the energy of the beam (which defined the depth of the Bragg peak) was only sufficient to treat superficial lesions (such as those of the eye) or intermediate-depth lesions (such as those at the base of the skull). Because of these technical factors and the interests of the involved physicians, the tumors that initially received the most attention were uveal melanomas in the eye and sarcomas at the base of the skull. The major emphasis in proton therapy clinical research initially was on dose escalation for tumors for which local control with conventional (at that time, two-dimensional) radiotherapy was poor.

The development of hospital-based cyclotrons with higher-energy beams capable of reaching deep-seated tumors (up to ~30 cm with a 235-MeV beam), field sizes comparable to those of linear accelerators, and rotational gantries has greatly facilitated proton radiation therapy. Increasingly, researchers are interested in developing protocols that will reduce morbidity at sites where tumor control with photons has proven to be beneficial. At about the same time that hospital-based cyclotrons appeared in the 1990s, intensity modulated photon radiation therapy (IMRT) emerged as a technique that also facilitated dose escalation. IMRT may produce comparable or even higher conformality of the prescription dose compared to passively scattered protons, although the integral dose with protons may be ~50% to 60% lower. Intensity modulated proton radiation therapy (IMPT) can theoretically match the conformality of IMRT in the high-dose prescription volume while simultaneously reducing the integral dose, although making IMPT robust in the face of range and setup uncertainties requires careful treatment planning. For pediatric patients,

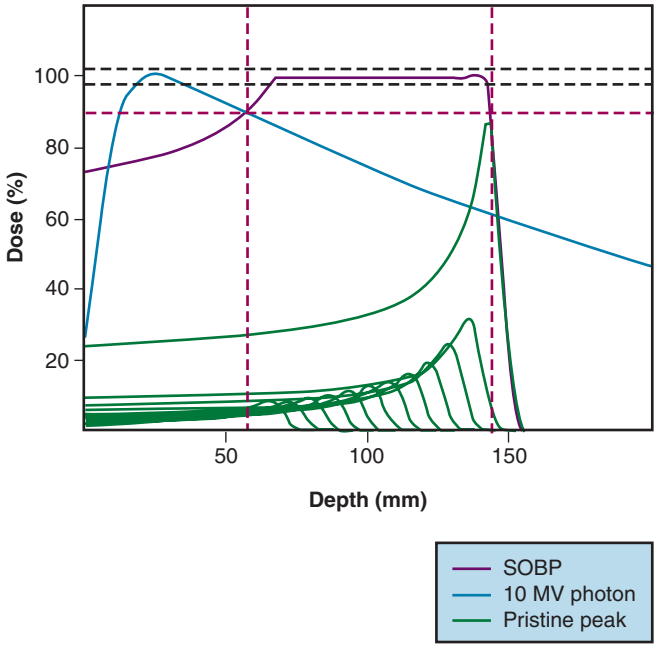

Figure 19-1 Depth-dose distributions for a spread-out Bragg peak (SOBP, *red*), its constituent pristine Bragg peaks *(green)*, and a 10-MV photon beam *(blue)*. The SOBP dose distribution is created by adding the contributions of individually modulated pristine Bragg peaks. The penetration depth, or range (measured as the depth of the distal 90% of the plateau dose), of the SOBP dose distribution is determined by the range of the most distal pristine peak. The *dashed lines (black)* indicate the clinically acceptable variation in the plateau dose of ±2%. The *dot-dashed lines (red)* indicate the 90% dose and the spatial, range, and modulation width intervals. The SOBP dose distribution of even a single field can provide complete target volume coverage in depth and lateral dimensions, in sharp contrast to a single photon dose distribution; only a composite set of photon fields can deliver an appropriate clinical target dose distribution. Note the absence of dose beyond the distal fall-off edge of the SOBP.

the lower integral dose with protons has led many clinicians to conclude that protons are the preferred curative radiation treatment modality for children. In fact, if the cost of proton therapy were the same as photons, it has been argued that protons would also be the treatment of choice for adult patients. Because of the greater cost of accelerating and delivering protons to the tumor, however, cost and cost-effectiveness, particularly in an era of concern about rising healthcare costs, must be considered in the selection of treatment modality. Hence, the current primary focus of discussion about and research in proton radiation therapy is the magnitude of the reduction in clinical toxicity using protons (related to its lower integral dose), at which clinical sites protons provide the greatest clinical benefit and where they are cost effective, and the optimum strategy to assess the benefits in adult patients (i.e., are randomized clinical trials of photons versus protons ethical, can other comparative strategies such as registries provide valid comparisons?). A priori, large target volumes, large target volumes relative to the involved organ (i.e., eye tumors), or sensitive adjacent normal tissues (i.e., spinal cord, critical areas of the brain), particularly in young patients, would be clinical scenarios where the elimination of exit dose would seem to be most important for the use of protons but these will need to be further validated by clinical studies.

TREATMENT OF SPECIFIC CANCERS WITH PROTON BEAM RADIOTHERAPY

Ocular (Uveal) Melanoma

Uveal melanoma is the most common primary ocular tumor. Historically, the primary treatment has been enucleation. Conventional radiotherapy is an alternative to surgery but does not ensure preservation of sight because of the proximity of nearby structures such as the cornea, lens, retina, fovea, and optic nerve. Radioactive plaque therapy is also used for its dose distribution. Because preservation of vision is of utmost importance (secondary only to tumor control), particle beam therapy, with its favorable dose distribution characteristics, has increasingly been employed in the treatment of uveal melanomas.

At Massachusetts General Hospital (MGH), in cooperation with the Massachusetts Eye and Ear Infirmary, patients have undergone placement of tantalum clips to demarcate the location of the tumor for proton radiotherapy planning. When the patient is undergoing treatment, the clips can be identified by fluoroscopy to allow for accurate daily setup. Most institutions employ a fixed horizontal beam for treatment of uveal melanomas, so the patient is able to sit upright. Immobilization is achieved with a mask and a bite block. Patients are asked to stare at a small light to help set the eye position and are monitored with a video camera during treatment. Typically, a total of 70 Gy(RBE) is administered over five fractions.

As of December 2002, more than 3000 patients with uveal melanoma had been treated with protons at MGH in collaboration with the Massachusetts Eye and Ear Infirmary.[6] The 5-year actuarial local control rate was 96% for all sites within the globe, with an 80% survival rate. The probability of eye retention at 5 years was estimated to be 90% for the entire group and 97%, 93%, and 78% for patients with small, intermediate, and large tumors, respectively. Independent risk factors for enucleation were involvement of the ciliary body, tumor height greater than 8 mm, and distance between the posterior tumor edge and the fovea. These results compare favorably with the 5-year local control rates of 93% reported with protons in Nice, France,[7] and 98.9% from the Paul Scherrer Institute in Villigen, Switzerland.[8]

Because some patients have experienced deteriorating vision after doses of 70 Gy(RBE), a randomized trial of 50 Gy(RBE) versus 70 Gy(RBE) for small and intermediate-sized lesions located within 6 mm of the optic disc or macula was conducted. Interim analysis of 188 patients, with a median follow-up of 60 months, suggested no reduction in either local control or survival rates. No significant improvement in visual outcome or complications has been observed. However, visual field analysis does show a smaller mean defect in the patients randomized to 50 Gy(RBE).[9] Hence, smaller posterior tumors that are near the macula or optic disc can be treated with 50 Gy(RBE).

Egger et al[10] reported long-term results of eye retention after treatment of uveal melanoma with proton beam therapy. A total of 2645 patients (2648 eyes) were treated at the Paul Scherrer Institute between 1984 and 1999. The overall eye retention rate at 5, 10, and 15 years after treatment was 89%, 86%, and 83%, respectively. Enucleation was related to large tumor size (mainly, tumor height), male gender, high intraocular pressure, and large degree of retinal detachment at treatment time.

Sarcomas of the Skull Base and Spine

Treatment of patients with sarcoma of the skull base is challenging because of the proximity of critical structures, notably, the brain, brainstem, cervical cord, optic nerves, and chiasm.

Accordingly, surgery and conventional photon therapy have not been successful at controlling these tumors. Because of the necessity of delivering the dose in a precise manner, the use of proton therapy is becoming the treatment of choice for these tumors.

At the Harvard Cyclotron Laboratory, MGH, physicians used a combination of protons and photons to treat patients with tumors of the skull base and cervical spine.[11] A total of 169 patients with chordoma and 165 patients with chondrosarcoma were treated. The 10-year local control rate was highest for chondrosarcomas, intermediate for males with chordomas, and lowest for females with chordoma (94%, 65%, and 42%, respectively). For cervical spine tumors, 10-year local control rates were not significantly different for chordomas and chondrosarcomas (54% and 48%, respectively), nor was there any significant difference in local control rates between males and females. In a Cox multivariate analysis, predictors of local control included gender and equivalent uniform dose, or gender and target volume, or gender and minimum target dose.[12] Five-year actuarial rates of endocrinopathy were as follows: 72% for hyperprolactinemia, 30% for hypothyroidism, 29% for hypogonadism, and 19% for hypoadrenalism. The minimum target dose (Dmin) to the pituitary gland was found to be predictive of endocrinopathy: Patients receiving 50 Gy(RBE) or more at Dmin to the pituitary gland had a higher incidence of and greater severity of endocrine dysfunction. Posterior pituitary dysfunction, represented by vasopressin activity with diabetes insipidus, was not observed.[13]

Between 1998 and 2005, 64 patients with skull base chordomas (42 patients) and chondrosarcomas (22 patients) were treated at the Paul Scherrer Institute with protons using a spot-scanning technique.[14] Patients with chordoma received a mean dose of 73.5 Gy(RBE) (range, 67 Gy[RBE] to 74 Gy[RBE]), and patients with chondrosarcoma received a mean dose of 68.4 Gy(RBE) (range, 63 Gy[RBE] to 74 Gy[RBE]). With a mean follow-up of 38 months, actuarial 5-year local control rates were 81% and 94% for chordomas and chondrosarcomas, respectively. The actuarial 5-year rate for freedom from high-grade toxicity was 94%.

Torres et al[15] performed a planning study where they compared three-dimensional (3D) conformal proton (PR) therapy, IMRT with photons (PH), and combined proton and IMRT photon (PP) irradiation of skull-base chordomas to determine the optimal technique. For each of five patients, they generated four treatment plans: (1) an IMRT plan with a 1-mm planning target volume (PH1) for stereotactic treatment; (2) an IMRT plan with a 3-mm planning target volume (PH3) for routine treatment; (3) a PR plan with beam-specific expansion margins on the clinical target volume; and (4) a plan for PP treatment. The mean percentage of planning target volume (%PTV) receiving the prescription dose of 74 Gy(RBE) was highest in the PP plans and lowest in the PH3 plans. The PR plans were the least homogeneous and conformal. The PH3 plans had the highest mean percentage of volume (%V) of brain, brainstem, chiasm, and temporal lobes above the tolerance dose for those organs. The PH1 plans had the lowest brainstem mean %V receiving 67 Gy(RBE) and temporal lobe mean %V receiving 65 Gy(RBE). Global evaluation of the plans based on objective parameters revealed that the PP plans yielded the best target coverage and conformality. This study indicates that there may be dosimetric advantages to using a combination of IMRT and 3D protons, to optimize conformality and minimize integral dose, which may be an important option until intensity-modulated proton therapy is more widely available.

As with skull-base tumors, treatment of spinal and paraspinal tumors is complicated by the proximity of the spinal cord. Radiation tolerance of the spinal cord is generally quoted at 45 Gy to 50 Gy, well below the doses necessary to reliably control most sarcomas: doses of approximately 60 Gy are needed for subclinical microscopic disease, 66 Gy for tumors with microscopically positive margins, and more than 70 Gy for gross residual disease. Proton radiotherapy, with its ability to spare adjacent tissues, offers advantages for treatment of tumors in these locations.

Hug et al[16] presented results on combined photon/proton treatment of 47 patients with osteogenic and chondrogenic tumors of the axial skeleton. Radiation was delivered postoperatively in 23 patients, preoperatively and postoperatively in 17 patients, and as the sole treatment in 7 patients. Mean radiation doses of 73.9 Gy(RBE), 69.8 Gy(RBE), and 61.8 Gy(RBE), respectively, were delivered to group 1 (20 patients with recurrent/primary chordoma or chondrosarcoma), group 2 (15 patients with osteogenic sarcoma), and group 3 (12 patients with giant cell tumors, osteoblastomas, or chondroblastomas). Five-year actuarial local control and survival rates for patients with chondrosarcoma were 100% and 100% and with chordoma, 53% and 50%. The actuarial 5-year local control rate for patients with osteosarcoma was 59%. The 5-year actuarial local control and survival rates for the group 3 patients were 76% and 87%. Overall, improved local control was noted for patients with primary versus recurrent tumors, those who underwent gross total resection, and those who received target doses of more than 77 Gy(RBE).

At the Francis H. Burr Proton Therapy Center at MGH, a Phase II study was conducted of combined photon and proton beam radiation therapy, with or without surgical resection, for patients with spinal and paraspinal sarcomas.[17] Doses of 77.4 Gy(RBE) at 1.8 Gy(RBE) per day were used for patients with gross residual disease and 70.2 Gy(RBE) for patients with microscopic residual disease. A total of 50 patients (29 with chordoma, 14 with chondrosarcoma, and 7 with other cancers) underwent gross total (25 patients), subtotal (12 patients) resection, or biopsy (13 patients). With a 48-month median follow-up, the 5-year actuarial local control, recurrence-free survival, and overall survival rates were 78%, 63%, and 87%, respectively. Two of 36 patients (5.6%) treated for primary tumors versus 7 of 14 patients (50%) treated for recurrent tumors developed local recurrence ($p < 0.001$). The spinal cord center dose was limited to 54 Gy(RBE) and the cord surface dose to 63 Gy(RBE) over a length of 5 cm or less. The cauda equina was constrained to 70.2 Gy(RBE), except for areas in direct contact with tumor, where the dose limit was 77.4 Gy(RBE). Five patients developed late radiation-associated complications; no myelopathy developed, but three grade 3 sacral neuropathies appeared after doses of 77.1 Gy(RBE) to 77.4 Gy(RBE) had been delivered. A recent update with median follow-up of 7.3 years, continues to show excellent local control in patients with primary tumors, with estimated local control at 8 years of 85% with an acceptable rate of grades 3 to 4 complications of 13% at 8 years.[18]

Recently, the MGH group reported the results on 24 patients treated with high-dose proton based definitive radiotherapy for unresected spinal chordomas.[19] Tumor locations included cervical (2), thoracic (1), lumbar (2), S1 to S2 (17), and S3 or below (2). Median total dose was 77.4 Gy(RBE). Analysis at median follow-up of 56 months showed overall survival of 91.7% and 78.1%, chordoma specific survival of 95.7% and 81.5%, local progression free survival of 90.4% and 79.8%, and metastases-free survival of 86.5% and 76.3%, at 3 and 5 years, respectively. Long-term side effects included eight sacral insufficiency fractures (none required surgical stabilization), one secondary malignancy, one foot drop, one erectile dysfunction, one perineal numbness, two worsening urinary/fecal incontinence, and four grade-2 rectal bleeding. None required new colostomy. All surviving patients remained ambulatory.

Optic Pathway Glioma

At Loma Linda University, seven children with optic pathway gliomas were treated with proton radiation therapy.[20] At a median follow-up of 37 months, all tumors were locally controlled. A reduction in tumor volume was seen in three patients, and tumor volume was stable in the other four. Visual acuity was stable in those who presented with useful vision. Proton plans were compared with 3D conformal photon plans for individual patients. With proton therapy there was a 47% reduction in the dose to the contralateral optic nerve. There was an 11% reduction in the dose to the chiasm and a 13% reduction in the dose to the pituitary gland. There was also a reduction in the dose to the temporal lobes and frontal lobes.

Astrocytoma

Between 1993 and 1998, 48 patients were treated for nonresectable grades II and III intracranial tumors at the Center for Proton Therapy in Orsay, France.[21] Mean tumor doses ranged from 63 Gy(RBE) to 67 Gy(RBE) at 1.8 Gy(RBE)/fraction. With a median follow-up of 18 months, local control rates were 97% (33 of 34 patients) and 43% (6 of 14 patients) for nonparenchymal and parenchymal lesions, respectively.

At the Harvard Cyclotron Laboratory (HCL) and MGH a Phase II study was undertaken to assess whether dose escalation to 90 Gy(RBE) with conformal protons and photons in accelerated fractionation twice a day would improve local tumor control and survival rates.[22] A total of 23 patients were enrolled, with ages of 18 to 70 years. Actuarial survival rates at 2 and 3 years were 34% and 18%, respectively. The median survival time was 20 months, with 4 patients alive 22 to 60 months after diagnosis. All patients developed new areas of gadolinium enhancement during the follow-up period. Histologic examination of tissues obtained at biopsy, resection, or autopsy was conducted in 15 patients. Radiation necrosis only was demonstrated in 7 patients, and their survival was significantly longer than patients with recurrent tumor. Tumor regrowth occurred most commonly in areas that received doses of 60 Gy(RBE)to 70 Gy(RBE) or less; recurrent tumor was found in only 1 patient in the group that received a dose of 90 Gy(RBE). The authors concluded that attempts to extend local control by enlarging the volume would likely be complicated by a high incidence of radionecrosis.

Benign Meningioma

Surgical resection of meningiomas is often limited by their location, which may be the sphenoid ridge, parasellar area, or posterior fossa. Likewise, radiation therapy for these intracranial tumors is complicated by the proximity of critical structures, notably, the visual system. Proton beam radiation, with its high degree of conformality, therefore would seem to be an attractive treatment modality.

Between 1981 and 1996, 46 patients with partially resected, biopsied, or recurrent benign meningiomas were treated with combined proton/photon radiation at HCL/MGH.[23] The median dose to the tumor was 59 Gy(RBE). Overall survival rates at 5 and 10 years were 93% and 77%, respectively, and recurrence-free rates at 5 and 10 years were 100% and 88%, respectively. Three patients presented with local tumor recurrence at 61, 95, and 125 months. One patient died of focal brain necrosis at 22 months. Neurologic complications, including memory deficits and hearing loss, were also seen. Four patients developed ophthalmologic toxicity. In all of these cases, the maximum dose to the optic structures was more than 58 Gy(RBE). Endocrine abnormalities following treatment were also seen.

Investigators from the Paul Scherrer Institute reported on the treatment of 16 patients with recurrent, residual, or untreated intracranial meningiomas.[24] The median prescribed dose was 56 Gy(RBE) (range, 52 Gy[RBE] to 64 Gy[RBE]) at 1.8 Gy[RBE] to 2 Gy(RBE) per fraction. Cumulative 3-year local control, progression-free survival, and overall survival rates were 91%, 91%, and 92%, respectively. No patient died of recurrent meningioma. Radiographic follow-up (median, 34 months) revealed an objective response in 3 patients and stable disease in 12 patients. The cumulative 3-year toxicity-free survival rate was 76%. One patient with an optic nerve sheath meningioma presented with sudden visual field deterioration of the ipsilateral eye 30 months after irradiation with 56 Gy(RBE). Another patient with optic nerve encasement by disease developed visual deterioration at 9 months. A third patient developed symptomatic brain necrosis 7 months after treatment. No radiation-induced hypothalamic/pituitary dysfunction was observed.

Paranasal Sinus, Nasal, and Nasopharyngeal Tumors

Mock et al[25] performed a planning comparison study of various photon and proton techniques for the treatment of paranasal sinus carcinoma. In five patients, proton plans were compared with conventional, conformal, and IMRT photon plans. The evaluations analyzed dose-volume histogram findings of the target volumes and organs at risk (i.e., the pituitary gland, optic pathway structures, and brain).

The mean and maximal doses, dose inhomogeneities, and conformity indexes for the planning target volumes were comparable for all techniques. Photon plans resulted in greater volumes of irradiated nontarget tissues at the 10% to 70% dose level compared with the corresponding proton plans. Compared with conventional techniques, conformal and IMRT photon treatment planning options similarly reduced the mean dose to the organs at risk. The use of protons further reduced the mean dose to the organs at risk by up to 65% and 62% compared with conformal and IMRT techniques, respectively.

Truong et al[26] performed a retrospective review of 20 patients with locally advanced primary sphenoid sinus malignant tumors treated between 1991 and 2005 with proton radiotherapy to a median dose of 76 Gy(RBE) to determine treatment outcome and prognostic factors. With a median follow-up of 27 months, the 2-year local, regional, and freedom from distant metastasis rates were 86%, 86%, and 50%, respectively. The disease-free and overall survival rates at 2 years were 31% and 53%, respectively. In multivariate analysis, oropharyngeal involvement ($p = 0.005$) and anterior cranial fossa invasion ($p = 0.02$) were predictive for poor disease-free survival rates. Brain invasion was predictive for decreased overall survival ($p = 0.05$). No grade 3 or 4 late visual toxicity was reported.

Three patients developed chronic nasal symptoms after radiotherapy, consisting of common toxicity criteria (CTC) grades 2 to 3 nasal obstruction secondary to fibrous adhesions. One patient required surgical removal of adhesions to relieve chronic nasal congestion. One patient with symptomatic CTC grade-2 brain toxicity experienced seizures and short-term memory loss. The seizures were controlled with anticonvulsant medications and a short course of steroids. Two patients experienced cerebrospinal fluid leakage after surgery and irradiation. One patient developed a CTC grade-2 cerebrospinal fluid leak from the external auditory canal, secondary to tumor shrinkage and erosion of the petrous temporal bone 5 months after radiotherapy. One patient developed a CTC grade-5 cerebrospinal fluid leak without evidence of tumor recurrence at 2 months after completion of radiotherapy. The patient underwent four surgical repairs, including transethmoid packing of the ethmoid and sphenoid sinuses and placement of a lumboperitoneal shunt. The patient subsequently died from infectious meningitis. Two patients had endocrinopathies that were medically corrected. The authors concluded that proton radiation therapy results in excellent local control in patients with advanced primary sphenoid sinus malignant disease. Brain invasion and involvement of the oropharynx and anterior cranial fossa were important prognostic factors. Nasal symptoms, brain injury, endocrinopathies, and cerebrospinal fluid leaks, however, complicated treatment.

At Loma Linda University, 16 patients with recurrent nasopharyngeal carcinoma were treated with conformal proton irradiation.[27] Patients had initially been treated with photon therapy at doses of 50 Gy to 70 Gy. Conformal proton boost radiation was then delivered to bring the total dose to 59 Gy(RBE) to 70 Gy(RBE). With a mean follow-up of 23 months, the 24-month actuarial overall and locoregional progression-free survival rates were both 50%. No central nervous system complications were observed. An update now includes data on 39 patients. Twenty-four-month actuarial overall and locoregional progression-free survival rates were 49% and 70%, respectively. When critical central nervous system structures were reirradiated, doses were low (0 Gy[RBE] to 22 Gy[RBE]); one patient experienced grade-4 central

nervous system side effects. Grade-3 late head and neck toxicity occurred in seven patients and grade-4 toxicity in two patients.

Acoustic Neuroma

Between 1991 and 1999, 30 patients with acoustic neuroma were treated with proton therapy at Loma Linda University.[28] Patients with useful hearing before treatment received 54 Gy(RBE) in 30 fractions, and patients without useful hearing received 60 Gy(RBE). Follow-up ranged from 7 to 98 months (median, 34 months), during which no patients demonstrated disease progression on magnetic resonance imaging (MRI) scans. Eleven patients demonstrated radiographic regression. Of the 13 patients with useful hearing before treatment, 4 (31%) maintained their hearing. No transient or permanent treatment-related trigeminal or facial nerve dysfunction was observed. Investigators are now interested in evaluating a reduction in tumor dose in an attempt to increase hearing preservation rates.

Carcinoma of the Prostate

Investigators at MGH completed a Phase III trial comparing 67.2 Gy of photons with 75.6 Gy(RBE) of combined photons/protons using a conformal perineal proton boost.[29] From 1982 to 1992, 202 patients with stage T3 or T4 prostate cancer received 50.4 Gy by four-field photons. Patients then received either 25.2 Gy(RBE) with conformal protons or a 16.8-Gy photon boost. No differences between the two groups were found in overall survival, total recurrence-free survival, or local recurrence-free survival rates. The local recurrence-free survival rate at 7 years for patients with poorly differentiated tumors (Gleason score of 9 or 10) was 85% for the proton arm and 37% for the photon arm. Rates of grades 1 and 2 rectal bleeding were higher in the proton arm (32% versus 12%), as were those for urethral stricture (19% versus 8%). Dose escalation to 75.6 Gy(RBE) by conformal proton boost led to increased late radiation sequelae but not to increased total survival rates in any subgroup. However, there was an improved local recurrence-free survival rate in patients with poorly differentiated tumors.

The Loma Linda University experience of conformal proton therapy for prostate cancer was reported[30] for 1255 patients treated from 1991 to 1997. The overall biochemical disease-free survival rate was 73%, and it was 90% in patients with an initial prostate-specific antigen (PSA) level of ≤4 ng/mL; it was 87% in patients with posttreatment PSA nadirs of ≤0.50 ng/mL. Rates dropped with higher initial and nadir PSA values.

In general, conformal proton beam radiation therapy was well tolerated; the rate of Radiation Therapy Oncology Group (RTOG) grade 3 or higher acute gastrointestinal or genitourinary morbidity was less than 1%. RTOG grade-3 late morbidity was seen in 16 patients (1%) and grade-4 late morbidity in two patients (0.2%). Late gastrointestinal toxicity included grade-3 bleeding and pain in two patients and a bowel obstruction requiring diverting colostomy in one patient. All cases of severe gastrointestinal toxicity presented within the first 2.5 years after treatment. The actuarial 5-year and 10-year rates for freedom from grades 3 and 4 genitourinary toxicity were both 99%.

Late genitourinary morbidity was seen more frequently than gastrointestinal morbidity. Fourteen patients developed grade-3 late toxicity, with eight of them having urethral strictures, followed by hematuria (four patients) and dysuria (two patients). The actuarial 5-year and 10-year rates for freedom from grades 3 and 4 genitourinary toxicity were both 99%. One patient developed necrosis of the symphysis, which was partially included in the treatment field. Because of the low incidence of grades 3 and 4 side effects, no statistically significant prognostic variables for toxicity could be found. These results, when accounting for length of follow-up, compare favorably with those of conformal photon therapy and intensity-modulated photon therapy.

MGH and Loma Linda University conducted a Phase III randomized dose escalation trial in patients with early-stage prostate cancer.[31] Between 1996 and 1999, 393 men with stage T1b to T2b prostate cancer and PSA levels of 15 ng/mL or less were randomly assigned to a total dose of either 70.2 Gy Gy(RBE) or 79.2 Gy(RBE). No patient received androgen suppression therapy with irradiation. Conformal radiation therapy was given in two phases. In phase I, conformal proton beams were used to treat the prostate alone. Either 19.8 Gy(RBE) or 28.8 Gy(RBE) was given in 1.8-Gy(RBE) fractions. In phase II, all men—regardless of trial arm—received 50.4 Gy delivered with photons in 1.8-Gy fractions to the prostate and seminal vesicles. Rates of local failure, biochemical failure, and overall survival were measured as outcomes. With a median follow-up of 8.9 years, men receiving high-dose radiation therapy were significantly less likely to have local failure, with a hazard ratio of 0.57. The 10-year American Society for Therapeutic Radiology and Oncology defined biochemical failure rates were 32.4% for conventional-dose and 16.7% for high-dose radiation therapy ($p < 0.0001$). This difference held when only those with low-risk disease (227 patients; 58% of total) were examined: 28.2% for conventional-dose and 7.1% for high-dose radiation therapy ($p < 0.0001$). There was a strong trend in the same direction for the intermediate-risk patients (144 patients; 37% of total; 42.1% versus 30.4%, $p = 0.06$). Eleven percent of patients subsequently required androgen deprivation for recurrence after conventional-dose radiation therapy compared with 6% after high-dose radiation therapy ($p = 0.047$). There remains no difference in overall survival rates between the treatment arms (78.4% versus 83.4%; $p = 0.41$). Two percent of patients in both arms experienced late grade 3 or higher genitourinary toxicity, and 1% of patients in the high-dose arm experienced late grade 3 or higher gastrointestinal toxicity. This randomized controlled trial shows superior long-term cancer control for men with localized prostate cancer receiving high-dose versus conventional-dose radiation. This dose escalation was achieved with protons without an increase in grade 3 or higher late urinary or rectal morbidity.

Given the significant cost difference and lack of level-1 evidence showing a clear clinical benefit, great controversy exists about the use of proton radiation for prostate cancer instead of conventional photon radiotherapy. Treatment planning studies and retrospective analyzes addressing these issues exist, but prospective head-to-head comparisons between the two treatment modalities are lacking. With that in mind, investigators at MGH and the University of Pennsylvania developed a multiinstitutional randomized trial comparing proton therapy to IMRT in the treatment of patients with low or low-intermediate risk prostate cancer.[32] Patients are randomized to receive 79.2 Gy in 1.8 Gy fractions via IMRT or proton beam therapy. The primary endpoint is post-treatment bowel function. Secondary outcomes to be examined include, quality of life, clinical efficacy, biological, and physics endpoints, and cost.

Just as IMRT radically changed the delivery of photon-based radiation for the treatment of prostate cancer, IMPT offers the possibility of a similar change in the future. IMPT relies on the use of spots scanning to deliver a more conformal dose distribution of radiation, with the potential for an even greater reduction of treatment-related toxicity in comparison

to passive scatter techniques.[33] Another approach being investigated is the use of anterior-oriented beams, which may overcome the issues of tissue heterogeneity brought on by treating through the hip joints.[34]

Gastrointestinal Tumors

Investigators at Tsukuba University in Japan have reported impressive long-term control and survival in 122 patients with primary hepatocellular carcinoma treated with proton radiotherapy.[35] The dose per fraction was 4 Gy(RBE) and the mean total dose was 72 Gy(RBE) (the Tsukuba group did not correct for RBE, so these doses are in physical Gray; hence, the biologically effective dose may have been up to 10% higher). The 7-year local control and survival rates were 94% and 27%, respectively. Proton irradiation did not cause clinically symptomatic changes in liver function. The only notable change observed was a transient increase in liver transaminase levels. In 2012, the group from Tsukuba published a retrospective analysis of 259 patients who received pencil beam therapy for hepatocellular carcinoma between 2001 and 2007.[36] Univariate analysis revealed a significant association between the percentage volume abnormal liver receiving a particular radiation dose and the liver function, as quantitated by the Child-Pugh score.

Investigators at MGH carried out a feasibility study for neoadjuvant hypofractionated proton therapy for pancreatic adenocarcinoma.[36] Tumor and normal tissue dosimetry was evaluated for a treatment regimen of 5 Gy(RBE) × 5 fractions. These plans were compared with IMRT plans with conventional fractionation generated for the same nine patients. Both techniques yielded plans with acceptable target volume coverage and dose homogeneity. Dose-volume histograms for the kidneys, liver, and small bowel were significantly better for the proton plans, and stomach and duodenum doses were similar.

In 2012, the M. D. Anderson Cancer Center (MDACC) group reported results of a prospective study of patients treated with proton beam therapy and concurrent chemotherapy for esophageal cancer.[37] Normal tissue toxicity was the primary focus of this study. Passive scattering protons with a two- or three-field beam arrangement were used. The median dose was 50.4 Gy. The median follow-up for survivors was 20 months. The most common grades 2 to 3 adverse events were dysphagia (43.6%), esophagitis (46.8%), fatigue (43.6%), nausea (33.9%), anorexia (30.1%), and radiation dermatitis (16.1%). There were two cases of grades 2 and 3 radiation pneumonitis and two cases of grade 5 toxicities. The pathologic complete response rate for the surgical cohort (n = 29) was 28%.

Lung Cancer

At Loma Linda University, a prospective study was undertaken to assess the efficacy and toxicity of conformal proton beam radiotherapy for 37 patients with medically inoperable non–small cell lung cancer.[38] Eligible patients had clinical stage I to IIIa non–small cell lung cancer and were not candidates for surgical resection either for medical reasons or because of patient refusal. Patients with adequate cardiopulmonary function received 45 Gy to the mediastinum and gross tumor volume with photons with a concurrent proton boost to the gross tumor volume of an additional 28.8 Gy(RBE). Total tumor dose was 73.8 Gy(RBE) given over 5 weeks. Patients with poor cardiopulmonary function received proton beam radiotherapy to the gross tumor volume only, with 51 Gy(RBE) given in 10 fractions over a 2-week period. Follow-up ranged from 3 to 45 months, with a median of 14 months. Two patients in the proton and photon arm developed pneumonitis that resolved with oral steroids; otherwise, no significant toxicities were encountered. The 2-year actuarial disease-free survival rate for the entire group was 63%; for stage I patients, the 2-year disease-free survival rate was 86% and the local control rate was 87%.

The MDACC group carried out a treatment planning study on 10 patients with stage IIIB non–small cell lung cancer.[39] Dose-volume histograms were generated for plans using IMPT, IMRT, and passive scattering proton therapy (PSPT). The IMRT cases were planned to 60 Gy to 63 Gy, and the proton cases were planned to 74 Gy. The possibility of increasing the total tumor dose with IMPT for each patient without exceeding the dose volume constraints (maximum tolerated dose) was also investigated. Compared with IMRT, IMPT showed improved tissue sparing for virtually every parameter measured, even with dose escalation from 63 Gy to 83.5 Gy, with a mean maximum tolerated dose of 74 Gy. IMPT also showed dosimetric advantages for those cases with complicated tumor anatomies.

Now open to accrual, RTOG 1308 is a Phase 3 randomized trial comparing proton versus photon radiation with concurrent chemotherapy for inoperable stage II-IIIB non–small cell lung cancer.[40] The primary objective is to compare overall survival between arms. Secondary end points will measure toxicity, quality of life, and cost effectiveness of treatment.

Pediatric Cancers

Investigators in Switzerland looked at the potential influence of improved dose distribution with proton beams compared with conventional or intensity-modulated (IM) x-ray beams on the incidence of treatment-induced secondary cancers in children.[41] Two children, one with parameningeal rhabdomyosarcoma and a second with medulloblastoma, were used as models for this study. After defining the target and critical structures, treatment plans were calculated and optimized, four for the rhabdomyosarcoma case (conventional x-ray, IM x-rays, 3D conformal protons, and IM protons) and three for the irradiation of the spinal axis in medulloblastoma (conventional x-ray, IM x-rays, 3D conformal protons). The secondary cancer incidence was estimated using a model by the International Commission on Radiologic Protection. This model allowed estimation of absolute risks of secondary cancer for each treatment plan based on dose-volume distributions for nontarget organs. Proton beams reduced the expected incidence of radiation-induced secondary cancers for the patient with rhabdomyosarcoma by a factor equal to or greater than 2, and for the medulloblastoma cases a factor of 8 to 15 when compared with either IM or conventional x-ray plans. Risks were higher for the patients with medulloblastoma because the target and radiated volumes were larger. This study underscores the concern with using radiation therapy in the treatment of pediatric cancers. It is the goal of clinicians to not only eradicate the primary tumor but also to minimize the risk of radiation-induced malignant tumors over the lifetime of these patients.

In a second MGH study, treatment plans were compared from standard 3D conformal photon therapy to intensity-modulated x-rays (IMRT) and 3D conformal protons for craniospinal axis irradiation and posterior fossa boost in a patient with medulloblastoma.[42] Substantial normal tissue sparing was realized with IMRT and proton irradiation of the posterior fossa and spinal axis (Figures 19-2 and 19-3). The dose to 90% of the cochlea was reduced from 101% of the prescribed posterior fossa boost dose from conventional x-rays to 33% and 2% from IMRT and protons, respectively. The dose to 50% of the heart volume was reduced from 72% for photons to 30% for IMRT and 0.5% for protons.

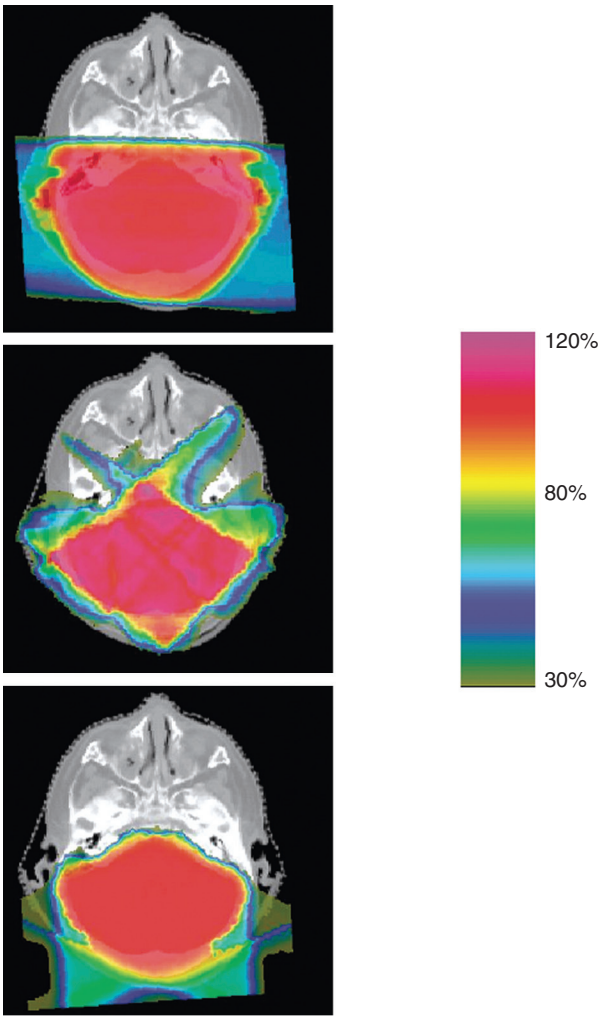

Figure 19-2 Three-dimensional conformal photon therapy *(upper panel)*, IMRT *(middle panel)*, and passively scattered proton therapy *(lower panel)* dose distributions for delivery of the posterior fossa boost in a patient with medulloblastoma. Note the absence of dose to the temporal lobes, pituitary, orbits, and cochlea that can be achieved with protons but that is not possible with three-dimensional conformal therapy or IMRT. This additional dose to nontarget normal tissues offers only potential morbidity to these young patients.

Merchant et al[43] modeled the dose characteristics to critical normal tissue volumes using data from patients with four types of childhood brain tumors. 3D imaging and treatment planning data, including targeted tumor and normal tissue contours, were acquired for 40 patients, 10 each with optic pathway glioma, craniopharyngioma, infratentorial ependymoma, and medulloblastoma. Dose-volume data were collected for the entire brain, temporal lobes, cochlea, and hypothalamus from each patient. The data were averaged and compared based on treatment modality (protons versus photons) using dose-cognitive effects models. Outcomes were estimated over 5 years. The results suggested that relatively small critical normal tissue volumes such as the cochlea and hypothalamus may be spared from radiation exposure when they are not adjacent to the primary tumor volume. It was found that larger normal tissue volumes such as the supratentorial brain or temporal lobes receive less of the low and intermediate doses with protons. When applied to longitudinal models of radiation dose-cognitive effects, these differences resulted in estimated clinically significant higher IQ scores for patients with medulloblastoma and craniopharyngioma and higher academic reading scores in patients with optic pathway glioma. Extreme differences between proton and photon dose distributions precluded meaningful comparison of protons and photons for patients with infratentorial ependymoma. The authors concluded that differences in the overall dose distributions, as indicated by modeling changes in cognitive function, showed that a reduction in the lower-dose volumes or mean dose with protons would have long-term, clinical advantages for children with medulloblastoma, craniopharyngioma, and optic pathway glioma.

Loma Linda University investigators evaluated the safety and efficacy of proton beam irradiation in the treatment of

pediatric patients with intracranial low-grade astrocytoma.[44] Between 1991 and 1997, 27 patients underwent fractionated proton radiation therapy for progression of recurrent low-grade astrocytoma. Patients were 2 to 18 years old. Twenty-five of the 27 patients (92%) were treated for progressive, unresectable, or residual disease following subtotal resection. The mean target dose was 55.2 Gy(RBE) (range, 50.4 Gy[RBE] to 63 Gy[RBE]) and the fraction size was 1.8 Gy(RBE). At a mean follow-up period of 3.3 years (range, 0 years to 6.8 years), 6 of 27 patients experienced local failure within the irradiated field and 4 of 27 had died. Local control and survival rates were 87% and 93%, respectively, for centrally located tumors, 71% and 86% for hemispheric tumors, and 60% and 60% for tumors of the brainstem. All children with local control maintained their performance status except one, who developed moyamoya disease. All 6 patients with optic pathway tumors and useful vision maintained or improved their visual status.

Atypical teratoid/rhabdoid tumors (AT/RT) are rare, aggressive tumors that often affect infants. Although they can occur anywhere in the body, they are frequently found in the central nervous system. Fear of significant long-term neurocognitive sequelae in this population has historically limited the use of radiation therapy. Recently, investigators at MGH published their early clinical experience for 10 consecutive patients (median age of 2.3 years) who underwent maximal resection followed by 3D-conformal proton therapy.[45] With a median follow-up of 27.3 months, 2 patients had a distant relapse; 1 patient was successfully treated with involved field irradiation and chemotherapy, whereas the second patient died of disease. At last follow-up, 9 patients were alive without evidence of disease without major radiation therapy-related toxicities.

Investigators at Loma Linda and MGH developed a proton radiation technique for the treatment of orbital rhabdomyosarcoma. The technique, along with a dosimetric analysis for two patients was recently published.[46] Dose-volume histograms were obtained for target and nontarget regions, including the lens, bony orbit, pituitary gland, optic chiasm, optic nerves, lacrimal gland, and ipsilateral frontal and temporal lobes. Doses to 90%, 50%, and 5% of lens volume were kept at less than 1%, less than 2%, and less than 8%, respectively. At a mean follow-up of 3 years, visual acuity for both patients was excellent and there was no evidence of cataract formation. Furthermore, pituitary function was normal; cosmetically, only mild enophthalmos was noticeable. The steep dose gradient beyond the orbit minimized irradiation of normal brain parenchyma, with sparing of the pituitary gland (Figure 19-4).

The MGH group recently updated their experience for pediatric patients treated with proton irradiation for intracranial ependymoma.[47] Seventy patients with localized ependymoma were treated with conformal proton radiation using at least three fields. The median age at diagnosis was 38 months (range, 3 months to 20 years). At a median follow-up of 46 months, 3-year local control, progression-free survival, and overall survival were 83%, 76%, and 95%, respectively. In a subset of patients (n = 14), mean intelligence was 108.5 at baseline and 111.3 after a mean 2.05 years of follow-up. In a larger group of patients (n = 28), overall adaptive skills were 100.1 at baseline and 100.8 after 2.21 years of follow-up. Few patients developed evidence of growth hormone deficiency, hypothyroidism, or hearing loss (Figure 19-5).

Breast Cancer

Some patients with breast cancer have anatomic configurations that make it difficult to adequately treat the breast while sparing the underlying lung and heart. A treatment planning exercise was undertaken comparing standard photon therapy with IMRT and proton therapy in the treatment of breast cancer.[48] Using computed tomography (CT) data from a patient with breast cancer, treatment plans were computed for the different treatment techniques. A dose of 50 Gy was prescribed to the target volume consisting of the involved breast and the internal mammary, supraclavicular, and axillary nodes. Comparison of plans revealed worse dose heterogeneity for the photon plan versus the other two plans. Lung dose-volume histograms for the photon and IMRT plans were comparable, whereas the proton plan showed the best sparing over all dose levels. Mean doses to the ipsilateral lung for the three plans were 17 Gy, 15 Gy, and 13 Gy, for the photon, IMRT, and proton plans, respectively. For the heart, the IMRT plan delivered the highest mean dose (16 Gy), reflecting the extra dose delivered through this organ to spare the lungs. This was reduced somewhat by the standard plan (15 Gy), with the best sparing being provided by the proton plan (6 Gy). When the IMRT plan was reoptimized with an increased precedence to the normal tissues, the mean doses to all neighboring organs at risk could be reduced but only at the cost of substantial target dose heterogeneity. Only the two-field, energy-modulated proton plan had the potential to preserve target dose homogeneity while simultaneously minimizing the dose delivered to the lungs, heart, and contralateral breast.

The MGH group recently published results of a prospective study investigating the use of proton therapy for the delivery of postmastectomy radiation.[49] The 12 patients enrolled received proton radiation to a dose of 50.4 Gy(RBE) to the chest wall and 45 Gy(RBE) to 50.4 Gy(RBE) to the regional lymphatics. The maximum skin toxicity observed was grade 2. No cases of radiation pneumonitis have been reported.

Proton therapy is also being investigated for partial breast irradiation. The Loma Linda group recently reported results of their Phase II trial.[50] Fifty patients who underwent lumpectomy for early stage breast cancer were enrolled. The median follow up was 48 months. Acute toxicities were limited to mild radiation dermatitis. Late skin toxicities included three grade 1 telangiectasias. There were no posttreatment infections or ulcerations and no cases of fat necrosis, rib fractures, radiation pneumonitis, or cardiac events. Actuarial 5-year overall survival and disease-free survival rates were 96% and 92%, respectively.

TECHNIQUES OF PROTON BEAM DELIVERY

Currently, most proton facilities use passive scattering for beam delivery. With this technique, a spatially uniform dose distribution is achieved by scattering and degrading the primary proton beam in a set of distributed absorbers. Passive systems use either single- or double-scattering foils. The foil is made of high-Z material such as lead, and effectively scatters the beam while keeping energy loss to a minimum. Generally speaking, double-scatter systems are preferred because larger, more uniform beams can be generated (Figure 19-6).

Beam shaping is accomplished with the use of some devices that are patient- and field-specific and some that are not. *Range modulation* refers to the concept that pristine Bragg peaks must be spread out to be clinically useful. In the passive scatter system this is done with either a propeller-shaped modulator (Figure 19-7) or a ridge filter, which is not patient-specific but may be range-specific, with a small library of range modulators available to address the different range modulator options that might be clinically desired. The Bragg peaks are spread out by placing these devices, which have variable thicknesses in the path of a given beam. The thicker the modulator, the more the beam is shifted in range.

Additional beam conformality is achieved with the use of patient-specific devices (Figure 19-8). Brass apertures are formulated to be used for a specific field for a given patient. Apertures are equivalent to the blocks used in conventional radiation therapy. In January 2010, the University of Pennsylvania Health System received approval from the Food and Drug Administration (FDA) to use multileaf collimators in their new proton facility.

A range compensator is another patient-specific beam modulator. This device is a block of plastic that is milled by a computer lathe for a specific field and is responsible for conforming the distal edge of the beam, necessary because of the variability in individual proton range secondary to differences in radiologic density in the tissue along their particular trajectory. Unfortunately, for historical reasons, a range compensator is sometimes referred to as a "bolus." But this should not be confused with the bolus that is directly applied to the patient's skin in conventional radiation therapy. This device is actually located adjacent to the brass aperture in the snout of the accelerator, above the patient.

Use of patient-specific devices that must be formulated for each beam angle is not a trivial matter in terms of labor and

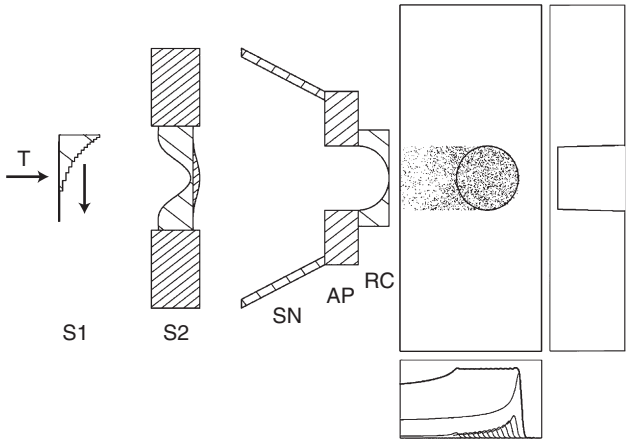

Figure 19-6 Double scattering system uses a first *(S1)* and second *(S2)* scatterer with a beamline snout *(SN)*, which shields scattered protons and permits the mounting of patient-specific apertures *(AP)* and range compensators *(RC)*. The example illustrates the effect of the range compensator in water and indicates the sharp lateral fall-off achieved by the aperture.

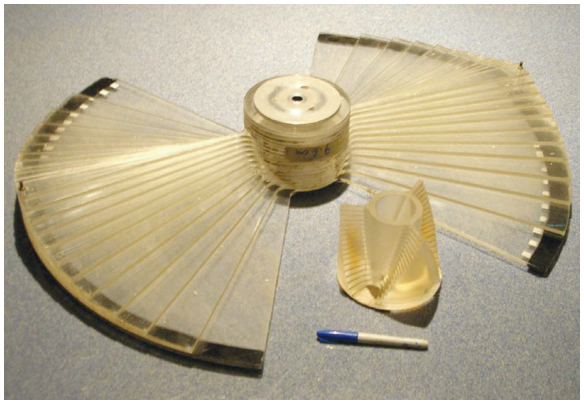

Figure 19-7 Two examples of range modulators, upstream *(small)* and downstream. Both are characterized by a "staircase" structure to achieve the differential pullback of the pristine proton beam and variable widths of the "stair steps" to achieve differential weighting of the shifted pristine peak contribution to the spread-out Bragg peaks. The downstream range modulator is large to cover the clinical area of the scattered proton beam at the downstream position.

cost. Furthermore, insertion and removal of the heavy apertures for each field is time-consuming and potentially dangerous for therapists and technicians. This process adds a significant amount of time to each patient's treatment and limits the total number of patients treated by an accelerator.

Although proton therapy has the potential to spare more healthy tissue than x-ray therapy, by virtue of physical qualities of the Bragg peak, there is a concern for increased neutron production. Neutrons can be generated whenever high-energy protons are slowed down by nuclear interactions. Such events can take place inside or outside of the patient. There is a certain amount of neutron production that takes place from proton interactions within the patient, and this is unavoidable and relatively modest. But with the passive scatter system, neutrons are primarily produced from proton interactions with scattering material and collimators in the accelerator. Hall[51] determined that this external neutron dose was more than 100 times the internal dose. Others argue that Hall's technical assumptions and calculations reflect the worst case scenario of treatment of a small target with a large amount of brass in the aperture, and still other investigators have measured substantially lower levels of neutrons, because the number of neutrons generated will be a function of the specific beam line as well as the beam-modifying hardware upstream from the patient.[52]

Chung et al[53] quantified the risk of a second malignant tumor associated with the use of proton therapy compared with photon radiation therapy. In this retrospective cohort analysis, 558 patients treated with protons at the HCL from 1973 to 2001 were matched with 558 patients from the Surveillance Epidemiology and End Results (SEER) Program database. With a median follow-up of more than 6 years, a second cancer developed in 5.2% of proton patients and 7.5% of photon patients (adjusted hazard ratio of 0.52 [0.32 to 0.85]; $p = 0.009$). Although the magnitude of neutron production and its clinical significance in contributing to radiation-induced malignant disease have been hotly debated, these data indicate that the use of proton radiotherapy was not associated with a significantly increased risk of secondary malignancies compared with photon therapy. Furthermore, active beam scanning will markedly reduce external neutron contamination, and for this reason, will be preferred over the passively scattered beam technique.

Active Scanning

The next step in the evolution of proton beam delivery is active (spot or pencil beam) scanning. With passive scanning, it is difficult to obtain large, uniform fields without significant energy loss, even with double scattering systems. In 1980, investigators in Japan first described a spot scanning system.[54] The technique was further refined by the group at the Paul Scherrer Institute in Switzerland.[55] With this technique, the beam is not spread out or scattered; rather, a narrow pencil beam is precisely steered through the treatment volume by magnets in the beam line nozzle. One of the benefits of this system is that there may not be any field-specific or patient-specific hardware; therefore, the time and cost of fabrication are avoided. Furthermore, the speed of the treatment is increased because these heavy devices do not need to be changed for each treatment field. Most importantly, neutron production is greatly diminished with the absence of this hardware.

These pencil beams deposit the dose layer by layer, with the distal edge treated first and the more superficial layers treated thereafter (Figure 19-9). Active scanning also allows for good conformation of the proximal edge of the treatment volume, which is typically not the case with passive scanning. This ability to conform the dose to the proximal tumor volume may further be enhanced with the use of IMPT. This excellent dose-shaping ability of IMPT makes it the best technique for the treatment of irregularly shaped tumors.

Perhaps the greatest concern about active scanning is the issue of organ motion. Because of this, active scanning should be reserved for tumor sites that have minimal motion and can be well immobilized, such as the head and neck, spinal cord, and low pelvis unless specific organ motion strategies are implemented. Several strategies have been developed to address the problem of organ motion. One technique is to repaint the same volume several times with the scanning beam, allowing for an averaging effect of the dose. Gating, as is used in the treatment of lung cancer, with photons is also an option. The spot size of the beam, as well as the scanning speed, can be manipulated as well.

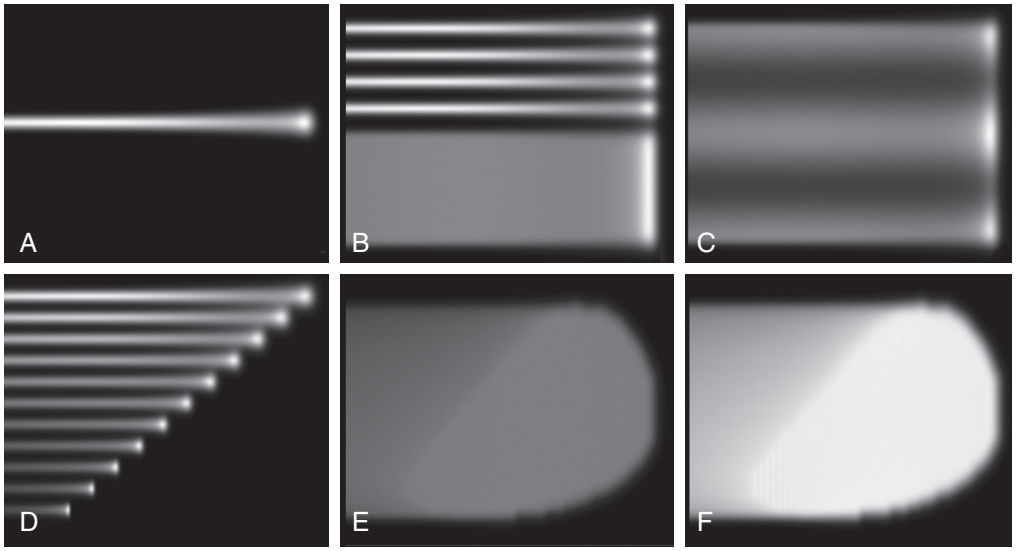

Figure 19-9 **A,** The proton pencil, with a (gaussian) spread of about 3 mm, enters into the patient. The lateral broadening of the pencil beam resulting from multiple coulomb scattering (MCS) in the patient body is small but not negligible. The dose distribution of such a pencil beam shows a sharp maximum near the end of the range and is well localized in the Bragg peak in all three dimensions within a "spot" volume of about 1 cm^3. The superposition of these spots, scanned on a three-dimensional grid in steps of ~5 mm, can be delivered to produce a three-dimensional dose distribution that conforms to the target volume in all three dimensions **(F),** albeit with an unavoidable entrance dose. **A,** Single pencil beam. **B,** Lateral scanning. **C,** The dose is shaped by changing the dosage of each spot, the speed of the scan, or the intensity of the beam. **D,** A homogeneous dose is produced by changing the energy of the beam. **E,** Repainting delivers a lower dose to the target volume per painting and is repeated to deliver the total target dose. **F,** The summation of many pencil beams in the lateral direction and in depth results in a conformal homogeneous dose distribution. *Reprinted with permission from Pedroni E: Pencil beam scanning. In DeLaney TF, Kooy H, editors: Proton and charged particle radiotherapy. Philadelphia, 2007, Lippincott Williams and Wilkins, Figure 5B-1, p 42.*

COST COMPARISONS FOR PROTON BEAM RADIOTHERAPY

All of the clinical and treatment planning results that have been reported indicate that proton beams offer a significant potential for improvements in clinical outcomes for cancer patients over a broad range of disease sites. There is hope that prospective clinical trials that have begun in the new hospital-based proton therapy facilities will establish the magnitude of these improvements. It will be important for physicians and patients and even society in general to have some sense of the cost of these benefits, to be able to place them in an appropriate context and allow comparison with other medical interventions. Goitein and Jermann[56] performed cost comparisons between proton radiation therapy and technically sophisticated photon radiation therapy in an effort to define the relative costs of the technologies. The expense of proton therapy per patient is expected to decrease as more facilities are built and greater numbers of patients are treated. The adoption of hypofractionation and beam scanning, as well as technical advances including smaller proton facilities, is expected to further reduce the cost. At the present time, when neither costs nor benefits have been adequately determined, it is not possible to carry out a reliable cost-benefit analysis. Goitein and Jermann[56] were able to estimate that the relative cost of proton beam radiation therapy compared with intensity-modulated photon beam radiation therapy was in the range of 2.4 in 2003 but might come down to 1.7 to 2.1 over time. Studies that have assessed cost-effectiveness suggest that protons will be cost-effective for pediatric malignant disease because of the reduction in late effects associated with the 50% to 60% reduction in integral dose associated with protons.[57]

CARBON ION RADIOTHERAPY

Carbon ions have a slight physical advantage over protons in that they will have a narrower penumbra than protons, particularly for deep-seated tumors.[58] On the other hand, carbon ions will also produce some spallation products deep to the Bragg peak. Whether the higher RBE and differential effect on hypoxic cells of carbon ions will translate into a clinical advantage remains to be determined, particularly because the clinical use of carbon has generally been with larger fraction sizes where there will be less RBE difference between carbon ions and protons. Because of the higher ionization and double-strand break density with carbon ions, they would logically of the greatest potential value in areas of gross tumor to minimize late normal tissue injury.

The Heavy Ion Medical Accelerator (HIMAC) in Chiba, Japan, began clinical studies in 1994. Kamada et al[59] reported the results of a Phase I/II study evaluating the tolerance and effectiveness of carbon ion radiotherapy in patients with unresectable bone and soft-tissue sarcomas. Fifty-seven patients with 64 sites of sarcomas not suited for resection received carbon ion therapy. Tumors involved the spine or paraspinous soft tissues in 19 patients, pelvis in 32 patients, and extremities in 6 patients. The total dose ranged from 52.8 to 73.6 carbon GyE and was administered in 16 fractions over 4 weeks (3.3 GyE/fraction to 4.6 GyE/fraction). Seventeen of the patients treated with the highest total dose of 73.6 GyE experienced RTOG grade-3 acute skin reactions. No other severe acute reactions (grade >3) were observed. The overall local control rates were 88% and 73% at 1 and 3 years of follow-up, respectively. The 1- and 3-year overall survival rates were 82% and 46%, respectively. It will be important to continue close follow-up to ensure that the large dose fractions are not associated with late injury of normal tissue.

Raster scanned carbon ion radiation therapy was used to treat patients at the Gesellschaft für Schwerionenforschung in Darmstadt, Germany, from 1997 to 2009, following which the program was transferred to the Heidelberg Ion Therapy Center. Between November 1998 and July 2005, a total of 96 patients with chordomas of the skull base were treated with carbon ion radiation therapy.[60] All patients had gross residual tumors. The median total dose was 60 Gy(RBE) (range, 60 Gy[RBE] to 70 Gy[RBE]), delivered in 20 fractions within 3 weeks. The mean follow-up was 31 months (range, 3 months to 91 months). Fifteen patients developed local recurrences after carbon ion radiation therapy. The actuarial local control rates were 80.6% and 70% at 3 and 5 years, respectively. Target doses in excess of 60 Gy(RBE) and primary tumor status were associated with higher local control rates. Overall survival rates were 91.8% and 88.5% at 3 and 5 years, respectively. Grade 3 toxicity was seen in 4% of patients and consisted of fat necrosis and optic neuropathy.

Kato et al[61] from Chiba, Japan, recently reported the results of a carbon ion dose escalation study for 24 patients with hepatocellular carcinoma. Fifteen fractions were delivered over 5 weeks, and total doses ranged from 49.5 Gy to 79.5 GyE. During a median follow-up of 71 months (range, 63 months to 83 months), no severe adverse effects or treatment-related deaths occurred. The overall tumor response rate was 71%. The local control and overall survival rates were 92% and 92%, 81% and 50%, and 81% and 25% at 1, 3, and 5 years, respectively.

Additional encouraging results with carbon ions have been reported for uveal melanoma, head and neck malignancies of multiple histologies, prostate cancer, and early stage non–small cell lung cancers. No clinical trials directly comparing lower LET protons with higher LET carbon ions have been completed to date but these are now under way. Randomized clinical trials of carbon ions versus protons are now being conducted at the Heidelberg Ion Therapy Center for patients with glioblastoma and skull-base chordomas and chondrosarcomas.

NEON ION RADIOTHERAPY

High-LET charged particle therapy with neon ions was studied in the treatment of glioblastoma of the brain because of the neon ion's increased biologic potential for destruction of radioresistant tumors. At the University of California, San Francisco (UCSF), and Lawrence Berkeley Laboratories (LBL), 15 patients were entered into a randomized protocol comparing two dose levels of neon ion irradiation,[62] either 20 Gy or 25 Gy in 4 weeks. However, there was no significant difference in overall survival time (13 to 14 months). Furthermore, an optimal dose level was not identified. Neon ions are not in current clinical use.

π-MESON RADIOTHERAPY

Subatomic particles called *π-mesons* provide the nuclear binding force between nuclei. These particles are produced when protons (600+ MeV) affect a target. Three types of mesons are produced: a neutral form, a positive form, and a negative form. It is the negative form, π^-, that is used for radiotherapy. When the π^- slows down, it is "captured" by a nucleus, causing it to "explode" in a "star" event, producing neutrons and charged nuclear fragments having high-LET properties[63] (Figure 19-10).

Negative π-mesons (pions) were used to treat 228 patients at the Los Alamos Meson Physics Facility between 1974 and 1981. One hundred twenty-nine patients received pion therapy only. All patients had locally advanced disease, and a number of different sites were treated. Local control was achieved in

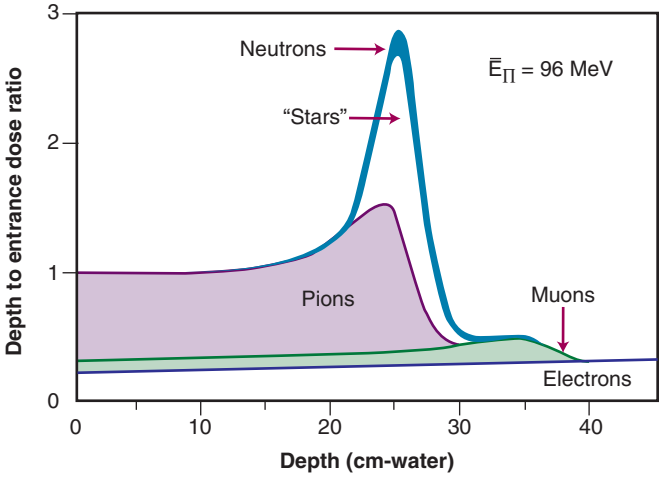

Figure 19-10 Illustration of negative π^- meson capture. When the π^- slows down, it is "captured" by a nucleus, causing it to "explode" in a "star" event, producing neutrons and charged nuclear fragments with high-LET properties.

86% of patients with prostate cancer, in 26% with head and neck cancers, and in none with pancreatic cancer. A steep rise in the complication rate was seen beyond a dose level of 3750 cGy.[64] π-Mesons are also no longer in clinical use.

HELIUM RADIOTHERAPY

A retrospective study was done at UCSF and LBL to evaluate the use of helium ions in the treatment of uveal melanomas.[65] Ten years after helium ion radiation, 208 of the 218 eyes irradiated had local tumor control (95.4%). At 10 years, 46 eyes (22%) had been enucleated; the majority resulting from anterior ocular segment complications. At 10 years, 51 patients (23%) had died of metastatic melanoma. The best corrected visual acuity after irradiation was greater than 20/40 in 21 of 93 eyes (23%) of patients who were alive and who had retained their eyes 10 or more years after treatment. Visual acuity was related to height of tumor and location near the nerve or fovea.

Schoenthaler et al[66] reported on the use of charged particle irradiation for sacral chordomas. At LBL, 14 patients with sacral chordomas were treated with charged particles, either lower LET helium or higher LET neon. All patients were treated postoperatively; 10 had gross disease. The median dose was 7565 cGy and the median follow-up was 5 years. The Kaplan-Meier survival rate at 5 years was 85%, and the overall 5-year local control rate was 55%. A trend in improved local control at 5 years was seen in patients treated with neon ions compared with patients treated with helium ions (62% versus 34%), in patients following complete resection versus patients with gross residual tumor (75% versus 40%), and in patients who had treatment courses less than 73 days (61% versus 21%). No patient developed neurologic sequelae or pain syndromes. One patient who had been previously irradiated required colostomy; 1 patient had delayed wound healing following a negative postradiation biopsy; and 1 patient developed a second malignant tumor. There were no genitourinary complications.

CONCLUSIONS

As discussed, the main benefit of protons over conventional photon beam radiotherapy is a reduction in integral dose. With intensity modulation, dose conformality with protons

and photons are comparable (assuming a small enough proton pencil beam diameter). It remains to be determined how much clinical benefit this reduction in integral dose achieves for patients. From planning studies, the greatest benefit is projected for larger targets (or larger targets relative to the size of the involved or closely approximated critical organ such as would be the case for eye tumors or skull-base tumors) and in younger patients, where studies project a reduction in second cancers[68] and other late effects to render protons cost-effective.[57] With minimization of the normal tissue dose, protons may allow for better tolerance of combined chemotherapy and radiation therapy regimens; indeed, many of the trials of pediatric proton radiation therapy employ chemotherapy in the same way that it has been commonly employed in pediatric protocol-directed therapy for solid tumors.[67]

Heavier charged particles have a sharper penumbra than protons when treating deep targets and may also confer a biologic advantage against tumor because of the higher RBE and differential effect on hypoxic cells, although comparison studies with protons are recommended to see if there indeed is a clinical advantage in using carbon ions over protons, because of the greater complexity and cost of carbon or other heavier charged particles.

CHAPTER

20 Neutron Radiotherapy

Jason K. Rockhill and George E. Laramore

The neutron was discovered by Sir James Chadwick in 1932 during an analysis of certain nuclear reactions. Shortly thereafter, investigators proposed using it to treat various human malignant diseases. There have been two main areas of clinical investigation: fast neutron radiotherapy and boron neutron capture therapy (BNCT). We briefly describe the underlying physics of each type of therapy, summarize the historical development, and discuss current clinical usage. Space permits only a brief discussion of neutron brachytherapy using californium-252 (^{252}Cf) sources, which is in limited clinical use today. We will restrict our review to the clinical arena and not discuss ongoing basic research.

FAST NEUTRON RADIOTHERAPY

Overview

Fast neutron radiotherapy uses neutrons having typical energies of several tens of megaelectron volts (MeV) that are generated by accelerating either protons or deuterons with cyclotrons or particle accelerators and then delivering them to an appropriate target, most generally beryllium. The resulting distribution of neutrons is approximately spherically symmetric, and the beams used in therapy are collimated in much the same manner as the photon therapy beams generated by electron linear accelerators. Fission neutrons from nuclear reactors that have energies in the range of 1 MeV to 2 MeV can also be used to treat patients. Neutrons are neutral particles and interact directly with the atomic nuclei in tissue, producing recoil protons and nuclear fragments, which in turn create dense chains of ionization events. For neutrons of energies used in radiotherapy, about 85% of the deposited energy is via a "knock-on" reaction ("billiard-ball" type of collision) involving the hydrogen-1 (^{1}H) nucleus, meaning that the kinetic energy release in matter (KERMA) is larger in high-hydrogen-content tissue such as fat or myelin.

The resulting energy transfer is in the range of 20 keV/μm to 100 keV/μm compared with 0.2 keV/μm to 2 keV/μm for the megavoltage photons and electrons used in conventional radiotherapy. It is this higher energy transfer that gives rise to the different radiobiologic properties of fast neutrons, which are advantageous in certain clinical situations. The higher relative biologic effectiveness (RBE) accounts for the different clinical response observed with neutrons as opposed to conventional photon irradiation. Fast neutrons have RBEs in the range of 3 to 3.5 in terms of most normal tissue late effects, RBEs in the range of 4 to 4.5 in terms of damage to the central nervous system, and RBEs in the range of 8 for salivary gland malignant tumors.[1-3] High–linear energy transfer (LET) radiation causes a dense chain of ionizing events affecting both strands of the DNA and therefore makes DNA repair more difficult. Other cellular targets are similarly affected to a greater degree by high LET radiation. Furthermore, high-LET radiation from fast neutrons is less sensitive to the reduced cell-killing effects of hypoxia, with there being nearly equal cell killing under normoxic and hypoxic conditions.

Historical Perspective

Patients were first treated with fast neutron radiotherapy in 1938 by Robert Stone et al[4] at the Crocker Radiation Laboratory (later to become Lawrence Berkeley Laboratories). Two hundred forty patients were treated between 1938 and 1942. Many of these patients had received prior photon irradiation. There were significant radiation sequelae in the few long-term survivors such that clinical interest in fast neutron radiotherapy dropped off significantly for the next 20 years. Brennan and Phillips[5] subsequently reviewed the initial work by Stone et al and showed that an inappropriate value for the neutron RBE had been used in the dose calculations. Hence, many of those initial patients had been inadvertently overdosed.

With a better understanding of the RBE of fast neutron radiotherapy in different tissue types, in the 1970s Catterall et al[6-8] resumed neutron clinical trials at Hammersmith Hospital in London, England. Their results indicated that many advanced head and neck cancers exhibited a good response with acceptable side effects. The interest in fast neutron radiotherapy grew and to date, approximately 30,000 patients have been treated in 41 centers in North America, Europe, Asia, and Africa. Clinical utility has been elucidated through clinical trials and single-institution experiences, and neutron radiotherapy now has fairly well defined and limited indications. There are currently only four operating fast neutron radiotherapy centers throughout the world. These are listed in Table 20-1, along with some of their more important characteristics.

A summary of clinical situations and tumor histologic types for which neutrons have been shown to be advantageous compared with standard photon irradiation follows.

Salivary Gland Tumors

The therapeutic advantage of fast neutron radiotherapy compared to conventional radiotherapy is best established in salivary gland tumors. The RBE for salivary gland tumors is approximately 8, whereas for surrounding normal tissues, the RBE is 3 to 3.5.[1] A typical neutron dose for a salivary gland cancer is approximately 18 nGy (neutron Gray) to 20 nGy. The approximate equivalent photon dose is 60 Gy equivalents (GyE) to 70 GyE as far as normal tissues are concerned but it is in the range of 150 GyE to 160 GyE as far as the tumor is concerned. The therapeutic gain factor for salivary gland tumors is therefore in the range of 2.3 to 2.6.

Early single-institution studies showed neutrons to be beneficial in the treatment of salivary gland tumors. These results led to a prospective randomized trial sponsored by the Radiation Therapy Oncology Group (RTOG) and the Medical Research Council (MRC) of Great Britain.[9] Local control at 10 years was improved in the neutron arm (56% versus 17%; $p = 0.009$). The final report showed a trend toward increased median survival of about 8 months in the neutron arm, but this was not statistically significant. However, the cause of death differed between the two subgroups. Metastatic disease

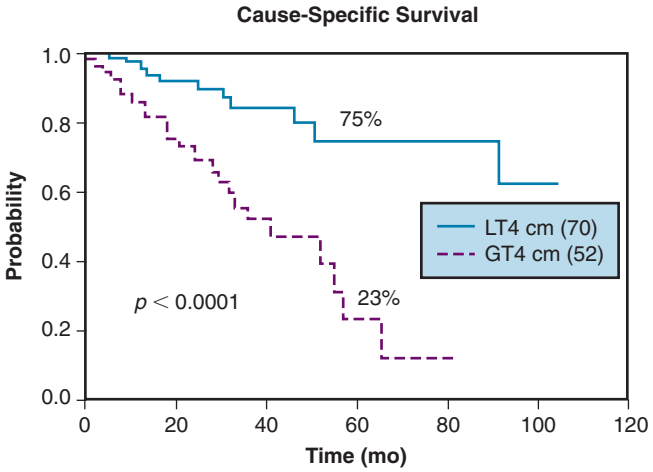

Figure 20-2 Actuarial cause-specific survival curves as a function of tumor size for patients with major salivary gland tumors treated with curative intent at the University of Washington neutron treatment facility. The *blue solid curve* depicts the results for patients with tumors smaller than 4 cm in the greatest diameter, and the *dashed purple curve* depicts the results for patients with tumors larger than 4 cm in the greatest diameter. The difference between the two curves is statistically significant at the $p < 0.0001$ level.
Adapted from Douglas JG, Lee S, Laramore GE, et al: Neutron radiotherapy for the treatment of locally advanced major salivary gland tumors. Head Neck 21:255, 1999.

was the main cause of death for the neutron patients, whereas locoregional tumor failure was the main cause of death for the photon patients. Of note, the study was stopped early for ethical reasons when 2-year survival data showed a strong trend in favor of the neutron patients. Local tumor recurrence curves for this study are shown in Figure 20-1.

The University of Washington experience was reviewed by Douglas et al.[10,11] Two hundred seventy-nine patients treated with curative intent were included in the analysis. A majority (263 patients) had evidence of gross disease, with 141 having major salivary gland neoplasms and 138 having minor salivary gland neoplasms. The 6-year actuarial cause-specific survival rate was 67%. On multivariate analysis, stage I/II disease, minor salivary gland primary tumors, lack of base-of-skull involvement, and primary (rather than recurrent) disease were associated with improved survival rates. Improved locoregional control was associated with tumors having the following characteristics: greatest diameter less than 4 cm, no base-of-skull invasion, prior surgical resection, or no previous radiation therapy. The 6-year actuarial rate for freedom from the development of metastases was 64% for patients without lymph node involvement or base-of-skull involvement. There was a 6-year actuarial rate of 10% for developing RTOG grade 3 or 4 toxicity. Cause-specific survival curves for the patients with major salivary gland cancer as a function of tumor size are shown in Figure 20-2.

The poorer outcome of salivary tumors with base-of-skull involvement appears to be the need to reduce the dose to portions of tumors that are adjacent to critical central nervous system structures (recall that the RBE for fast neutrons for central nervous system tissue is 4 to 4.5). With a standard 20 nGy dose to the involved site, the dose to the temporal tips could be approximately 80 photon GyE. Reducing the temporal lobe dose to a safe level sometimes required blocking portions of tumor. In an attempt to compensate for the reduced neutron dose, a stereotactic radiosurgical boost with photon radiation has been instituted at the University of Washington. At 40 months there was improved local control compared with historically treated patients with skull-base invasion who did not receive a stereotactic radiosurgical boost (82% versus 39%; $p = 0.04$).[12] Complications appear to be acceptable.

The use of both neutrons and photons in a composite "mixed beam" treatment has been explored by Huber et al[13] in a series of patients with advanced adenoid cystic carcinomas treated at the Heidelberg neutron facility. They found a

5-year local control rate of 75% for patients treated with neutrons alone compared with 32% for patients treated with "mixed beam" irradiation or with photons alone. It appeared that patients who had a greater portion of their treatment with neutrons fared better. Distant metastatic disease once again prevented improved local control from translating into an increase in overall survival rates.

The neutron facility in Orleans has reported similar results for 59 patients treated with fast neutron radiotherapy.[14] The 5-year local control rate was 69.5%, with a crude 5-year survival rate of 66% and a 5-year tumor-free survival rate of 64.5%.

Adenoid cystic carcinomas arising in uncommon locations are also amenable to treatment with fast neutron radiotherapy. Thirty-four patients with adenoid cystic carcinomas of the trachea received neutron radiotherapy at the University of Washington.[15] Those patients who received neutron radiotherapy as their primary treatment had a 5-year survival of 89%, whereas those who received postoperative neutron radiotherapy following surgery had a 5-year survival of 60%. There was no significant advantage to adding a brachytherapy (HDR) boost following the neutron radiotherapy. Gensheimer et al reported on 11 high-risk patients with adenoid cystic carcinomas of the lacrimal gland who were treated with fast neutron radiotherapy.[16] Most had undergone a surgical resection but gross disease was present in eight patients at the time of treatment. Disease extending to the skull base was treated with a Gamma Knife radiosurgery boost in four patients and with a proton radiotherapy boost in one1 patient. Median overall survival was 11.1 years and median disease-free survival was 6.3 years. Kaplan-Meir local control at 5 years was 80%. Long-term, ipsilateral vision preservation was not possible in most cases, although only two patients required an enucleation for treatment-related side effects.

Prostate Cancer

Prostate cancer is another tumor for which there has been significant clinical work using fast neutron radiotherapy. The National Cancer Institute (through RTOG 77-04) conducted a randomized trial for patients with T3, N0/N1 disease.[17] One arm received a mixed beam (neutron/photon) dose to 70 GyE versus a second arm that received standard photons to 70 Gy. Pelvic lymph nodes were treated to doses appropriate for microscopic disease. At the 10-year endpoint, survival rates (46% versus 29%, $p = 0.04$) were improved in the mixed beam arm. There was also improved locoregional control (70% versus 58%, $p = 0.03$) for the mixed beam subgroup. There was no difference in the rate of significant complications between the two arms. Survival curves for the patients in this study are shown in Figure 20-3.

A follow-up randomized trial was conducted that compared 70-Gy standard photon irradiation with 20.4-nGy fast neutron therapy. Pelvic lymph nodes were treated to doses appropriate for microscopic disease. This study was carried out by the National Cancer Institute (NCI)–sponsored Neutron Therapy Collaborative Working Group (NTCWG) and included patients with high-grade T2 tumors or T3 to T4, N0 to N1, M0 tumors of any grade.[18] With a median follow-up of 68 months, the 5-year actuarial locoregional failure rate was 11% for neutrons versus 32% for photons ($p < 0.01$). Actuarial overall survival and cause-specific survival rates were statistically equivalent. The incidence of severe complications was higher in the neutron group than in the photon group (11% versus 3%). Complications were fewer and less severe in the centers that had more sophisticated beam-shaping abilities. Local failure curves for the patients in this study are shown in Figure 20-4.

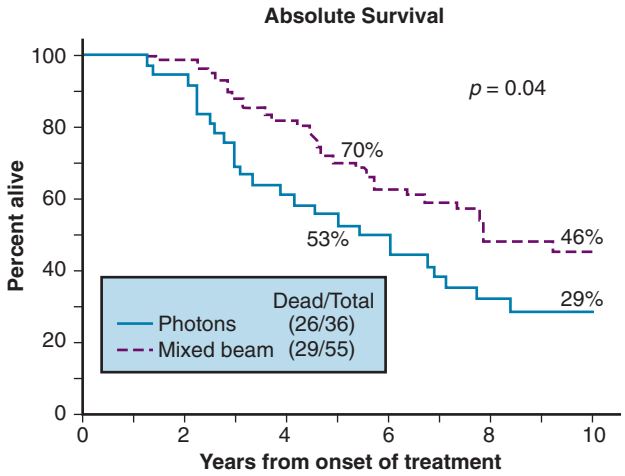

Figure 20-3 Actuarial survival curves for patients with locally advanced prostate cancer treated on Radiation Therapy Oncology Group (RTOG) protocol 77-04. The mixed (neutron and photon) beam group is shown by the *dashed purple curve,* and the photon control arm is shown as the *solid blue curve.* The difference between the curves is statistically significant at the $p = 0.04$ level.
Adapted from Laramore GE, Krall JM, Griffin TW, et al: Fast neutron radiotherapy for locally advanced prostate cancer. Am J Clin Oncol 16:164, 1993.

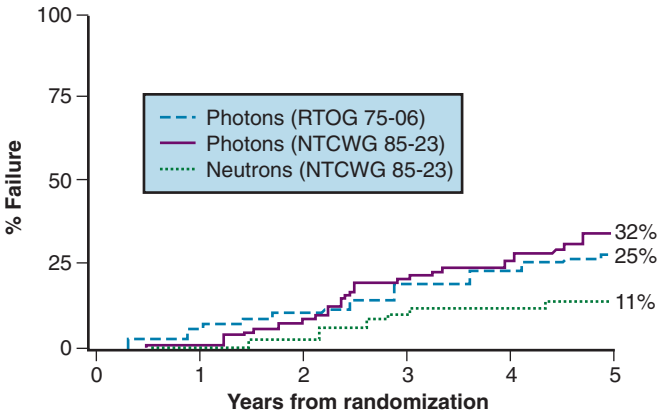

Figure 20-4 Actuarial percent local failure curves for patients with locally advanced prostate cancer treated on Neutron Therapy Collaborative Working Group (NTCWG) protocol 85-23. The group treated with neutrons is shown as the *dotted green curve,* and the group treated with photons is shown as the *dashed blue curve.* The difference between these two curves is statistically significant at the $p < 0.01$ level. A local control curve *(solid purple line)* for photon-treated patients from another Radiation Therapy Oncology Group study (RTOG 75-06) is shown for comparison. There is no statistical difference between the latter curve and the photon control arm of the neutron study.
Adapted from Russell KJ, Caplan RJ, Laramore GE, et al: Photon versus fast neutron external beam radiotherapy in the treatment of locally advanced prostate cancer. Results of a randomized prospective trial. Int J Radiat Oncol Biol Phys 28:47, 1993.

Following the randomized trials, additional studies were conducted at several centers in the United States,[19-23] Europe,[24,25] and Asia.[26,27] These single-institution results showed good locoregional control and appeared to corroborate the results of the randomized trials described previously.

Sarcomas

Sarcomas are generally considered to be among the more "radioresistant" histologic types of tumors and so would fall into the category of tumors thought to be more responsive to high-LET radiation.[1] A retrospective review by Schwarz et al[28] reports on 1171 patients with soft-tissue sarcomas from 11 European centers treated with fast neutron radiotherapy. In those patients with either inoperable tumors or gross disease after surgery, the local control rate was approximately 50%. Toxicity was higher than what was generally seen with photon irradiation. The local control rates were thought by the authors to be better than what would have been expected with standard radiotherapy. This conclusion is supported by other single-institution studies.[29]

Other Tumor Types

Fast neutron radiation has been tested on a variety of other tumor types. Generally, the rationale for the use of fast neutrons came from trying to overcome a perceived limitation of standard photon irradiation. A good example of this is malignant glioma of the brain. Dose-escalation studies with photons have failed to increase overall survival rates.[30] By definition, *glioblastoma multiforme* tumors have associated areas of necrosis that are often surrounded by regions of hypoxia, which might make the tumors more radioresistant. Studies of malignant gliomas in the 1970s and 1980s used neutrons either alone or in combination with photons.[31] None of these initial trials showed an improvement in overall survival rates with the addition of neutrons. However, with relatively high doses of fast neutrons alone, autopsy and second-look surgical data indicated that tumor cells were sterilized in the treated region.[32] Unfortunately, there was also significant coagulative necrosis caused by the neutron irradiation, which indicated too much damage to normal brain tissue. A more recent study used fluorodeoxyglucose–positron emission tomography (FDG-PET) scanning to determine the final boost volume that received 18 nGy.[33] Only 10 patients were treated and all exhibited tumor progression by 39 weeks, perhaps because of the restricted fields that were employed. Gliosis and microvascular sclerosis consistent with radiation injury were noted in regions of the contralateral brain receiving 6 nGy to 10 nGy. Much of the current interest in neutron radiotherapy for malignant gliomas is focused on boron neutron capture therapy (BNCT), which is discussed later in this chapter.

Squamous cell carcinoma of the head and neck region is another tumor for which neutrons have been used to try to overcome the relative radiation resistance of hypoxic cells. However, randomized studies and several single-institutional trials in Europe and the United States failed to show a significant improvement in locoregional control with the use of neutrons compared with standard photons. Furthermore, the side effects were generally more severe.

Summary

Neutron radiotherapy is best used in the treatment of certain tumors that exhibit a "resistance" to standard low-LET radiotherapy. The niche that it occupies is small, but it remains a highly important treatment option for a small number of patients for whom it appears to be better than more traditional forms of treatment. Examples are patients with inoperable or recurrent salivary gland malignant tumors or in high-risk situations where there has been an incomplete surgical extirpation or patients with inoperable or incompletely resected sarcomas of bone, cartilage, and soft tissue or locally advanced prostate cancers, particularly those that are not hormonally responsive. In highly selected circumstances, it may also be beneficial in the treatment of metastases from melanoma and renal cell cancer. Future research may extend these indications. The declining number of active treatment centers is attributable to the aging of the equipment and the narrow niche indications making it not economically feasible to build new centers.

BORON NEUTRON CAPTURE THERAPY

Overview

Conceptually, BNCT is a "magic bullet" approach to treating tumors. Pure beams of very low energy neutrons do not directly deposit much energy in tissue via collisions but rather interact via nuclear transmutation reactions. The basic idea is to selectively attach to the cancer cells a nuclide having a large cross section for capturing a thermal neutron. The nuclide then undergoes a nuclear reaction with the localized release of a substantial amount of energy. In principle, this kills the "tagged" cell but does not damage the surrounding "untagged" normal cells. Although there is ongoing work in developing high-current particle accelerators to produce low-energy thermal or epithermal beams for BNCT, at the present time, all clinical work is being done using moderated neutron beams from nuclear reactors. There are other nuclides besides boron-10 (^{10}B) that have a high neutron capture therapy cross section, and some of these (e.g., gadolinium-157 [^{157}Gd]) are of interest in neutron capture therapy for cancer. The ^{157}Gd neutron capture reaction produces high LET Auger electrons rather than nuclear fragments and so the agent must be in close proximity to the cellular DNA to be effective. There is little data on the clinical use of ^{157}Gd and so we will confine our discussion to BNCT. Space limitations preclude our describing ongoing research in radiobiology, compound development, or physics research into nonreactor sources of appropriate beams.

Historical Perspective

The basic idea for BNCT dates to 1936, when Locher[34] proposed treating malignant tumors with low-energy thermal neutrons via a capture process with ^{10}B. A few years later, Kruger[35] and Zahl et al[36] experimentally verified some of the basic tenets of this concept and demonstrated the high RBE of the resulting helium-4 (^{4}He) and lithium-7 (^{7}Li) fission fragments. The theoretical advantage of "tagging" the tumor-specific carrier with an innocuous substance such as ^{10}B and then activating it, rather than tagging it with a toxic compound such as ricin, is that the "binary approach" is more forgiving of other body tissues that might also display some avidity for the carrier agent.

In the real world, the thermal and epithermal beams produced by nuclear reactors are contaminated with gamma rays and fast neutrons, which can cause considerable normal tissue damage even in the absence of a high ^{10}B concentration.[37] Moreover, even in the absence of such beam contaminants, nuclear species such as ^{1}H, nitrogen-14 (^{14}N), and chlorine-35 (^{35}Cl), which are commonly found in tissue, interact with thermal neutrons via capture events of their own, and their reaction products cause biologic damage to non–^{10}B-containing normal tissues. Although the respective capture cross sections for these commonly found nuclei are much lower than for ^{10}B and other nuclear species of interest for neutron capture therapy, the concentrations of these commonly found nuclei are many orders of magnitude greater than the concentrations of ^{10}B. Hence, reactions involving these nuclides can result in an appreciable tissue dose, even in the absence of ^{10}B. The key to BNCT as a practical therapy is the development of compounds that localize specifically in tumors and deliver

sufficient ^{10}B concentrations to yield a significant therapeutic advantage compared with the radiation doses delivered to normal tissues.

Early Clinical Studies

The first set of human clinical trials was carried out in the 1950s at Brookhaven National Laboratory using ^{10}B-enriched, boric acid derivatives.[38,39] These compounds yielded high concentrations of ^{10}B in the blood at the time of irradiation and unfortunately produced relatively low ^{10}B levels in the tumors. This resulted in considerable blood vessel endothelial damage and no therapeutic benefit from treatment either in these trials or in subsequent trials that were carried out in the 1960s.[40-42] Interest in the technique waned until Hatanaka et al in Japan[43] reinstituted BNCT for malignant gliomas using a different ^{10}B-carrier, ^{10}B-sodium-mercaptoundecahydrododecaborate (BSH). This compound produced better tumor-to-blood boron ratios than the compounds used in the prior Brookhaven National Laboratory studies and the treatments caused less damage to normal brain tissue. Favorable reports regarding the efficacy of BSH[43-45] led to renewed worldwide interest in the technique.

Many patients have received BNCT treatments using thermal neutron beams from various reactors in Japan, but to date, no randomized clinical trials have been carried out. An analysis of the RTOG database by Curran et al[46] demonstrated that there are some subsets of patients with high-grade gliomas who will do well with conventional photon irradiation. A few years ago, an analysis of a subset of patients from the United States who were treated with BNCT in Japan showed no improvement over that which would have been expected with conventional therapy after correcting for the appropriate prognostic factors.[47] A comparison of the survival rates of these patients with a pseudo-matched group from the RTOG database is shown in Figure 20-5. The prognostic factors identified by Curran et al[46] were used to generate these curves. There is no statistical difference between the two curves.

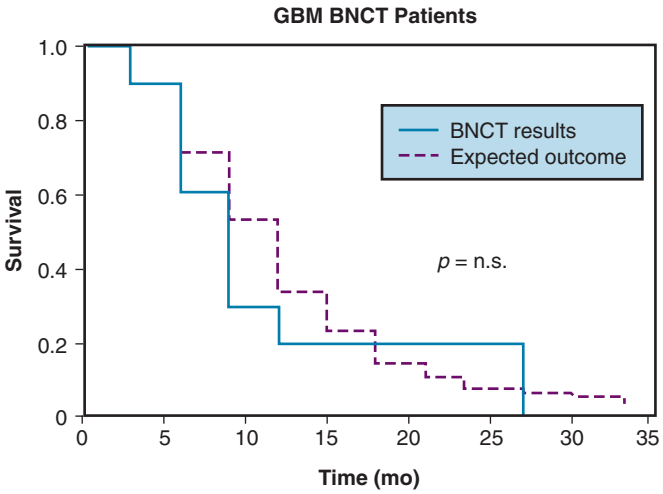

Figure 20-5 Actuarial survival curves for a group of 10 patients from the United States with glioblastoma multiforme (GBM) histology who were treated with boron neutron capture therapy (BNCT) *(solid blue curve)* and the expected survival curve for a matched cohort who received conventional treatment according to various Radiation Therapy Oncology Group study (RTOG) protocols *(dashed purple curve)*. There is no statistically significant difference between the two curves.
Adapted from Laramore GE, Spence AM: Boron neutron capture therapy [BNCT] for high grade gliomas of the brain. A cautionary note. Int J Radiat Oncol Biol Phys 36:241, 1996.

Moreover, review of the data for the entire group of evaluable patients showed that in all except one patient there was a documented tumor recurrence within the primary radiation field.[47] The only long-term survivor in this group of American patients had an anaplastic astrocytoma and fell into the most favorable category I of Curran et al.[46]

There is no doubt that many aspects of the early Japanese BNCT clinical research program were suboptimal. The use of a poorly penetrating beam of thermal neutrons meant that an open craniotomy was required to expose the tumor bed. Because of the low neutron fluxes, treatment times of 4 to 8 hours were required to deliver a surface fluence of approximately 10^{13} neutrons/cm^2, and during treatment the patient had to be under general anesthesia with the brain exposed in a converted operating room adjacent to the nuclear reactor. Although BSH is conceptually attractive as a ^{10}B-carrier agent in that it is excluded from normal brain tissue by the blood-brain barrier, typical tumor boron concentrations for glioblastoma multiforme were in the range of only 15 μg/g to 25 μg/g. It is now possible to improve on many of these shortcomings.

Modern Clinical Trials

In the modern era, clinical trials have been conducted in Japan, Europe, Argentina, and the United States. Most of this work has dealt with the treatment of malignant brain tumors and metastatic melanomas, but there is increasing interest in using this modality to treat recurrent head and neck cancers and high-grade meningiomas

In Japan, there have been three reactor facilities involved in patient treatments: (1) KURRI in Osaka, (2) MITR in Musashi, and (3) JRR-4 at the Japan Atomic Energy Research Institute in Ikargi.[48] Although most patients have been treated using thermal neutron beams, the KURRI facility has been modified to produce a higher-energy epithermal beam allowing treatment through the intact skull. The majority of the patients have been treated for various types of brain tumors using BSH as the ^{10}B-carrier agent and with a single fraction of neutron radiation. A report by Nakagawa et al[49] shows that in the subset of glioblastoma multiforme patients, 12% of treated patients lived longer than 2 years. Depending on other prognostic factors, this may or may not be better than expected with more conventional forms of treatment. A report by Kawabata et al shows a modest survival benefit in 21 glioblastoma patients treated with either BNCT alone or in combination with standard photon radiotherapy when compare to patients having similar RTOG prognostic factors.[50] Currently only the KURRI and JRR-4 reactors are treating patients.

There were several reactor facilities in Europe with BNCT clinical programs for malignant brain tumors, all using epithermal neutron beams. The program that treated the most patients was based at the HFR reactor in Petten (the Netherlands) and was directed by the European Collaboration on Boron Neutron Capture Therapy. BSH at 100 mg/kg was used as the ^{10}B-carrier. Researchers conducted a phase I dose-searching study restricted to the subsets of patients with glioblastoma multiforme whose expected median survival time with conventional radiotherapy would be less than 10 months. Unlike the other ongoing treatment regimens, which employed a single BNCT treatment, the Petten program used four fractions requiring multiple administrations of the boron-carrier compound. BNCT dose reporting is complex, and the Petten group has chosen to specify each component of the radiation field separately rather than state a Gray-equivalent dose.[51] The starting dose from the ^{10}B component was set at 80% of the dose that produced neurologic changes in a dog brain study, D_B = 8.6 Gy. The other components of the radiation dose were limited

to $D_n < 0.9$ Gy, $D_N < 1.1$ Gy, and $D_g < 5.8$ Gy, where D_n is the neutron-absorbed dose delivered by the thermal, epithermal, and fast neutrons and the charged particles produced by their reactions, D_g is the gamma ray absorbed dose, and D_N is the absorbed dose from the protons produced by the ^{14}N capture reaction. Twenty-five patients were entered into the initial dose arm of the study, with 21 actually receiving BNCT treatment.[52] The median survival time of the BNCT-treated patients was 31 weeks, with 6 patients alive at the time of a preliminary report. All 21 patients exhibited tumor recurrence.

A second BNCT program is based at the FiR No. 1 reactor in Helsinki, Finland. The initial protocol was a Phase I dose-searching study that used l-*para*-boronophenylalanine (BPA) in a fructose solution at 290 mg BPA/kg as the B-carrier. Only a single treatment was given using two radiation fields. Thus far, 10 patients have been treated with tumor doses between 35.1 and 66.7 GyE. This effective dose has been determined using weighting factors for each of the radiation components (see Kankaanranta et al[53] for specific details). With a median follow-up of 9 months, 7 of 10 patients had recurrent or persistent tumor, with the median time to tumor progression being 8 months.[53] The toxicity in both of the European trials was thought to be acceptable, making future escalation of the radiation dose possible. Small numbers of patients were also treated at Studsvik Medical AB in Uppsala University[54] and at the Nuclear Research Institute in the Czech Republic.[55] Currently, only the FiR No. 1 reactor is treating patients.

After approximately a 30-year hiatus, the first "modern era" BNCT clinical program in the United States was begun at the Massachusetts Institute of Technology (MIT) research reactor in collaboration with Tufts Medical Center. The first patient was treated in September 1994. This project was under the clinical direction of the New England Deaconess Hospital. Treatments were delivered using an epithermal beam with BPA as the ^{10}B-carrier agent. Between 1996 and 1999, a total of 22 patients with intracranial lesions, either glioblastoma multiforme or metastatic melanoma, were treated.[56] The initial clinical trial was a dose-searching toxicity study with the target dose ranging between 8.8 GyE and 14.2 GyE. At the higher radiation doses, the time required to deliver the dose ranged up to 3 hours. At the higher dose levels, significant skin and mucosal reactions were observed. No adverse effects were noted because of the BPA administration, and no long-term complications relating to the BNCT treatment were noted. Some tumor responses were noted in the patients with metastatic melanoma, but there was no obvious prolongation of survival rates in either group of treated patients. This facility is no longer treating patients.

A second clinical BNCT program focusing on high-grade gliomas of the brain was initiated at Brookhaven National Laboratory. This program differed from the Japanese glioma program in two main respects: (1) a higher-energy epithermal neutron beam was used instead of a thermal neutron beam, and (2) a different ^{10}B-carrier agent (BPA) was used rather than BSH. The epithermal beam meant that patients could be treated without recourse to a craniotomy and intraoperative irradiation and that more deeply located tumors could be given adequate doses. It was expected that BPA would produce higher tumor ^{10}B concentrations than could be achieved with BSH. Based on ^{10}B blood levels, it appeared that tumor ^{10}B concentrations of approximately 35 μg/g to 50 μg/g were achieved. However, unlike BSH, BPA is not excluded from the normal brain by the blood-brain barrier, and tumor enrichment depends on other mechanisms of selective uptake (perhaps relating to an enhanced amino acid transport system). A dose-escalation approach was used. Before June 1996, all patients were treated using a simple appositional field with a single treatment fraction being given. A critique of this early Brookhaven National Laboratory treatment technique indicated significant deficiencies in the basic approach relating to the inability to achieve a tumor dose adequate to sterilize glioblastoma multiforme tumors using a single appositional field.[57]

Between September 1994 and May 1999, 53 patients with primary glioblastoma multiforme received BPA-fructose–mediated BNCT at Brookhaven National Laboratory using one, two, or three irradiation fields on a sequential, dose-searching protocol. The median age for the subjects treated with one field was 56.5 years, with a median tumor volume of 20.5 cm^3 (2 cm^3 to 70 cm^3) and a median Karnofsky Performance Status (KPS) of 80. The volume-weighted average radiation dose to normal brain (ABD) varied from 1.9 GyE to 4.1 GyE for one field, from 4.1 GyE to 6.6 GyE for two fields, and from 6.7 GyE to 9.5 GyE for the three-field group.

Fifty of the 53 subjects have exhibited tumor persistence/recurrence within the treatment volume.[58] The median time to progression was independent of dose. In fact, there was a significant trend toward worse local control in subjects treated using three fields. Survival as an endpoint was found to be more dependent on the aggressiveness of the postrecurrence treatment than the BNCT dose given and, as such, was not a useful indicator of treatment-dependent tumor control. The functional brain tolerance was reached in the three-field group. All except one patient treated with three fields exhibited significant acute or subacute functional neurologic toxicity at average brain doses as low as 6.7 GyE. This may indicate a "volume effect" in that multiple fields generally treat a larger volume of normal brain to a lower dose compared with when a single field is used. The early stopping criterion of a more than 20% incidence of grade 3 or 4 toxicity (RTOG and European Organization for Research and Treatment of Cancer [EORTC] criteria) was reached during this study. However, no significant tumor response was observed in the patients treated to minimum tumor doses above those predicted by Laramore et al to be therapeutic.[57,58] We also note that preclinical studies using a 9-L rat gliosarcoma model showed significant tumor response of the tumor to BPA-fructose–mediated BNCT at comparable doses.[59] Hence, neither the preclinical radiobiologic studies nor the mathematical modeling based on fast neutron data provided an accurate guide to the necessary therapeutic dose. The Brookhaven National Laboratory clinical program is no longer in operation.

In parallel with the BNCT program for malignant gliomas, a second area of major interest is the treatment of malignant melanoma metastatic to the brain. This work was instigated by Mishima et al[60,61] in Japan. They used BPA as the ^{10}B-carrier agent with a single treatment fraction of thermal neutrons. BPA acts as a dopamine analog in the melanin synthetic pathway and concentrates well in pigmented tumors. Initial reports describe good clinical results with this treatment,[62,63] but no randomized trials have been performed. Reports from the MIT/Massachusetts General Hospital program indicate that responses are better in this setting than in the treatment of glioblastoma multiforme, which is consistent with BPA being better suited to the treatment of pigmented tumors. Under the auspices of the Atomic Energy Commission of Argentina, a program for the treatment of metastatic melanoma has been instituted at the RA-6 research reactor in San Carlos de Bariloche, and this program is still clinically active.[64] An updated report showed an overall response rate of 69% in treated skin nodules with an additional 31% of nodules showing stable behavior.[65]

A third area of increasing interest in the BNCT community is the treatment of patients with recurrent head and neck cancers. A report on 26 patients treated at the KURRI and JRR-4 reactors using both BSH and BPA as boron carrier agents

showed an overall response rate of 85% although there were three instances of osteoradionecrosis and one case of brain necrosis.[66] The majority of these patients was treated for tumor recurrence after having received previous standard radiotherapy and therefore represent a high-risk population with respect to complications. Thirty patients with recurrent head and neck cancers were treated in Finland between 2003 and 2008 using the FiR 1 reactor. Like the Japanese work, a combination of BSH and BPA was used to maximize the boron concentration in the tumors. Two portals were irradiated and the mean boron dose was 19.6 μg/g for the first portal and 16.4 μg/g for the second portal.[67] For 29 evaluable patients, 76% had some response and the 2-year locoregional control rate was 27%. There were 3 patients who developed osteoradionecrosis and 1 patient who developed a soft-tissue necrosis.

Kawabata et al recently reported on using BNCT to treat 20 patients with recurrent, high-grade meningomas who had failed surgery followed by one or more courses of radiotherapy.[68] Either BPA alone or combined with BSH was used as the boron carrier agent. The radiation dose to normal brain was restricted to 15 Gy-equivalent or less in the planning process. With a median follow-up duration of 13 months, 6 patients were still alive and only 3 deaths were as a result of in-field failure. The majority of deaths were the result of systemic metastases or cerebrospinal fluid (CSF) dissemination indicating the aggressive nature of the tumors that were treated. The authors noted a rapid tumor shrinkage in many of the treated patients.

An interesting approach to the treatment of liver metastases was begun at the University of Pavia in Italy. The patient is infused with BPA, and the diseased liver is extirpated and irradiated in the reactor and then reimplanted into the patient. Two patients have been treated in this manner, with one long-term survivor at 3 years from the time of the procedure. Model calculations indicate that it may be possible to perform this treatment without first removing the liver.[69] There is continued work on this concept through EORTC 11001. This biodistribution trial showed that BPA is taken up preferentially in liver metastases of colorectal adenocarcinoma to an extent that is high enough for therapeutic BNCT whereas BSH does not preferentially accumulate.[70]

Summary

To date there is no convincing evidence that BNCT offers a therapeutic advantage over conventional treatments for glioblastoma multiforme. Reactor-based treatment centers are sufficient in number to conduct well-designed clinical trials to provide a "proof of concept" but certainly will not be adequate to treat large numbers of patients in the event that a therapeutic advantage is demonstrated. In this event, accelerator-based sources must be designed and placed in hospital settings. The main hurdle at the present time is the lack of tumor-specific ^{10}B-carrier agents. Besides BSH and BPA, only one other boron compound, GB-10 ($Na_2B_{10}H_{10}$), is approved for human trials. GB-10 and BSH are global agents with no specific tumor cell targeting, whereas BPA has some specificity for certain types of tumors. All three are suboptimal for clinical use. Support of research in compound development is key to further development of the field.[71-73]

CALIFORNIUM 252 BRACHYTHERAPY

Californium was the sixth transuranium element that was produced by a team at the Lawrence Berkeley Laboratories in 1950 by bombarding a curium target with α particles. The particular isotope used in radiotherapy, californium-252 (^{252}Cf), is produced in high-neutron flux reactors and is made available for peaceful uses by the U.S. Department of Energy. ^{252}Cf is a neutron-rich isotope that has a half-life of 2.647 years. It decays either by α-particle emission or by spontaneous fission with a branching ratio of 96.9% to 3.1%. It is a highly prolific neutron emitter with a spectrum of energies similar to that produced by nuclear reactors. Although its use in medicine requires significant radiation protection precautions, it is theoretically attractive for brachytherapy applications wherein high-LET radiation is advantageous from a radiobiologic aspect. It has also been proposed as a hospital-based teletherapy source for BNCT applications.

Gynecologic applications of ^{252}Cf brachytherapy were explored by Maruyama et al,[74] who developed appropriate dosing schedules. More recently, Tacev et al[75] reported on long-term results of a randomized trial for patients with advanced cervical cancer (stages IIB and IIIB) that compared ^{252}Cf brachytherapy with a supplementary gamma ray boost of 16 Gy with conventional brachytherapy alone with gamma ray–emitting radium-226 (^{226}Ra) or cesium-137 (^{137}Cs) sources following 40-Gy external beam radiotherapy. Using an RBE of 6 for the ^{252}Cf neutrons, point A doses of 56 GyE were given with the implants. Two hundred seventy-seven patients were entered into the study, and there was an improved 5-year survival rate in the group receiving the ^{252}Cf implant (75.2% vs. 56.3%; $p < 0.001$).

Also of note is a pilot study using ^{252}Cf interstitial brachytherapy in 56 patients with high-grade gliomas of the brain.[76] After surgical debulking, catheters were placed under CT guidance followed by ^{252}Cf placement. A dose of 3 Gy was given over 4 to 6 hours to the residual tumor, and then patients received 60-Gy to 70-Gy doses of conventional external beam radiotherapy. The median survival time was only 10 months, and recurrent tumor was found in all patients who died and were autopsied. Given the dose inhomogeneties and the relatively small amount of neutron radiation given, this outcome is not surprising.

Summary

^{252}Cf sources offer a means of performing brachytherapy with neutrons. Conceptually, this is intriguing for tumors in which hypoxia is thought to be a factor in limiting tumor control with standard treatment and which lend themselves to brachytherapy approaches. There has been one randomized study for advanced cervical cancer showing benefit compared with standard brachytherapy with gamma ray sources, but this field still requires considerable development. Remote afterloading devices allow implementation of this technique without high risk to medical personnel. A recent review shows that there are 21 ^{252}Cf brachytherapy systems being used in China today.[77]

CHAPTER

21 Hyperthermia

Mark Dewhirst, Paul R. Stauffer, Shiva Das, Oana I. Craciunescu, and Zeljko Vujaskovic

The biological rationale for hyperthermia (HT) as a cancer treatment is based on several mechanisms, particularly relating to its combination with other therapies: (1) HT is directly cytotoxic. (2) When used with radiotherapy (RT), HT inhibits potentially lethal- and sublethal-damage repair and has complementary cytotoxicity with reference to the cell cycle. Hyperthermic killing is not influenced by hypoxia, whereas hypoxia has a significant effect on radiosensitivity. HT causes reoxygenation, which can increase RT sensitivity. (3) HT increases drug uptake into cells, enhances DNA damage, and partially or completely reverses drug resistance. (4) HT improves delivery of nanoparticle drug carriers, such as liposomes, and macromolecular drugs, such as antibodies and drug-carrying polymers. (5) The process of thermal adaptation (thermotolerance) may enhance exposure of tumor cell antigens to immune cells and increase innate immunity, thereby augmenting host immune responses against tumor cells.

Despite strong biological rationale, delivery of HT presents significant challenges. The goal is to be able to heat tumor tissue volumes reproducibly and to do so using methods that are clinically practical. A significant impediment to this goal is that current thermometry is invasive. Consequently, definition and calculation of thermal dose is not well defined. Priorities in the area of engineering and physics center on improvements in technologies to deliver HT, to measure thermal dose noninvasively, and to use such data to control power to the tumor in real time.

Despite the technical difficulties in delivering HT, however, several positive randomized trials using HT in combination with RT and chemotherapy in human patients with cancer have been published in addition to three positive canine randomized trials. The majority have demonstrated local control or survival advantages with therapies involving HT. These trials have involved patients with cervix cancer, primary brain tumors, head and neck cancers, esophageal cancer, chest wall recurrences of breast cancer, bladder cancer, melanoma, and most recently, high-grade soft-tissue sarcomas.

In this chapter, the biological rationale for using HT will be examined in more detail, a survey of methods used to heat tissues will be provided, and a comprehensive overview of key Phase III studies will be presented. The emerging discipline of thermal ablative technologies will also be presented briefly because it is approved for treatment of a range of diseases and is used widely by interventional radiologists and surgeons.

THE BIOLOGY OF HYPERTHERMIA

Definition of Hyperthermia

Hyperthermia means elevation of temperature to a supraphysiologic level, between 40°C and 45°C. Typical durations of hyperthermia treatment are 30 minutes to 60 minutes a session. Temperatures in the range of 50°C to 100°C for a few minutes per session are used for thermal ablation.[1]

The Arrhenius Relationship and Thermal Isoeffect Dose

Arrhenius found a temperature dependence of sucrose hydrolysis in the presence of various acids that was a logarithmic function of the absolute temperatures at which the reactions were conducted.[2] These observations were physiologically relevant in that the rate of cellular metabolism increases as temperature rises in cells or tissues, up to a point where thermal damage is created. The principles discovered by Arrhenius extend to cell killing by HT as well. The temperature dependence of the rate of cell killing is referred to as the "Arrhenius relationship."

The temperature dependence of the rate of cell killing has been used as a method for thermal dosimetry. This is done by plotting temperature versus log of the slope of the survival curve ($1/Do$). Do is analogous to a Do in a radiation survival curve (the dose to reduce survival to 37% of a starting value on the exponential portion of the survival curve). In the case of HT, "dose" is the number of minutes at a specified temperature (Figure 21-1). Typically, Arrhenius plots have a biphasic curve and the point at which there is a change in slope is referred to as a *breakpoint*. Above the breakpoint for nearly all cell types, a change in temperature of 1.0°C doubles the rate of cell killing. Acquired resistance to HT killing (thermotolerance) that occurs during HT is responsible for the change in slope of the heat cell survival curve at longer heating times for temperatures below 43°C (see Figure 21-1, *A*). Arrhenius plots for human cell and rodent lines are well described. The breakpoint for human cells is near 43.5°C, and the slope below the breakpoint, which is caused by thermotolerance induction during heating, is between 2 and 4. The slopes of Arrhenius plots derived from in vivo studies are virtually identical to those that are derived from in vitro studies.[4]

Sapareto and Dewey[5] proposed using the Arrhenius relationship to normalize thermal data from HT treatments. The rationale came from the observations that time-temperature histories are not stable, that they vary from patient to patient, and that temperatures within tumors were almost always nonuniform. Using the Arrhenius relationship, it would be possible to convert all time-temperature data to an equivalent number of minutes at a standard temperature (defined as 43°C). The formulation takes the following form.

$$\text{CEM } 43^\circ\text{C} = t R^{(43-T)} \qquad \text{Equation 1}$$

Where CEM 43°C = cumulative equivalent minutes at 43°C (the temperature most commonly used for normalization), t is the time of treatment, T is the average temperature during desired interval of heating, and R is a constant. When above the breakpoint, which is assumed by convention to be 43°C, $R = 0.5$. When below the breakpoint, $R = 0.25$

For a complex time-temperature history, the heating profile is broken into intervals of time t length, where the temperature remains relatively constant. CEM 43°C is calculated using the average T (T_{avg}) for each interval, and the resultant data

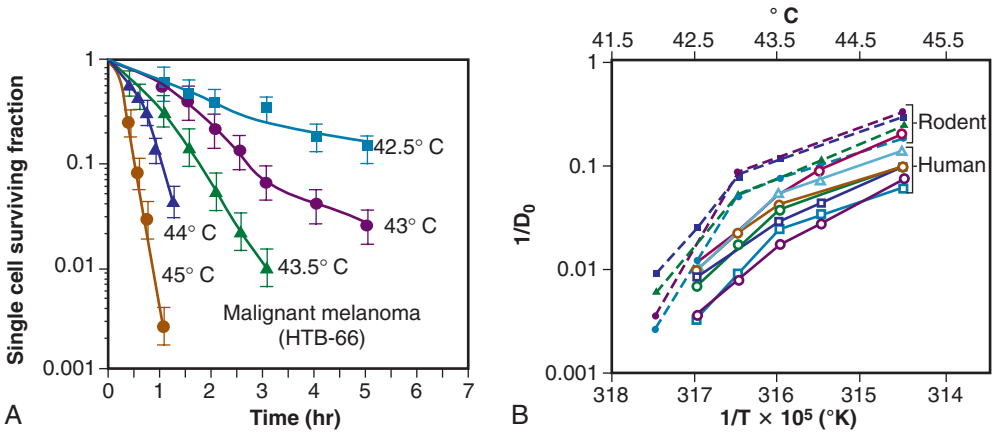

Figure 21-1 **(a)** Cell survival curves for human melanoma cells, plotted as log of surviving fraction as a function of time of heating at a defined temperature. **(b)** Arrhenius plots derived from survival curve data of several human and rodent tumor lines. Note change in slope (known as the "breakpoint") of Arrhenius plots for both types of cells. For human cell lines, this appears to be around 43.5° C, whereas for rodent lines it is approximately 43° C.
Data reproduced from Roizin-Towle,[3] with permission of the publisher and author.

are summed to give a final CEM 43°C for the entire heating regimen.

$$\text{CEM } 43^\circ\text{C} = \Sigma t R^{(43-T_{avg})} \qquad \text{Equation 2}$$

The CEM 43°C (thermal isoeffect dose) formulation has been used extensively and successfully in clinical trials to assess the efficacy of heating. This is despite that the *R* values and breakpoints have historically been derived from studies done in rodents, which are somewhat different from the parameters derived from human cells.[4]

There appears to be a relatively common threshold for thermal coagulation, which is used for thermal ablation. CEM 43°C >240 minutes is sufficient to achieve full coagulation of most tissues.[1]

Mechanisms of Hyperthermic Cytotoxicity

Cellular and Tissue Responses to Hyperthermia

Protein Is the Primary Target for Hyperthermic Cytotoxicity

When cells are exposed to elevated temperatures (≥41.0°C), damage is inflicted in multiple sites, but the predominant molecular target appears to be protein. The heat of inactivation for cell killing and thermal damage to tissues is in the range of that necessary for protein denaturation (130 kcal/mole to 170 kcal/mole).[6] Additional evidence for proteins as being the primary target for cell killing is the importance of heat shock proteins in protecting thermotolerant cells from thermal damage. One of the primary functions of heat shock proteins is to refold other proteins that have been damaged.[7]

Some organelles are especially important in controlling thermal response. For example, modification of membrane lipid content or use of membrane active agents, such as alcohols, can sensitize cells to heat killing, but the sensitization is probably related to destabilization of the membrane as it relates to lipid-protein interactions.[8] The cytoskeleton of cells is particularly heat sensitive.[9] When it is collapsed by heat, there is disruption of cytoskeletal-dependent signal transduction pathways as well as inhibition of cell motility.[10,11] The heat sensitivity of the centriole leads to chromosomal aberrations following thermal injury.[12] Finally, the DNA repair process is heat sensitive, and this may be one of the mechanisms that leads to heat-induced radio- and chemosensitization.[13]

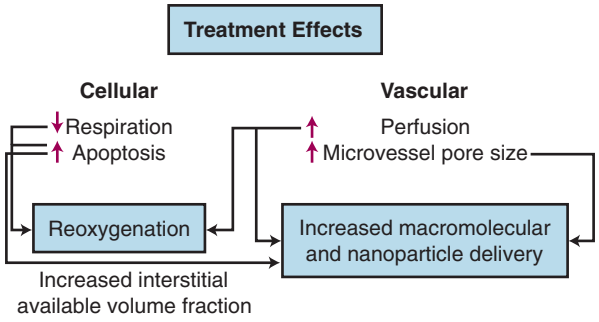

Figure 21-2 Overview of the beneficial physiologic and metabolic effects of HT.

Physiologic Response to Hyperthermia

Tumor blood flow and metabolism have important influences on the efficacy of HT, and conversely, the physiologic consequences of HT can influence the efficacy of other treatments.

As temperatures are increased, there is an increase in blood flow. The temperature threshold for this change is 41°C to 41.5°C in skin.[14] Changes in vascular permeability also occur, leading to edema formation in the heated volume. At higher thermal doses, vascular stasis and hemorrhage develop. The change in normal tissue perfusion upon heating is much greater (10-fold) than one sees in tumors (1.5- to 2-fold).[15] Mechanisms underlying vascular stasis may include arteriovenous shunting, thrombus formation, and leukocyte plugging.[16] Importantly, physiologic changes occur in tumors at temperatures below those that damage normal tissue (Figure 21-2).

Taking Advantage of Physiological Response to Hyperthermia

Improvement in Macromolecular and Liposomal Drug Delivery. A liposome is a small lipid vesicle (≈100 nm diameter) that contains water or saline in the center. Drugs can be loaded into liposomes at high concentration. HT increases microvascular pore sizes preferentially in tumor microvessels, which leads to enhanced liposomal accumulation in tumor.[17] The threshold for increased liposomal extravasation is 40°C

and increases by a factor of two for every degree temperature rise until vascular damage occurs.[18] The effects of HT on liposomal extravasation have been studied extensively in preclinical models, but 2-fold to 13-fold enhancement in accumulation occurs in spontaneous soft-tissue sarcomas of pet cats, an encouraging result that may translate to human tumors.[19] HT also increases the available volume fraction (fraction of tissue not occupied by cells or stromal fibers), which may develop as cells undergo either necrosis or apoptosis following heat treatment.[20] This increases the tissue space available for nanoparticles to be deposited. The increase in liposomal drug delivery achieved with HT has been shown to result in increased antitumor effect in many preclinical studies.[21] HT has been used in conjunction with liposomal doxorubicin and radiation in one small clinical series of patients with chest wall recurrences of breast cancer and encouraging results were obtained.[22]

Selective delivery of drug to a targeted tumor volume can be enhanced by using thermosensitive liposomes. These liposomes undergo a phase transition from a solid to a liquid state as they are heated.[23] When the phase transition occurs, the liposomes become permeable and release their contents. The phase transition temperature can be modified by changing the lipid composition. The original idea for a thermosensitive liposome is attributed to Dr. Milton Yatvin,[24] but the phase transition temperature of his formulation was too high and the rate of drug release was too slow for clinical use.[24] Needham developed the first low temperature, rapid release thermosensitive liposome, which exhibited complete doxorubicin release in <20 seconds upon reaching a transition temperature of 41.3°C.[25] Since then, other formulations have been reported that exhibit similar properties.[26,27] A key feature of this liposome is the fact that the majority of drug delivery achieved is via intravascular drug release (Figure 21-3). This feature essentially creates a local drug infusion within the heated volume that drives the drug down its concentration gradient and into the tumor interstitial space. This feature yields significantly greater drug penetration than can be achieved by increasing pore sizes to solid liposomes.[28] The Needham doxorubicin-loaded formulation yielded 5-fold higher accumulation of drug following HT treatment of 60 minutes at 42°C than the nonthermally sensitive Doxil formulation and 25-fold higher accumulation than free drug. The antitumor efficacy of the Needham formulation with HT was substantially greater than the liposomal drug without HT or free drug with HT in several different tumor lines.[29] The degree of enhancement in antitumor properties was directly proportional to the amount of drug accumulation in tumor.[30]

For relatively small chemotherapeutic drugs, there is no advantage gained via increased vascular permeability to macromolecules or nanoparticles, unless the drugs are protein-bound.[31] For drugs with molecular weight <1000 mw, the primary mechanism that governs drug transport is diffusion,[32] which is not highly temperature dependent. In contrast, the primary driving force for transport of macromolecules with >1000 mw is convection, which is controlled by the pressure gradient across the vessel wall. Accordingly, HT can augment the transvascular delivery of agents such as monoclonal antibodies[33] and polymeric peptides that carry drugs or radioisotopes.[34] Dreher et al used a novel peptide polymer that undergoes an inverse phase transition at 41°C, to "pump" polymer into tumors. The inverse phase transition refers to a

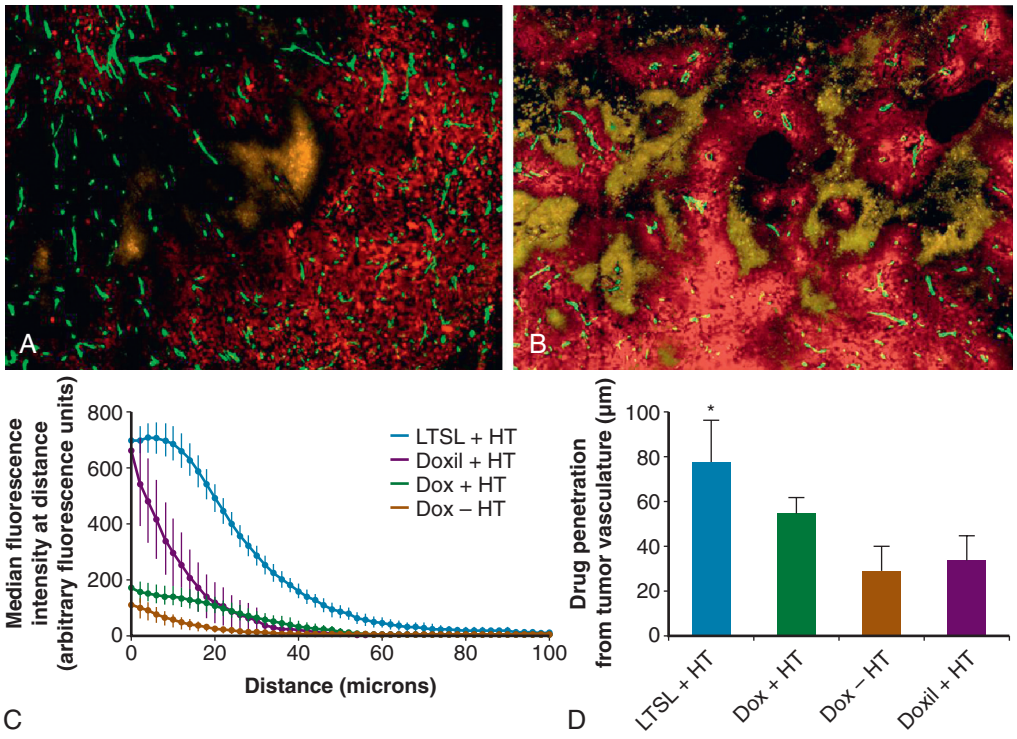

Figure 21-3 Immunohistochemistry images of doxorubicin penetration (red fluorescence) from vessels in the FaDu head and neck tumor xenograft. **A** and **B,** histology images following free doxorubicin with 42°C heating **(A)** and thermosensitive doxorubicin containing liposome (Dox-LTSL) with heating **(B).** Microvessels were stained with CD31 (green), and tissues assessed for hypoxia, using EF5 *(yellow)*. Qualitatively, the drug penetration is far greater with Dox-LTSL than with free drug. Quantification of penetration distance from nearest blood vessel shows that Dox-LTSL + heat delivers more drug at all distances from vessels compared with Doxil™ and free doxorubicin with heat **(C).** Doxorubicin delivered with Dox-LTSL penetrates twice as far as Doxil™ liposomes (78 vs. 34 mm; $p = 0.0106$) **(D).**

physical feature of the polymer that renders it to be water soluble below 41°C; above this temperature, the polymer comes out of solution in aggregates. The aggregation occurs primarily intravascularly but is reversible. Thus, when the tissue is cooled down, the particles rapidly disaggregate and diffuse into the tissue down their concentration gradient.[35] Additional nanoparticles have been designed since this work, which also have attractive thermal properties that would enhance drug delivery.[36,37]

Effects of HT on Tumor Metabolism and Oxygenation. Heat also modulates cell metabolism, by switching it toward glycolysis. This reduces oxygen consumption rate, which, in combination with increased perfusion, may contribute to heat induced reoxygenation.[38] Decreases in ATP concentration after HT are inversely related to the temperatures achieved during HT in preclinical models and canine sarcomas[39,40] and are related to pathologic CR rate in human sarcomas.[39] Decreases in ATP and increases in lactate concentration occur following tumor blood flow reduction after HT.[41] In human patients with soft tissue sarcomas who were treated preoperatively with HT and radiation therapy, reduction in ATP/Pi ratio (measured using ^{31}P magnetic resonance spectroscopy; Pi = inorganic phosphate) was significantly correlated with a higher probability for pathologic complete response.[39] These results are consistent with the theory that tumor respiration decreases after HT treatment.

Several pre-clinical studies have shown that mild temperature heating (between 40°C and 42°C for an hour) can lead to improvements in tumor pO_2 up to 24 hours after heating.[42] However, in some models, the extent of reoxygenation is quite heterogeneous between and even within individual tumors.[43] It has been reported that HT improves tumor oxygenation in canine and human soft tissue sarcomas, with reoxygenation being associated with greater probability for pathologic complete response (pCR) in human tumors.[44,45] In a canine study, median temperatures <44°C improved oxygenation, whereas median temperatures >44°C for 60 minutes led to decreased oxygenation.[44] In a follow up study with canine sarcomas, reoxygenation 24 hours after the first heat treatment was associated with increased likelihood for reduction in tumor volume at the end of therapy.[46] In patients with locally advanced breast cancer who were treated in a phase II study with preoperative HT + radiotherapy and taxol, there was a significantly increased likelihood for achieving pCR if the tumors reoxygenated 24 hours after the first HT treatment. The probability for achieving a pCR was greater when the median temperatures were below 41.5°C.[47] Improvement in oxygenation does not occur in all tumors, however, and currently there is no method for predicting which tumors will show this effect.[48] In summary, mild temperature elevations during HT will benefit some patients if HT induces reoxygenation. To take full advantage of this effect it will be necessary to utilize methods to enhance the reoxygenation effect, such that it occurs in the majority of patients. Song and Griffin have suggested that the addition of hyperoxic gas breathing after HT, but during radiotherapy, may achieve this goal.[49,50]

Hyperthermia and Metastases

HT causes abrupt changes in tumor microvascular function, as described above, which could enhance tumor cell shedding from the heated site. Pre-clinical studies are mixed on this issue. One report showed that local HT alone enhanced the metastatic rate of B16 melanoma.[51,52] When curative doses of radiotherapy were added to HT in the B16 melanoma model, however, the incidence of lymph node and lung metastases was decreased, compared with controls.[52] The combination of curative doses of radiation and HT has generally been reported in other tumor models to reduce the incidence of metastases,[53,54] although in a few models, simultaneous administration of HT with radiation has been reported to increase metastases.[53,54]

The question of whether local HT increases the risk for metastasis is difficult to answer in clinical trials unless the primary therapy has a high probability for local control. This is because of the problem of competing risks. In a phase III trial of canine patients with primary malignant melanomas treated with the combination of HT and radiation or radiation alone, no difference in the likelihood for metastasis between the two groups was seen.[55] However, local recurrence was a common event, and its onset was frequently followed by appearance of distant metastases. In a phase III randomized trial of human melanomas treated with thermoradiotherapy vs. radiotherapy alone, there was significant improvement in the likelihood for survival when the local tumor was controlled. Since the use of HT in that trial resulted in improved local control, the implication is that the combination therapy reduced the probability for metastases.[56,57] In a study comparing graded doses of radiation ± HT for treatment of canine soft-tissue sarcomas, higher normal tissue temperatures in the region of the tumor were correlated with lower likelihood for distant metastases.[58] A large series of patients (N = 95) with previously untreated high-grade soft tissue sarcomas who were treated preoperatively with HT and radiation achieved a local control rate near 90%, but 50% developed distant metastases.[59] This rate of metastasis is essentially identical to that seen with preoperative RT alone, however, suggesting that HT had an undetectable influence on metastases.[60]

The conclusion is that with the exception of one study with the B16 melanoma murine model involving HT alone, there is not any evidence from pre-clinical models or human trials that local-regional HT causes an increase in metastases, particularly when HT is combined with radiotherapy.

Normal Tissue Damage from Hyperthermia

Thresholds for thermal damage depend on the tissue type being heated and the severity of the injury. Mild damage can merely lead to edema, whereas more severe injury can lead to massive necrosis and organ failure. This subject has been reviewed in detail.[1,3] The ranking of tissue thermal sensitivities does not follow classical principles derived from other cytotoxic agents, such as radiation or chemotherapy. With such agents the most sensitive tissues are those with the highest proliferative potential or activity. For HT the most sensitive tissue classification includes brain, which is comprised of cells with almost no proliferative potential, as well as testis, which has high proliferative potential. There has been speculation as to whether tumor tissues might be more sensitive to thermal damage than normal tissues. Many studies have compared tumor to normal cells, in vitro. There is no inherent difference in the thermal sensitivity. However, the microenvironment of tumors, which is often acidotic and nutritionally deprived, leads to an increase in thermal sensitivity that has been reported in a clinical series.[61]

Radiation and Hyperthermia

Rationale for Combining Hyperthermia with Radiotherapy

When radiation is combined with HT, complementary effects occur. Cells in S-phase are radioresistant, but sensitive to HT. Hypoxic cells are three-fold more resistant to radiation, compared to aerobic cells, but there is no difference in thermal sensitivity between aerobic and hypoxic cells. As discussed

earlier, HT can lead to reoxygenation, which will further improve radiotherapy response.[42,45,46,62] Finally, HT inhibits the repair of both sublethal and potentially lethal damage by inactivating crucial DNA repair pathways.[63-65]

Factors to Consider When Combining Hyperthermia with Radiotherapy

The interaction between radiation and HT is described by the "thermal enhancement ratio" or TER, which is defined as the ratio of doses of radiation to achieve an isoeffect for RT/RT + HT. TERs for local tumor control have been estimated for a number of human tumors using historical control data for radiation alone.[66] In most tumor types examined, these ratios were >1. Assessment of normal tissue TER has not been attempted except in a few cases. For those examples, TER values for normal tissue damage have been less than those for tumor in the same patient population, suggesting potential for therapeutic gain for RT + HT compared with RT alone.[66] Prospective randomized trials in dogs with spontaneous tumors have also shown evidence for improved local tumor control with RT + HT compared with RT alone[58,67-69] with no observable increase in the frequency of clinically relevant late normal tissue complications. In one canine trial enhancement of late radiation damage (as assessed histologically) was reported and the duration of acute radiation complications was prolonged.[69] There is clinical evidence, however, that excessively high intratumoral temperatures (i.e., >45°C for 60 minutes) can lead to damage to surrounding normal tissues, an effect that is often caused by rapid tumor regression.[67,70] Such damage is not easily repaired and can lead to chronic tissue consequences, such as fibrosis, fistulae formation, and bone necrosis.

Two cases of fatal pelvic necrosis have been reported as a late complication in patients with locally advanced cervix cancer treated with thermoradiotherapy.[71] There was speculation as to whether the complication was the result of HT. More recently, however, this rare complication has been reported following chemoradiotherapy treatment of cervix cancer.[72,73] Thermal doses achieved in the HT series were several degrees lower than has been reported to be associated with enhancement of normal tissue complications by radiotherapy, which strongly suggests that these two cases were not the result of HT, but more likely a result of the radiotherapy treatment, perhaps complicated by a heavy smoking history associated with both patients.[71]

In summary, most available data from pre-clinical and clinical studies indicate that therapeutic gain is achievable for the combination of HT with RT. There is very little evidence to suggest that HT enhances the incidence or severity of late normal tissue complications from radiotherapy, particularly when excessively high intratumoral temperatures are avoided.

Hyperthermia and Chemotherapy

Rationale for Using Hyperthermia with Chemotherapy

Many chemotherapeutic agents have been shown to exhibit synergism with HT, including cisplatin and related compounds, melphalan, cyclophosphamide, nitrogen mustards, anthracyclines, nitrosoureas, blyeomycin, mitomycin C, and hypoxic cell sensitizers.[31] The mechanisms that underlie the synergy may include: (1) increased cellular uptake of drug, (2) increased oxygen radical production, (3) increased DNA damage and inhibition of repair, and (4) reversal of drug resistance mechanisms.[74-77] Hypoxia and pH are also important in the thermochemotherapeutic response.[78-82] There are some classes of drugs, such as etoposide and vinca alkaloids, that do not synergistically interact with HT.[31]

Rationale for Using Hyperthermia with Targeted Agents

(MAP) Kinase, Heat Shock Response and HIF-1

It has been reported that hyperthermia can increase expression of HSP40 (40 KD heat shock protein) via the ERK1/2 (MAP) kinase pathway.[83] The upregulation of HSP40 protects against heat killing, but blockade of MAP kinase activation by SiRNA or by targeted drugs sensitizes tumor cells to hyperthermic cell killing.

HIF-1 is also upregulated by hyperthermia in a process mediated by ERK1/2 transcription of NADPH oxidase in tumor cells.[38] The increased production of peroxide by NADPH oxidase stabilizes the labile subunit, HIF-1α. Increased levels of HIF-1α bind to its heterodimer, HIF-1β, leading to HIF-1 mediated gene transcription. The increased transcriptional activity of HIF-1 upregulates: (1) production of VEGF (vascular endothelial growth factor), which promotes angiogenesis and (2) PDK-1, (pyruvate dehydrogenase lipoamide kinase isozyme 1) which promotes a switch to anaerobic metabolism. Both of these responses and other HIF-1 regulated genes promote survival of tumor cells. The upregulation of HIF-1 mediated transcripts has been verified clinically in canine sarcomas after treatment with thermoradiotherapy.[84] Further, inhibition of HIF-1 after radiotherapy has been shown to enhance growth delay.[85] Thus, there is rationale to inhibit the HIF-1 response after hyperthermia particularly when combined with radiotherapy.

Genomic Analyses

Genomic analysis of U937 cells, a human myelomonocytic tumor, exhibited differential expression in approximately 1000 genes, following a non-cytotoxic treatment of 41°C for 30 minutes.[86] A higher thermal exposure of 42°C for 90 minutes led to more significant change in pro-apoptotic signaling pathways,[87] in addition to the expected heat shock response in both cases. Genome-wide analysis has also been done on one rat tumor line in vivo, following local heating (43°C for 60 minutes).[88,89] The effects of hyperthermia were rather pleiotropic, involving over 1200 genes and a host of cellular responses, including apoptosis regulation, cell cycle control, MAP kinase and calcium regulated cell signaling and genes involved in angiogenesis and metabolism regulation. There was also substantial downregulation of a number of genes involved in immune function at 3 hours after treatment, which recovered to baseline by 24 hours. These results suggested that HT does not adversely affect immune function. The fact that hyperthermia appears to augment pro-apoptotic signaling pathways suggests that it could work additively to with targeted agents that promote apoptosis.

Chi et al conducted the first clinical study comparing gene expression patterns and functional imaging (diffusion weighted MRI) prior to and 24 hours after the first HT fraction during a course of thermoradiotherapy for spontaneous canine soft tissue sarcomas.[84] Patterns of gene expression change of VEGF, DNA repair and inflammation were correlated with response, as assessed by changes in diffusion weighted MRI. Using connectivity mapping, the differential in gene expression was found to be linked to several drugs, the most promising of which was geldanomycin, an HSP90 inhibitor. The authors went on to show that this drug sensitizes cells to thermoradiotherapy, in vitro. This provides rationale for such combinations in future human clinical trials.

PARP-1 (Poly [ADP-ribose] Polymerase 1) Inhibitors

It has recently been reported that mild hyperthermia (41°C and 43°C) inhibits double strand DNA break repair after

radiotherapy.[90] This is due to downregulation of BRCA2 accumulation at double strand break sites of DNA. BRCA2 is a protein that is essential for completion of homologous recombination. Based on prior knowledge that cells deficient in BRCA2 are sensitive to PARP-1(Poly [ADP-ribose] polymerase 1) inhibitors, the authors went on to show that inhibition of PARP-1 sensitizes tumor cells to killing by hyperthermia. The authors termed this strategic approach an "induced synthetic lethality." Given that PARP inhibitors are currently in clinical trials <http://clinicaltrials.gov/ct2/results?term=PARP+inhibitor&Search=Search>, this therapeutic approach may be rapidly translated to trials involving hyperthermia.

It has been reported that HT can induce autophagy via activation of NFκB, as a protective mechanism against cell death.[91,92] Thus it would make sense to consider combining agents that inhibit NFκB activation with HT as a means to enhance thermal cell killing. Alternatively, the combination of 43°C hyperthermia with increased oxidative stress can increase cell killing via inhibition of the Akt pathway and induction of irreversible autophagy.[92] Pajonk et al reported that inhibition of proteasome activity in combination with (44°C for 60 minutes) hyperthermia was particularly effective in augmenting apoptosis, in addition to causing substantial radiosensitization.[93]

In summary, there appears that there is emerging rationale for targeting various signal transduction pathways and other cellular adaptation processes as a means to enhance cell killing when combined with hyperthermia.

Factors to Consider when Combining Hyperthermia with Chemotherapy

Temperature Dependence

The degree of enhancement of cytotoxicity has been shown to be temperature dependent for many drugs.[94] Combinations of camptothecins with HT have not shown consistent results in vitro. The interaction between these agents and HT is schedule and temperature dependent.[95,96] In one report, temperatures up to 41.8°C increased the activity of topoisomerase II, which may be the explanation for the increased activity of these drugs at elevated temperatures.[95]

In Vitro Results May not Predict In Vivo Activity

Tubulin binding agents, such as taxol, show no evidence for interaction in vitro,[97] but studies in combination with radiation therapy in vivo are more encouraging.[98] There may be physiologic consequences of the combination of taxol and HT that make the combination work better than predicted from in vitro studies.

Sequencing

For most drugs (excluding 5-FU and perhaps other antimetabolites), the optimal sequence between heat and drug is to administer them simultaneously or to give the drug immediately before the onset of heating. For platinum-containing drugs, the tissue extraction rate is increased with HT, further substantiating the rationale for use of this sequence.[99] It has been shown recently that thermal enhancement of cisplatin uptake by cells is the result of multimerization of the CTR1 transporter (otherwise known as the copper transporter).[100] Most antimetabolites do not interact with HT when given concomitantly.[31] However, 5FU has been shown to interact supra-additively with HT by controlling temperatures to be between 39°C and 41°C. Temperatures in this range lead to enhanced conversion to active metabolites, thereby increasing drug cytotoxicity. In addition, continuous infusion protocols with this drug may lead to cell cycle block in S phase, a relatively sensitive part of the cell cycle to HT.[101]

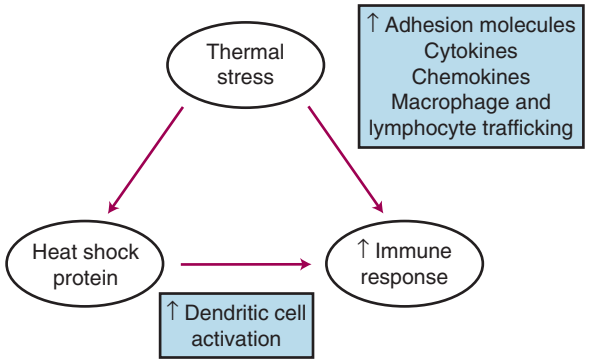

Figure 21-4 Summary of known beneficial immunological effects of mild temperature hyperthermia.

Immunological Effects of HT

Heat shock proteins have been recently recognized for their potential role in regulating immune responses. There are several recognized functions of these proteins: (1) They are known to bind, in a non-covalent fashion, to immunogenic peptides. (2) When tumor cells are exposed to HT, HSP-peptide complexes are presented on the cell surface. These complexes can be recognized by antigen-presenting cells (dendritic cells) via MHC class I molecules. Once dendritic cells have received this type of stimulus, they migrate to lymph nodes, where they prime T-cell lymphocytes to be cytotoxic toward cells that express the peptide-HSP complex. Hyperthermia has been shown to enhance the rate of dendritic cell migration.[102] (3) Heat shock proteins also induce dendritic cell maturation and pro-inflammatory cytokine release.[103,104] (4) Cell membrane localization of heat shock proteins also activates the innate immune system by activating natural killer cells (NK cells).[105] Other sources of cellular stress—such as viral infection, fever, hypoxia, and radiation exposure—have been shown to upregulate heat shock proteins as well. Because this process appears to occur naturally, there have been efforts to exploit the use of hyperthermia to produce tumor-derived vaccines and to augment the in vivo response to such vaccines.[104] HT has also been reported to upregulate a number of pro-inflammatory cytokines and adhesion molecules that facilitate immune cell trafficking across endothelial cells to gain access to tumor interstitium.[106] Additionally, shed heat shock proteins, with or without associated peptides, may act as chemokines to attract immune cells (particularly macrophages) toward a region tissue that has undergone heat stress.[107] A summary of some key immunological effects of HT is shown in Figure 21-4. Note that a special issue of the International Journal of Hyperthermia was recently published, which covers this subject in detail.[108]

HYPERTHERMIA PHYSICS/ENGINEERING

Clinical HT is usually achieved by exposing tissues to non-ionizing radiation (e.g., electromagnetic [EM] or ultrasonic [US] fields) or by conducting heat into tissue from a heated source (e.g., hot pad or needle). Although these modalities deposit energy in tissue by different physical mechanisms, they have general similarities. Uniformity of heating is sensitive to the heterogeneity of tissue properties, geometry of blood flow, and practical problems of coupling the energy source into tissue. Hyperthermia can be delivered non-invasively with externally applied power sources or invasively by placing heat sources either interstitially or inside natural body cavities. An overview of non-invasive methods is provided below and is summarized in Table 21-1. Invasive

TABLE 21-1 Summary of Methods Used to Heat Tissues

Class	Method	Power Directed to Tumor Site?	Frequency	Coupling Medium	Invasive Thermometry Requirements	Advantages	Disadvantages
ELECTROMAGNETIC							
Superficial							
	Capacitive radiofrequency	Partially, by changing position and relative size of electrodes	5-30 MHz	Saline	RF-shielded EMI-resistant probes and readout electronics	Simple to operate	Superficial fat heats; use limited to thinner patients
	Microwave waveguide	Yes, by placing waveguide over tumor	433, 915, 2450 MHz	Water	Non-perturbing EMI-resistant fiberoptic probes or high-resistance lead thermistors	Simple to operate	Limited depth of heating; heat pattern dependent on tissue properties and applicator coupling
	Microwave array	Yes, by adjusting relative power to multiple antennas	433, 915, MHz	Water	Non-perturbing EMI-resistant fiberoptic probes or high-resistance lead thermistors	Adjustable size, shape and location of heating; available in planar or conformal arrays	Limited depth of heating
Deep							
	Magnetic induction	No	0.05-15 MHz	Air	RF-shielded EMI-resistant probes and readout electronics	Simple to operate; focus with implanted particles or seeds	Eddy currents follow path of least resistance; heating pattern controllable with particles or seeds
	Capacitive radiofrequency	Partially, by changing position and temperature of electrodes	5-30 MHz	Saline	RF-shielded EMI-resistant probes and readout electronics	Simple to operate	Superficial fat heats; use limited to thinner patients
	Phased radio-frequency arrays	Partially, by adjusting phase and amplitude of power from different antennas	70-150 MHz	Water	Non-perturbing EMI-resistant fiberoptic probes or high-resistance lead thermistors	Ability to focus heat at depth and move the heat focus around	Limited control over size and location of heat focus
ULTRASOUND							
Superficial							
	Planar non-focused ultrasound transducer	Partially, by placing transducers over tumor	1-5 MHz	Degassed water	Metal probes required; avoid plastic	Simple to operate	Good coupling to soft tissue required—air and air prohibit penetration and can lead to pain
	Planar non-focused ultrasound transducers—multiple	Yes, by adjusting relative power and/or frequency of transducers	1-5 MHz	Degassed water	Metal probes required; avoid plastic	Improved control of size, shape and perhaps depth of heating	Good coupling to soft tissue required—air and air prohibit penetration and can lead to pain
Deep							
	Focused transducer array	Yes, by adjusting relative power, phase and/or scanning of transducers	0.5-2 MHz	Degassed water	Metal probes required; avoid plastic	Precise steerable focus possible at depth	Practical limit on size and location of appropriate acoustic window, air and bone prohibit penetration and can lead to pain

methods have been developed extensively and include radiofrequency (RF) electrodes, microwave antennas, ultrasound transducers, hot water tubes, and inductively heated ferromagnetic implant rods or seeds. Further details on all methods are available elsewhere.[109-118]

Electromagnetic Heating

The primary mechanism of EM heating varies with frequency. For radiofrequency (RF) fields below about 30 MHz, the EM field induces a net movement of free electrons and power deposition results from resistive (ohmic) losses due to electric currents through lossy tissue. The term "lossy" means that the tissue is both a poor conductor and poor insulator. As such, electromagenetic fields are absorbed as they traverse the tissue. At microwave frequencies above about 150 MHz, heating results primarily from friction between polar water molecules that oscillate to maintain alignment with the time-varying field. This is called "dielectric loss." Improved penetration is obtained for lower frequencies with longer wavelengths, but the ability to localize EM energy in a desired target improves with higher frequency and corresponding shorter EM wavelengths. Accordingly, there is a trade-off between depth of penetration and ability to focus energy. In practice, heating may be localized in tumor targets within 2-4 cm from a microwave applicator at >430 MHz, whereas lower frequency multiple antenna phased arrays are used to heat larger regions that include tumor deep in the body.

Considering the effects described earlier, electromagnetic heating devices are quite different for superficial heat applications with effective penetration less than 4 cm than they are for deep heating of tissue more than 4 cm. Superficial heat applicators include waveguides (Figure 21-5) and microstrip or patch antennas (Figure 21-6) operating at microwave frequencies of 433, 915, or 2450 MHz. These devices can be separated into two categories: superficial applicators with effective penetration into tissue <4 cm, and deep heating devices that have effective penetration >4 cm. Superficial devices include waveguides (Figure 21-5) and microstrip or patch antennas (Figure 21-6) operating at microwave frequencies of 433, 915, or 2450 MHz.[115-117,119-121] Microwave energy is usually coupled into tissue through a temperature-controlled deionized water bolus to maintain skin temperature below 44°C.

In order to heat at depths >4 cm, radiofrequencies between 5 and 200 MHz are used. There are three basic techniques for EM deep heating: inductively coupled magnetic fields, capacitively coupled electric fields, and radiated fields from multiple antenna phased arrays.

Magnetic Induction Heating

Magnetic induction heating uses a 0.05-15 MHz magnetic field to induce eddy currents in conductive tissue.[122] The magnetic field can penetrate to the body center but heating is caused by eddy currents in lossy tissue that depend on tissue type and geometry of the induction coils and tissue load.[123] Heating may be concentrated deep in the body around implanted ferromagnetic seeds or particles that couple into the external magnetic field more effectively than surrounding tissue. Without insertion of ferromagnetic material into the body, the distribution of power deposition in tissue directly from induced eddy currents is not adjustable. By inserting ferromagnetic seeds or particles in the tumor, the distribution

Figure 21-5 Example of a commercial microwave waveguide applicator heating system for superficial hyperthermia treatments. Typical systems operate at 915 MHz or 430 MHz for heating 2-4 cm depth. Energy is usually coupled into tissue through a thin layer of deionized water, which is temperature controlled to maintain the skin surface below 44°C. A single waveguide applicator provides no control of power distribution in the x-y plane, aside from what can be achieved by physically moving the applicator. The arrow indicates the aperture of the waveguide. The water bolus would be attached to the waveguide in this location.

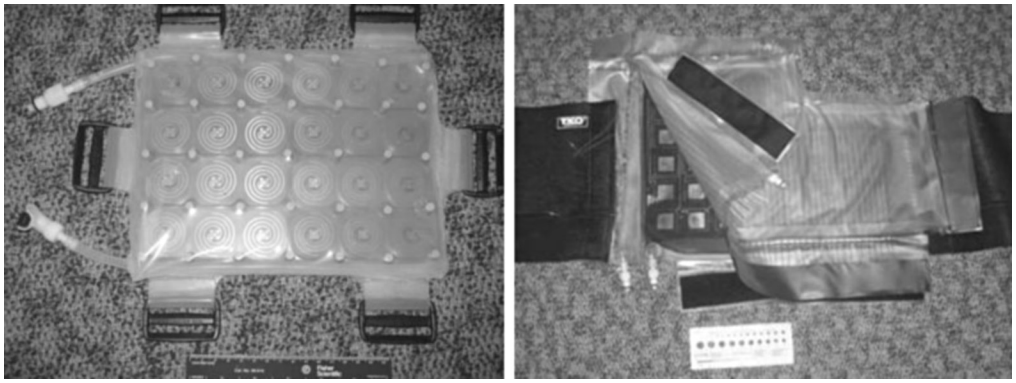

Figure 21-6 Two examples of thin and flexible microstrip antenna array applicators currently under development for superficial hyperthermia. A <1 cm thick temperature controlled deionized water bolus is used to couple microwaves into tissue and maintain the skin surface below 44°C. These conformal array applicators are driven with 8 or more microwave power sources to provide adjustment of the power distribution across the tissue surface.

of heating may be adjusted by changing the density of implanted material. There has been a resurgence of interest in ferromagnetic materials for hyperthermia. See recent special edition of the International Journal of Hyperthermia for more details.[123]

Capacitive Heating

Capacitive heating uses radiofrequency fields between 5 and 30 MHz to generate electric current between two or more conductive electrodes. Heating tends to be concentrated nearest the electrodes, but temperature-controlled saline boluses are used to reduce hot spots on the skin surface and help cool superficial fat.[124] Using different size electrodes, the maximum power deposition may be shifted toward the smaller electrode. This technique can be used with large electrodes on the skin[125,126] and one or more small intracavitary electrodes such as a balloon electrode for esophageal tumors.[127] The thickness of the superficial fat layer is a significant factor for this method because of extra heating in high resistance fat tissue relative to deeper lying high conductivity soft tissues. To date, RF capacitive heating has been used most widely in Asia, where patients tend to be thinner.

Radiofrequency Phased Array

The third option for heating with electromagnetic fields is the radiofrequency phased array.[128-131] These devices consist of an array of RF antennas arranged in a geometric pattern surrounding the target body region. Antennas are driven with multiple independently controllable power amplifiers but using a common radiofrequency source, allowing phase addition fields from all antennas to add together to form a heat focus in the center of the array. The focus can be shifted off center and around the tumor by variation of relative phase of the drive signals from each amplifier. For a multiple antenna phased array deeper power deposition into tissue is possible than using several independent antennas without phase addition. The phased array technique has more flexibility for controlling power deposition pattern than direct tissue magnetic induction and capacitive techniques which are altered significantly by heterogeneous tissue properties and few power control variables. Figure 21-7 shows one example of a 12 antenna annular phased array applicator mounted on the patient table of a magnetic resonance imaging (MRI) system. This MR compatible 100 MHz RF phased array applicator fits inside the bore of 1.5 T magnet allowing MR imaging of temperature to rise inside the body during hyperthermia treatment.

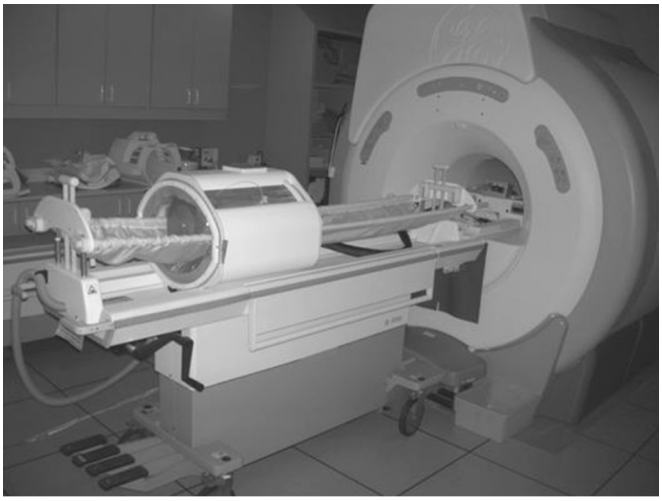

Figure 21-7 Example of 12 antenna radiofrequency phased array applicator for deep regional hyperthermia treatments. This array is driven at 100 MHz and has appropriate filtering to enable use inside a magnetic resonance (MR) imaging system for monitoring deep tissue temperatures with proton resonance frequency shift based MR thermal imaging. The large focus of heating inside the phased array applicator may be guided into the tumor by adjusting phase and amplitude of the 12 antennas, in response to real-time feedback from the MR thermal images.

Ultrasound Heating

Energy transfer from an ultrasound acoustic pressure field results from viscous friction within the tissue caused by successive compression and expansion from the high and low pressure wavefront. As with electromagnetic sources, heating falls off exponentially with distance from a single source, and penetration of the ultrasound field decreases with increasing frequency. However, because the wavelength of an US field is several orders of magnitude smaller than that of EM fields, and on the order of mm, ultrasound energy may be focused into small volumes deep in the body, given sufficient number of transducers to spread out the surface power density over a large surface. In practice, it is anatomic geometry and tissue heterogeneity (air reflects and bone preferentially absorbs ultrasound) that restrict the utility of US for heating large tumor volumes at depth. The availability of an adequate "acoustic window" (a path unobstructed by bone or air proximal and distal to the target) is the primary concern in clinical HT with ultrasound, wherein the entry window and acoustic gain to the target determines the maximum size and depth of the target volume.

Energy is coupled into tissue using temperature-controlled degassed water. Single and multiple transducer unfocussed devices have been designed for superficial tumor (2-5 cm) heating which typically operate in the 1-5 MHz range.[132-135] Deep heating with ultrasound is accomplished by using electrically or mechanically scanned focused transducers, phased arrays, or multiple scanned focused transducers, normally in the 0.5 to 2 MHz range.[135]

High intensity focused ultrasound systems are now available with high density multiple transducer arrays that are integrated into magnetic resonance imaging systems for simultaneous anatomic imaging, real-time thermal monitoring and beam steering control, and immediate post treatment assessment of ablation volumes. These systems produce a tight focus inside the cranium[136] or torso,[137] and are used most often for high temperature thermal ablation treatments.[139] For some treatment sites, additional localization is obtained using transducer arrays implanted in interstitial or intracavitary catheters. Excellent reviews of the physics and clinical aspects of focused ultrasound therapy have been published.[138-141] Focused ultrasound has also been tested extensively for its potential to augment nanoparticle delivery. This includes applications to open the blood brain barrier.[142-145]

Measurement of Temperatures during Hyperthermia

Invasive Thermometry

Invasive thermometry is the current standard for most hyperthermia treatments, involves physically placing thermometry probes into the tumor within implanted needles or catheters to read subsurface temperatures.[146-148] Although the accuracy of invasive thermometers is sufficiently precise (typically ± 0.3°C) to resolve important differences in thermal dose (as described earlier), this type of thermometry has many disadvantages. Disadvantages include discomfort to the patient and

risk of hemorrhage and/or infection, the expense of physician time required for catheter placement, and necessity for imaging to verify placement of thermometers in the target volume. In addition, the sparse nature of the data obtained makes it difficult to spatially control power deposition or alter treatment to improve temperature distributions.[149,150] The most common method for doing invasive thermometry is to insert blind ended catheters into a tumor, using either ultrasound or CT guidance.[147] Alternatively, for deep-seated tumors, thermometers may be placed inside orifices that are surrounded by tumor, such as the rectum, urethra, bladder, or cervix.[151] The probes can be multipoint sensors that remain fixed in place, or sensors are moved cyclically during treatment to record temperatures at many points along the catheter. There are guidelines published for how these measurements should be taken for all HT devices.[147,151-154] In spite of its sparse nature, invasive thermometry can provide valuable information about the quality of a treatment. A number of clinical reports have correlated temperature-related parameters to clinical response.[67,155-160]

Noninvasive Thermometry

Noninvasive thermometry is emerging in answer to the critical need for volumetric thermometry to visualize complete 3D temperature distributions in real time during deep hyperthermia treatments. In typical treatments using radiofrequency phased array applicators monitored only by invasive probes the number of thermal monitoring points is insufficient to adequately characterize the heating pattern. Parts of the tumor are unheated whereas too much heat is sometimes generated in surrounding normal tissues. Similarly, multiple element array superficial hyperthermia applicators require more temperature measurements than are possible with a limited number of invasive probes to monitor and control all independently powered heat sources. Insertion of multiple interstitial probes is clinically impractical. For superficial tumors (<1.5 cm depth), thermal dosimetry is often limited to probes placed in fixed positions on the skin or mapped through catheters lying on the skin to characterize the distribution of heating across large area disease as a prediction of subsurface temperatures.

To address the shortcomings of invasive thermometry, a number of noninvasive techniques are under investigation. Infrared thermography has been available for years for monitoring surface temperature distributions.[161] Although spatial resolution and accuracy are excellent, the method requires open access to visualize the surface so is not compatible with most heating technologies. A new approach for monitoring 2D surface temperature distributions even when the surface is buried under a water-bolus coupled applicator involves use of high density arrays of fiberoptic sensors mounted in a large surface-conforming Thermal Monitoring Sheet (TMS).[162,163] Other noninvasive thermometry approaches under development include electrical impedance tomography (EIT) sometimes called applied potential tomography,[164-165] ultrasonic temperature imaging using change in backscattered energy,[166-167] electron paramagnetic resonance (EPR),[168] active microwave imaging or tomography,[169] microwave radiometry,[170-176] and real-time multislice magnetic resonance thermal imaging (MRTI).

While there are clinical applications for each of these technologies, MRTI is being studied most intensively for volumetric characterization of temperature distributions and control of radiofrequency beam steering for deep tissue hyperthermia. Although several MR tissue parameters are sensitive to changes in temperature, attention has focused on investigation of the change in water proton resonance frequency shift (PRFS),[138,177-179] even in tissues with low water content like breast.[180,181] Use of noninvasive MR thermometry should translate into improved treatment efficacy by providing quantitative volumetric thermal dosimetry in real-time to assist the delivery of improved quality HT treatments. Figure 21-8 shows an example of non-invasive thermometry with MRTI during heat treatment of a lower leg sarcoma with a four antenna 140 MHz mini annular phased array applicator. The method has yielded a temperature resolution of better than 1.0°C compared with calibrated with invasive sensors in human patients.[182] Moreover, MR imaging offers opportunities for validation of treatment planning systems,[183-185] dynamic control of treatment delivery,[186-189] and posttreatment assessment of tissue damage.[190] The use of MRTI has been increasing rapidly in recent years for clinical applications in both moderate temperature hyperthermia and high temperature thermal ablation therapy such as radiofrequency, laser, and high intensity focused ultrasound.[191] The International Journal of Hyperthermia summarized the status of MR thermometry in a

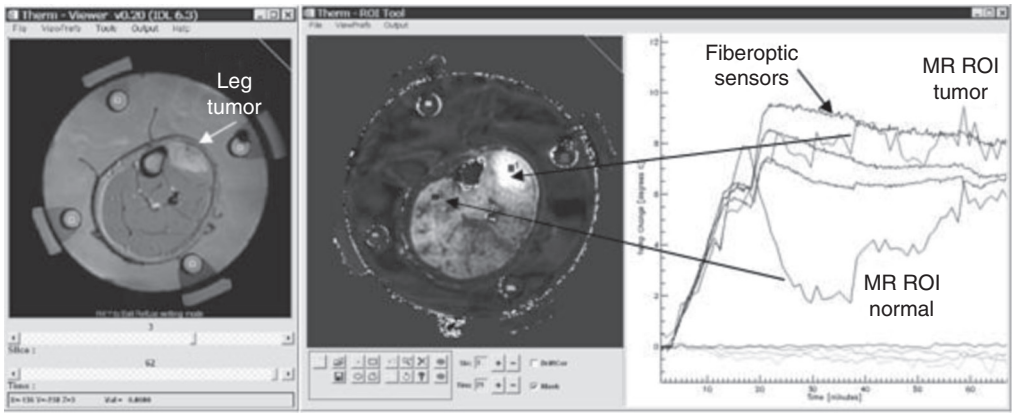

Figure 21-8 Real-time display during MR monitoring of heat treatment. Left panel shows anatomical image of leg in 24 cm diameter phased array applicator. The central image shows a typical differential temperature image display at about 20 minutes into heat treatment, after the phase of the four 140 MHz twin dipole heating antennas had been adjusted to move the heat focus into the tumor at upper right of leg. The PRFS calculated temperature rise is displayed on the same plot as invasive fiberoptic sensors in the tumor. The dramatic refocusing of power deposition at 18 minutes into treatment is seen to shift heating away from normal tissues in upper left of image and into the tumor at upper right, as indicated qualitatively by the brightness of the temperature image and quantitatively in the calculated temperature rise for tumor in the plot at right.

special issue.[192]; additional background can be found in review articles by Rieke and Butts[193] and MacFall and Soher.[178]

In a paper by Craciunescu et al[182] the critical steps were presented to attain rapid volumetric real-time image-guided hyperthermia treatments. With update times of the order of minutes, the claim of real-time treatment control agrees with an accepted definition of "real-time" given for thermal therapies by Rieke and Butts,[193] as "an update time that is small compared to significant changes in temperatures during treatment." This update time is different in hyperthermia applications (minutes or more) versus ablation therapies (a few seconds to minutes). This whole process lends credibility to the idea that future hyperthermia systems will use image feedback to control beam steering and focus heating in tumor targets.

CLINICAL HYPERTHERMIA

General Considerations

HT Alone

HT alone has been studied in the treatment of superficial tumors. While an occasional response is noted, the duration is typically quite short.[194,195] No long-term tumor control has been described with the use of HT as a sole treatment modality. HT alone remains widely practiced in certain alternative and complementary medicine clinics. Its use, however, is not supported by any peer-reviewed published scientific data.

Thermal Ablation

In contrast to effects of mild to moderate temperature hyperthermia, thermal ablation can yield durable long-term results. A meta-analysis was conducted of four phase III trials (766 patients) comparing percutaneous ethanol injection to radiofrequency ablation (RFA) for patients with liver metastases. Survival and local control rates were superior for RFA with a hazard ratio of 0.66 for survival.[196] However, the complication rate and costs of application were higher for RFA. RFA is generally used when patients are not suitable surgical candidates.[196-199]

HT with Radiotherapy

A large number of reports attest to the efficacy of HT in combination with radiotherapy (RT). The majority of publications have been from phase II trials involving patients with superficial malignancies (and thus more amenable to heating) as a component of more generalized disease, such as local recurrence of breast carcinoma on the chest wall. With the addition of HT to radiation, clinical response rates have approximately doubled from 25% to 35% with radiation alone to 50% to 70% with RT + HT.[200] In addition to phase II studies, several phase III trials have now been conducted worldwide with approximately two-thirds published in the English literature. These trials generally have been positive, lending additional validity to the information obtained from phase II studies.

HT with Chemotherapy

Published data on the efficacy of locoregional HT in conjunction with chemotherapy (CT) is much less frequent. Both animal and human data have been reviewed.[200] Particularly encouraging phase II results were reported for sarcomas,[201] which led to a recently completed phase III trial (see section on phase III trials for outcomes on the sarcoma trial and a small esophageal cancer trial).

Wessalowski et al recently reported results of a phase II study, conducted on 44 children ranging in age from 7 months to 16 years who had refractory or recurrent germ cell tumors.[202] All of these patients had received cisplatin previously as part of their initial treatment. They were treated with a combination of cisplatin, etoposide, and ifosphamide, where HT was given twice weekly in three cycles. The objective response rates were similar to what is expected from front line therapy. The 5-year overall survival rate was 62%. The results were better than anticipated given the likelihood that the majority had drug resistant tumors. As discussed earlier, hyperthermia reverses drug resistance. This effect may have played a role in the overall success of the trial.

Trimodality Therapies with HT, RT, and CT

A small randomized phase III trial involving patients with esophageal cancer showed a higher pathologic CR rate when HT was added to chemoradiotherapy compared with chemoradiotherapy alone.[203] More recently, the combination of HT + cisplatin + radiotherapy has been evaluated in patients with locally advanced cervix cancer. Twelve patients were treated in this series, with local control being achieved in ten. The two patients with local failure presented with local recurrence following hysterectomy.[204] In a follow-up report, Westermann et al combined results of this trial (with longer follow-up) with results from several other institutions that had conducted similar studies.[205] A total of 68 patients were included in the analysis. Of these, 61 achieved a complete response. At a median follow up of 538 days, 74% of patients were disease free. This is a favorable outcome, compared with historical controls. To date, however, a confirmatory phase III trial has not been reported.

The combination of 5FU, HT, and radiation therapy yielded favorable responses in patients with locally advanced colorectal cancer in a phase II study.[206] In a retrospective study comparing sphincter sparing in patients with locally advanced rectal cancer, those who received HT in addition to RT and chemotherapy tended to have a higher sphincter preservation rate, compared with those who were treated with radiochemotherapy.[207] To date, no phase III trials have been reported comparing the addition of HT to chemoradiotherapy for locally advanced rectal cancer.

Normal Tissue Damage from HT

HT does not significantly increase early or late toxicity of radiation.[67-69] The most common toxicities of HT are superficial or subcutaneous tissue burns. They are usually first or second degree and small in volume. Such burns occur in approximately 5% of patients treated in the Duke experience; characteristically they do not exceed 3 to 4 cm in maximum diameter. Third-degree burns are infrequently observed (<1% incidence). Complications from thermometry catheters are infrequent if the catheters are removed following each HT treatment.[208] When catheters are left in place throughout the course of HT (e.g., for several weeks), the frequency of complications rises significantly, particularly secondary infections.[209]

There are potential medical contraindications to deep-regional HT related to the physiological stress. Guidelines for patient selection for deep hyperthermia have been developed.[154,211]

Relationship between Thermal Dose and Outcome

Quality assurance for delivery and measurement of temperatures during hyperthermia are essential to identify quantifiable thermal dose parameters. Negative phase III clinical trials conducted by the RTOG in the 1980s were attributed to this issue.[212-214] Quality assurance standards as well as data acquisition procedures were subsequently established by both the

The maximum size that one can ablate in a single session is <5 cm. Recurrence at the margin can occur, which may require additional treatments. Feasibility of performing ablation can be affected by proximity of the lesion to thermally significant vessels[199] or other key structures that should be avoided (e.g., diaphragm, bile ducts). The FDA has granted 510K approval for three commercial RFA devices. High intensity focused ultrasound can also be used for thermal ablation. The FDA recently approved one system for use in treatment of painful bone metastases. The approval is specifically for patients in whom radiotherapy is not an option <http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/DeviceApprovalsandClearances/Recently-ApprovedDevices/ucm327521.htm>.

RTOG[147] and European Society of Hyperthermic Oncology (ESHO).[210,211,215] The biological underpinning for thermal dosimetry was discussed previously in the biology section of this chapter.

Dosimetry for hyperthermia is distinctly different from that for radiation therapy in that the amount of energy deposited does not correlate with the degree of damage. This is because damage is related to the amount of temperature rise and the time of exposure, both of which are governed by the net balance between how much energy is deposited vs. how much is carried away by thermal conduction and perfusion. In the case of hyperthermia, the dosimetric unit used most often has been one that was derived empirically from evaluation of the Arrhenius relationship for cell killing in vitro as well as from numerous studies of degree of tissue damage as a function of temperature and time of exposure.[1] As was described in detail previously, the unit most often used has been equivalent minutes at 43°C (CEM 43°C). Application of this concept to the clinic, however, requires integration of non-uniform temperature history data with CEM43°C.

Since temperatures during hyperthermia treatment are non-uniform, it is necessary to derive descriptive parameters from the temperature distribution to which the CEM43°C parameter can be applied. A number of clinical parameters have been described based on simple descriptions of the multipoint thermometry, such as minimum temperature, average temperature, etc. Parameters that have proven useful for describing temperature distributions are the 10th percentile of the temperature distribution, which is commonly referred to as the T_{90} (90% of measured points exceed this value) or the T_{50}, which is the median temperature. Use of these types of parameters leads to dosimetry that is comparable across patients and studies, as long as quality assurance guidelines are followed with respect to the placement and number of thermometers used. The resultant units are referred to as CEM43°CT_{90} or CEM43°CT_{50}.

Retrospective evaluation of many phase II and phase III trial results have shown positive relationships between measures of thermal dose and treatment outcome, suggesting that higher thermal doses will yield better responses when HT is combined with radiotherapy.[156,158-160] In all positive studies reported to date, thermal analysis was performed retrospectively. It has been more difficult to correlate variations in thermal dose administered a priori and clinical outcome. Two studies compared various numbers of heat treatments given in combination with fractionated RT,[216,217] using the assumption that more treatments would yield greater cumulative thermal dose. Neither study showed any benefit with higher numbers of HT fractions, which could in part be due to the fact that there was considerable overlap in thermal doses between the treatment arms. This is because temperature is a stronger determinant of thermal dose than time-at-temperature (see biology section previously). A canine study compared radiation therapy combined with whole body HT + local HT compared with local HT alone. The CEM43°CT_{90} was higher in the group that received whole body hyperthermia, but there was no difference in duration of local control between the two treatment arms.[218] One potential explanation for the lack of improvement in local control might have been the induction of thermotolerance during the whole body HT, which was administered prior to application of local heating.

The first attempt to prospectively control thermal dose, as prescribed by the CEM43°CT_{90}, was a study of preoperative RT + HT for soft tissue sarcomas.[59] The outcome variable was pCR assessed at the time of surgery, and the percentage of patients predicted to achieve a pCR as a result of achieving CEM43T_{90} > 10 minutes was predicted to be 75%, based on prior phase II studies.[158] The pCR rate in this study was 54%, which was below the 95% confidence level for the projected rate. A number of explanations are possible for failing to achieve the projected pCR rate, including the sparseness of the temperature information gained. Recently, it was reported that other mitigating physiologic factors may have confounded the results of this study.[219]

Two additional phase III trials have been completed by the same group—one in patients with superficial tumors and the other in pet dogs with soft tissue sarcomas. In both of these trials there was clear separation in thermal doses between the two treatment arms.[156,220] Most importantly, improved response and duration of local control was observed in the groups that prospectively received the higher thermal dose. These are the first two and only trials conducted in which prospective control of thermal dose has yielded demonstrated improvement in local tumor response and/or control. They clearly indicate that better prospective control of thermal dose may ultimately lead to methods to truly optimize hyperthermia treatment. A recent study by this same group evaluated the question of how many fractions of HT (1 vs. 4 fractions/week) should be delivered in conjunction with fractionated RT.[46] The cumulative thermal dose was kept equal between the two arms. In prior clinical trials, the number of hyperthermia treatments has been restricted to no more than 2/week, because of concerns about persistence of thermotolerance between HT fractions. However, heat radiosensitization is not affected by thermotolerance, thus it was reasoned that giving 4 fractions of HT/week might yield superior results to giving 1 fraction/week. Surprisingly, giving 1 fraction/week was significantly better than 4, based on tumor response at the end of therapy.

Phase III Clinical Trials Overview – HT + RT

Phase III trials have involved a wide variety of diseases, including superficial malignancies and tumors deep within the body. Trials have been conducted with either palliative or curative intent. A summary of the most important of these trials is presented in Table 21-2.

Breast Cancer

Chest wall recurrences of breast cancer are difficult to control with conventional approaches, and many patients develop such recurrences despite prior adjuvant radiotherapy or systemic therapy. Since they are superficial tumors, they have been amenable to HT trials. Five separate phase III trials were combined for analysis in an international collaborative study by Vernon et al.[221] Patients were randomized to either RT alone or RT with HT. Treatment was prescribed according to ESHO and RTOG guidelines. HT techniques differed somewhat between institutions but are well documented, as is information concerning temperature distributions and thermal dosimetry.[160] Overall, the five trials demonstrated a significant improvement in the complete response rate for patients receiving HT + RT (59%) compared with RT alone (41%), with an odds ratio of 2.3 (95% CI 1.4-3.8) (see Table 21-2). The greatest effect was observed in patients with recurrent lesions in previously irradiated areas where further irradiation was of necessity limited to low doses. No survival advantage was seen.

Other Superficial Malignancies

A study was conducted by the RTOG in the 1980s comparing RT alone with RT + HT in superficial measurable tumors (RTOG 8104).[213,214] Three hundred seven patients were included in the study; approximately half of the patients had head and neck tumors, one-third had breast carcinoma (chest wall recurrences), and the remaining had a variety of superficial malignancies. Patients treated with RT + HT had a

complete response rate of 32% compared with 30% for those receiving RT alone. Subgroup analysis revealed significant improvements in duration of local control only in patients with tumors less than 3 cm in depth and in those with breast and/or chest wall recurrences. It was postulated that the better outcome in smaller tumors was a consequence of better heating. This trial was plagued by highly variable heating techniques and crude thermal dosimetry. These problems led to the development of subsequent RTOG guidelines for performing HT.[147]

Head and Neck Cancer

There are two randomized series demonstrating an advantage to HT combined with RT (see Table 21-2). The first study by Datta et al randomized 65 patients to radiation alone vs. RT and HT.[222] RT doses consisted of 50 Gy in 5 weeks to the primary site and regional lymphatics followed by 10 to 15 Gy given to sites of gross disease in daily fractions of 2 Gy. HT was given twice a week with 72 hours between each session. The HT + RT arm showed significant improvement in response in patients with stage III and IV disease. For example, patients with stage III disease receiving combined treatment had a 58% CR compared with 20% in the RT alone group. There was no benefit for patients with stage I and II disease, with greater than 90% of these patients achieving a CR with either treatment. This trial from India evaluated both the primary site as well as neck nodes, despite the recognized difficulties of effectively delivering heat to most primary head and neck tumors.

A second trial from Italy by Valdagni et al restricted treatment and evaluation to metastatic cervical lymph nodes. This study randomized 41 patients with advanced local regional squamous cell carcinoma of the head and neck to treatment with either RT alone or RT combined with HT.[223,224] Long-term follow-up allowed for analysis of response, duration of local control, and survival. The five-year actuarial local control in the neck with RT alone vs RT + HT was 24 vs 69%, and 5-yr OS was 0 vs. 53%; all of these differences were statistically significant. There was no clear enhancement of toxicity or any clear relationship between thermal dose received and outcome. Nonetheless, this well-executed and described phase III trial, despite the relatively small number of patients, is an important component of the evidence suggesting the value of HT.

A trial of interstitial hyperthermia was carried out primarily in head and neck patients by the RTOG.[212] This trial entered 173 patients with persistent or recurrent tumors after prior radiotherapy and/or surgery that were amenable to interstitial radiotherapy. The lesion site was the head and neck in approximately 45% of patients, the pelvis in approximately 40%, with miscellaneous sites accounting for the rest. The patients were randomized to receive interstitial RT alone ± interstitial HT. Overall there was no difference in complete response rates or 2-year survival. There were major quality assurance issues with this trial. Only one patient in the entire group was considered to have had adequate HT. This trial, as well as the previously mentioned RTOG trial, provided impetus for the subsequent development of HT guidelines by the RTOG.[153]

Esophagus Cancer

Two randomized studies demonstrated an advantage to the addition of HT to chemoradiotherapy or chemotherapy alone in the neoadjuvant treatment of esophagus cancer. In the first study by Kitamura et al 66 patients with squamous cell carcinoma of the thoracic esophagus were randomized to preoperative HT, RT, and CT, compared with chemoradiotherapy alone.[225] The chemotherapy (bleomycin) and HT were given concurrently 1 hour prior to the radiation in a 3-week regimen with a total RT dose of approximately 32 Gy. Clinical complete responses and pathologic responses were significantly improved in the tri-modality arm, with a pathologic CR of 26% combined in the tri-modality group vs. 8% in the chemoradiotherapy group (see Table 21-2).

In a follow-up study, an additional 40 patients were treated with chemotherapy alone (bleomycin and cisplatin) or combined with HT.[225] No RT was given in this trial. Again, an improvement in histopathologic response was noted favoring the HT group (19% vs. 41%).

Malignant Melanoma

A major multicenter trial was conducted in patients with metastatic melanoma by Overgaard et al.[57] Seventy patients with 134 metastatic or recurrent malignant melanoma lesions were randomized to receive RT ± HT. Overall there was a significant benefit for the addition of HT with a 2-year local control of 46% in the combined group compared with 28% for those receiving RT alone (see Table 21-2). Quality assurance issues were problematic in this trial, with only 14% of treatments achieving the protocol objective of 43°C for 60 minutes. Despite this, positive benefits were seen.

Glioblastoma Multiforme

A University of California San Francisco study by Sneed et al evaluated interstitial HT combined with a brachytherapy boost for selected patients with glioblastoma multiforme.[226] One hundred twelve patients were entered into this trial, which randomized patients whose tumor was implantable following external beam RT and chemotherapy to receive brachytherapy ± HT. Seventy-nine were randomized; 33 patients were dropped from the protocol due to disease progression. Both time to tumor progression and survival were significantly improved for the HT patients compared with those treated with brachytherapy alone (see Table 21-2). Two year survivals in the two groups were 31% and 15%, respectively. Toxicity appeared to be slightly greater in the HT patients, with seven grade 3 toxicities reported compared with one in the brachytherapy alone group. Thermal dose data showed that good heating was achieved in most patients. No significant correlation was seen between thermal dose and response.

Pelvic Tumors (Cervix, Bladder, Colorectum)

The Dutch hyperthermia group conducted a study by Van der Zee et al in which 358 patients with previously untreated locally advanced pelvic tumors were randomized to receive RT alone or RT + HT (see Table 21-2).[227] HT treatments were given once weekly for a total of five treatments. Generally, thermal goals were not achieved, but detailed thermal dose analyses have not been published. There were approximately equal numbers of patients with bladder, colorectal, and cervical carcinomas. Complete response rates were 39% and 55% after RT alone and RT + HT, respectively ($p \leq 0.001$). Duration of local control was also significantly improved with RT + HT. Patients with cervical carcinoma benefited the most. Three year survivals were 27% and 51% in the RT and RT + HT groups, respectively ($p = 0.003$). This study has been criticized for suboptimal therapy in the control arm, namely RT alone as opposed to the combination of RT + CT. At the time the trial was initiated in 1990, the role of chemotherapy in cervix carcinoma was not established. Subsequently, a number of studies published in 1999/2000 have demonstrated a survival advantage for concurrent cisplatin-based chemotherapy in cervical carcinoma.[228-232] Additional phase III trials are needed to establish whether there is an advantage to thermochemoradiotherapy compared with chemoradiotherapy for locally advanced cervix cancer.

Phase III Clinical Trials Overview – HT + CT

Soft Tissue Sarcoma

The EORTC recently reported on results of a phase III trial by Issels et al that compared neoadjuvant thermochemotherapy to chemotherapy (etoposide, ifosfamide and doxorubicin; Table 21-3).[233] A total of 341 patients were enrolled. Patients received four cycles of neoadjuvant treatment before receiving definitive surgery and/or radiotherapy for the primary tumor. The hazard ratio for local PFS, the primary outcome variable, was 0.58 for patients receiving thermochemotherapy (p = 0.003). At 2-year follow-up, the combined arm had a 15% higher rate of PFS. DFS analysis showed a hazard ratio for the combined arm of 0.7 (p = 0.011). For those patients who completed the combined arm treatment, the hazard ratio for OS was 0.66 (p = 0.038).

Bladder Cancer

Colombo et al conducted a randomized phase III trial for recurrent superficial bladder cancer, which utilized intravesicular mitomycin C with and without bladder HT, using an intravesicularly placed microwave antenna to heat the bladder contents and wall (see Table 21-3).[234] A large majority of these patients had already failed mitomycin C previously. Eighty-six patients were enrolled and 75 completed therapy and were evaluable. Treatment of the bladder commenced after surgical removal of the tumor. The hazard ratio for local control after chemotherapy alone vs. thermochemotherapy was 4.8 (p = 0.0002). The heated group had a higher rate of complications, particularly related to thermal damage to the posterior bladder wall. Most of this damage resolved quickly, with only one patient experiencing a prolonged several month recovery period. Long term follow-up data from this trial has recently been reported (88% of patients in prior trial available).[235] The 10 year disease free survival rates were 53 and 15%, in favor of the addition of HT to mitomycin C (p = 0.001). Bladder preservation rates were comparable between the two arms.

There has been increasing interest in using HT for treatment of non-muscle invasive bladder cancer, as a result of the Colombo trial.[236-239] A recently completed pilot trial using the BSD2000 to heat the bladder noninvasively, in combination with mitomycin C, demonstrated that this approach was feasible and well tolerated.[240] This may prove to be an effective alternative approach to the intravesicular microwave antenna used by Colombo.

Summary of Clinical Trials

Results of the published phase III trials above are intriguing. Apart from the RTOG trials, they all appear to demonstrate substantial benefits with the addition of HT to RT or HT with chemotherapy. However, several of the trials were associated with significant design and implementation problems, including relatively small numbers of patients, thermal dosimetry information that was highly variable in nature, thermal goals that were often not achieved, and control arms that may not have represented optimal standard therapy. Despite these difficulties, the positive clinical outcome of these trials and the sound scientific rationale for adjuvant hyperthermia justify continued efforts in technological refinements and the conduct of well-designed clinical trials.

CHALLENGES/CONTROVERSIES/ FUTURE POSSIBILITIES

There are significant challenges to the continued development of hyperthermia. These can be roughly categorized into three types: (1) improvements are needed to make the treatment less technically challenging, (2) widespread establishment of chemo-radiation for many locally advanced cancers have reduced the potential population of patients who could benefit from thermoradiotherapy, and (3) emphasis on development of targeted therapies, such as tyrosine kinase inhibitors and anti-angiogenic drugs, which show promise for selective targeting of tumors while greatly minimizing normal tissue toxicities are easier to implement than HT. It is important to consider how hyperthermia can fit into this rapidly changing landscape of oncology research and practice and this is discussed next.

Technical Challenges

The FDA recently approved the use of deep heating with the BSD-2000, in combination with radiotherapy, to treat women with recurrent cervix cancer, where chemotherapy is not an option <http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/DeviceApprovalsandClearances/Recently-ApprovedDevices/ucm286404.htm>. Aside from this orphan designation, the use of hyperthermia for deep-seated tumors is still experimental in the United States. In Europe, deep hyperthermia has been more widely accepted and is approved in The Netherlands, Germany, and Italy as an adjunct therapy with radiotherapy and chemotherapy. Regardless of whether it is approved or not, it is technically challenging and expensive to administer, because it requires time of a dedicated team involving highly skilled physicists, engineers, physicians, and nurses to perform it safely and accurately. Invasive thermometry requires dedicated physician time to place thermometry catheters, and imaging is

needed to document thermometry placement. Currently, control of applied power requires significant technical skill and experience. These issues place important constraints on the promulgation of hyperthermia to the broader medical community. Progress will continue to be impeded until the technology is made more user-friendly. Advances in noninvasive thermometry, as discussed above, hold great promise for reducing the burdens associated with invasive temperature measurements.

Thermal Dose Prescription

Even if noninvasive thermometry were available, until recently there has been no information on what target temperature ranges are needed to optimize this therapy. Such information is the second key for providing a quantitative assessment of hyperthermia treatment adequacy (i.e., establishes a method for writing a hyperthermia prescription). In spite of extensive phase II data suggesting that higher temperatures yield improved likelihood for effective therapy, until recently there have been no successful prospective trials showing that escalation of thermal dose yields improved antitumor effect. However, two clinical trials have been reported where thermal dose was controlled during application of hyperthermia.[156,220] These trials set the stage for establishing realistic goals for how to administer this treatment in combination with radiotherapy.

These two trials were designed to perform a "test" hyperthermia treatment first, to determine whether the tumor was heatable, as defined by pre-established criteria. If the tumor was "heatable" then the patient was randomized to receive either a low cumulative thermal dose or a high thermal dose that was at least 10-fold higher than the low dose group. The inclusion of the "test" treatment was key in both studies, as about 12% of all eligible patients were excluded from randomization because their tumors could not be heated. The first trial was in patients with superficial tumors and the second was in pet dogs with spontaneous soft tissue sarcomas. Both trials demonstrated that cumulative thermal doses >10CEM 43°CT_{90} yielded improved tumor responses and durations of local control[156,220] (Figure 21-9). To put this into perspective, this cumulative thermal dose is equivalent to achieving a temperature of 40°C for 1 hour, once or twice a week, at the 10th percentile of the temperature distribution. Importantly, this thermal goal was reached in >90% of patients who randomized to the high thermal dose group.

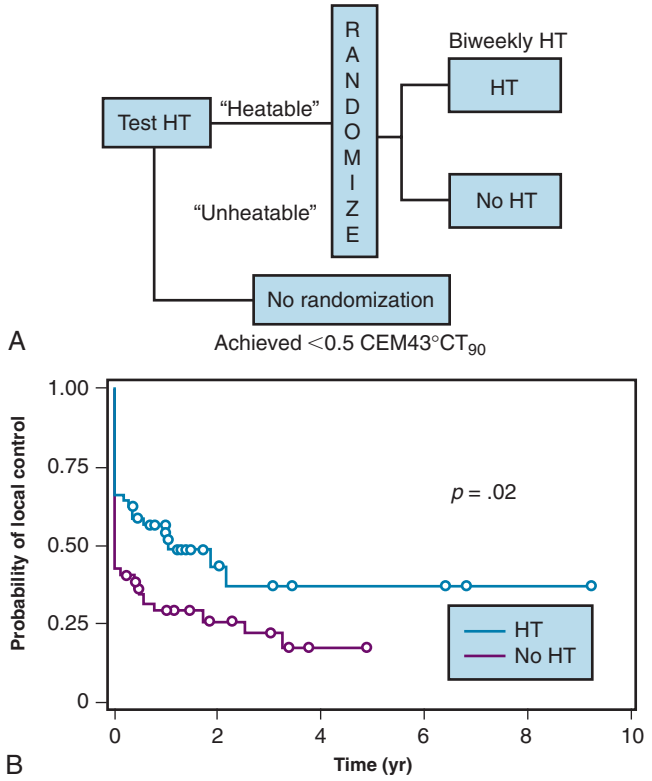

Figure 21-9 **A,** Clinical trial design. **B,** Duration of local control in patients with superficial tumors treated with a low vs. high cumulative thermal dose combined with RT. The difference in CR rate was significant.

Future Directions

Tri-Modality Therapies

There are important observations that have been made about hyperthermia that provide strong rationale for its continued development. First, although the addition of chemotherapy to radiation therapy has improved treatment outcome for many diseases, there is still a long way to go. The addition of hyperthermia to chemoradiotherapy protocols may be what is needed to push the therapies further toward the goal of reaching 100% local control. Since hyperthermia provides synergistic interaction with many chemotherapeutics, some targeted drugs as well as radiation therapy, this general approach is compelling.

Augmentation of Drug Delivery

Drug delivery to tumors remains a major challenge due to physiologic barriers such as high interstitial fluid pressure and heterogeneous perfusion. As noted earlier, hyperthermia has been shown to augment macromolecule and nanoparticle drug delivery by increasing blood flow, available volume fraction, and tumor vascular permeability. Furthermore, local hyperthermia can be used as a trigger for temperature-sensitive drug delivery systems such as liposomes, polymers, and hydrogels.[23,28,34,36,241] In this manner, site-specific bioavailability can be achieved. For example, a temperature-sensitive liposome containing doxorubicin (ThermoDox™) has been developed to release rapidly at clinically achievable temperatures of 40°C to 42°C. This formulation has shown dramatic improvement in tumor drug concentration and anti-tumor efficacy in preclinical studies[23,242] and is currently being investigated in phase I/II/III clinical trials for chest wall recurrences of breast cancer and radiofrequency ablation of liver metastases, respectively. As thermal technology and liposomal formulations advance, this method has the potential for precise control of drug delivery independent of tumor phenotype and drug composition.

Newer applications of thermosensitive liposomes have contained both drug and MR contrast agents and this tandem has been used to monitor drug delivery to heated tumors in real time, as the MR contrast agents change the MR signal when released from the liposomes[243-245] (Figure 21-10). There is increasing interest in using the dual MR/drug containing liposomes in combination with high intensity focused ultrasound to enhance drug delivery to a variety of tumor sites, including brain.[23,26,27,145,246-251]

ACKNOWLEDGEMENTS

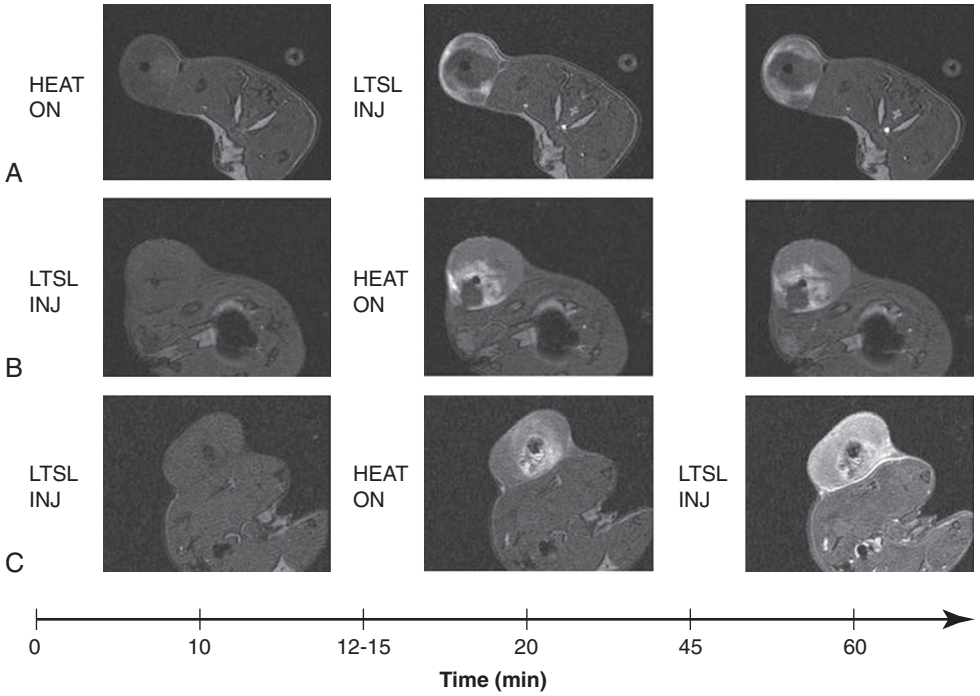

Figure 21-10 Example of monitoring drug delivery in real time, using liposomes containing an MR contrast agent (MnSO4) and doxorubicin. Calibration studies showed that the change in T1 relaxation time, induced by the Mn^{++}, is linearly proportional to drug concentration, in vivo. HT is delivered to the tumor using a catheter containing circulating hot water at the center of the tumor (shows as a dark spot near the center of each tumor). **(A)** When HT is administered, prior to and during drug administration, drug deposition is highest at the periphery of the tumor. **(B)** When drug is administered first, followed by HT, the drug accumulates around the cathether, yielding a centralized drug deposition pattern. **(C)** When drug dosing is split in half and given prior to HT and after HT has started, a more uniform drug deposition pattern is seen. Interestingly, the peripheral drug delivery pattern was most efficacious.[243] *LTSL*, Thermally sensitive liposome.

CHAPTER

22 Targeted Radionuclide Therapy

Joseph Gerard Jurcic, Jeffrey Y.C. Wong, Susan J. Knox, Daniel R. Wahl, Todd L. Rosenblat, and Ruby F. Meredith

Selective delivery of radionuclides to cancer cells using an antibody or other conjugate has been under investigation for >20 years. In 2002, the first Food and Drug Administration (FDA) approval was issued for a radiolabeled antibody. Initially this form of radionuclide therapy mainly involved the use of antibodies, or antibody-derived constructs as carriers of radionuclides and is therefore called *radioimmunotherapy (RIT)*. However, because the concept also includes binding to nonantigen receptors, targeted radionuclide therapy (TaRT) is a more comprehensive term, and Paul Wallner coined the acronym *STaRT* for systemic targeting. The development of TaRT has required the cooperation of basic scientists in the areas of radiation biology, chemistry, physics, and immunology with multiple clinical specialists. With the exception of some gene therapy approaches, TaRT differs from external beam radiation therapy in that selective targeting can be at the cellular rather than target volume level. Among its potential applications, TaRT provides a means of irradiating multiple tumor sites throughout the body with relative sparing of normal tissues. A number of challenges hampering the use of TaRT have been overcome, whereas others are areas of active investigation. Many of these are covered in more detail in other reviews.[1-16] A more extensive version of this chapter can be found on the Expert Consult website. The supplemental text contains tables, figures, and references that enhance the print version of this chapter.

TUMOR TARGETING

Antibodies

The efficacy of TaRT is dependent on a number of factors including properties of the targeted antigen or receptor, tumor, and targeting agent. Antigen/receptor variables include affinity, avidity, density, availability, shedding, and heterogeneity of expression.[17] Tumor factors include vascularity, blood flow, and permeability. Antibody features to consider are specificity of the binding site, which affects selective tumor uptake; immunoreactivity, which can affect localization; stability in vivo; and both avidity and affinity.[18-20] Affinity can be described by an intrinsic association constant K that characterizes binding of a univalent ligand (formation of a stable antibody-antigen complex) and can be calculated from the ratio of the rate constants for association and dissociation. Because intact antibodies and most antigens are multivalent, the tendency to bind depends on the affinity, number of binding sites, and other nonspecific factors involved in aggregation. The term *avidity* encompasses all of these factors and is therefore used to describe the overall tendency of antibody to bind to antigen.

A wide variety of antibodies have been made against a number of tumor-specific and tumor-associated antigens, that although present on some normal cells, are usually expressed at lower levels than on the targeted tumor cells. Most RIT trials have used monoclonal antibodies (Mabs), and many have used intact murine immunoglobulin G (IgG) antibodies. Early on, the immunogenicity of the nonhuman antibodies was recognized as a serious limitation of TaRT.[32] With the exception of patients with lymphoma, who are less prone to develop an immune response to murine antibodies (human antimouse antibody [HAMA] response), >80% of patients usually develop an immune response against a therapeutically administered murine or other species antibody after a single injection of antibody.[32] Such an immune response can occur even after doses as small as 1 mg used for imaging studies or following administration of antibody fragments or smaller constructs (but with less frequency than found following administration of intact IgG). Administration of antibody in a patient with a HAMA response can result in a severe immune reaction and rapid blood clearance, limiting tumor uptake of radiolabeled antibody.[33] Several approaches have been employed in an effort to ameliorate the problem of antibody immunogenicity such as: (1) the development of less immunogenic (chimeric and humanized) antibodies, (2) the use of immunosuppression by cyclosporine or deoxyspergualin to prevent an immune response, (3) the removal of HAMA directed to the therapeutic antibody by administration of an excess of unlabeled antibody before the administration of the radioimmunoconjugate, or (4) posttreatment removal of immune complexes by passing the patient's blood through an extracorporeal immunoadsorption column.[34-37] Genetic engineering has been successful in providing numerous targeting agents with reduced immunogenicity and has allowed for optimization of other aspects of the therapy.[38-40] Genetic constructs have been produced that vary in specificity and can be altered by conjugating them to other agents (e.g., cytokines, toxins, or radiosensitizers) to form fusion proteins.[41,42]

Technologic advances have provided a wide variety of antibodies and constructs varying in specificity, size and number of antigen combining sites, rapidity of distribution, immunogenicity, and immunological function.[43] Use of small antibody constructs such as single-chain antigen binding proteins may be most useful for diagnostic studies or for multistep targeting strategies.[44] The decreased immunogenicity of fragments/constructs and human and humanized antibodies now allows for administration of repeat courses or fractionated TaRT dosing.[45] As immunogenicity of antibodies has been ameliorated, some investigators have had concern about the potential immunogenicity of other components of therapy. For example, as more macrocyclic chelators have been developed to improve stability of conjugates, some data suggest that these molecules may be immunogenic as has been the streptavidin used in some pretargeting schemes.[46-48] Thus, immunogenicity of the various components of TaRT remains a challenge that requires further innovation.

Nonantibody Targeting

Several of the factors affecting antibody development and efficacy for TaRT are also pertinent to nonantigen targeting such as receptor density, availability, affinity, shedding, and heterogeneity of receptor expression, as well as features of the tumor including vascularity, blood flow, and permeability. The discovery more than a decade ago that many tumors overexpress receptors for peptide hormones opened the field for TaRT and other forms of targeted therapy. Radiolabeled peptide analogs such as those for somatostatin, bombesin, calcitonin, oxytocin,

ABBREVIATIONS

ADCC = antibody-dependent cellular cytotoxicity
AML = acute myeloid leukemia
APL = acute promyelocytic leukemia
ASCT = autologous stem cell transplant

MIRD = Medical Internal Radiation Dose Committee of the Society of Nuclear Medicine
MR = minor response of 25% to 49% decrease from baseline in overall tumor size for ≥1 mo
MW = molecular weight
NA = not available
NHL = non-Hodgkin's lymphoma
NED = no evidence of disease
OS = overall survival
PCR = polymerase chain reaction
PEG = polyethylene glycol
PFS = progression-free survival
PML/RAR-α = promyelocytic leukemia gene/retinoic acid receptor-α
PR = ≥50% decrease from baseline in overall tumor size for ≥1 mo
PRRT = peptide receptor radionuclide therapy
PSMA = prostate-specific membrane antigen
RBE = relative biologic effectiveness
RIT = radioimmunotherapy
ROI = regions of interest
RT = reverse transcriptase
SCT = stem cell transplant
scFv = single chain monovalent constructs
SPECT = single photon emission tomography
TaRT = targeted radionuclide therapy
TBI = total body irradiation
TLDs = thermoluminescent dosimeters
TMZ = temozolomide
$T_{1/2}$ = half time
V_H = variable heavy regions
V_L = variable light regions

Increased antibody affinity or avidity does not always correlate with increased in vivo efficacy and the optimal level of affinity remains controversial.[21,22] One might expect that higher affinity antibodies would result in increased tumor uptake, retention, and improved efficacy.[23-25] High affinity antibodies, however, may preferentially bind to perivascular regions in the periphery of tumors, whereas antibodies of lower affinity are able to penetrate deeper into tumors.[26,27] Hence, the optimal affinity of an antibody is likely to depend on a number of factors including level of target antigen expression, vascular permeability, and bulkiness of disease.[28]

In many cases, targeting of radiolabeled antibodies to tumor can also be improved through preinfusion of unlabeled antibody, which decreases splenic and urinary uptake of radiotracer.[29] The optimal amount of unlabeled antibody remains undetermined for most agents, but relatively high doses have been as good or better than lower doses in most imaging studies.[29,30] Efforts by the Seattle transplant team to optimize the amount of unlabeled antibody for individual patients by tracer studies with varying amounts often showed the highest concentration studied to be as good or better for direct RIT with iodine-131 (^{131}I)-antibody conjugates.[31]

and epidermal growth factor have been studied. Analogs of somatostatin are the most studied to date, with radiolabeled peptides being used for detection and treatment of a variety of neuroendocrine tumors.[10,49-51] Initial treatment of tumors expressing somatostatin receptor subtype 2 was with higher doses of the diagnostic agent (^{111}In-DTPA)-octreotide.[52] Subsequently the higher affinity (DOTA, Tyr^3) octreotide and (DOTA, Tyr^3) octreotate were introduced and used with yttrium-90 (^{90}Y) and ^{177}Lu labeling as the therapeutic beta emitter for peptide receptor radionuclide therapy (PRRT). (Tyr^3) octreotate differs from octreotide by substitution of tyrosine as the third residue and the replacement of threoninol by threonine. Early studies show impressive response rates, and that fractionation of administered dose as well as infusion of amino acids has ameliorated the dose-limiting renal toxicity.[3,53-55] Various multicenter studies have been conducted for optimization of ^{90}Y-(DOTA, Tyr^3) octreotide, ^{177}Lu-(DOTA, Tyr^3) octreotate, and ^{90}Y-(DOTA) lanreotide, another somatostatin analog.[56] In addition to objective clinical response rates often >25% and improved survival, clinical benefit in terms of decreased symptoms has usually been observed in the majority of patients with progressive neuroendocrine tumors.[14,51,54,57,58] Although PRRT is not FDA approved in the United States, its use continues in Europe.[59] Radiolabeled peptides targeting tumor neovasculature are also under investigation and may provide therapy for nonendocrine malignancies[60] with promising results in preclinical models.[61] The use of liposomes or nanoparticles as alternative targeting mechanisms for radionuclides is currently under investigation; however, these agents are still in the preclinical stage.[62-64] There continues to be progress on strategies that are independent of tumor type such as targeting tumor vasculature and the broad applications of nanoparticles.[65-67]

SELECTION OF RADIONUCLIDES

Early reviews provide detail on radionuclide selection, primarily with regard to the radiolabeling of whole immunoglobulins with beta-emitters.[68-70] Some later publications have focused on the selection of radionuclides for use with smaller, engineered antibody-derived constructs[71-73] and small nonantibody targeting delivery entities.[74] Alpha-emitters are also of increasing use.[62,75-80] The utility of a given radionuclide for TaRT is influenced by a number a radionuclide-specific factors such as half-life, emission profile, path length, efficiency of energy transfer, and ease of conjugation to its targeting ligand, as well as disease-related factors such as bulkiness of disease and heterogeneity of antigen expression. In a one-step RIT, administration using directly labeled antibodies, matching of the physical half-life of the radionuclide with the initial peak of tumor-to-nontumor antibody concentration was reported to be the most important factor for optimal radionuclide selection.[68] For example, a good therapeutic ratio would not be obtained if one used a radionuclide that decays within several hours linked to an antibody that has a circulation time of several days because most of the radiation exposure would have occurred before the radiolabeled antibody localized in the tumor. In this case, the resulting radiation dose to normal tissues would be nearly as great as that to the targeted tumor. Pretargeting strategies, discussed in more detail in the Optimization section, allow for use of radionuclides with shorter half-lives because unlabeled methods of tumor targeting precede administration of the radionuclide.[76]

The emission profile of radionuclides determines their suitability for therapy and imaging. A variety of radionuclides have been used in TaRT including alpha-emitters; low-, medium-, and high-energy beta-emitters; and those that work through electron capture or internal conversion (Auger electrons). Gamma-emitters, on the other hand, are more appropriate for imaging.[13] Some radionuclides such as ^{131}I have beta and gamma emissions that allow for both therapy and imaging. The therapeutic effect from such radionuclides is primarily the result of the beta radiation, whereas the gamma component allows for imaging but contributes substantially more to normal tissue toxicity than efficacy. Features of some of these radionuclides are compared in Table 22-1.

Tumor characteristics such as size (e.g., micrometastases vs. bulky masses) and the level and heterogeneity of antigen expression help dictate the efficacy of a given radionuclide for TaRT. Beta-emitters (e.g., ^{131}I and ^{90}Y) have been the most popular radionuclides for clinical TaRT trials to date. These radionuclides have the advantage of not needing to target every individual tumor cell because the mean radiation range is approximately 0.4 mm and 2.5 mm, respectively. This long path length allows for "cross fire" (e.g., killing of nonantigen-expressing tumor cells); however, it can also be associated with increased levels of normal tissue toxicity. Hence, beta-emitters may be more effective for sizable tumors and those with heterogeneous antigen expression but be less useful in the setting of micrometastatic disease. Auger electron emitters, such as iodine-125 (^{125}I), may be suitable for treatment of micrometastases that abundantly express internalizing antigen on every cell because targeting of the nucleus is necessary for effective cell killing with this very short range emitter (mean path length, 10 nM).

Compared with beta-emitters, alpha-emitters typically have shorter path lengths (40 μM to 80 μM), higher linear energy transfer (LET), and higher kinetic energies.[88] Together these features allow alpha-emitters to efficiently kill tumor cells by inducing double-stranded DNA breaks over a radius of several cells, even when antigen expression is heterogeneous. Hence, alpha-emitters may be most useful for the treatment of micrometastatic disease, such as leukemia in bone marrow, minimal intraperitoneal disease, and intratumoral

TABLE 22-1 Comparison of Selected β-Emitting Radionuclides Used in TaRT

Isotope	$T_{1/2}$ (d)	γ Energy (kev)	Percent γ Intensity	β Range in Tissue (mm)		Advantages	Disadvantages
				Maximum	Mean		
^{90}Y	2.7			11.9	2.5	Long β range	Chelator, bone seeker
^{131}I	8.0	364	81	2.4	0.3	No chelator needed	Dehalogenation, toxicity from γ
^{186}Re	3.7	137	9	5.0	0.9	Less γ than ^{131}I	Chelator, scarce
^{67}Cu	2.5	184	48	2.2	0.4	Less γ than ^{131}I	Chelator, scarce
^{177}Lu	6.7	208/113	11 and 7	2.2	0.3	Less γ than ^{131}I	Chelator, scarce
^{125}I	60.4	35	7	0.02	—	Low-normal tissue toxicity	Does not image well
^{188}Re	0.8	155	15	11.0	2.4	Long β range	Chelator, scarce

The development of labeling and chelation chemistry for the production of stable radioconjugates has greatly facilitated TaRT. Iodine-131 (^{131}I) can be directly attached to antibody without a chelator. However, if a targeted antigen/receptor undergoes modulation (internalization), the tumor cells can dehalogenate the conjugate and release free iodine. ^{131}I can also be attached by a secondary molecule conjugated through an iodinatable linker rather than directly linked to antibodies. These radioimmunoconjugates appear to be more resistant to dehalogenation.[81] A variety of increasingly stable chelators have been developed for yttrium-90 (^{90}Y) and other metal radionuclides, but some have been found to be immunogenic (probably partly as a result of aggregation).[46,48] The chemistry, stability, and in vivo processing of radioimmunoconjugates also have implications for toxicity. The filtration of small radioconjugates or their metabolites through the kidneys may result in considerable radiation to the kidneys. Renal toxicity has been reported to be the dose-limiting toxicity for some small MW peptide conjugates and alpha-emitter conjugates.[78,82] Hepatic uptake, metabolism of radioimmunoconjugates, and retention of ^{90}Y-complexes in the liver, are potentially dose limiting in myeloablative TaRT.[83] Designing chelators with special characteristics can also affect radionuclide "matching" with the targeting agent. For example, selective degradation of a cathepsin-sensitive chelate reduced liver uptake of radiometal.[84] The use of such chelators may allow for dose escalation of radiometal conjugates such as copper-67 (^{67}Cu) that otherwise would be limited by hepatic toxicity. Other conditionally cleavable chelators are also under study.[85] The synthesis of the TCMC chelator has allowed progress in the use of lead-212 (^{212}Pb).[86] Macrocyclic chelators such a DOT, which have been developed for stable chelation to ^{90}Y, and other beta-emitting radiometals have shown acid lability with ^{212}Pb, and likely other alpha-emitters.[87] To overcome this, the bifunctional chelating agent 2-(4-isothiocyanotobenzyl)-1,4,7,10-tetraaza-1,4,7,10-tetra-(2-carbamonyl methyl)-cyclododecane (TCMC) was synthesized, characterized, and subsequently used in several animal studies.[86]

delivery.[89] These favorable characteristics of alpha-emitters have led to considerable progress in their use in clinical trials as well as improving their availability.[78,80,90-92] The National Laboratories of the USA have established cooperation to increase the supply of actinium-225 (^{225}Ac), and AREVA Med has developed the ability to ship ^{212}Pb generators all over the world.[93,94]

The alpha-emitters bismuth-213 (^{213}Bi) and ^{225}Ac have been conjugated to anti-CD33 antibodies and have shown promising results in Phase I and Phase II clinical trials in acute myeloid leukemia (AML), with ^{225}Ac recently advancing to the multiinstitutional setting.[95-97] Alpha-emitters also have increasing use in the treatment of metastatic prostate cancer. Radium-223 (^{223}Ra) is an unconjugated alpha-emitting calcium-mimetic that accumulates in areas of high bone turnover by physiologic rather than ligand-guided targeting.[98] The alpha-particles emitted by ^{223}Ra are high energy and have a relatively short path length of 10 μM, which allows efficient tumor cell killing with minimal marrow suppression.[99] In a recent Phase III clinical trial, treatment with ^{223}Ra has shown a survival benefit in patients with metastatic prostate cancer. Similar results have not been achievable with bone-targeted beta-emitters such as strontium-89, which are limited by marrow suppression, presumably because of their longer path lengths.[98-100] These results, along with considerable experience in Europe, led to FDA approval for ^{223}Ra in 2013, making it the first alpha-emitter to receive such approval.

RADIOBIOLOGY

Biological effects of TaRT may be associated with both the radionuclides and their carriers, either alone or in combination.[101-103] This is particularly true for certain antibody carriers that may have antitumor efficacy alone (e.g., anti-CD20 antibodies). Another important determinant of efficacy may be whether or not the antibody in internalized.[104] Antibody-induced responses can include apoptosis, complement-dependent cytotoxicity, and antibody-dependent cell-mediated cytotoxicity.[105] Radiation effects can result in cell death during mitosis or by apoptosis, necrosis, or a metabolic cell death. The relative importance of these types of cell death depends on factors such as the inherent genetic makeup of the cells. For lymphomas, apoptosis is an important mechanism of cell death, whereas apoptosis usually plays less of a role in killing solid tumor cells. Lymphomas are especially sensitive to apoptosis induced not only by radiation, but by a variety of cytotoxic agents including antibody therapy alone.[106-109] Several signal transduction pathways have been found to be associated with radiation-induced apoptosis. These have been reviewed by Hernandez and Knox.[101] Antibody-induced intracellular signaling may also function to enhance the effects of TaRT and dose rate effects, as well as the relative biological effectiveness of the associated radiation (e.g., high LET of alpha-particle emitter labeled monoclonal antibodies) may be important to the efficacy of TaRT as well.[110,111]

Several studies have shown that cells exposed to either continuous or exponentially decreasing low dose rate (LDR) radiation arrest in the radiosensitive G_2/M phase of the cell cycle and undergo apoptosis.[112-115] This G_2/M block from LDR radiation as delivered via TaRT may also sensitize tumor cells to killing by other therapies such as external beam radiation.[116] Data from some experiments showing this effect suggest that therapy may be optimized by using TaRT before external beam radiation.[116,117] External beam radiation has also been given before TaRT to increase tumor uptake of radionuclide conjugates. In addition, regulating cell-cycle distribution or altering the underlying apoptotic potential by drugs or biologic response modifiers in tumor cells can affect the susceptibility of such cells to radiation-induced apoptosis.[118] Recent studies include the exploration of the use of gene transfer technology to induce expression of high affinity membrane receptors to enhance the specificity of radioligand localization or the use of genetically engineered antibody molecules (e.g., diabodies: noncovalent single chain F_v dimers) as carriers for TaRT that may be able to enhance the efficacy of this therapy.[119-122]

Although there is usually a positive correlation between the level of radiation-induced cell killing and dose rate, an inverse dose rate effect has been reported with LDR irradiation in the range of about 0.3 Gy/hour, with some cell types being more sensitive to this inverse dose rate effect than others.[123] Knox et al showed lymphoma cells to be sensitive to ^{131}I-labeled antibody LDR radiation in a direct comparison to high dose rate external beam irradiation.[124] At least one mechanism for this observation appears to be greater arrest in the G_2/M phase of the cell cycle. Another mechanism of lymphoma radiation sensitivity may be less efficient DNA repair among lymphomas compared to some other cell types.[101,102]

CLINICAL RESULTS

A wide variety of human malignancies have been treated with RIT in the setting of clinical trials. Antibodies carrying radionuclides have targeted tumor-associated antigens, growth factor receptors, and other cell surface markers, usually expressed at a high level on malignant cells and to a lesser extent on subsets of normal cells. Nonantibody targeting has primarily been against neuroendocrine receptors. Several routes of administration have been employed including intravenous, intraarterial, intrathecal, intraperitoneal, intratumoral, and rarely, intrapleural administration. The most prevalent route of administration has been intravenous for systemic therapy. However, for localized disease, regional or intracavitary administration may be advantageous. Intraperitoneal RIT has generally been more efficacious than intravenous RIT for the treatment of small volume disease confined to the peritoneal cavity, but there are conflicting reports concerning the relative merits of arterial and venous routes of administration of radiolabeled antibodies for other sites.[125-129]

RADIOIMMUNOTHERAPY OF NONHEMATOLOGIC MALIGNANCIES

RIT for solid tumors continues to be actively investigated as a form of systemic targeted radiation therapy in a variety of tumor types and clinical settings. Initial clinical efforts were with polyclonal antibodies.[130] With the development of hybridoma technology, large-scale production of clinical grade Mabs selected against specific tumor-associated antigens became possible and greatly expanded the number of agents evaluated in clinical trials. Subsequent molecular engineering efforts allowed for the customized design of antibody constructs with properties better optimized for therapy.

RIT demonstrated initial promise in animal models with dozens of studies in tumor-bearing animal models documenting significant tumor growth delay and cures in a wide variety of solid tumor types.[6,131-134] Tumor doses often exceeded 10 Gy to 15 Gy after a single infusion.[135,136] In some preclinical studies RIT achieved comparable tumor growth delays as equivalent doses of single fraction or conventionally fractionated external beam radiation therapy[135-140] or equitoxic doses of chemotherapy.[141] Initial clinical trials evaluating biodistribution and pharmacokinetics confirmed tumor targeting and demonstrated that therapeutic doses of radiation to tumor were potentially achievable.[142-147] Table 22-2 provides an overview of Mabs that have been evaluated in clinical trials. RIT has been evaluated in most major disease sites, including gastrointestinal, breast, brain, ovarian, head and neck, medullary

Ongoing studies will help elucidate the radiobiology of TaRT, which will facilitate optimization of TaRT therapy in the future, and provide the prerequisite understanding of underlying biological mechanisms to determine how best to use TaRT in combination with other treatment modalities.

TABLE 22-2 Examples of Monoclonal Antibodies Evaluated for RIT of Nonhematologic Malignancies

Malignancy	Antigen	Antibody
Colorectal cancer	CEA	cT84.66, hMN-14, A5B7, F6
	TAG-72	B72.3, CC49
	A33	anti-A33
	EpCAM	NR-LU-10, NR-LU-13, 17-1A
	DNA histone H1	chTNT-1/B
Breast cancer	MUC1	huBrE-3, m170
	L6	chL6
	TAG-72	CC49
	CEA	cT84.66
Ovarian cancer	MUC1	HMFG1
	Folate receptor	cMov18
	TAG-72	B72.3, CC49
Prostate cancer	PSMA	huJ591, CYT-356
	TAG-72	CC49
Lung cancer	DNA histone H1	chTNT-1/B
	TAG72	CC49
Head and neck cancer	CD44v6	U36, BIWA4
Gliomas	EGFR	425
	Tenascin	816C, BC4
Melanoma	p97	96.5
	chondroitin sulfate proteoglycan	9.2.27
Renal cancer	G250 glycoprotein	cG250
Pancreatic cancer	PAM4 reactive mucin	hPAM4
	CEA	KAb201
Medullary thyroid	CEA	cT84.66, hMN-14, NP-4
Neuroblastoma	Ganglioside GD2	3F8
	NCAM	UJ13A, ERIC-1

thyroid, melanoma, renal, lung, and prostate cancers. Results from selected solid tumor trials evaluating systemically administered nonmyeloablative doses of RIT as single modality are summarized in eTable 22-1, available in the expanded chapter on the Expert Consult website. Early efforts used Mabs labeled with ^{131}I because of availability and ease of labeling, with subsequent trials using radiometals such as ^{90}Y, rhenium-186 (^{186}Re), and lutetium-177 (^{177}Lu), and several alpha-emitters. Almost all of the antibodies studied have been administered at low protein doses (~5 mg to 50 mg), have had no significant clinical immunomodulatory or antitumor properties, and have therefore served primarily as a delivery vehicle for radiation. Dose-limiting toxicities have primarily been thrombocytopenia and leukopenia. Results have been comparable regardless of disease site or a particular radionuclide-antibody combination.

Until recently, most of the clinical experience involved Phase I trials, evaluating RIT as monotherapy in patients with advanced, bulky, chemotherapy refractory disease progressing into therapy. As expected in this patient population, partial and complete responses have been infrequent regardless of disease type,[148-158] with most antitumor effects reported as stable disease and serologic, mixed, or minor responses.[159-181] This is in contrast to clinical results observed with RIT in hematologic malignancies with objective responses ranging from 30% to 85%.[29,182-189]

A number of factors have been put forth to explain the limited responses seen. With hematologic malignancies, at least some of the observed response rates can be attributed to the immunologic effects of the antibody itself,[190] which is not the case for most radiolabeled antibodies directed against solid tumors. Other factors involve those that restrict antibody targeting and uptake to tumor more so for solid tumors than lymphomas. These include differences in tumor physiology, tumor vascularity, antigen accessibility, and heterogeneity of antigen expression.[191,192] However, these factors probably play a minor role because the clinical literature demonstrates no significant differences in estimated RIT dose to tumor between solid tumors and hematologic malignances. This suggests that the difference in radiosensitivity between solid tumors and hematologic malignancies is the major factor in explaining the difference in RIT response rates.

eTable 22-2, available in the expanded chapter on the Expert Consult website, compares tumor doses achieved after single administration of nonmyeloablative activities of RIT for solid tumors and lymphomas and demonstrates that tumor doses are comparable for most antibodies evaluated in the clinic. Median and mean doses are approximately 10 Gy to 20 Gy, with select tumors occasionally achieving doses of 20 Gy to 70 Gy or greater. For example, with ^{90}Y-cT84.66 anti-CEA RIT, approximately 25% of tumors achieve tumor doses >15 Gy to 20 Gy after single infusion. These data support the hypothesis that the differences in response rates between solid tumors and hematologic malignancies are largely the result of differences in radiosensitivity rather than differences in tumor antibody uptake. This is even after accounting for effects of unlabeled antilymphoma antibodies because clinical trials have demonstrated no significant response rates with unlabeled antibodies such as Lym-1,[193,194] but in the case of ^{90}Y-ibritumomab, there was a 24% increase in response rate was observed with the addition of radiolabeled antibody compared to unlabeled antibody alone in a recent randomized trial.[190] Similarly for tositumomab, there was significant improvement in all therapeutic outcomes by additional ^{131}I-labeled antibody.[195]

Although tumor doses with RIT are a fraction of what can be delivered by standard teletherapy or brachytherapy, doses currently achievable are at levels that can potentially result in clinically important antitumor effects in solid tumors if applied in the appropriate clinical setting, particularly in patients with subclinical or microscopic disease. In a review of the literature for conventionally fractionated external beam radiotherapy given as adjuvant therapy for solid tumors, Withers et al[196] noted an inverse linear relationship between radiation dose and tumor recurrence rate with doses ranging from 2000 to 5000 cGy. No threshold effect was seen, and doses in the range of 2000 cGy had measurable effects in the adjuvant setting. Clinical trials have also demonstrated important antitumor effects in rectal cancer with doses in the range of 3000 cGy.[197,198] Finally, doses as low as 3000 cGy conventionally fractionated have been combined with chemotherapy in esophageal and anal cancer resulting in pathologic complete responses.[199-201] Therefore, cGy doses to tumor achievable through RIT may have more clinical importance in low tumor burden situations or as an additional agent added to a multiagent systemic therapy approach.

To further improve RIT clinical outcomes in solid tumors requires increasing radiation dose to tumor or increasing the antitumor effect of the targeted dose. Strategies to achieve this goal include (1) improving the antibody delivery system to either increase antibody targeting to tumor or decrease uptake to critical organs; (2) decreasing dose-limiting toxicity (usually marrow toxicity) that would allow for escalation of administered activity; (3) altering the tumor environment to enhance

radiolabeled macromolecule targeting; and (4) increasing the tumoricidal effect of the targeted radiation dose. Clinical trials evaluating these optimization strategies are summarized in this chapter. Those that have been studied include regional administration, combined modality approaches, and therapy in the minimal tumor burden or adjuvant setting. Pretargeting antibody based delivery strategies that seek to amplify the differences between tumor and normal organ uptake also continue to be explored and remain promising. There has also been increasing interest in the use of high LET α-emitters in patients with solid tumors.

Autologous Stem Cell Support
(See eTable 22-1)

Because hematologic toxicity is dose-limiting, groups have explored dose intensification strategies using stem cell reinfusion after myeloablative doses of radiolabeled Mabs. Most have been Phase I studies treating a limited number of patients. Stem cell supported RIT studies primarily in breast cancer have reported objective responses.[202,203] Other studies have reported fewer or no objective responses.[83,154,202-206] Stem cell reinfusion has permitted higher myeloablative doses to be administered, but it appears that dose intensification alone will not result in the level of objective response rates initially hoped for and will need to be combined with other optimization strategies.

Fractionation of Administered Activity
(See eTable 22-1)

Fractionated RIT usually involves administration of the total activity through divided infusions spaced days to a week apart instead of as a single infusion and takes advantage of the differences in uptake and clearance kinetics of activity between tumor and normal tissues, such that with the appropriate fractionation schedule the ratio between tumor dose and marrow dose can be amplified. The optimum schedule therefore may be dependent on a complex interplay of multiple factors including uptake and clearance kinetics of the antibody construct, decay kinetics of the radionuclide, tumor size, radiosensitivity of tumor and organs, and clearance kinetics of the individual patient. A number of groups have reported in animal models reduced hematopoietic toxicity and greater antitumor effects with fractionation.[207-210] Meredith et al[211] used a fractionated RIT schedule with ^{131}I-chimeric B72.3 in patients with colorectal cancer who received 28 mCi/m^2 or 36 mCi/m^2 in two to three weekly fractions of 12 mCi/m^2 to 18 mCi/m^2. There was a modest but statistically significant ($p = 0.04$) decrease in hematopoietic toxicity adjusted for whole-body dose when compared to a similar population treated in a previous trial who received similar doses of ^{131}I-chimeric B72.3 as a single infusion.[211] Divgi et al[212] also evaluated a fractionated schedule with the anti-TAG-72 antibody CC49 radiolabeled with ^{131}I. Six patients with colorectal cancer received 15 mCi/m^2 biweekly for up to a maximum of four infusions. This schedule was well tolerated with no dose-limiting toxicities observed.

Engineered Immunoconstructs

Molecular engineering of antibodies with properties optimized for therapy continue to be pursued. Reducing antibody immunogenicity to permit multiple administrations has been successful in the clinic. Murine derived Mabs have the disadvantage of being recognized as foreign by the patient's immune system, which can lead to the formation of HAMA in 50% to 100% of patients after single administration,[213-216] resulting in faster blood clearance of subsequently administered antibody and potentially compromised efficacy.[216-217] Reduction in antibody immunogenicity has been observed with the use of immunosuppressive agents, such as cyclosporine A.[34,218,219] Others have reduced antibody immunogenicity through modification of the antibody molecule using recombinant DNA techniques to replace murine with human antibody domains (e.g., chimeric antibodies, where the murine variable domains are retained, and humanized antibodies, where only the murine complementarily determining regions CDR antigen recognition sites are retained; see eTable 22-3, available in the expanded chapter on the Expert Consult website).[152,174,178,220-231]

Recombinant antibodies can be designed with improved biodistribution and pharmacokinetic properties to optimize their use for therapy. Antibody fragments and other smaller molecular weight antibody constructs may ultimately prove superior for therapy because of their faster clearance, greater tumor penetration,[26] more uniform distribution in tumor,[232] higher initial dose-rate in tumor,[233] decreased immunogenicity,[234] higher tumor to background ratios,[132] and potential for higher administered activities and tumor doses for the same level of toxicity. Initial efforts evaluated radiolabeled Fab and F(ab')$_2$ fragments generated from whole immunoglobulin through enzymatic digestion (see eTable 22-1).[149,150,154,168,235] Unfortunately, antitumor effects appeared to be no better than with radiolabeled intact antibody. Although blood clearance may be more rapid with fragments, retention time in tumor is also reduced, resulting in no significant improvement in radiation dose to tumor over the intact antibody for equitoxic administered activities.

More recent efforts have used recombinant DNA technology to genetically engineer antibody constructs with properties to improve tumor to normal organ biodistribution, enhance in vivo stability, reduce immunogenicity, aid in conjugation and radiolabeling, and increase clearance kinetics. Constructs have ranged from approximately 25 kDa to 160 kDa in size. The genes encoding the antibody's variable light (V_L) and variable heavy (V_H) domains can be cloned and linked by a contiguously encoded peptide into a single chain (sc) Fv construct. This small monovalent scFv, 28 kDa, clears rapidly from the circulation increasing the tumor-to-blood ratio, making them attractive as potential imaging agents.[236,237] However, the absolute peak uptake and retention time in tumors are often reduced, limiting their use as therapy agents.[236-239] In addition, low-molecular-weight constructs can filter through the renal glomeruli, resulting in increased kidney uptake and radiation dose compared to higher molecular weight constructs. A more suitable construct for therapy might be bivalent, of intermediate molecular weight, and exhibit uptake and retention in tumor comparable to intact antibodies, but with faster clearance times than an intact Mab, resulting in an improved therapeutic ratio. Multivalent, intermediate molecular weight constructs have been produced through covalent linking of monovalent fragments.[209,238,240-248] Alternatively, single chain monomers can be engineered with properties that promote spontaneous formation of dimeric and trimeric species. For example, Figure 22-1 shows an engineered series of recombinant fragments derived from the intact anti-CEA T84.66 MAb.[249] This cognate family of anti-CEA constructs was radioiodinated and evaluated in animal biodistribution studies. The minibody (80 kDa), formed by the self-association of two scFv-C_H3 single chain monomers, was potentially suitable for therapy and resulted in peak tumor uptakes of more than 20% to 30% injected dose per gram, which exceeded that of the diabody and F(ab')$_2$ and approached that of the intact antibody.[250]

A pilot imaging trial[251] evaluating the biodistribution and tumor targeting properties of the ^{123}I-cT84.66 minibody in 10 patients with colorectal cancer demonstrated faster blood

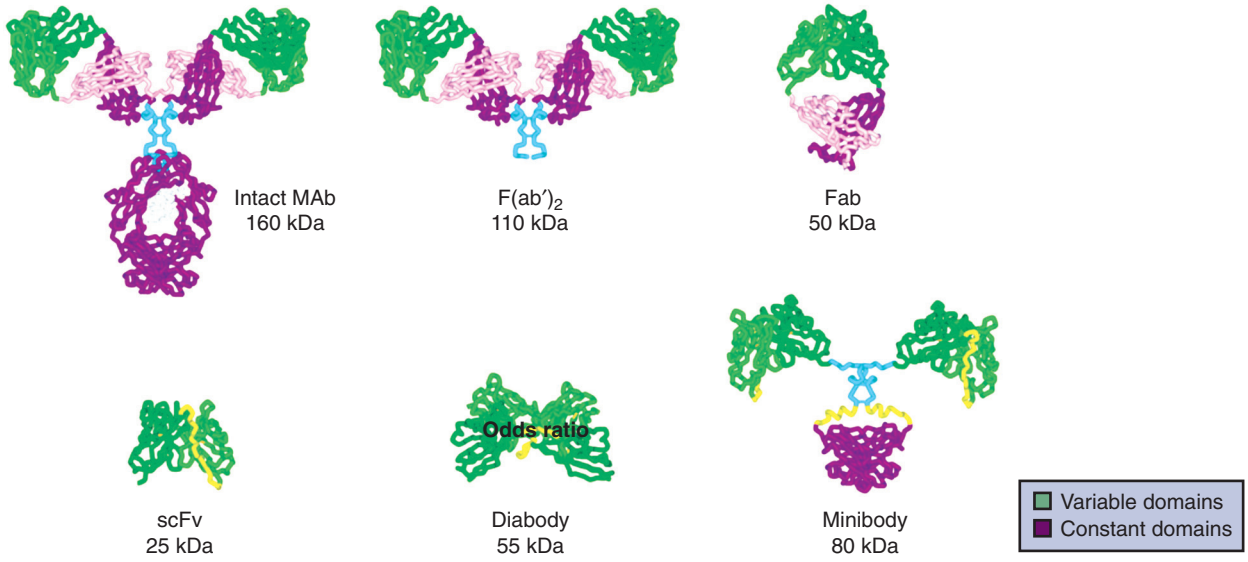

Figure 22-1 Comparison of the variable and constant domains for six types of engineered antibodies.

clearance than intact cT84.66.[145] To further evaluate its potential as a therapy agent, a follow-up pilot study evaluated ^{111}In-DOTA-cT84.66 minibody, with 4 of 5 patients demonstrating tumor imaging. Predicted mean radiation dose to liver was 19.6, kidney 33.3, lung 1.5, and marrow 2.2 cGy/mCi ^{90}Y. Mean tumor dose was 12.4 (6.8 to 25.1) cGy/mCi ^{90}Y. Tumor dose to marrow dose ratio was 5.6, comparable to that seen in murine models, but less than the ratio of 10.5 seen for intact ^{90}Y-DTPA-cT84.66[176] and 11.6 for ^{90}Y-DOTA-cT84.66[231] seen in previous Phase I trials.

Other groups have investigated similar strategies.[239,252-256] Forero et al reported on a 153 kDa ^{131}I labeled humanized C_H2 domain deleted construct (HuCC49ΔCH_2) derived from CC49 anti-TAG72.[257] Blood clearance $T_{1/2}$ was 20 hours, comparable to cT84.66 minibody. Early results from a Phase I dose escalation therapy trial in metastatic colorectal cancer indicated reduced hematologic toxicity compared to intact murine ^{131}I-CC49. At the initial dose level of 75 mCi/m^2, only 25% of patients (one of four) developed more than grade 3 hematopoietic toxicity, compared to >60% of patients with ^{131}I-murine CC49 in a previous trial.[258]

Modifying Tumor Environment
(See eTable 22-1)

Upregulation of tumor antigen expression as a means of increasing antibody targeting and radiation dose to tumor has been explored. Alpha- and gamma-interferon have been shown to increase CEA and TAG-72 expression,[259-262] resulting in increased tumor antibody uptake and RIT efficacy in animal models.[263,264] In the clinic, interferon has also increased tumor antigen expression and antibody uptake in breast, colorectal, and prostate cancers.[265-268] However, antitumor effects remain modest with this strategy alone, leading investigators to now combine this approach with other optimization strategies.

Strategies to modify the tumor vasculature to increase blood flow or vascular leakage, using vasoactive agents, vasoactive immunoconjugates, radiation therapy, or hyperthermia, have been explored primarily in experimental models.[269] Interest has focused on an emerging class of agents directed against the tumor neovasculature. Jain et al[270] and others[271] have proposed using antiangiogenic agents, such as anti-vascular endothelial growth factor (VEGF) antibodies, to "prune" or normalize the tumor vasculature, decrease tumor interstitial pressure, and increase tumor perfusion, which should increase macromolecule delivery. In some experimental models tumor oxygenation is also increased,[271] which can further enhance antitumor effects of RIT. In a similar strategy Burke et al have looked at using cyclic RGD peptide, which recognizes the αvβ3 integrin receptor on tumor neovasculature. In a tumor-bearing breast cancer mouse model, the combination of RGD peptide and ^{90}Y-chimeric L6 RIT resulted in higher tumor uptake of antibody and a greater percentage of mice cured than either therapy alone.[272,273] In mice with colorectal cancer, Kinuya et al[274] combined the antiangiogenic agent 2-methoxyestradiol with ^{131}I-A7 RIT and demonstrated prolonged survival with the combination, compared to either agent alone. Bodet-Milin et al[275] combined ^{131}I-F6 anti-CEA RIT and bevacizumab (anti-VEGF) in mice with medullary thyroid cancer and reported an increase in tumor growth delay with the combination compared to either agent alone.

Agents that increase vascular permeability also have been evaluated. A response-selective peptide agonist to human C5a, resulted in an increase in ^{131}I-B72.3 anti-TAG72 Mab and a two-fold increase in colon cancer xenograft growth delay in vivo.[276] The vascular disrupting agent combretastatin A-4-phosphate (CA4P) has been shown to increase tumor retention of ^{131}I-AB7 anti-CEA antibody, resulting in increased radiation dose to tumor[277] and a significant increase in tumor growth suppression compared to ^{131}I-AB7 RIT alone.[278] A Phase I/II trial was initiated and preliminary results reported.[279] Twelve patients received ^{1311}-A5B7 anti-CEA Mab given on day 1 and CA4P on days 2 and 3. Dynamic contrast-enhancing magnetic resonance imaging (MRI) demonstrated reduction in tumor vascular kinetics in 9 of 12 patients. Dose-limiting hematopoietic toxicity was observed at ^{131}I-A5B7 administered activities of 43.2 mCi/m^2 and CA4P of 54 mg/m^2. Of ten evaluable patients one had stable disease.

Minimal Tumor Burden Setting
(See eTable 22-1)

Tumor size plays a dominant role in influencing antibody uptake and clinically important outcomes are predicted if systemic RIT is applied in the subclinical or microscopic disease setting. Jain et al[26,280] have identified key physiologic factors

that limit uptake of macromolecules. These factors include spatial heterogeneity of tumor vascularity, increased interstitial pressure in poorly vascularized areas, and limited diffusion distances of macromolecules, which work to significantly limit the ability of the antibody to reach all sites within the tumor. These factors are amplified as the tumor grows, resulting in an exponential decrease in tumor antibody uptake, that has been demonstrated in vivo[281-284] and in clinical trials.[285,286] Given this inverse exponential relationship, a very modest reduction in tumor size will result in a substantial increase in antibody uptake.

RIT should therefore have its greatest impact in the adjuvant setting and in the treatment of minimal or microscopic disease. For example, Behr et al[155] and Vogel et al[208] successfully demonstrated improved survival and prevention of liver metastases in animal models with RIT delivered with adjuvant intent. Subsequent clinical trials evaluated this strategy in patients with small volume disease. Behr et al[155] reported initial Phase I trial results in 12 patients with colorectal cancer with metastatic lesions ≤2.5 cm. Patients received a single administration of 50 mCi/m^2 to 70 mCi/m^2 ^{131}I-hMN14 anti-CEA RIT. Of 11 evaluable patients, 2 partial responses and 5 minor/mixed responses of up to 12 months duration were observed (see eTable 22-3). This was followed by a Phase II study of 30 patients with colorectal cancer and liver metastases who received a single administration of ^{131}I-hMN14 anti-CEA RIT (60 mCi/m^2).[287] Of 19 evaluable patients who had small volume disease of ≤3.0 cm, 3 experienced a partial response of 3 to 15 months' duration and 8 patients had a minor response of 3 to 14 months' duration. Five patients received a second cycle at time of progression at 8 to 16 months, which resulted in partial responses in 2 patients. In addition, 9 patients received RIT for microscopic disease similar to the results in an adjuvant setting after a complete resection of hepatic metastases. Seven of 9 remained disease free at more than 24 to 36 months, which compared favorably to historical controls at the same institution receiving 5-fluorouracil (5-FU) based regimens posthepatic resection (see eTable 22-1).

These initial encouraging observations led to a Phase II adjuvant RIT trial of ^{131}I-hMN14 administered after resection of colorectal cancer liver metastases.[288] In a subsequent report, 23 patients who underwent R0 resection of liver metastases from colorectal cancer, received a single administration of 40 mCi/m^2 to 60 mCi/m^2 of ^{131}I-hMN14 anti-CEA (see eTable 22-1).[289] Results were compared to a contemporaneous control group of 19 patients from the same institution treated postresection with 5-FU–based chemotherapy regimens. Median follow-up for the RIT group was 91 months and for the control group, 51 months. A statistically significant improvement in median overall survival in the RIT group (58 months versus 31 months) was reported. Median disease-free survival was greater for the RIT group (18 months versus 12 months), but the difference did not reach statistical significance. The investigators concluded that a prospective randomized trial to evaluate ^{131}I-hMN14 as adjuvant therapy in this patient population was warranted given the suggestion of a survival advantage. This same group evaluated administering two courses of RIT after resection of liver metastases in patients with colorectal cancer.[290] Thirty-two patients received a 40 mCi/m^2 to 50 mCi/m^2 ^{131}I-hMN14 anti-CEA, with 24 receiving a second RIT administration. Sixteen patients had no residual disease detectable after surgery and comprised the group that received adjuvant RIT. With follow-up of 21 months, disease-free survival was 18 months for the adjuvant group and 6 months for the nonadjuvant group. The authors concluded that a second cycle of RIT is feasible with acceptable toxicity.

An adjuvant RIT trial in colorectal cancer was carried out by Ychou et al[181] who administered a preoperative dose of ^{131}I-F6 F(ab')$_2$ anti-CEA (8 mCi to 10 mCi) prior to planned surgery to 22 patients with one to four liver metastases. After complete resection (R0) resection, 13 patients, including 10 who had tumor to liver uptake ratios of >5, received 180 mCi/m^2 to 200 mCi of ^{131}I-F6 F(ab')$_2$ anti-CEA RIT. With a median follow-up of 127 months, median disease-free survival was 12 months and median overall survival was 50 months. One patient remained disease free at 93 months. The investigators concluded that RIT is feasible after surgery in this poor prognostic group and that RIT combined with chemotherapy should be further evaluated in this clinical setting.

At City of Hope, a Phase I trial evaluated the feasibility and toxicities of ^{90}Y-cT84.66 anti-CEA RIT combined with hepatic arterial fluorodeoxyuridine (FUdR) and systemic gemcitabine in patients with colorectal cancer after resection and or radiofrequency ablation of liver metastases. No dose-limiting toxicities were observed in 16 patients with FUdR of 0.1 to 0.2 μg/kg/d × 14 days, gemcitabine 105 mg/kg and RIT 16.6 mCi/m^2. Median time to progression was 9 months, with two patients still progression free at 38 and 90 months (see eTable 22-1). Encouraging results in the minimal tumor burden setting are also promising with regional administration of RIT and are detailed below.

In summary, preclinical studies predict that RIT should have its greatest impact in the minimum tumor burden or adjuvant setting. Initial clinical trials remain promising and demonstrate feasibility of RIT alone or in combination with chemotherapy in the posthepatic resection setting. Further trials are warranted to better define the potential benefits of this approach.

Combined Modality Approaches (eTable 22-4)

RIT and Chemotherapy

Multiple preclinical studies have documented additive or supraadditive antitumor effects when RIT is combined with radiation enhancing chemotherapy or other systemic agents, including gemcitabine,[291-293] taxanes,[294,295] cisplatin,[296] 5-FU,[297-299] doxorubicin,[300] halogenated pyrimidines,[301] topoisomerase inhibitors,[299,302,303] tirapazamine,[304,305] epidermal growth factor receptor (EGFR) tyrosine kinase inhibitors,[306] and anti-EGFR Mabs.[307] A growing number of clinical trials are evaluating the feasibility and potential improved efficacy of concomitant chemotherapy and RIT, either by adding chemotherapy to maximum tolerated doses of RIT or adding RIT as additional therapy to established chemotherapy regimens. RIT-chemotherapy trials have been performed in a number of different solid tumor types including ovarian, breast, prostate, medullary thyroid, and colorectal cancers and are summarized in eTable 22-4, available on the Expert Consult website.[205,235,308-321] In some studies, the strategy of chemotherapy and RIT has often been combined with other strategies, including regional delivery, interferon, and hematopoietic stem cell support.

Radiolabeled anti-CEA Mabs have been evaluated in Phase I trials in combination with single-agent chemotherapy. One of the first reported Phase I trials combined ^{90}Y-cT84.66 at MTD doses of 16.6 mCi/m^2 (defined from a previous trial[176]) with 5-day continuous infusion 5-FU at doses escalating from 700 mg/m^2/day to 1000 mg/m^2/day.[312] One mixed response and 11 patients with stable disease of up to 8 months' duration were reported in 21 patients treated with up to two courses of combination therapy. 5-FU did not appear to alter the pharmacokinetics and biodistribution of cT84.66. human anti-chimeric antibody (HACA) responses were more than 50% less frequent compared to that seen with ^{90}Y-cT84.66 alone,[176] suggesting that the 5-FU may have played a role in reducing immune response to the chimeric antibody. This was followed

by a Phase I trial of similar design combining ^{90}Y-cT84.66 at doses of 16.6 mCi/m^2 on day 1 with gemcitabine 30 mg/m^2 to 165 mg/m^2 on days 1 and 3. The maximum tolerated dose (MTD) of gemcitabine was 150 mg/m^2. Of 32 patients treated with one to three courses of therapy, one partial response, and 10 patients with stable disease were observed.[321] HACA response was less frequent than with ^{90}Y-cT84.66 alone,[176] suggesting that, as with 5-FU, the addition of gemcitabine may have reduced the incidence of HACA.

RIT using ^{90}Y-cT84.66 anti-CEA has also been combined with standard radiotherapy and chemotherapy regimens. Phase I trials using autologous stem cell support with full intensity chemotherapy have also been reported (eTable 22-4). The established chemotherapy regimen of gemcitabine and cisplatin was combined with a single infusion of ^{90}Y-cT84.66 (15 mCi/m^2 to 31.4 mCi/m^2) in 8 patients with metastatic breast cancer. Four patients demonstrated mixed responses or stable disease of 3 to 14 months' duration.[205] More recently, ^{90}Y-cT84.66 RIT was administered to 11 patients with unresectable stage III non–small cell lung cancer in combination with standard radiotherapy (60 Gy) and chemotherapy (cisplatin/etoposide or carboplatin/paclitaxel). RIT was administered concomitantly with radiochemotherapy in 4 patients (10 mCi/m^2) or 6 weeks after completion of radiochemotherapy in 7 patients (8 mCi/m^2 to 12 mCi/m^2) (Wong, unpublished data). Three patients remain progression free at 5, 14, and 70+ months (eTable 22-4).

^{90}Y-hPAM4 has been evaluated with gemcitabine in patients with pancreatic cancer. The initial Phase I trial established an MTD of 20 mCi/m^2 when administered as a single infusion in 20 patients with advance pancreatic cancer, with 3 patients demonstrating a partial response (see eTable 22-1).[322] A successor Phase I/II trial combined fractionated (weekly) ^{90}Y-hPAM4 with low dose gemcitabine (200 mg/m^2 weekly).[323] The MTD was established at 12 mCi/m^2 weekly for 3 weeks for the first cycle and ≤9 mCi/m^2 weekly for 3 weeks for subsequent cycles. Of 38 patients with stage III/IV pancreatic cancer, 13 received more than one cycle of therapy. Partial responses were observed in 6 patients (16%) and stable disease in 16 patients (42%) (see eTable 22-4). In medullary thyroid cancer, escalating doses (20 mCi/m^2 to 50 mCi/m^2) of ^{90}Y-hMN-14 anti-CEA were combined with single cycle doxorubicin at 60 mg/m^2 in 14 patients, with 1 partial response, 2 mixed responses, and 4 with stable disease observed.[318]

Taxanes have shown promise in combination with systemic and intraperitoneal (IP) RIT. ^{90}Y-m170 at 5 mCi/m^2 to 20 mCi/m^2 with paclitaxel 75 mg/m^2 has been evaluated in prostate and breast cancers.[315,317] ^{90}Y-CC49, paclitaxel 60 mg/m^2 to 80 mg/m^2, and interferon, to increase tumor antigen expression, was administered to 34 patients with stage IIB and IV non–small cell lung cancer with 13 demonstrating stable disease. Regional combined modality approaches remain promising. In patients with ovarian cancer with recurrent or refractory microscopic disease or macroscopic disease <5 cm, combination therapy was evaluated, consisting of a single cycle of IP ^{177}Lu-CC49 RIT, IP paclitaxel, and subcutaneous alpha-interferon.[309] Four of 17 patients with CT measurable disease had a partial response, and 4 of 27 patients with nonmeasurable disease remained progression free at 18+ to 37+ months. A subsequent Phase I study of the same design evaluated IP ^{90}Y-CC49 in combination with IP paclitaxel and alpha-interferon.[310] Two of 9 patients with measurable disease demonstrated a partial response and 4 of 11 with nonmeasurable disease remained progression free at 15+ to 23+ months. A pilot study of IP ^{90}Y-cT4.66 anti-CEA RIT and IP gemcitabine in patients with CEA-expressing cancers with disease primarily confined to the peritoneal cavity demonstrated that the combination was well tolerated with no dose-limiting toxicities observed (see eTable 22-4, unpublished data). Results were encouraging with 4 of 7 patients demonstrating antitumor effects (1 with mixed response and 3 with stable disease of 2 to more than 15 months). One had complete resolution of malignant ascites, whereas another had >50% reduction of ascites, no longer requiring frequent abdominal paracenteses. Regional RIT is also actively being evaluated in combination with chemotherapy in patients with high-grade gliomas.

In summary, combining RIT with single agent or multiagent chemotherapy regimens is feasible with acceptable toxicity and has resulted in antitumor activity in heavily pretreated patients. Similar efforts should continue in the appropriate patient populations and should consider combining RIT with established chemotherapy regimens in less heavily pretreated patients with minimal tumor burden.

RIT and External Beam Radiotherapy

RIT in combination with external beam radiation therapy is an attractive concept for a number of reasons.[324] The two modalities combined may deliver a higher cumulative radiation dose to the tumor than either modality alone. If external beam radiotherapy precedes RIT, radiolabeled macromolecule uptake can potentially be increased through reduction in tumor size,[325] increase in vascular permeability,[326,327] or increase in antigen expression.[328-330] If RIT precedes external beam radiation, low dose-rate RIT irradiation has been shown to potentiate tumoricidal effects of subsequent external beam radiotherapy in vitro through mechanisms that involve a G_2 block,[331] or through a phenomenon termed *protracted exposure radiosensitization* as described by Williams et al.[332]

A limited number of external beam radiotherapy and RIT combined therapy efforts have been reported (see eTable 22-4). Markoe et al[333] treated 53 patients with ^{125}I-17-1A anti-Ep-Cam antibody in a phase I study. Forty-six patients with liver metastases also received 1500 cGy whole liver radiotherapy in 10 daily fractions to increase RIT uptake to hepatic lesions. No significant hepatotoxicity was reported. One partial response, 1 mixed response of 12 months duration and 10 patients with stable disease of 3- to 8-months' duration were observed. Buchegger et al[235] combined ^{131}I-anti-CEA F(ab')$_2$ RIT with liver radiotherapy (20 Gy in 2-2.5 Gy daily fractions) in 6 patients with metastatic colorectal cancer. Hematopoietic toxicity was the primary toxicity and grade 1-3 transient elevations in liver transaminases and alkaline phosphatase were observed. One minor response, 3 patients with stable disease and 5 patients with a decrease in CEA were reported. Clinical trials combining local regional external beam radiotherapy with RIT have been completed with acceptable toxicity in patients with hepatobiliary cancers[333-336] and high-grade gliomas.[337-339]

Combining total body irradiation as a form of systemic external beam radiotherapy with RIT in a myeloablative transplant setting has also been performed by one group in patients with breast and prostate cancers.[308] Twelve patients received 1320 cGy total body irradiation in 8 fractions over 4 days combined with a single infusion of 100 mCi/m^2 to 150 mCi/m^2 of ^{131}I-CC49 anti-TAG72 RIT, followed by autologous hematopoietic cell reinfusion, with four partial and one mixed responses observed.

Although the experience is limited, combining RIT with external beam radiotherapy appears to be feasible and is associated with acceptable toxicity. Efforts evaluating RIT as an adjunct to external beam radiotherapy should continue to be evaluated.

RIT Using Antibodies with Immunomodulatory or Biologic Activity

Although most Mabs evaluated to date have had no significant biologic activity, there have been some exceptions. In a

RIT and Hyperthermia

Hyperthermia has demonstrated promise in experimental models as a means of enhancing the efficacy of RIT through a number of possible mechanisms, which include increasing tumor antigen expression,[340,341] increasing tumor blood flow or vascular permeability, decreasing tumor interstitial pressure, radiosensitization by inhibition of sublethal damage and potentially lethal damage repair,[342-344] and direct cytotoxic effects on tumor. Mittal et al[345] treated mice with LS174T colon cancer with ^{131}I-anti-CEA C110, followed 2 days later with 42.5°C for 45 minutes hyperthermia. Greater tumor growth delay was seen when hyperthermia was added to RIT. The same group then performed a Phase I/II combined therapy trial of ^{131}I-NP4 anti-CEA RIT combined with hyperthermia in six patients with liver metastases. RIT (30 mCi/m^2 or 60 mCi/m^2) was administered intravenously followed 24 hours later by 42°C interstitial hyperthermia to the liver lesions. One partial response was observed and two of three patients had resolution of abdominal pain after therapy.

pilot trial of 10 patients with breast cancer, unlabeled chL6 (200 mg) was administered before the ^{131}I-chL6 therapy dose. chL6 resulted in an increase in serum interleukin-2 and interleukin-2-receptor levels, a decrease in serum C3 and C4 complement levels, and an increase in antibody dependent cellular cytotoxicity (ADCC) activity. In addition approximately a two-fold increase in radiolabeled antibody uptake to tumor was seen, which the authors hypothesized was secondary to changes in tumor vascular permeability as a result of chL6 bioactivity.[152] This may explain, in part, the higher than usual response rate on this trial, with four partial and two mixed responses reported (see eTable 22-1).

HuJ591, which recognizes an external domain of prostate specific membrane antigen (PSMA), may have similar bioactivity. HuJ591 has been radiolabeled with ^{90}Y and ^{177}Lu and evaluated in Phase I RIT trials with encouraging results (see eTable 22-1).[179,180] In a Phase II trial, 47 patients with hormone refractory prostate cancer received 65 mCi/m^2 to 70 mCi/m^2 of ^{177}Lu-HuJ591.[346] A total of 10.6% of patients experienced ≥50% decline in prostate-specific antigen (PSA) and 36.2% experienced ≥30% decline in PSA. Median overall survival was 22.2 months for those with any PSA decline compared to 11.4 months for those with no decline. Unlabeled huJ591 has also been evaluated in several trials in patients with hormone refractory metastatic prostate cancer. The initial Phase I trial treated 14 patients with 4 weekly doses of huJ591 with dose levels of 25 mg/m^2, 50 mg/m^2, 100 mg/m^2, or 200 mg/m^2.[347] PSA stabilization was observed in 3 patients. This was followed by a pilot trial of 14 patients with each patient receiving four escalating doses of unlabeled Mab of 10 mg, 25 mg, 50 mg, and 100 mg.[348] Increasing ADCC activity was seen with increasing antibody dose. One patient demonstrated >50% reduction in PSA. Given the ability of huJ591 to mediate ADCC, a Phase II trial of huJ591 and low dose IL-2 therapy has been initiated with stabilization of PSA observed in some patients.[147]

Using radiotherapy and RIT as a means to enhance immunotherapy through other mechanisms has also received recent attention.[349,350] Tumor cell death after irradiation can release antigens that can then activate or potentiate an immune response against tumors.[349] Radiation therapy can alter the tumor cell phenotype, by increasing expression of tumor associated antigens, such as CEA, upregulate tumor chemokines and adhesion molecules,[351] and upregulate Fas and major histocompatibility complex (MHC) molecules expression, which can work in concert to enhance immune recognition.[352] Low-dose total body irradiation (TBI) in murine models can enhance effects of subsequent adoptive transfer of tumor-specific T cells by selectively depleting cell populations that compete for needed cytokines.[353] Charkraborty et al[354] evaluated the combination of anti-CEA RIT (^{90}Y-COL-1) and vaccine therapy in a transgenic mouse with colon cancer model for human CEA. The combination resulted in a significant increase in survival compared to either therapy alone. RIT resulted in an upregulation of Fas by tumor cells and an increase in infiltrating CEA-specific CD8$^+$ T cells in tumor.

Antibodies now used as part of standard regimens in nonhematologic malignancies are also being evaluated as potential radioimmunotherapeutics. This concept is attractive because these antibodies have known antitumor effects that can add to the cytotoxic effects of RIT. Trastuzumab (Herceptin) is one the first Mabs to be approved for use in the treatment of nonhematologic malignancies and recognizes epidermal growth factor receptor 2 (HER2/neu), which is overexpressed by 20% to 30% of breast cancers. Trastuzumab radiolabeled with the β-emitters ^{90}Y, ^{177}Lu, and ^{188}Re, the Auger electron emitter ^{111}In, and α-particle emitters ^{212}Pb, ^{211}At, and ^{225}Ac has been evaluated in in vitro and in vivo preclinical therapy studies with encouraging results.[89,355-361] Imaging doses of ^{111}In-trastuzumab were administered to 17 patients with metastatic Her2 overexpressing breast cancers.[357] The tumor detection rate was 45% with new tumor lesions detected in 13 of 15 evaluable patients.

Cetuximab, a monoclonal antibody directed against epidermal growth factor receptor (EGFR), is used in the treatment of head and neck cancers with radiotherapy and in colorectal cancer in combination with standard chemotherapy regimens. The antitumor effects of the antibody may also enhance the efficacy of radiotherapy,[362-364] although the exact mechanism is unclear. Preclinical in vivo studies have also reported increased RIT efficacy when combined with EGFR inhibiting agents.[306,365] Radiolabeled anti-EGFR Mabs have been evaluated in animal models and in a limited number of clinical trials to assess biodistribution, tumor targeting, and their potential as radioimmunotherapy agents. Goldenberg et al[366] evaluated biodistribution and tumor localization of ^{111}In-labeled murine 225 anti-EGFR in mice bearing a high EGFR-expressing vulvar squamous cell cancer tumors. This was followed by an imaging and biodistribution trial with ^{111}In-Mab 225 in 19 patients with squamous cell lung cancer.[367] At the 300-mg level, mean %ID of tumor was 3.1%, liver 21.6%, heart 4.3%, and bowel 24.5%. The low tumor uptake and low tumor to organ uptake ratios appear to limit the potential of Mab 225 as a RIT agent. In contrast to this, Milenic et al[368] evaluated ^{111}In-cetuximab in mice bearing a variety of tumor xenografts. For the human colon cancer line LS174T, tumor uptake at 72 hours was high at 52 %ID/g, with blood uptake of 10.6 %ID/g and liver uptake of 7.9 %ID/g. The authors concluded that ^{111}In-cetuximab may be a useful radioimmunoconjugate for therapy.

Bevacizumab, an anti-VEGF Mab, has been introduced as part of standard systemic therapy regimens for metastatic colorectal, lung, and breast cancers.[369,370] Preclinical models also report that bevacizumab combined with RIT can potentially increase antitumor effects compared to RIT alone.[275] Evaluation of bevacizumab as a possible radioimmunoconjugate for imaging and therapy is in the preclinical stages. Stollman et al[371] performed imaging and biodistribution studies in mice with LS174T colon cancer administered ^{111}In labeled bevacizumab. At 3 days postadministration, mean tumor uptake of ^{111}In-bevacizumab was 19.4 %ID/g, which is comparable to the levels observed for ^{111}In-anti-CEA antibodies evaluated in the same tumor-bearing mouse model. Bevacizumab labeled with zirconium-89 (^{89}Zr) or alpha-particle emitting radionuclides[372,373] have also been evaluated in vivo and have demonstrated targeting to tumor and successful tumor imaging.

Pretargeting Delivery Systems

Pretargeting or multistep approaches may overcome the limitations of direct-radiolabeled antibody therapy approaches. Pretargeting separates the antibody's slow pharmacokinetics from the rapid delivery of a therapeutic radionuclide ligand. The end result is an increase in the therapeutic ratio primarily through a decrease in radiation dose to marrow and normal tissue, allowing for increased administered activities. This strategy is described in more detail elsewhere in this chapter. Pioneering work used the high-binding affinity streptavidin- or avidin-biotin system in which an antibody-streptavidin conjugate or a biotinylated antibody is coupled to a reciprocal ligand bearing the therapeutic radionuclide.[374-376] Results using pretargeted approaches have been promising in animal models[377,378] and have been studied in the clinic.[48,379-386] However, immunogenicity to the bacterial-derived reagents, such as streptavadin, has limited the ability to deliver multiple administrations.

Bispecific antibodies provide an attractive alternative for pretargeting by fusing antitumor targeting to the capture of

the small molecular weight hapten.[387] Bispecific antibodies have one arm of the antibody recognizing the tumor antigen and the other recognizing the radiolabeled ligand. Although initial studies used chemically conjugated[388] or quadroma fusions,[389] recombinant DNA technology has enabled the production of human or humanized molecules to lower the potential for immunogenicity. The antihapten antibody can be highly specific for the radiometal-chelate complex, exhibiting vastly reduced binding affinity if a different metal is used to coordinate the complex.[390] To circumvent this metal specificity, antibodies against the hapten peptide, histamine-succinyl-glycine (HSG), have been generated, which is independent of the radionuclide or chelate.[391] This provides a platform technology that enables multivalency and multifunctionality, where for example, two antitumor Fabs can self-assemble with an anti-HSG Fab.[392]

eTable 22-5, available in the expanded chapter on the Expert Consult website, summarizes some of the clinical therapy trials performed to date using pretargeting approaches. Trials in colorectal, ovarian, lung, medullary thyroid, and brain cancers have been carried out with most trials reporting objective responses. Chatal et al[393] reported on 29 patients with metastatic medullary thyroid cancer treated using a bispecific anti-CEA Mab. The median overall survival for high-risk patients with a calcitonin doubling time of <2 years was 110 months, which compared favorably to the 61 months for historical controls. Recently, the same group reported on 42 patients with medullary thyroid cancer. A complete response was seen in 1 patient, stable disease in 31 patients, and significant increases in doubling times or decreases in levels of calcitonin or CEA were observed in 21 patients.[394] Grana et al,[384] using the anti-tenascin Mab BC-4, reported on 37 patients with newly diagnosed high-grade gliomas. After standard therapy of surgical resection and external beam radiotherapy, 19 patients received adjuvant intracavitary RIT. There was a significant improvement in median overall survival for grade-4 gliomas of 33.5 months with RIT versus 8 months without RIT. Results from pilot Phase I/II trials using pretargeting approaches are encouraging, and this approach warrants further investigation.

Regional Administration

Regional administration (intraperitoneal, intracavitary, intralesional, and intraarterial) to optimize uptake at the tumor site relative to dose-limiting normal organs has been extensively explored with the most encouraging results in the minimal tumor burden and adjuvant setting. eTable 22-6, available in the expanded chapter on the Expert Consult website, summarizes RIT trials that have administered therapy through the intraperitoneal (IP) route. Preclinical[395] and clinical[396] studies indicate that IP administration has pharmacologic advantages over intravenous administration for cancers confined to the peritoneal cavity because of reduced circulating activity and lower hematologic toxicity secondary to increased antibody uptake in tumor, particularly for small volume disease.[397,398]

The agent most extensively studied is ^{90}Y-HMFG1. Epenetos et al[399] first evaluated HMFG1, along with a panel of other antiovarian cancer antibodies radiolabeled with ^{131}I in patients with ovarian cancer after debulking surgery, first-line chemotherapy, and second-look laparoscopy. Objective responses were more frequent in patients with smaller tumors or lower tumor burden. This led to a Phase II trial evaluating adjuvant IP ^{90}Y-HMFG1 at 18 mCi/m^2 in patients with initial stage Ic-IV after surgery, first-line chemotherapy and negative second-look laparoscopy.[400] With a median follow-up of 59 months, a 5-year actuarial survival of 80% was reported that was significantly better than the 55% observed for a matched historical control group (p = 0.0035). This was followed by a multinational Phase III trial entering 447 patients with stage Ic-IV ovarian cancer with negative second-look laparoscopy after surgery and platinum-based chemotherapy. Patients were randomized to standard treatment versus standard treatment plus a single IP infusion of RIT (18 mCi/m^2).[401] With a median follow-up of 3.5 years, there was no significant difference in time to relapse, relapse-free survival, or overall survival between the two arms. The overall survival at 5 years was 55% to 60%, less than that reported in the Phase II study. The authors put forth a number of factors to explain the lack of benefit with RIT, including the fact the type of standard treatment varied with each center and that more patients received consolidative chemotherapy on the control arm than the RIT arm (19.7% versus 12.5%). A subsequent analysis reported a significant decrease in IP time to relapse and IP recurrence rates, which was offset by a significant increase in extraperitoneal time to relapse and recurrence rates.[402]

Strategies to improve on IP RIT in this population may involve more effective systemic therapy delivered concomitantly with IP RIT, multiple administrations of IP RIT or combined IP RIT-chemotherapy approaches that are currently being evaluated by a number of groups (see eTable 22-6). Meredith et al recently reported their long-term results of IP RIT in patients with ovarian cancer.[403] Ninety-two patients with persistent disease after debulking surgery and chemotherapy received IP ^{90}Y labeled or ^{177}Lu labeled CC49 either alone, combined with interferon to increase tumor TAG-72 antigen expression or combined with interferon and paclitaxel. A statistically significant improvement in progression free survival was seen in patients <60 years of age or with tumor nodules <2 cm in size. Use of interferon and paclitaxel, development of a HAMA response and use of ^{90}Y was associated with a trend toward improvement which did not reach statistical significance.

Regional delivery of RIT has also been evaluated in central nervous system (CNS) malignancies, primarily high-grade gliomas (eTable 22-7, available in the expanded chapter on the Expert Consult website). Studies have investigated intracavitary administration after surgical resection, intralesional, intraarterial, or intrathecal administration. Early efforts in patients with recurrent disease were encouraging, leading to trials evaluating this approach as adjuvant therapy in combination with standard surgical resection, external beam radiotherapy, and chemotherapy in patients with newly diagnosed high-grade gliomas. Reported toxicities have been acceptable and were primarily hematologic and neurologic, including temporary headache, seizure and worsening of neurologic symptoms, with a few studies reporting irreversible neurologic symptoms in a small subset of patients at maximum tolerated doses.[338,404] Intracavitary and intralesional delivery of radioiodinated antibodies against tenascin, an extracellular matrix protein expressed by gliomas, but not by normal brain tissue, has been evaluated as single-cycle therapy by investigators at Duke University and as multicycle therapy in Italy. Bigner et al have evaluated single administration of intracavitary ^{131}I-81C6[404,405] in recurrent and newly diagnosed high-grade gliomas (see eTable 22-7). This led to a Phase II adjuvant RIT trial.[338] Thirty-three patients with previously untreated high-grade gliomas received a single administration of 120 mCi ^{131}I-81C6 directly into the surgical resection cavity, followed by conventional radiation therapy and 1 year of alkylator-based chemotherapy. The average radiation dose from RIT to the 2-cm rim around the resection cavity was 48 Gy. A median survival of 86.7 weeks for all patients and 79.4 weeks for glioblastoma patients was observed.

A pilot study with ^{131}I-murine 81C6 was completed (see eTable 22-4)[320] where RIT was combined with standard therapy

eTABLE 22-5 Select RIT Trials Using Pretargeting Approaches

Study (First Author, Year)	Phase	Antigen	No. of Steps	Tumor Type

in 21 patients with newly diagnosed high-grade gliomas. After surgical resection, RIT was administered into the surgical cavity to deliver 44 Gy to the cavity rim, followed by 55 Gy to 60 Gy external beam radiotherapy and chemotherapy. Toxicities were acceptable demonstrating the feasibility of this combined modality first-line therapy approach. With a median follow-up of 151 weeks, the median overall survival was 90.6 weeks for patients with glioblastomas. A Phase I study evaluated a ^{131}I labeled chimeric version of 81C6 in a similar combined modality approach also demonstrating encouraging results (see eTable 22-4).[406] Finally, chimeric 81C6 radiolabeled with the α-emitter ^{211}At is being evaluated in a Phase I setting.[91] Riva et al in Italy have also investigated intracavitary and intralesional radiolabeled antitenascin RIT in patients with resected high-grade glioma (see eTable 22-7).[407-410] Recent efforts have focused on pretargeting approaches combined with chemotherapy (see eTable 22-4).[313,314] In a Phase I/II trial of 73 patients with recurrent glioblastomas, 38 received RIT alone versus 35 who received RIT and temozolomide. A median of three cycles of therapy were administered. With RIT and temozolomide the overall survival was 25 months and progression-free survival 10 months, which compared favorably to the RIT alone group with overall survival of 17.5 months and progression-free survival of 5 months.

Other antibodies have also been evaluated in a similar approach[411,412] with mean doses to the cavity rim of 5120 cGy[413] and 5500 cGy.[414] In addition, regional intrathecal administration has been evaluated in meningeal carcinomatosis and medulloblastoma with objective responses observed.[415-417] CNS malignancies have also been treated through intraarterial, intravenous, and intracavitary approaches using antibodies directed against EGFR.[412,418,419] Brady et al[337,412,418-421] have administered ^{125}I-Mab 425, an internalizing murine IgG_{2a} directed against EGFR, in patients with high-grade gliomas (see eTable 22-7). A Phase II study was conducted in 192 patients with newly diagnosed glioblastoma multiforme who received adjuvant RIT using ^{125}I-Mab 425 6 weeks after conventional radiotherapy and debulking surgery.[422] Approximately 31% received nitrosoureas and another 31% temozolomide. The median survival was 15.7 months. For the subgroups receiving ^{125}I-Mab 425 alone versus ^{125}I-Mab 425 and temozolomide, the median survival was 14.5 versus 20.2 months, respectively. Median survival for 80 patients with anaplastic astrocytoma was 55.6 months and 5 year survival 47% (eTable 22-7).[423]

Finally, hepatic arterial delivery of RIT in hepatocellular carcinoma has been investigated. Zeng et al reported their single-institution experience and observed a significantly higher rate of conversion to resectability for the group receiving hepatic arterial ^{131}I-Hepama-1 RIT compared to patients receiving hepatic arterial 5-FU, cisplatin, and doxorubicin[424] or chemoembolization and 46 Gy external beam radiotherapy.[425] A 5-year survival rate of 28.1% for the RIT group was reported, which compared favorably to 9.1% for the chemotherapy group. In a recent multicenter Phase I/II trial, 134 patients with unresectable hepatoma received one to two cycles of ^{131}I-metiximab via the hepatic artery, with a reported 8.2% partial response rate and median survival of 19 months.[426]

High LET Alpha-Particle Emitters

There has been increasing interest in evaluating RIT using α-particle emitters in patients with nonhematologic malignancies. The high LET of alpha particles increase the radiobiologic effect of the targeted dose. Although their short range may limit efficacy in large macroscopic tumors, there may be use in the setting of microscopic or small volume disease. Their short range limits dose to normal tissues, potentially reducing dose-limiting toxicities traditionally associated with RIT using β-emitting radionuclides.

Zalutsky et al evaluated the feasibility and safety of intracavitary administration of the antitenascin chimeric antibody ^{211}At-ch81C6 in 18 patients with recurrent grade II/IV gliomas after surgical resection (see eTable 22-7).[91] No dose-limiting toxicities were observed. Median survival for patients with glioblastoma multiforme was 54 weeks. Andersson et al administered ^{211}At-MX35 $F(ab')_2$ to 9 patients with recurrent ovarian cancer in complete clinical remission after second-line chemotherapy and after negative second-look laparoscopy.[427] The antigen recognized by MX35 is a sodium dependent phosphate transport protein overexpressed by ovarian cancers (NaPi2b). No dose-limiting toxicities were observed. Absorbed dose to the peritoneum was 15.6 and red marrow 0.14 mGy/MBq/L. The authors concluded that therapeutic doses to microscopic IP disease were achievable without significant toxicity. Finally, Meredith et al at the University of Alabama are evaluating in a Phase I trial IP ^{212}Pb-trastuzumab in HER-2 positive intraperitoneal cancers.

Allen et al have evaluated systemic α-particle RIT using ^{213}Bi-cDTPA-9.2.27 in patients with stage IV metastatic melanoma or in-transit metastases (see eTable 22-1).[428] Thirty-eight patients were treated with 1.25 mCi to 25 mCi in this Phase I study. Partial responses were observed in 10% and stable disease of at least 8 weeks' duration seen in 40%. Intralesional administration of ^{213}Bi-cDTPA-9.2.27 has been reported by the same group in 16 patients.[429]

Summary of Solid Tumors

As one of the first forms of targeted therapy, the introduction of radiolabeled antibodies into the clinic was understandably accompanied with high expectations. What has been learned through preclinical and clinical studies is a better understanding of the limitations and the challenges associated with RIT, many of which apply to both nonhematologic as well as hematologic malignancies. As with other emerging therapies, RIT will likely find its role not as monotherapy, but rather as a therapy used rationally in combination with other modalities. Although a number of strategies to increase tumor uptake and antitumor effects of these agents have proven encouraging, it is likely that no one strategy will be sufficient and that multiple strategies will be needed to realize clinically important results in the solid tumor setting. As clinical trials suggest, RIT will likely be best defined in the minimal tumor burden or adjuvant setting.

RIT OF LYMPHOMA AND LEUKEMIA

RIT has been most successful for the treatment of lymphoma and leukemia. Representative clinical trials using RIT for B-cell NHL and T-cell lymphoma and leukemia have been summarized in eTables 22-8[29-31,186,188,430-455] and 22-9[456-459] (available in the expanded chapter on the Expert Consult website) in terms of general study design (nonmyeloablative versus myeloablative), radionuclide and antibody used, number of treatments, number of treated evaluable patients, and responses. Myeloablative studies have included bone marrow or peripheral stem cell collection and reinfusion. These trials differ in terms of eligibility criteria, antibody and radionuclides used, dose, number of treatments, doses of unlabeled antibody preinfused or coinfused, and the biodistribution or dosimetry estimations required for administration of a therapeutic dose of radiolabeled antibody. The results summarized in eTable 22-8 are particularly promising and show a relatively high response rate with a number of durable PRs and CRs, with a subset of these responses ongoing at ≥5 yrs, and many

patients experiencing remissions of longer duration than had been achieved with previous chemotherapy. The highest overall response and CR rates and the longest remission durations have been reported in patients treated with high doses of radiolabeled antibody in single doses in conjunction with autologous bone marrow transplantation (BMT) or stem cell transplantation (SCT).[31,436,441,460,461] Although higher doses of RIT have tended to be more efficacious, there has not been a direct correlation between dose and response in most reported studies. These results are particularly encouraging because all of the patients treated in these trials have had recurrent disease following at least one form of conventional therapy. Many of the patients had failed multiple courses of therapy, and some were unable to tolerate additional chemotherapy for a variety of reasons.

Two anti-CD20 Mabs conjugated to either ^{131}I (^{131}I-tositumomab or Bexxar) or ^{90}Y (^{90}Y-ibritumomab tiuxetan or Zevalin) have been approved by the FDA for patients with relapsed or refractory low-grade or transformed B-cell NHL,[447,449,451] and have demonstrated efficacy in patients even after the use of rituximab (Rituxan).[450,452] ^{90}Y-ibritumomab was also approved for upfront treatment of previously untreated patients with low-grade B-cell NHL in 2009. The Bexxar (tositumomab and ^{131}I-tositumomab) regimen consists of the sequential administration of a dose of unlabeled murine Mab, tositumomab, to optimize biodistribution and increase tumor localization of the ^{131}I-tositumomab that is administered thereafter.[184,462] An initial biodistribution study uses a dosimetric dose to allow for the calculation of a patient specific therapeutic dose to deliver an absorbed whole-body dose of 75 cGy in patients with a platelet count of ≥150,000/μL. FDA approval was based on a study in 40 patients with relapsed/refractory disease after rituximab therapy and was further supported by the demonstration of durable responses in four other studies enrolling 190 patients with relapsed/refractory disease following chemotherapy. Objective tumor responses occurred in approximately 60% of patients, with CRs in approximately 30%. Median response durations have been in excess of 12 months, with occasional durable complete responses lasting for years.[447,449,463,464] Despite these encouraging results, manufacturing of ^{131}I-toxitumomab was discontinued in 2014 because of its limited clinical use.

The ^{90}Y-ibritumomab tiuxetan or Zevalin regimen uses the chimeric anti-CD20 antibody rituximab for predosing. The pivotal study that supported FDA approval of Zevalin randomized 143 patients to receive either rituximab alone (four weekly doses of 375 mg/m^2, as it is used as a therapeutic agent) or RIT with a lower dose (250 mg/m^2) of rituximab for purposes of optimizing the biodistribution of Indium-111 (^{111}In)-labeled ibritumomab tiuxetan for an imaging/dosimetry study. Seven days later patients received 250 mg/m^2 rituximab followed by 0.4 mCi/kg ^{90}Y-labeled ibritumomab tiuxetan. Based on the International Workshop NHL Response Criteria, the overall response rate was 80% for ^{90}Y-ibrutuomab tiuxetan versus 56% in the rituximab arm ($p = 0.002$). CRs were achieved in 30% of patients with ^{90}Y-ibrutuomab tiuxetan versus 16% for rituximab ($p = 0.04$).[190] Of those patients who have since progressed, the time to next therapy was 11.5 months after ^{90}Y-ibrutuomab tiuxetan and 7.8 months after rituximab.

Two randomized studies of either ^{90}Y-anti-CD20 Mab[190] or ^{131}I-anti-CD20 Mab[453] versus unlabeled anti-CD20 Mab have demonstrated the importance of the radiation associated with RIT as a determinant of both the efficacy and toxicity of the RIT treatment. The radiobiology of RIT targeting the CD20 antigen is critical to tumor and normal tissue effects associated with this therapy and has been reviewed.[101] Retreatment with radiolabeled anti-CD20 Mab has also been reported to be well tolerated and efficacious in a subset of patients.[29,438,465]

The optimal time to use RIT in the course of NHL has not been defined.[12,469] A trial using ^{131}I-tositumomab as primary therapy for low-grade disease in 76 previously untreated follicular lymphoma patients has shown impressive results, with a response rate of 95% and evidence of conversion to molecular negativity by polymerase chain reaction (PCR) testing for Bcl-2 rearrangements in 80% of patients with a complete response. Actuarial 5-year survival was 59% with a median PFS of 6.1 years.[470] Patients who have failed BMT have experienced excellent tumor responses to RIT as well.[455,471] In addition, RIT is also being studied in other histologies, such as diffuse large cell lymphoma (DLCL), mantle cell lymphoma,[472] early-stage extranodal indolent ocular adnexal lymphoma,[473] and multiple myeloma[474] with encouraging results.[475-477] For example, in a study of 104 patients with relapsed B-cell DLCL following treatment with either chemotherapy alone, or chemotherapy and rituximab, the overall response rate was 44%, with median overall survival of approximately 22 months for patients previously treated with chemotherapy, and 4.6 months for patients who had failed chemotherapy plus rituximab.[475]

RIT has also been useful as a preparatory regimen for transplantation.[31,436,441,460,461] In a clinical trial comparing high dose RIT with conventional high dose chemotherapy with hematopoietic SCT, the RIT group had higher overall survival and progression-free survival than the group of patients who received the conventional preparatory regimen for transplantation.[478] Other trials of ^{131}I-tositumomab combined with etoposide, cyclophosphamide, and autologous stem cell transplant (ASCT) compared with TBI combined with etoposide, cyclophosphamide, and ASCT also demonstrated improved overall survival and progression-free survival in the group receiving RIT.[479] The same regimen has yielded encouraging results in patients with mantle cell lymphoma, with 3-year progression-free survival of 61%.[480] ^{131}I-tositumomab has also been studied in combination with BCNU, etoposide, Ara-C, and melphalan (BEAM) followed by ASCT. Toxicity was similar to BEAM alone. The CR rate was 57% and overall response rate was 65%, with 3-year event-free survival 39% and overall survival 55%.[481] However, when conditioning with standard doses of ^{131}I-tositumomab added to BEAM before ASCT was compared to rituximab and BEAM in 224 patients with relapsed diffuse large B-cell lymphoma, no difference in progression-free survival or overall survival was seen.[482] The lack of benefit may be the result of decreased administered activity of ^{131}I compared to other myeloablative transplant approaches. In another study, ^{131}I-rituximab combined with BEAM conditioning and ASCT for relapsed/refractory aggressive non-Hodgkin's lymphoma resulted in a very high CR rate (15/16), with 12 out of 16 patients alive and disease-free at a median of 44 months posttransplant.[483]

A similar approach using ^{90}Y-ibritumomab with BEAM has also yielded promising results.[484] In a matched-cohort analysis of ^{90}Y-ibritumomab with BEAM versus 12-Gy fractionated TBI with etoposide and cyclophosphamide as a conditioning regimen for ASCT in diffuse large cell lymphoma, the 4-year cumulative incidence of relapse/progression was similar, but overall survival at 4 years was 81% for the RIT group compared with 52.7% for the TBI group, perhaps as a result, in part, of the lower incidence of cardiac toxicity in the TBI group.[485] Another study of ^{90}Y-ibritumomab, fludarabine, and 2 Gy TBI as a conditioning regimen for allogeneic transplantation for patients with persistent high-risk B-cell lymphoma resulted in an estimated 30-month survival, progression-free survival, and nonrelapse mortality of 54.1%, 31.1%, and 15.9%, respectively, with an acceptable toxicity profile.[486] ^{90}Y-ibritumomab therapy with stem cell support is also being studied with encouraging early results in studies of RIT as part of a reduced intensity conditioning regimen for allogeneic

^{131}I-rituximab has also been studied in patients with relapsed/refractory B-cell non-Hodgkin's lymphoma, with a response rate of 46%, and median progression-free survival of 4.5 months in patients with low-grade B-cell lymphoma, compared with only a 9% response rate and 1.3 month progression-free survival in patients with diffuse large B-cell lymphoma.[466] Repeat treatment with ^{131}I-rituximab was well tolerated and resulted in a two-fold increase in response rate and median duration of response.[467] Recently, ^{177}Lu-DOTA-rituximab was also studied for safety and feasibility for the treatment of follicular and mantle cell lymphoma with encouraging results.[468]

stem cell transplant.[487,488] Investigators at M. D. Anderson Cancer Center found a 3-year progression-free survival of 87% for chemosensitive patients with relapsed follicular lymphoma after conditioning with ^{90}Y-ibritumomab tiuxetan, fludarabine, and cyclophosphamide and an 80% 3-year progression-free survival for patients with chemo-refractory disease.[489] A variety of extended Phase II trials using RIT combined with high-dose chemotherapy are ongoing to better define the safety and efficacy of this therapeutic approach, which may be further improved by radiobiological optimization of RIT for stem cell transplantation.[490]

Other approaches to increase the efficacy of RIT in B-cell NHL include the use of a pretargeting regimen using an anti-CD20-fusion peptide, which is discussed later in this chapter.[385] This approach is based on the dissociation of the delivery of antibody from the delivery of radionuclide, with a clearing agent used in between to eliminate unbound circulating antibody that if radiolabeled, would be a source of nonspecific radiation and therefore toxicity. Proof of principle for this platform technology has been demonstrated in a clinical trial with significantly increased tumor-to–whole-body, tumor-to-blood, and tumor-to-normal organ ratios than achievable with directly labeled Mab.[385]

Another area of active investigation is the study of RIT as part of a combined modality approach with either nonmyeloablative chemotherapy or conventional radiation therapy.[491,492] For example, the combination of low-dose–involved field radiation therapy to sites of active disease ≥2.5 cm prior to RIT in patients with relapsed/refractory B-cell lymphoma was well tolerated, did not add toxicity to that of RIT alone, and resulted in excellent progression-free survival, especially in patients with a CR.[493] In addition, a small study of 18 Gy whole brain radiation combined with RIT following CNS chemotherapy resulted in a 100% CR rate, with no relapses after 12 to 20 months and no associated neurocognitive function decline.[494] Numerous trials have explored the combination of RIT with a variety of chemotherapy drugs. The combination of RIT, CHOP, and involved field radiation therapy in aggressive DLCL (SWOG 0313) was reported to result in outcomes that compared favorably to historical experience with relatively short follow-up.[495] Additionally, combination fludarabine or CHOP chemotherapy with RIT as upfront therapy in Phase II trials has resulted in high overall response and excellent progression-free survival.[496] In a recent Phase II trial (SWOG 9911) of CHOP chemotherapy combined with ^{131}I-tositumomab as consolidation in 90 patients newly diagnosed with follicular non-Hodgkin's lymphoma (NHL), the CR rate was 39% with CHOP alone and 69% for patients receiving both CHOP and RIT, respectively. Five-year progression-free survival and overall survival was 67% and 87%, respectively, for patients receiving the combination therapy.[491] These results provided the rationale for a Phase III trial (SWOG 0016) comparing CHOP plus rituximab with CHOP followed by ^{131}I-tositumomab. In this trial, with a median follow up of 4.9 years, the 2-year estimated progression-free survival was 76% for the CHOP-R arm and 80% for the CHOP-RIT arm (p = 0.11), with 2-year overall survival 97% for CHOP-R and 93% for CHOP-RIT (p = 0.08).[497] Chemotherapy combined with RIT has also been studied in 20 previously untreated elderly patients with DLBCL, using CHOP and ^{90}Y-ibritumomab tiuxetan.[498] In this Phase II trial the overall response rate was 100%, with 95% CRs. Importantly, four of five patients with an initial PR to CHOP alone, converted to CRs following consolidative RIT. With median follow-up of 15 months, 2 year progression-free survival is 75% with 2-year overall survival of 95%. A randomized Phase III study of induction chemotherapy followed by observation or ^{90}Y-ibritumomab in 409 patients with advanced stage follicular NHL, with a median of 7.3 years follow up, demonstrated that ^{90}Y-ibritumomab consolidation after PR or CR/CR$_u$ following induction resulted in a 3-year benefit in median progression-free survival, with a durable 19% progression-free survival advantage at 8 years, and improved median time to next treatment by 5.1 years.[499]

Other studies have investigated the role of ^{90}Y-ibritumomab therapy as consolidative therapy following CHOP, and CHOP/rituximab therapy, respectively, in early stage disease. In a Phase II trial of R-CHOP followed by ^{90}Y-ibritumomab in patients with previously untreated stages I and II diffuse large cell NHL (ECOG E3402), 88% of patients who received both R-CHOP and RIT were progression free with ongoing complete responses, and 98% were alive at 4 years.[500] Other data suggests that consolidative RIT with ^{90}Y-ibritumomab tiuxetan may prolong survival of patients with chemosensitive mantle cell lymphoma who achieve a clinical response after chemotherapy.[501] Indeed, data from multiple trials have demonstrated that consolidative RIT increases rates of complete remission and duration of response.[502] Encouraging results have also been reported in patients with untreated mantle cell lymphoma using ^{90}Y-ibritumomab following four cycles of rituximab/CHOP with a 75% RR (43% CR) and 93% overall survival at 18 months.[472] It is noteworthy that patients with NHL who undergo RIT therapy can well-tolerate subsequent chemotherapy regimens or ASCT with toxicity from subsequent therapy being similar to that observed in patients not previously treated with RIT.[503] More recently, RIT is being studied in combination with biological response modifiers, such as bortezomib, to try to further increase the therapeutic index of RIT.[504] RIT has also been studied in combination with immunostimulatory C$_p$G 7909 oligodeoxynucleotide in relapsed B-cell lymphoma with promising results.[505]

Results from clinical studies of RIT for the treatment of patients with recurrent Hodgkin lymphoma have been encouraging. These studies have used ^{131}I[506] or ^{90}Y[182,507-509] labeled antiferritin antibody. Overall, 134 patients with recurrent Hodgkin's disease have been treated in five different studies with radiolabeled antiferritin antibody.[510] Results obtained with ^{90}Y-antiferritin antibody were better than those obtained with ^{131}I-antiferritin antibody. ^{90}Y-antiferritin antibody therapy resulted in a response rate of 60%, with a CR rate of 30%. The extent of response was associated with survival, with 50% of patients with CR, PR, and progressive disease alive at 2 years, 1 year, and 4 months, respectively.[510] Responses in these studies were more common in patients with disease histories longer than 3 years, tumor volumes less than 30 cm^3, and in patients receiving at least 0.4 mCi/kg of ^{90}Y-labeled antiferritin antibody.[510] ^{131}I-tositumomab has also been studied in recurrent lymphocytic-predominant Hodgkin lymphoma.[511] More recently, ^{90}Y-anti-CD25 Mab therapy in patients with refractory and relapsed Hodgkin lymphoma yielded encouraging results with seven PRs and 12 CRs in 30 patients.[512]

A variety of radiolabeled antibodies have also been safely administered to patients with advanced acute leukemias and have been shown to have significant antileukemic activity and to enhance the antileukemic effects of SCT conditioning regimens (e.g., beta-emitting ^{131}I-anti-CD33, ^{90}Y-anti-CD33, ^{131}I-anti-CD45, and ^{188}Re-anti-CD66c) (eTable 22-10).[513] Radioimmunoconjugates that emit alpha-particles with a very short range (e.g., ^{213}Bi) may be most useful for low volume or microscopic residual leukemic disease.[78,514] Studies using RIT targeting the CD33 antigen, which is expressed on early myeloid progenitor cells and myeloid leukemia cells, have yielded promising results that may improve the efficacy of marrow transplantation. In a dose escalation trial of ^{131}I-murine anti-CD33 (M195) in patients with relapsed or refractory myeloid leukemias,[515] 8 of 24 patients treated with 50 mCi/m^2 to 210 mCi/m^2 in divided doses had sufficient marrow

eTABLE 22-10 Selected Clinical Trials Using RIT for AML and MDS

Author, Year	Agent	Phase of Study	Antigen	Isotope Dose
Schwatz,[515] 1993	^{131}I-M195	I	CD33	50 mCi/m^2-210 mCi/m^2
Burke,[519] 2003	^{131}I-M195, ^{131}I-Lintuzumab	I	CD33	120 mCi/m^2-230 mCi/m^2
Appelbaum,[183] 1992	^{131}I-p67	Pilot	CD33	110-mCi 330 mCi
Matthews,[520] 1999	^{131}I-BC8	I	CD45	76 mCi-612 mCi
Pagel,[522] 2006	^{131}I-BC8	I/II	CD45	102 mCi-298 mCi
Pagel,[524] 2009	^{131}I-BC8	I	CD45	246 mCi-1084 mCi
Bunjes,[770] 2001	^{188}Re-BW 250/183	I/II	CD66	10.3 GBq (mean)
Jurcic,[95] 2002	^{213}Bi-Lintuzumab	I	CD33	0.28 mCi/kg-1 mCi/kg
Rosenblat,[529] 2010	^{213}Bi-Lintuzumab	I/II	CD33	0.5 mCi/kg-1.25 mCi/kg
Jurcic,[97] 2011	^{225}Ac-Lintuzumab	I	CD33	0.5 μCi/kg-4 μCi/kg

AML, *acute myeloid leukemia;* BMT, *bone marrow transplantation;* BU, *busulfan;* CR, *complete response;* CRp, *complete response with incomplete platelet recovery;* CY, *cyclophosphamide;* DFS, *disease-free survival;* Flu, *fludarabine;* MDS, *myelodysplastic syndrome;* OS, *overall survival;* PR, *partial response;*TBI, *total body irradiation.*

No. of Patients	Results	Comments
24	CR in 3 of 8 patients receiving BMT	5 patients received autologous BMT; 3 received allogeneic BMT
31	24/25 evaluable patients had marrow remissions; long-term DFS in 3 patients	Used with BU/CY before allogeneic BMT
9	75% CR; 3 of 4 patients treated with therapeutic doses relapsed	Given with CY/TBI before BMT; many patients had unfavorable biodistribution
44	7 of 25 patients with AML or MDS had long-term DFS	Given with CY/TBI before BMT
46	3-yr DFS, 61%	Given with BU/CY prior to allogeneic BMT to patients in first remission
58	100% CR, 1-yr DFS, 41%	Given to older patients with advanced AML/MDS with Flu/low-dose TBI as part of reduced-intensity transplant
57	47% DFS at median of 26 months	Given as part of preparative regimen prior to BMT
18	14 patients had reductions in marrow blasts; no CRs	First demonstration of safety of α-particle therapy
31	2 CRs, 2 CRp, 2 PRs	Given after partial cytoreduction with cytarabine
18	10 patients with reductions in marrow blasts; 3 with ≤5%	

cytoreduction to proceed to BMT, and 3 of these patients achieved marrow remission, but 37% of assessable patients developed HAMA. ^{131}I-M195 (120 mCi/m^2 to 230 mCi/m^2) was combined with busulfan (BU) and cyclophosphamide (CY) in an effort to intensify therapy prior to first or second BMT.[187] All patients engrafted, and 18 achieved CRs. Six patients relapsed, and 10 patients died in CR of transplant-related complications.[187] HAMA occurred in 37.5% of evaluable patients. Next, a study was performed with ^{131}I-M195 (50 mCi/m^2 or 70 mCi/m^2) in 7 patients with relapsed acute promyelocytic leukemia (APL) in second remission following treatment with all-trans retinoic acid.[516] Two of 6 patients with detectable promyelocytic leukemia gene/retinoic acid receptor-α (PML/RAR-α) messenger RNA after all-trans retinoic acid therapy had negative reverse transcriptase-PCR determinations following ^{131}I-M195. Median disease-free survival was 8 months, which compared favorably with other approaches for the treatment of relapsed APL.[516] Because of the immunogenicity of the murine M195 antibody, a humanized M195 antibody was developed that had avidity 4 to 8.6 times higher than the murine antibody.[517] This humanized M195 (HuM195, also known as lintuzumab) was subsequently used in a Phase 1B trial,[518] in which patients with relapsed or refractory myeloid leukemia were treated at dose levels of 0.5 mg/m^2 to 10.0 mg/m^2 and patients received six doses over 8 days. Optimal biodistribution occurred at 3 mg/m^2, and HAMA responses were not observed.[518] ^{131}I-labed M195 and lintuzumab, its humanized counterpart, have been studied in combination with BU and CY as a conditioning regimen for allogeneic transplant. Absorbed doses to the bone marrow ranged between 272 cGy and 1470 cGy. Median survival was 4.9 months (range 0.3 to 90+), and 3 patients with relapsed AML have ongoing CRs at 59+ to 90+ months following BMT. These results demonstrate the feasibility of using radiolabeled anti-CD33 in combination with a standard BMT preparatory regimen, but randomized trials will be needed to determine whether or not there is a statistically significant benefit to intensified conditioning with RIT.[519]

Other encouraging results have been achieved using RIT targeting the CD45 antigen with ^{131}I-anti-CD45 (BC8 antibody) combined with CY and TBI as a marrow transplant regimen for acute leukemia and myelodysplastic syndrome (MDS).[520] Forty-four patients received a biodistribution dose of 0.5 mg/kg ^{131}I-anti-CD45, which delivered 6.5 cGy/mCi ± 0.5 cGy/mCi to the marrow, with a mean dose to the spleen of 13.5 cGy/mCi ± 1.3 cGy/mCi. Doses to liver, lung, kidney, and total body were significantly less, and 84% of patients had a favorable biodistribution of antibody, with higher estimated radiation absorbed doses to the marrow and spleen than to normal organs. Thirty-four patients received a therapeutic dose of ^{131}I-anti-CD45 labeled with 76 cGy/mCi to 612 mCi ^{131}I in addition to CY and TBI. The maximum tolerated dose delivered 10.5 Gy to the liver. Seven out of 25 treated patients with AML/MDS survived disease-free for a median of 26 to 100 months posttransplant, and 3 of 9 patients with acute lymphoblastic leukemia (ALL) were disease-free 34 to 82 months posttransplant. This study demonstrates that RIT with ^{131}I-anti-CD45 can be used safely to deliver additional targeted radiation to bone marrow (approximately 24 Gy) and spleen (approximately 50 Gy) when combined with CY/TBI.[520]

A subsequent study with this preparative regimen in patients with relapsed AML following first remission or advanced MDS suggested that marrow doses >7 cGy/mCi may lead to lower posttransplant relapse rates.[521] This was followed by a trial of ^{131}I-anti-CD45 combined with BU and CY in 49 patients with AML in first remission.[522] In this study, the estimated mean dose to marrow was 11 Gy with almost 30 Gy to spleen. The results were superior to that expected for treatment with BU and CY alone (≥30% relapse rate), with a relapse rate of only 20% and estimated 3-year disease-free survival after transplantation of 61%.[523] The use of ^{131}I-anti-CD45 as part of a reduced intensity conditioning regimen along with fludarabine and TBI (2 Gy) was also examined in 58 patients older than age 50 years with advanced AML and high-risk MDS. Eight-six percent of patients had more than 5% blasts at the time of transplantation. All patients attained remission. Seven patients died of nonrelapse causes by day 100. The probability of recurrence at 1 year was 40%, and the 1-year survival rate was 41%, suggesting that this approach warrants further study.[524] More recently, a pretargeting approach using an anti-CD45 antibody-streptavidin conjugate and radiolabeled DOTA-biotin has been studied in patients with high-risk acute leukemia or MDS undergoing allogeneic stem cell transplantation.[525] ^{90}Y- and ^{188}Re-labeled anti-CD66 have also been studied as part of a dose reduced conditioning regimen for patients ≥55 years of age with acute leukemia and MDS, with a cumulative risk of relapse of 55% at 30 months posttransplant.[526,527]

In an effort to overcome the limitations of using beta emitting radionuclides for the treatment of leukemia, alpha-emitting radioimmunoconjugates have been studied with promising results. Alpha-emitters have the potential to increase the efficacy of RIT, without the nonspecific effects of beta-emitting radionuclides and also have promise for treatment of patients in a minimal disease state. In an early study using an alpha-emitter, ^{213}Bi, was conjugated to lintuzumab. ^{213}Bi has a $t_{1/2}$ of 45.6 minutes and emits high LET alpha particles (8 MeV) with a path length of approximately 60 μm to 90 μm in tissue. Therefore, ^{213}Bi-labeled Mab can theoretically kill leukemia cells with one or two alpha-particles with minimal bystander effect. A Phase I dose escalation study at Memorial Sloan Kettering Cancer Center using ^{213}Bi-lintuzumab in patients with refractory and relapsed myeloid leukemias demonstrated rapid targeting of disease sites within minutes, with evidence of antileukemic effects even at low dose levels.[528] In a study of 18 patients with relapsed and refractory AML or chronic myelomonocytic leukemia treated with 37.0 MBq/kg of ^{213}Bi-lintuzumab, there was no significant extramedullary toxicity. The median time to hematological recovery was 22 days. Target-to-background and target-to–whole-body ratios were greatly enhanced compared to those seen with immunoconjugates using beta emitters in this patient population. With this therapy 78% of patients had a decrease in the percentage of bone marrow blasts.[78] When ^{213}Bi-lintuzumab was used sequentially with cytarabine in patients with AML, significant reductions in marrow blasts were seen at all dose levels. Among patients treated at the maximum tolerated dose or higher, responses were seen in 24%, with a median duration of 6 months.[529] With the further development of chelator chemistry for linking alpha-emitting radionuclides to antibodies, it has become possible to use other alpha-emitters, with longer half-lives, and potentially longer marrow residence times than that achievable with ^{213}Bi.

Use of actinium-225 (^{225}Ac) offers several advantages over ^{213}Bi, including a longer half-life (10 days). Additionally, intracellular decay of ^{225}Ac to short-lived therapeutic daughter alpha-emitters (^{221}Fr, ^{217}At, ^{213}Bi) significantly increases the effectiveness of ^{225}Ac as compared to ^{213}Bi constructs.[530] A Phase I trial investigating the use of ^{225}Ac-lintuzumab for patients with relapsed and refractory AML was conducted in 18 patients with relapsed or refractory AML. Dose-limiting toxicity was prolonged myelosuppression, and there was no evidence of radiation-induced nephrotoxicity, despite the known uptake of free ^{213}Bi by the kidneys. Bone marrow blast reductions were seen in 10 of 15 evaluable patients (67%), including three patients who achieved marrow blast

reductions to 5% or less.[531] ^{225}Ac-lintuzumab is now being investigated in a multicenter Phase I/II trial in combination with low-dose cytarabine for older patients with AML.

The use of alpha-particle therapy may play a role as conditioning for SCT as well. Investigators at the Fred Hutchinson Cancer Research Center studied ^{213}Bi-labeled Mabs against CD45[532] and the T-cell receptor (TCRαβ)[533] before DLA-identical SCT in a canine model. Administration of both constructs along with additional immunosuppressive agents resulted in engraftment of transplanted marrow and stable mixed chimerism. Transient myelosuppression and liver enzyme abnormalities were observed. In similar studies, dogs receiving ^{213}Bi-anti-CD45 Mab achieved a high level of donor chimerism after receiving haploidentical grafts.[534] The use of ^{213}Bi for this application in humans may be limited by the high activities required to attain engraftment, as well as the short half-life and the need for an on-site generator to prepare drug immediately prior to administration. Subsequently, these investigators have shown in preclinical models that ^{211}At-anti-CD45 can produce sufficient immunosuppression to allow stable long-term engraftment in a canine SCT model.[535] Additionally, ^{211}At-labeled anti-CD25 and anti-CD30 Mabs are being studied as potential new antileukemia therapeutics, which have the additional advantage of being expressed by a high proportion of targeted neoplastic cells, but not normal resting cells.[536,537]

TOXICITIES ASSOCIATED WITH TaRT AND METHODS TO AMELIORATE THESE EFFECTS

There are a number of well-established factors that influence radionuclide toxicity. Among these are genetic makeup, immune factors, physiologic conditions, age, gender, radionuclide characteristics, dose rate, heterogeneous dose distribution, other prior and concomitant therapies, recovery from prior therapy, and radioprotector/sensitizer use. Many of these have been discussed in more detail in prior reviews.[538-540]

Bone marrow suppression has been the primary dose-limiting toxicity of most conventional systemic and IP TaRT. That is changing, however, with the increasing use of small molecule radionuclide delivery. Among multiple factors that may influence the extent and duration of myelosuppression, marrow reserve, recovery from prior therapy, and radioconjugate stability appear to be predominant determinants of this effect.[541,542] Hematologic support with transfusions and growth factors has been helpful, and bone marrow or peripheral stem cell reinfusion has allowed dose escalation of radioconjugates to at least three-fold over the dose that resulted in dose-limiting hematopoietic toxicity.[478] Interleukin-1 and GM-CSF have been reported to have radioprotective effects on the hematopoietic system.[543,544] The adjuvant use of these cytokines with TaRT has resulted in modest protection. Additionally, the radioprotector, amifostine, has been helpful in preclinical radionuclide studies, for the therapy of thyroid disease with ^{131}I,[545,546] and for reduction of renal toxicity from small molecule conjugates.[547] Similar effects with other radioconjugates are expected, but this potential effect has not yet been well studied. Adjuvant use of chelating agents in combination with unstable metal radioconjugates can help to minimize toxicity, but some have had only a minor protective effect on myelosuppression when used with stable chelators.[316,548,549] In addition to chelators that remove unbound radioactivity from the blood, "chasing" the radiolabeled antibody with a second unlabeled antibody directed against the radiolabeled antibody, has been reported to modestly decrease toxicity.[550] Pretargeting approaches, which dissociate and delay the delivery of the radionuclide from that of the targeting agent, can decrease toxicity and are discussed in more detail in the "Optimization" section. Although the second dose-limiting organ toxicity for myeloablative TaRT may vary with radionuclide, cardiopulmonary and liver toxicity has been reported for ^{131}I and anticipated for ^{90}Y immunoconjugates, respectively.[83,436,551]

The importance of stable chelators also impacts other potential toxicities as demonstrated with alpha-emitters. Renal accumulation leading to nephrotoxicity has been noted from a ^{212}Bi conjugate with an unstable chelator and may be dose-limiting for some applications. This was reported by Macklis et al after IP administration of ^{212}Bi-anti-Thy 1.2 IgM conjugate to mice with EL-4 tumor cells.[87] In the Macklis study, 8% of the injected radioactivity was in the cardiac blood pool by 2 hours and accumulation to kidneys was similar to that of free ^{206}Bi, indicating instability of the ^{212}Bi conjugate with the DTPA chelator. Subsequently, nephrotoxicity has been reduced with stable chelate-conjugates, including clinical experience in patients with AML receiving up to 1 mCi/kg ^{213}Bi.[78] Additionally, nephrotoxicity resulting from free ^{213}Bi could be mitigated by the use of adjuvant agents, including dithiol chelators and renin-angiotensin-aldosterone system inhibitors, as demonstrated in preclinical models.[552,553]

Acute symptoms from systemic RIT are usually related to administration of antibody products, not the radioactivity. The symptoms have usually been mild and have included rash, fever, chills, myalgia, diaphoresis, pruritus, nausea, vomiting, diarrhea, nasal congestion, and hypotension.[554] These side effects are transient and usually respond to antihistamines, acetaminophen, and nonsteroidal antiinflammatory agents. Rarely, more severe symptoms including rigors, bronchospasm, or laryngeal edema have been noted. These often respond quickly to steroids, antihistamines, oxygen, and meperidine. With CNS administration, various transient symptoms have been described, which are usually mild but can include cerebral edema, nuchal rigidity, aseptic meningitis, increased intracranial pressure, and seizure. Steroids have usually ameliorated these symptoms. A serum sickness type phenomenon has been commonly observed with IP administration of murine antibody conjugates (affecting about one third of patients), but is rare among patients receiving intravenous RIT, even with the same radioimmunoconjugate. Serum sickness–like symptoms occur about 2 weeks after treatment and may persist more than a week. Variations in the manifestation of symptoms may depend, in part, on the particular radioimmunoconjugate used because skin rash has been noted by the Hammersmith group, whereas fever with joint or muscle aches, but no rash, has been common among patients treated at the University of Alabama at Birmingham with a different radiolabeled monoclonal antibody.[399,555]

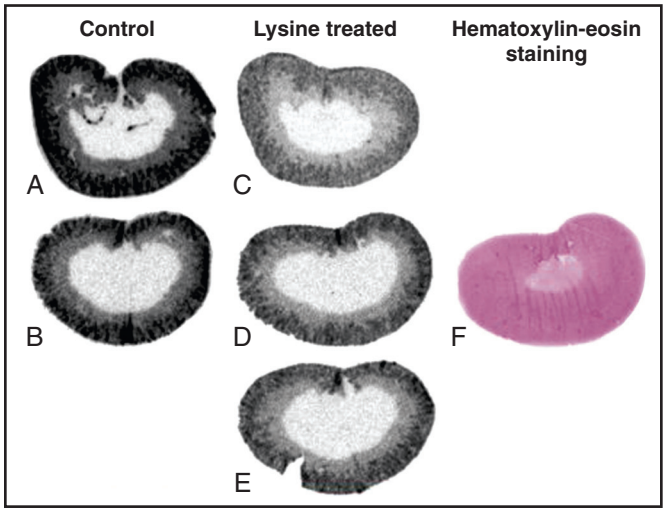
Other acute effects can include a temporary increase in bone pain for radionuclide targeting of bone metastases, as well as gastrointestinal disturbance, which usually manifests as nausea. Nausea has been more commonly associated with peptide receptor radionuclide therapy (PRRT) than conventional RIT. However, nausea from PRRT may be more related to the amino acid infusion given to reduce renal toxicity than to the radionuclide therapy itself. The targeting of receptors along the gastrointestinal tract may also contribute to nausea in PRRT. Nausea and vomiting can occur after oral ^{131}I as used in thyroid ablation or treatment of metastatic disease sites. ^{131}I therapy can also lead to sialadenitis, taste changes, transient swelling and pain at sites of metastasis, ocular dryness, nasolacrimal duct obstruction, and bone marrow suppression.[556] Radiation sickness has been reported with doses in excess of 300 mCi.[557] There are various reports concerning how fertility is impacted by the ^{131}I thyroid therapy. Short-term gonadal function may be impaired and the incidence of miscarriages

increased but there appears to be no increase in malformed offspring.[558,559] Also, the risk for development of certain malignancies shifts after ^{131}I thyroid therapy, with increases for some organs with excess exposure such as stomach and salivary glands but decreases for cancer of lung and cervix.[556,560]

In TaRT using small molecules such as peptides or radionuclide conjugates used in pretargeting approaches, kidney and bladder usually receive much higher doses than other normal organs. For these therapies, renal, rather than bone marrow toxicity can be dose-limiting.[10,48,53,55] Fractionated radionuclide delivery may reduce toxicity and increase efficacy.[10,14,561] Limited clinical studies as well as radiobiologic considerations of fractionated TaRT have been reviewed elsewhere.[210] Fractionation of dosing has been helpful for decreasing toxicity associated with peptide-radionuclide therapy and has been investigated in other TaRT applications.[210] Acute symptoms from PRRT are often related to adjuvant agents (amino acids with amifostine) used to decrease renal toxicity, rather than "foreign substance reaction" that may occur with larger immunoglobulin products. The nausea and vomiting commonly associated with use of the adjuvant agents may be ameliorated with antiemetics and other measures.

The importance of dose rate in urinary tract (renal and bladder) toxicity is suggested by early experience with PRRT and in patients with myeloma receiving holmium-166 (^{166}Ho). Although the calculated renal dose from high dose ^{166}Ho-DOTMP was only 710 cGy when 40 Gy was delivered to marrow, 30% of patients experienced grades 2 to 4 renal toxicity, with severe thrombotic microangiopathy. The risk of hemorrhagic cystitis was decreased by continuous bladder irrigation during the ^{166}Ho infusion.[562]

Unexpected rates of renal toxicity were also noted in early use of PRRT. Although the mean renal doses were well below tolerance limits for fractionated external beam radiation, the rapid accumulation of the radioactivity in the renal cortex, resulted in higher doses in that area, that were delivered at a relatively high dose rate. Further study has shown that renal toxicity of PRRT is associated with risk factors such as prior renal insufficiency and diabetes, whereas adjuvant infusion of amino acids and amifostine can help to prevent toxicity.[55,72] Incorporation of "protective" measures in PRRT regimens has allowed escalation of the fractionated radioactivity administered by as much as 50%.[547] The impact of the administration of lysine was shown in an animal study directly comparing autoradiographs of the same radionuclide conjugate with and without amino acid infusion (see eFigure 22-1, available in the expanded chapter on the Expert Consult website).[563] A 40% reduction of ^{111}In-octreotide accumulation in rat kidney was obtained in animals treated with either intravenous or oral lysine compared with controls. A similar illustration of the impact of lysine administration is demonstrated in single photon emission tomography (SPECT) images of a patient by Valkema et al.[547,563] Other efforts to understand and ameliorate the problem of renal toxicity by more accurate prediction of dose parameters includes publication of six age-dependent Medical Internal Radiation Dose (MIRD) Committee models that allow subregion radionuclide dose calculation,[564] a continuing education session at the 2003 Society of Nuclear Medicine Meeting from which contributions have been published, and MIRD suborgan modeling.[565,566] MIRD #20 examines renal toxicity from radionuclide therapy by modeling effects of (1) dose rate (BED), (2) heterogeneity of activity distribution over time, and (3) correlation of absorbed radiation dose and BED with observed clinical toxicity. The impact of application of patient specific dosimetry on renal toxicity is illustrated by Barone et al.[567]



Nonsystemic administration of radionuclides has been associated with other types of toxicity, dependent on the site of administration and other factors. Late bowel toxicity after IP RIT has been infrequent, which is an advantage compared with nonspecific radionuclide therapy (e.g., ^{32}P chromic phosphate solution). However, the most severe toxicities of ^{32}P therapy includes fibrosis and necrosis of bowel or body wall, and are the result of misplacement of the therapeutic agent into bowel lumen, loculation sac, or body wall rather than the IP space (FDA Medwatch). Even with proper administration, there has been an increased risk of bowel complications compared to chemotherapy, especially among patients who also received external beam radiation to the pelvis. Although nearly three quarters of postsurgery patients with ovarian cancer receiving 15 μCi ^{32}P IP in an early GOG trial (#7602) reported no side effects, some of the remaining patients had mild to moderate gastrointestinal symptoms. One developed bacterial peritonitis and four developed bowel obstruction.[568] A later GOG study compared cyclophosphamide/cisplatin to IP ^{32}P after surgical debulking. More patients treated with ^{32}P as compared to chemotherapy had bowel problems. Some had suboptimal distribution of the radionuclide within the peritoneal cavity with areas of loculation and likely would not currently have been considered candidates for IP therapy.[569] With targeted therapy using antibody carriers for radionuclides and pretreatment scans to rule out loculation, severe bowel toxicity has been infrequent.[309,310,570] In >90 patients treated at the University of Alabama at Birmingham with IP ^{90}Y- or ^{177}Lu-CC49 antibody therapy for relapsed ovarian cancer, no incidences of bowel toxicity severe enough to require surgery were observed, although a portion of patients who underwent surgery for recurrent disease were found to have areas of palpable fibrosis.[571] Specimen analysis after IP alpha-emitter administration has not shown tissue changes and early clinical experience with alpha-emitter conjugates have not reported peritoneal toxicity.[572-574]

^{32}P has also been injected into malignant lesions and other cavities, such as the pleural space for treatment of malignant effusions, and intraarticular spaces for hemarthoses.[557] Relatively high concentrations of ^{32}P injected directly into malignant lesions have been well-tolerated locally and have occasionally resulted in dose-limiting toxicity in other organs such as stomach and lungs from shunting. To overcome this potential hazard, pretreatment scans have been obtained to assess trace radionuclide distribution prior to administration of a therapeutic dose.[575] ^{32}P injected directly into subcutaneous nodules and pretargeted interstitial administration of ^{90}Y-radionuclide into more diffuse areas of chest wall recurrence of breast cancer have been well-tolerated.[576] In contrast, accidental delivery of radionuclide to subcutaneous tissues from intravenous infiltration has resulted in local necrosis.[577] ^{32}P applied as a skin patch for treatment of basal cell carcinoma has been well-tolerated and effective.[578]

Higher concentrations of beta- and alpha-emitters have been injected into glioma cavities than could be tolerated systemically with infrequent reports of severe toxicity.[91,577] Edema and seizures are the most common adverse events reported. Intrathecal radionuclide therapy has resulted in aseptic meningitis and occasion seizure activity.[580]

There are a number of other organs at risk for toxicity that have not been extensively addressed. For instance, cataracts would be anticipated as a risk after high dose total body radiation based on external beam data but have not been reported in long term follow-up studies.[581] Lung fibrosis is of concern for ^{131}I therapy of lung metastases and is under study in animals after plutonium inhalation.[582,583] Animal model radium inhalation studies have shown an increased risk of lung cancer that is enhanced by smoking.[584]

Thus far, late organ dysfunction following RIT with ^{131}I-labeled antibodies has been uncommon except for

eFigure 22-1 Ex vivo autoradiograms of renal tissue slices of control rats (**A** and **B**) and lysine-treated rats **(C-E)** 24 hours after injection of [^{111}In-DTPA]-octreotide, 3 MBq/0.5 μg. Greatest reduction of renal radioactivity was seen in rats treated with intravenous lysine coninjected with tracer **(C)** or lysine (400 mg/kg) orally 60 minutes before tracer **(D).** Increasing the interval between oral lysine (400 mg/kg) and tracer to 120 minutes **(E)** did not lead to greater renal reduction. **(F)** Hematoxylin- and eosin-stained section adjacent to **D** shows high uptake of radioactivity in cortex and outer medulla but almost no uptake in inner medulla.

abnormal thyroid function.[441] Despite measures to block thyroid uptake, elevated thyroid-stimulating hormone levels occurred in 59% of patients treated with myeloablative doses of ^{131}I-anti-CD20 antibodies, at a median of 6 months after treatment.[441] Some patients who received nonmyeloablative doses of ^{131}I have also had elevated thyroid-stimulating hormone levels at later times. Salivary gland inflammation and damage can be an acute or late toxicity. Parotiditis, which may result in xerostomia, has been more common with treatment of thyroid cancer than high dose radioconjugate therapy. However, this remains a potential toxicity of ^{131}I-antibody therapy.[585]

Risk of a second malignancy is of concern even if it has not been noted for any particular radionuclide therapy. A small percentage of patients treated with high-dose RIT for lymphoma have developed second malignancies. Myelodysplasia is the potential TaRT treatment related toxicity of most concern in the treatment of hematologic malignancies. Some lymphoma patients who were diagnosed with myelodysplasia after TaRT had evidence of dysplasia prior to radionuclide therapy.[449,586,587] These patients were also considered at increased risk for myelodysplasia because of prior alkylating agents with or without conventional external beam radiation. The risk of second malignancy for RIT lymphoma patients has been modest at 0.5% a year compared to that of patients with neuroendocrine tumors receiving ^{131}I-metaiodobenzylguanidine (MIBG).[499,588] Leukemia risk for adults treated with ^{32}P for polycythemia appears dose related whereas leukemia has been noted after lower doses (0.6 mCi to 1.5 mCi) of intraarticular ^{32}P administration in children (FDA Medwatch).[589] Second malignancies will be especially of concern as more radionuclide therapy is developed for children (e.g., MIBG, ^{90}Y-Ibritumomab) because an age effect in malignancy induction has been noted for thyroid cancer and other malignancies after ^{131}I exposure and MDS has been observed after MIBG (BEIR).[590]

DOSIMETRY

Dosimetry is the process of relating the administered amount of radioactivity to the absorbed radiation dose in tumors, organs, or the whole body. Dosimetry is important for dose correlation with clinical results, and in some instances, for treatment planning to avoid excess toxicity. In general the doses calculated for TaRT are less accurate than for external beam radiation therapy for a variety of reasons. These include limited radiation dose input data (e.g., few sample points for a therapy using continuous exponentially decreasing irradiation), inhomogeneous dose distributions, and the assumptions/calculation methodology used to estimate TaRT absorbed doses.[591] Dose calculation is also more complicated for internally distributed radionuclides than for external beam irradiation. Alpha particle dosimetry adds the complication of decay scheme cascade and daughter products that may have a different distribution than the parent radionuclide.[77,592,593] Additionally, the higher relative biologic effectiveness (RBE) delivered by alpha- compared to beta-radionuclide therapy needs to be considered.[594] Data required for TaRT dose estimate calculations include the mass of tumors and normal organs, the cumulative radioactivity taken up by organs and tumors, and the pharmacokinetics of the administered radioactivity.[595] Data is usually acquired by serial gamma camera imaging. Bone marrow dose estimates are based on imaging studies of bony regions of active marrow such as the spine or blood pharmacokinetics.[596-598]

Bremsstrahlung images from radionuclides that do not have gamma emissions are generally of suboptimal quality, making accurate quantitation difficult. However, progress with sophisticated methods has provided good images that have been useful for dose estimates.[599] As an alternative appropriate for many circumstances, estimates are often made for nongamma-emitters from tracer studies using a gamma-emitter that has a similar chemistry to that of the therapeutic radionuclide. Because animal studies have shown that the biodistribution is similar, although not usually identical, for ^{111}In and ^{90}Y, tracer/dosimetry studies with ^{111}In-labeled antibody have frequently been performed in conjunction with ^{90}Y-labeled antibody therapy to estimate the subsequent biodistribution/dosimetry of the ^{90}Y-immunoconjugate.[83,600,601] Quantitative immuno-PET with ^{89}Zr-labeled antibody has shown good correlation with ^{111}In-labeled antibody biodistribution and may be useful as a positron-emitting surrogate for ^{90}Y-labeled antibody therapy.[602] Position emission tomography (PET) scanning with ^{124}I-labeled conjugates can be useful for radionuclide dosimetry.[603,604] PET images from ^{89}Zr-cG250 antibody have been superior to those of ^{111}In-cG250 antibody in an animal model and compare favorably with ^{124}I.[605,606] Other examples include use of ^{99m}Tc-antibody for imaging/dosimetry studies in conjunction with ^{186}Re-antibody therapy.[607] Another variable in estimating the expected dose from therapeutic TaRT using a preliminary biodistribution/dosimetry is that even when a small amount of a therapeutic agent is used, the correlation between doses predicted and later delivered has ranged up to ~30% between estimated absorbed doses for the two procedures in the same patient.[162,436,551,608] With continued progress in refinement of methodology, improved correlation is anticipated. For instance, quantitative SPECT reports accuracy within 5% to 15% for diagnostic or therapeutic levels of radionuclide.

For many dose estimates, conjugate views of the whole body and regions of interest (ROI) (e.g., tumors and normal organs such as liver) are obtained.[596] The activity for each ROI is measured from the counts in that region at multiple time points. The counts in each ROI are corrected for background. Attenuation correction factors are calculated for each patient and a sample of the administered radionuclide is used for calibration so that counts per minute can be converted to units of radioactivity (mCi or MBq). Scatter correction may also be applied. SPECT for ROIs can provide superior definition and quantitation.[609] Despite expansion of this technology, SPECT has not yet become the standard for most quantitation as it is more time consuming than planar conjugate view methodology.[610,611] Absorbed radiation doses can be calculated from radioactivity quantitation and the specific absorbed fraction for the target. The specific absorbed fraction takes into account the type and energy of radiation emissions, the fraction of energy from the source absorbed by the target and mass of the target.[612] The mass of each ROI is usually determined by estimating volumes from computed tomography, MRI, or other methods such as 99mTc-sulphur colloid liver scans, and converting volume to mass by assuming a unit density of 1 g/mm^3 for most soft tissues. Accounting for excretory routes is needed in quantitating changes in radioactivity distribution over time. For radionuclides such as ^{131}I where the major route of excretion is renal, urinary activity measurements can provide an estimate of total body clearance if it is not feasible to obtain whole-body counts.

The MIRD Committee is one entity that provides guidance for methods to calculate radiation absorbed dose estimates for the whole body and organs.[613] This methodology has been adapted for TaRT, with continuing effort by this committee and others to further improve the models and methods available.[564,595,598,609,613-624] A Java applet was created, in collaboration with the MIRD Committee to provide worldwide access (http://mirdcell.njms.rutgers.edu/) to new software that facilitates multicellular dosimetry and biological-response modeling. In addition to MIRD publications and information

posted through the SNM.org website, other informational publications, websites, and computer programs have been developed to assist with dosimetry calculations.[624-627] Among websites available, www.doseinfo-radar.com was developed to provide information in a number of areas including standardized dose estimates, decay data, and absorbed fractions. With fusion of anatomic and physiologic images, dose estimates can be calculated in three dimensions at the voxel level, taking into account heterogeneity of radioactivity distribution within an organ.[628-633]

The relationship between outcome and radiation dose-related factors has been variable, with some studies showing a strong correlation, whereas others show no correlation.[639-642] Some of the factors making it more difficult to establish a dose response relationship for TaRT, as compared to external beam radiation therapy, may include relative uncertainty associated with TaRT dose calculations, the heterogeneity of dose deposition that occurs with TaRT, dose rate effects, and agent/patient variation in excretion/clearance. Whereas most normal organ tolerance levels for external beam radiation have been established using high dose rate radiation, and vary as a function of fraction size, the dose rate is often low and variable with TaRT, limiting the validity of extrapolating from high dose rate tolerance levels to those expected with TaRT. Fractionation of TaRT, as with external beam, can increase the total radionuclide dose tolerated.[53,210] Several studies have demonstrated how biologic factors affect tolerance but are not accounted for in standard dose/toxicity reporting. Many of these have been summarized in a review.[539] Improved dose/toxicity correlations for marrow suppression has included adjustment of calculated absorbed marrow dose for levels of a biomarker involved in hematopoiesis, as well as cellularity and patient specific marrow mass.[542,643,644] Although data suggests the presence of a relationship between TaRT radiation dose and tumor response, early analyses with relatively small numbers of patients receiving a limited dose range fail to show strong correlation between these two factors.[611,645] As dosimetry accuracy has improved and nondosimetry factors (that affect biologic response) have been considered, better correlation has been observed between dose delivered and tumor control.[639,646] Despite the progress toward improving accuracy of dosimetry and need for individualized dose administration,[603,611,647-651] most studies are still being done without required organ or tumor dosimetry in the nontransplant setting. Activity is usually given per kg or per square meter as is common with chemotherapy. For one of the FDA-approved agents (^{131}I-tositumomab), whole body effective half time is used to individualize administered activity, but no organ or tumor dosimetry is required.[647] As better correlation is achieved between dosimetry results and clinical outcome, additional tumor dosimetry may be required, as has usually been needed for high-dose therapy followed by stem cell rescue.[652-654] Individualized kidney dosimetry has been important in predicting toxicity of PRRT.[655] Like marrow dose versus toxicity studies, adjustment for diseases, conditions, and factors that influence kidney function such as hypertension have resulted in better correlation of calculated kidney dose and renal toxicity in peptide TaRT therapy.[648]

OPTIMIZATION OF TaRT

Encouraging results have been obtained in TaRT studies using a variety of targeting agents, radionuclides, and study designs.[14] The success with lymphomas has spurred much investigation to further optimize this form of therapy in NHL and other malignancies, including use as consolidation.[6,133,476,499,656-658] Although much progress has been made, especially in reducing immunogenicity of antibody-derived targeting, adding nonantibody-targeting agents and improving radionuclide conjugate chemistry, many challenges remain.[66,476] Information about overcoming some of the challenges has been included in the "Solid Nonhematologic Tumor" section.

One of the main limitations of systemic TaRT has been the low uptake of radioactivity (generally <0.001% ID/g) in tumors. This low uptake is affected by such factors as tumor vascularity, size, charge, affinity and avidity of the targeting agent, and the interstitial pressure in tumors.[659] The use of small targeting agents may improve tumor penetration with more rapid tumor uptake but are generally limited by a relatively short retention time/half life.[660,661] Other approaches for increasing tumor uptake of radiolabeled antibody include the use of external beam therapy to increase vascular permeability and expression of target antigens.[324,662] In patients the combination of external beam therapy with TaRT increased the objective response rate of liver tumors to RIT and was well tolerated in the setting of relapsed/refractory B-cell lymphoma with 11 of 13 patients treated achieving a complete response.[663] This combined approach has used both local as well as TBI in stem cell rescue studies during which radiolabeled antibody was still circulating.[308,334] In head and neck cancers, RIT has been combined with proton therapy in preclinical studies.[664] The use of hyperthermia and vasoactive cytokines such as IL-2 and tumor necrosis factor have also resulted in higher tumor uptake of radiolabeled antibody in early studies.[665-668] Of note, hyperthermia can have multiple effects including increased antigen expression, direct cytotoxic activity, inhibition of radiation repair at medium and low dose rates, and reduced interstitial fluid pressure.[669-672] Neovascular targeting is also a promising approach to use in combination with TaRT (e.g., upregulated receptors on new tumor vessels).[60,272,673,674] Antiangiogenic agents can also be combined with TaRT.[64,274] For example, a selective peptide agonist of humanC5a, given before and after radiolabeled antibody therapy to increase vascular permeability of tumor capillaries, improved the therapeutic outcome of TaRT in xenograft tumors,[276] and combining bevacizumab with ^{131}I-labeled anti-CEA antibodies significantly improves treatment response in a mouse model of medullary thyroid cancer.[394] Fractionation of TaRT dosing has generally been favorable in many preclinical investigations and in limited clinical experience.[3,210,675] However, more study is needed as some preclinical studies have shown decreased vascular permeability with fractionation, which could have a deleterious effect.[676] As previously discussed, high-affinity antibodies have been reported to improve antibody uptake, but not necessarily intratumor distribution, and in some cases high-affinity antibodies have produced a more favorable therapeutic ratio. Clinical trials using high affinity antibodies have been performed for cancer of the colon, breast, prostate, lung, and ovary.[161,162,677,678] Targeting may also be enhanced by increasing antigen expression on target cells.[679] Several studies show that interferon can increase the expression of some common tumor-associated antigens including CEA, TAG-72, and an antigen expressed on melanomas.[680,681] Applications of this approach in vivo using human tumor xenografts in mice have shown greater tumor growth inhibition with interferon administration before RIT compared to similarly treated mice without interferon.[264] Human tumor biopsy material has also confirmed increased antigen expression following interferon administration. Benefit from adjuvant interferon in clinical trials has been difficult to demonstrate. Potential benefit may be inferred because increased tumor antigen expression was demonstrated by biopsy, and imaging of antibody localization in known sites of disease was improved by interferon compared to results obtained in other trials with similar radiolabeled antibody that did not use interferon.[268,679] Targeting of two antigens with separate antibodies

Biopsy results are infrequently used for as a sole measure for dosimetry. Although biopsy provides a direct measurement and can be used for autoradiography, it is invasive, and not practical for most tumor or organ dosimetry. Biopsy data is of interest to correlate with other methods of dosimetry, but it is often of limited value alone because of the small sample size, which may not be representative, and is usually only done once. Thus biopsy dosimetry usually does not allow a time-activity curve to be generated. However, the development of alpha cameras now allows activity over time to be measured.[628,630,634-636] Implanted thermoluminescent dosimeters (TLD) and other devises have also been used for quantitation in experimental preclinical studies and in limited clinical trials.[637] When used in patients with ovarian cancer treated with intraperitoneal TaRT, TDL-obtained dose measurements were in the range of those estimated with other methods.[607] As with biopsy, TLDs provide a direct measurement of absorbed dose but also usually require an invasive procedure for placement that has the disadvantage of potentially introducing a sampling error. Like most other dosimetry methods, TLDs do not account for dose rate, which may be an important determinant of dose response relationships. Another implantable dosimeter has been developed and applied to external beam radiation that can give real-time wireless feedback to a computer. This technology should be applicable to radionuclides but, similar to TLDs, will only provide data from a small area.[638]

As experience grows and dosimetry techniques improve, insight may be provided for tolerance of new agents that become available. An example is the marrow studies pertinent to alpha-emitter ^{223}Ra.[630]

is also promising. Studies of unlabeled veltuzumab, a humanized anti-CD20 antibody, combined with ^{90}Y-epratuzumab, an anti-CD22 antibody, enhances the therapy response of lymphoma in mouse studies, and this has progressed to clinical trial, where it has been well tolerated in the initial Phase I experience.[682,683] Use of the nonidentical unlabeled antibody may promote apoptosis in conjunction with the radiolabeled antibody, but eliminate the potential for competition between additional unlabeled antibody when using the same antibody for unlabeled predose and as a radionuclide conjugate.[682] Although not a mechanism to increase uptake, removal of unbound radiolabeled agent decreases toxicity and can allow dose escalation.[684]

Several pretargeting methods have been proposed to overcome some of the limitations of conventional one-step TaRT where prolonged radiation exposure of the bone marrow results in dose-limiting marrow suppression.[685,686] As previously mentioned, pretargeting approaches dissociate the delivery of unlabeled antibody, or other targeting entity, from the delivery of the radionuclide. Ideally this approach delays the delivery of the radioactivity until the ratio of tumor-bound to nontumor-bound targeting agent has reached its maximum. Because the radionuclide is usually given conjugated to a small hapten that interacts with the targeting entity, any nonbound radioactivity will clear quickly because of the small molecular weight of the radionuclide conjugate. Thus, the pretargeting approach has the potential to improve tumor-to-normal tissue ratios several fold over that achieved with directly labeled antibodies by minimizing circulation time of unbound radionuclide. Proof-of-principle of the pretargeting approach has been established in multiple preclinical and early phase clinical trials while studies continue for further optimization.[48,378,385] Application of pretargeted radioimmunotherapy in a high-risk group of patients with medullary thyroid cancer improved survival compared to contemporaneous untreated controls.[393] A recently reported Phase II of pretargeted radioimmunotherapy in a similar population showed rates of disease control rates over 75% but with a 54% rate of grade III/IV hematologic toxicity, which was more pronounced in patients with diffuse bone marrow involvement.[394]

In an effort to increase the efficacy of TaRT in relatively radioresistant malignancies, TaRT is being studied in conjunction with other agents or therapies (e.g., external beam radiation that may increase targeting by affecting tumor vasculature while causing G_2/M arrest in a radiosensitive phase of the cell cycle). With G_2/M arrest during this radiosensitive phase of the cell cycle, tumors will receive prolonged low dose rate radiation from radionuclide emissions associated with TaRT. Other approaches include the use of radiosensitizers and radioprotectors,[724] but these combined modality approaches have generally not been optimized (e.g., dose sequence and timing).[725] Optimization of these regimens may vary with tumor and radionuclide systems.[726-731] Polyethylene glycol (PEG) modification of targeting agents is an example of an optimization strategy under study that provides multiple carrying sites for molecules such as radiosensitizers.[732,733] TaRT has been studied in combination with a variety of agents including the radiosensitizer SR2508, intercalating agents, and the hypoxic cytotoxin, SR 4233 (tirapazamine).[671] A variety of chemotherapy agents have also been studied as radiosensitizing agents in conjunction with TaRT.[296,303,312,728,734,735]

The taxanes radiosensitize tumors by arresting cells in the G_2/M cell cycle phase and have demonstrated synergistic effects in preclinical TaRT studies. Subsequently, they have been studied in clinical trials in combination with TaRT.[309,725] Cisplatin has also been shown to have a supraadditive effect in combination with low dose rate radiation and has been systematically studied with TaRT in murine xenograft model.[728,736] Buchsbaum et al have reported increased growth inhibition in human tumor xenografts in nude mice when bromodeoxyuridine, which is incorporated into the DNA in place of thymidine, was given for 4 days with a 1 day washout before RIT.[301] Tirapazamine-potentiated cytotoxicity by RIT in mice with human tumor xenografts.[304,671] Caffeine as well as poly ADP ribose polymerase (PARP) inhibitors have also been shown to modulate sensitivity to RIT in a variety of cell lines.[108,737,738] Although sensitization may be achieved with low doses of adjuvant agents, it has been feasible to use nearly full doses of each agent with acceptable toxicity in some trials.[309,316] Patients with recurrent glioblastoma were given the combination of locoregional pretargeted TaRT with temozolomide without significant neurologic toxicity or severe hematologic toxicity.[739]

At the preclinical level, gene therapy can enhance the efficacy of TaRT. Gene transfer methods have been used to genetically induce tumor cells to express enhanced levels of cell surface tumor-associated antigens or receptors, which have resulted in increased tumor uptake of radiolabeled antibody or peptides in animal models.[740] This approach could potentially result in enhanced therapeutic efficacy.[741] There is also the potential to use gene transfer techniques to radiosensitize tumors by knocking out genes involved in DNA repair, signal transduction, and control of the cell cycle that would result in sensitization of tumors to TaRT. Alternatively, gene therapy may be used to provide radioprotection of bone marrow. The combination of toxin-gene delivery and TaRT also offers the potential for improved therapeutic efficacy.[740] For example, specific genes can be targeted with short range radionuclides such as Auger emitters as demonstrated by ^{125}I-labeled triplex forming oligonucleotides.[742]

FUTURE CONSIDERATIONS

TaRT is a promising therapeutic modality and ongoing work in this area will result in expansion of indications and improved efficacy. In addition to acceptance of TaRT as a component of the standard armamentarium for lympho-hematopoietic malignancies, its efficacy for selected nonhematologic entities is continually being improved. It is expected that for many diseases, TaRT will be most useful as a component of multimodality therapy.[96,312,469,491] Future studies should define how to optimally combine TaRT with other therapeutic modalities. More investigation is needed to determine agents/schedules that result in synergistic antitumor activity without significantly greater toxicity. TaRT has been useful both as a component of early therapy, and as a salvage therapy (e.g., improved survival of patients with glioma).[743] It is also being studied in lymphoma as an adjunct to other agents in an effort to further improve therapeutic outcome.[469,499] Active areas of investigation include studies of TaRT using alpha particles, small non-antibody targeting agents, gene therapy, and other approaches for increasing tumor uptake of radionuclide and enhancing efficacy.[276]

A number of pretargeting designs have been devised and others are in development.[687-689] To date, the most popular are based on the use of bifunctional antibodies or biotin-streptavidin interactions, with these components complexed to a targeting agent and radionuclide.[8,378] Less common pretargeting approaches include the use of antibody-oligonucleotide conjugates, a prodrug/enzyme strategy, and DNA/DNA systems.[690,691] Other mechanisms that allow for amplification/enhancement of targeting are under study.[689,692] Common to all methods is the desire for (1) high specificity and retention of the targeting agent, without shedding or internalization, (2) high specificity of the radionuclide conjugate for the bound targeting agent, and (3) rapid clearance of radionuclide that does not localize to target.

Bifunctional antibodies have been constructed by cross-linking Fab' fragments from two antibodies that have different specificities.[388,693-695] For RIT, one end of a bifunctional antibody contains an unlabeled fragment directed toward a tumor-associated antigen/receptor, whereas the other binding site reacts with a hapten linked to a radionuclide. Sharkey et al have designed a "universal" system by making one Fab' fragment specific for the chelating agent that is conjugated to the radionuclide.[694-696] Thus, different radionuclides can be used as long as they are complexed to that chelating agent. Bivalent nonantibody peptides have also been developed.[694,697]

Advantages of the biotin-streptavidin system include not only the small molecular weight of biotin, which can quickly circulate throughout the body, but also the high binding affinity between biotin and avidin or streptavidin (10^{15} M^{-1}). Streptavidin is tetravalent (has four biotin binding sites) and can thereby increase the amount of radionuclide localization in tumor. On the other hand, a disadvantage of the biotin/streptavidin system is the immunogenicity of streptavidin or avidin. Polyethylene glycol modification can reduce this immunogenicity, but may also decrease the binding capacity of biotin.[694,698]

Although the concept of pretargeting does not require a clearing step between administration of the targeting agent and radionuclide, use of a clearing agent can further enhance the tumor-to-normal tissue ratio. Theoretical and experimental pharmacokinetic modeling studies suggest that pretargeting approaches using a two-step method will result in a two- to three-fold enhancement of efficacy compared to conventional one-step RIT.[694,699] Use of a clearing agent can further improve tumor-to-normal tissue ratios severalfold. A variety of clearing mechanisms have been studied to date including use of an antibody that reacts with the targeting agent, plasmapheresis/extracorporeal immunoadsorption, and large molecular weight agents that react with the targeting agent in the circulation, or other agents that are primarily confined to vasculature.[700-703] The primary objective of clearing strategies is to remove unbound targeting agent from the circulation without affecting that bound to tumor. Clearing designs for biotin-streptavidin systems have usually used three to five steps to promote clearance of unbound targeting agent to which the radionuclide-complex would otherwise bind.[384] By using a three-step approach, a mean tumor/marrow ratio of 19 was achieved in patients with glioma. Using this three-step pretargeting approach, 12 of 48 patients with glioma with residual or recurrent disease after conventional therapy achieved a greater than 25% reduction in tumor, with 8 of 48 patients in remission at 12 months.[579,704] Efficacy has been reported by Paganelli and his European Institute of Oncology colleagues using this biotinylated antibody in a three-step approach for therapy in patients with other solid tumors as well.[704,705] One of the most efficient clearing agents is a complex of galactosamine-biotin molecules that bind streptavidin-antibody and are extracted via the liver. After optimal tumor targeting, antibody complexes were efficiently removed such that blood concentrations of streptavidin were reduced by >95% within 6 hours of administration of a synthetic mono-biotin poly-N-acetyl-galactosamine compound developed by NeoRx Corp. investigators.[385,706] Extraction of clearing agent from blood occurs via interaction with Ashwell receptors in the liver. Use of clearing agents that complex with the targeting agent and are trapped in the liver has allowed dose escalation as high as 140 mCi/m^2 ^{90}Y, whereas the MTD for conventional RIT of ^{90}Y-antibody conjugates is usually <30 mCi/m^2 because of myelosuppression.[48,316,707] This synthetic mono-biotin poly-N-acetyl-galactosamine compound has been used with antibodies conjugated chemically with streptavidin and more recently with fusion proteins.[385,708] The genetically engineered Fusion proteins have been produced by fusing single chain antibody fragments with streptavidin. This has provided tetrameric products with four binding sites for the bivalent antibody and four binding sites for biotin.[42] Early study of an anti-CD20/streptavidin fusion protein in a pretargeted approach with the synthetic biotin-poly-N-acetyl-galactosamine compound has resulted in an average tumor to whole-body radiation dose ratio of 49, with most patients having no significant hematologic toxicity at 15 mCi/m^2 of ^{90}Y.[385]

The pretargeting approach is promising for treating solid tumors where efficacy has been limited primarily by the inability to deliver sufficient tumor doses with acceptable toxicity. Meaningful responses in a variety of nonmyelogenous solid tumors as well as lymphomas have been achieved with pretargeting.[48,379,380,703,709] Several reviews provide additional details of pretargeting development.[5,8,378,393,694,696] A new technique for partial breast treatment involves pretargeting of the tumorectomy cavity by intraoperative injection with avidin, followed later by intravenously radiolabeled biotin.[710,711]

Use of regional or direct injection of TaRT into tumors or tumor cavities has allowed dose escalation for treatment of relatively radioresistant tumors, with encouraging results as discussed in the Solid tumor section.[91,128,309,399,403,415,416,548,712-717] Other approaches that may improve uptake of radiolabeled antibody in tumors include the use of unlabeled antibody to bind circulating antigen and nonspecific binding sites, and the use of cocktails or mixtures of antibodies reactive with different tumor-associated antigens.[682,718-720] An advantage of antibody mixtures has been confirmed in animal studies, which showed superior detection and localization to smaller tumors and greater tumor growth inhibition with the combination of two ^{131}I-labeled antibodies than either antibody alone using the same total amount of radionuclide.[721,722] Several human trials have used two or more antibodies simultaneously. However, it has not been possible to make a direct comparison of one versus more than two antibodies in patients because most trials did not test one antibody alone compared to a combination of antibodies in the same study.[268] When optimized, antibody cocktails may include the combination of whole antibodies with smaller constructs, or use of different radionuclides. Radionuclides are chosen on the basis of their physical half-life, radiation emission characteristics, and pharmacokinetics in a manner that would complement one another and will be matched with the half-life of the antibody or antibody constructs. In addition, the use of antibodies with different affinities or the use of genetically engineered antibodies with greater avidity may also increase the targeting and retention of radioimmunoconjugates in tumors. Use of two radionuclides, even with the same carrier, shows improved results in a rat model of PRRT ^{90}Y and ^{177}Lu and in initial clinical experience.[72,73,723]

CHAPTER

23 Stereotactic Irradiation: CNS Tumors

Brian D. Kavanagh and Jason P. Sheehan

The term *radio-surgery* was possibly first used in a medical context more than 90 years ago, when Dr. Francis Hernaman-Johnson described in a lecture to the Royal Society of Medicine an assortment of indications where x-ray therapy might be combined with surgery for benign and malignant indications. From the modern perspective, Dr. Hernaman-Johnson's oration is quaint but wonderfully lyrical, at times invoking Biblical metaphors and Greek fables.[1] Prophetically, though, he concluded with the message that "no human mind can compass the whole field of medicine. Hence the hope of the future lies in specialism [*sic*] tempered by co-operation."

Fast-forward to the mid-20th century, and with the loss of a hyphen along the way, the term *radiosurgery* was repurposed to describe the procedure now widely used as treatment for a variety of benign and malignant intracranial neoplasms as well as a few selected functional disorders. Applying principles of stereotactic surgery and harnessing the tissue- and tumor-ablative potential of ionizing radiation, the Swedish neurosurgeon Lars Leksell designed the first prototype unit for stereotactic radiosurgery (SRS), opening up new clinical opportunities and launching a Hernaman-Johnsonian interspecialty cooperation between neurosurgeons and radiation oncologists that continues to provide valuable clinical service to patients and new insights into tumor and normal tissue biology.

In this chapter we review the distinct technical aspects of SRS, the current understanding of SRS radiobiology, and clinical outcomes after SRS for common indications.

DEFINITION AND TECHNICAL PRINCIPLES OF STEREOTACTIC RADIOSURGERY

In the half-century following Leksell's pioneering work in SRS, numerous other investigators around the world made important contributions to the technical development of SRS. Whereas Leksell eventually settled on a design involving a hemispherical pattern of multiple cobalt-60 sources shielded and arranged so that their output gamma rays would converge on the target, in the 1980s and 1990s various linear accelerator-based SRS platforms were also developed.[2,3] Many of these newer commercially available systems are also capable of delivering other forms of radiotherapy, and there came a period of time when the commonly used terminology describing SRS and non-SRS forms of radiotherapy were somewhat loosely interchanged. Ultimately, the American Association of Neurological Surgeons (AANS), the Congress of Neurological Surgeons (CNS), and the American Society for Radiation Oncology (ASTRO) agreed that a uniform description of SRS was required to avoid confusion, and the consensus definition is as follows[4]:

> *Stereotactic Radiosurgery is a distinct discipline that utilizes externally generated ionizing radiation in certain cases to inactivate or eradicate (a) defined target(s) in the head or spine without the need to make an incision. The target is defined by high-resolution stereotactic imaging. To assure quality of patient care the procedure involves a multidisciplinary team consisting of a neurosurgeon, radiation oncologist, and medical physicist.*
>
> *Stereotactic Radiosurgery (SRS) typically is performed in a single session, using a rigidly attached stereotactic guiding device, other immobilization technology and/or a stereotactic image-guidance system, but can be performed in a limited number of sessions, up to a maximum of five.*
>
> *Technologies that are used to perform SRS include linear accelerators, particle beam accelerators and multisource Cobalt 60 units. In order to enhance precision, various devices may incorporate robotics and real time imaging.*

Contained within this definition are references to several essential ingredients of SRS. The treatment is noninvasive and involves external radiation sources or beams. As it is also elaborated in other ASTRO statements concerning SRS,[5] the adjective *stereotactic* implies that the target lesion is localized relative to a fixed three-dimensional spatial coordinate system, using either a rigid head frame or reliable internal fiducial markers (bony landmarks or implanted markers). And, most importantly, SRS is a multidisciplinary endeavor in which the quality of patient care is of paramount importance.

Regarding the issue of patient safety, in 2011 ASTRO issued a white paper concerning quality and safety considerations for SRS and the extracranial application of high dose-per-fraction irradiation, stereotactic body radiation therapy (SBRT).[6] This report highlights structure and process elements that are essential for establishing and operating a clinical program with the proper recognition of the risks involved and attention to detail that maximizes the chance for successful treatment while minimizing the chance of error.

As for any clinical activity involving radiation therapy, developing a culture of safety is crucial.[7] Collegiality and a nonjudgmental atmosphere can contribute to an environment that fosters proactive recognition of ways to avoid systematic problems that might produce potentially harmful errors. In the context of SRS, mistakes can be magnified beyond what might be seen in conventionally fractionated radiotherapy treatments. The fact that an entire treatment course is delivered in only a single or perhaps a few fractions means that a targeting inaccuracy greatly increases the odds of tumor progression via geographic miss. Furthermore, the fact that each individual treatment involves a large amount of ionizing radiation dose deposition means that the risk of injury to normal tissue may be escalated beyond an acceptable range if the delivered dose hotspots drift into adjacent normal brain parenchyma rather than remain in the target volume. A thorough discussion of quality assurance methods in SRS is outside the scope of the present chapter. Among the high-priority tasks are accurate initial commissioning and periodic calibration of the treatment delivery technology, proper personnel training, and various patient-specific preparation routines.[6]

Common to all delivery technology for SRS is the use of multiple nonopposed radiation beams that converge on a

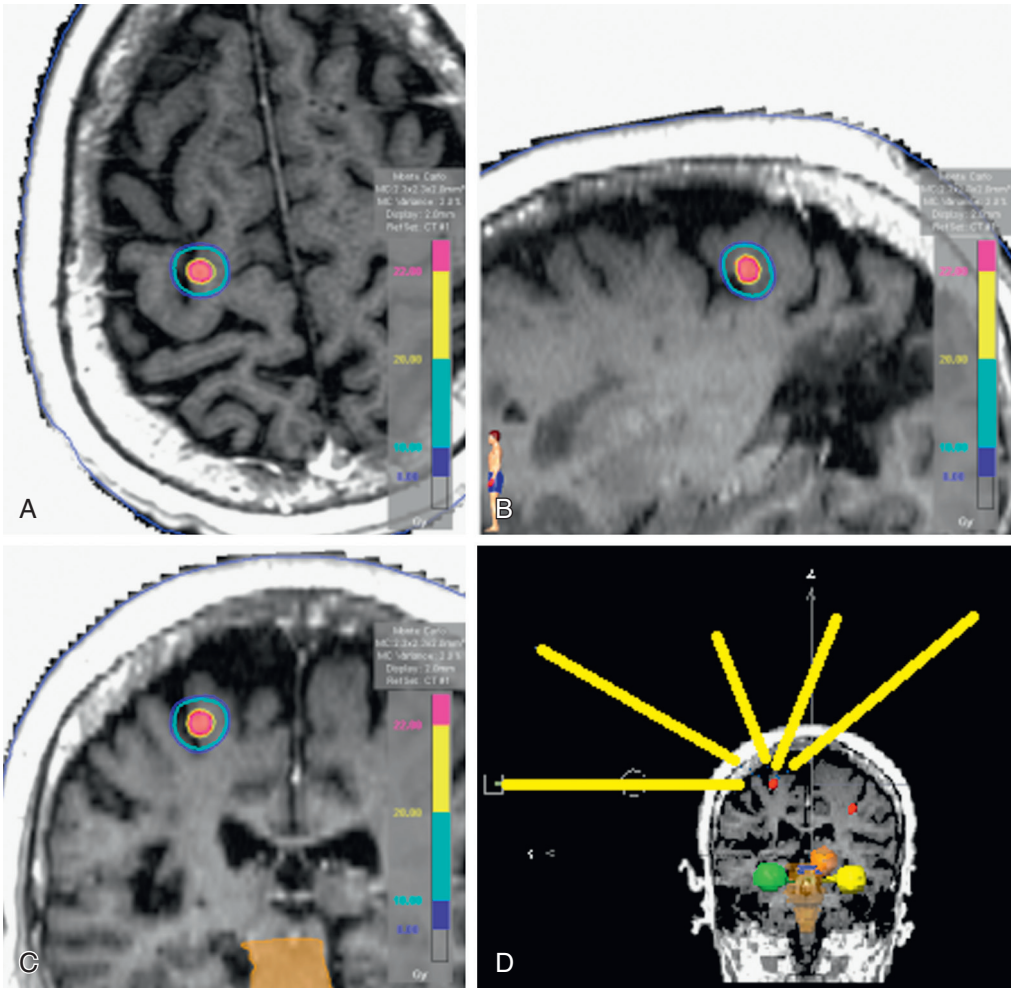

Figure 23-1 Example of an SRS treatment of a right parietal lesion to a prescription dose of 20 Gy, illustrating good conformality. The target is outlined in red and shaded in pink. The 20-Gy prescription isodose volume is outlined in yellow and is shown on axial **(A)**, sagittal **(B)**, and coronal **(C)** planes through the center of the lesion, in all views tightly surrounding the target. The treatment was delivered on a linear accelerator, and panel D is a coronal view showing the angles through which the arcs passed *(yellow lines)*. The beam angles were achieved by table rotations. A separately treated left-sided lesion is also seen in red in that panel, and several normal tissue structures are also outlined.

target in the brain, thus avoiding a high dose to normal tissues in the entrance and exit paths of the beams while depositing an ablative dose within the target volume. The ideal treatment delivery plan achieves a high level of conformality, implying that the volume receiving the prescription dose closely approximates the target volume, thus minimizing the volume of normal tissue exposed to a high dose (Figure 23-1). Unlike the case in some applications of conventionally fractionated radiation therapy, wherein dose homogeneity within the target volume is clinically valuable for cosmetic or other endpoints,[8] for SRS it is generally advantageous to allow for a dose hotspot to be present within the target volume, both for the purpose of increasing the intensity of therapeutic effect and also steepening the gradient of dose falloff into surrounding normal tissues in the brain. This latter goal in particular is often best achieved under the conditions whereby the beam's eye view of the tumor nearly surrounds the contour of the target itself, perhaps with even a "negative margin" where the beam is slightly smaller than the target in cross section—effectively exploiting the fact that the maximum slope of dose falloff outside the beam is generally at the midpoint of the lateral penumbra, a consideration also applicable in SBRT.[9]

THE RADIOBIOLOGY OF STEREOTACTIC RADIOSURGERY

Upon recall of the classic "4 R's" of radiobiology, it is readily apparent that SRS involves considerations that depart from the traditional views of conventionally fractionated radiotherapy. For a single treatment course, the interfraction processes of repair, repopulation, redistribution, and reoxygenation are not relevant realities. Furthermore, for single or extremely hypofractionated regimens, the utility of the popular linear-quadratic model of radiobiological potency has been challenged given the lack of agreement with some preclinical observations and emerging awareness of dose threshold effects that impact tumor and normal tissue responses via vasculature-related events.

By the 1980s SRS had become appreciated as a safe and effective therapy for arteriovenous malformations (AVMs),[10,11] and efforts were initiated to understand the nature of the therapeutic histologic effect on blood vessels in particular. Interestingly, a wide variety of animal models of SRS have been employed to study normal tissue effects including a goat, baboon, and cat, among others.[12-14] Some of these early reports

included experimental single fraction doses on the order of 150 Gy to 200 Gy, and thus their relevance to modern clinical practice, which frequently uses doses an order of magnitude smaller, is uncertain. However, using a dose more closely in line with current human clinical practice, Acker et al at Duke University studied the pial vasculature in a rat using a window chamber model that allowed for repeated direct visual inspection of the in vivo microcirculation.[15]

The experimental setup at Duke included a 4-MV linac fitted with a 2.2-mm diameter collimator. Doses in the range of 15 Gy to 30 Gy were administered in a single exposure, and serial observations were made to characterize the effect on blood flow, vessel density, and leukocyte-endothelial cell interactions. Acute reductions in vessel length density and blood flow were observed at 24 hours postirradiation and continued to become more pronounced 30 days after exposure, without a suggestion of dose-dependence above the level of a 15-Gy dose. Notably foreshadowing a future area of intense focus by others, morphologic changes that included extensive sections of endothelial cell loss were also observed within weeks after irradiation. The authors found this apparently apoptotic effect to be somewhat curious, speculating on its relationship to changes observed in white blood cell interactions with the vessel walls and hypothesizing that platelet-activating factor might play an important role.

This possibility that the tumor vasculature is an important target of radiotherapy is not an especially modern concept and was suggested at least as long ago as 1930, when James Ewing commented that with regard to certain tumors whose cells were thought to be relatively radioresistant, "it seems to me highly probable that the influence is mainly upon the blood vessels, which eventually shrink and cut off the blood supply."[16] However, there was rather limited investigation into this topic specifically between that statement and the SRS-inspired work of the late 20th and early 21st centuries. Many of these studies are cataloged in a recent review by Park et al, who concluded that there appears to be a suggestion of a threshold effect occurring at a fraction size on the order of 10 Gy, above which there appears to be substantial vascular damage that contributes indirectly to a tumoricidal effect.[17]

Perhaps best exemplifying these studies, while also adding fundamental mechanistic insights, is the work of Garcia-Barros et al from Memorial Sloan-Kettering Cancer Center.[18] In the experiments reported in 2003, these investigators implanted MCA/129 fibrosarcomas and B16F1 melanomas into mice that were either genetically wild type or deficient in acid sphingomyelinase (asmase), an enzyme needed for endothelial cell apoptosis. For both tumor cell types, host asmase deficiency was associated with radioresistance as evidenced by significantly enhanced tumor growth delay after a single dose of 15 Gy. Confirmatory assays of endothelial apoptosis reported in the same paper demonstrated that the effect occurs acutely, peaking within 3 to 6 hours after exposure. Additionally, there is an apparent threshold dose for inducing endothelial apoptosis between 7 Gy, where essentially zero apoptosis was seen, and 11 Gy, where the percentage of apoptotic cells in asmase wild type jumped up to approximately 20%. There was a continued increase in percentage of apoptotic endothelial cells up to approximately 60% with a dose of 25 Gy, the upper limit of dose evaluated in this study. As will be discussed, the profound vascular effects of SRS are also well illustrated clinically by the frequently successful obliteration of complex intracranial AVMs when using single fraction doses in the upper range of what was tested here preclinically.

For fractionated radiotherapy the most frequently applied mathematical model to relate radiation dose to expected tumor cell kill is the linear-quadratic (LQ) model, based on a formula that first appeared in Lea and Catcheside's description of the relationship between radiation dose and incidence of chromosomal translocations, using a plant model.[19] Although this model has been the most popular in recent decades and is discussed elsewhere in this book, sometimes overlooked in the original publication by Lea and Catcheside is recognition that for high dose exposure, there would in principle need to be a correction applied to the LQ model that accounted for a decaying effect when the dose is delivered over a prolonged interval, presumably related to what amounts to intrafractional repair as some radiation-induced single-stranded breaks recombine without translocation. Experimental data supporting this possibility in mammalian cells may be found in the work of Eley et al, who used a glioma cell line and modeled SRS-type dose effects, comparing radiosensitivity when the same 12-Gy dose was given either in a single brief exposure or else in a series of smaller exposures spread out over 1 hour.[20] The intent was to simulate SRS treatments that might be delivered clinically using multiple beam angle and table position changes, thus effectively prolonging the time of dose delivery. The results revealed that the cells underwent detectable cell cycle arrest at the G2/M after the first subfraction in intermittent exposure conditions and that this effect was associated with relative radioresistance, consistent with the Lea-Catcheside predictions.

In view of the vascular threshold dose effects and possible intrafraction repair effects, among other differences from fractionated radiotherapy, an argument can be made that alternatives to the LQ model are needed.[21] Indeed, numerous groups have proposed alternative models to characterize the relationship between radiation dose and tumor cell kill when doses in the realm used for SRS or SBRT are employed. For example, Guerrero and Li proposed a modified LQ (MLQ) model based largely on the lethal-potentially lethal model of Curtis,[22] except they proposed a new term, δ, to account for repair kinetics related to dose rate. In a model that combines elements of LQ formalism and a multitarget model, Park et al at the University of Texas–Southwestern Medical Center have described a "universal survival curve" (USC) that involves a step function: LQ estimates apply below a certain dose per fraction, but above a transition dose, D_T, there is a correction that effectively straightens the curve to maintain a linear relationship between dose and log cell kill above D_T.[23] The purpose of this construct is to match the true relationship between high dose exposure and log cell kill, which tends to be overestimated by the LQ model. The USC model may be used to derive a convenient index of radiobiological potency, the single fraction equivalent dose (SFED), by which different SRS or SBRT regimens might be compared. When the dose per fraction, d, exceeds D_T, SFED is calculated as follows:

$$SFED = D - (n-1)D_q$$

where D is the total dose, D_0 is the dose required to reduce the surviving fraction of cells to 37%, n is the total number of fractions, and D_q is the quasi-threshold dose of the multitarget model. The SFED metric has been demonstrated to describe a dose-control relationship for a variety of tumor types treated with SBRT.[24,25]

To gauge the true dose-related normal tissue toxicity risk in clinical settings, even the best predictive mathematical models are not a substitute for careful analyses of actual clinical data. The QUAntitative estimates of Normal Tissue Effects in the Clinic (QUANTEC) project was sponsored jointly by the American Association of Physicists in Medicine (AAPM) and ASTRO. Medical physicists, radiobiologists, and radiation oncologists from across North America, Europe, and Asia participated. The group's charge was to catalog, review, analyze,

and summarize all published literature concerning the quantitative relationship between dose of ionizing radiation and injury to normal tissues, with the intent of identifying practical guidelines for normal tissue dose constraints based not on models but on actual patient observations. Of direct relevance to SRS are the QUANTEC reports on radiation effects in the brain, brainstem, and optic nerves and chiasm.[26-28]

In each case there are acknowledged limitations concerning the quantitative data available for analysis; nevertheless the QUANTEC papers do offer dose-volume parameters that are clinically useful in the design and evaluation of SRS treatment plans for individual patients. Largely influenced by the synthesis of numerous reports involving the treatment of AVMs and subsequent risk of radionecrosis, the authors of the QUANTEC brain paper concluded that toxicity increases rapidly once the volume of the brain exposed to >12 Gy is >5 cm^3 to 10 cm^3.[26] An added caveat is that eloquent areas of the brain such as the brainstem or corpus callosum require extra caution.

The QUANTEC brainstem summary is mainly concerned with tolerance to fractionated radiotherapy, given the larger number of studies available for that setting relative to the setting of brainstem SRS and, in particular, the paucity of long-term reports after SRS to brainstem metastases.[27] One clinical indication for SRS in which long-term follow-up is typically available is for the treatment of acoustic schwannomas, a benign condition with negligible risk of mortality to the patient. Here, the dose to the brainstem is primarily just a glancing focus of scattered dose away from the actual target; a maximum point dose of less than 12.5 Gy is associated with a low risk of new cranial neuropathy in that setting. Regarding injury to the optic nerves or chiasm, the QUANTEC reviewers found that the risk of radiation-induced optic neuropathy in the more modern context of MRI-aided planning is low, with a maximum point dose of ≤12 Gy to the optic apparatus.[28] Figure 23-2 provides an illustration of a patient treated with SRS where the tumor approached the chiasm, necessitating caution with the optic chiasm dose.

CLINICAL OUTCOMES

In Leksell's report describing the first 762 cases treated with SRS at the Karolinska Institute, the three most common diagnoses were AVMs, Cushing disease, and acoustic neuromas.[29] No brain metastases were treated, and a large percentage of the cases were functional disorders such as trigeminal neuralgia, intractable pain elsewhere in the body, or pituitary tumors. Nowadays, the most common indication for SRS is brain metastases. Although many of the diagnoses treated in the early years by Leksell are still managed by SRS today, others such as Parkinsonism or anxiety or obsessive-compulsive disorder are managed with other interventions.

Pituitary Tumors

It is difficult to summarize the full spectrum of literature on SRS, primarily because there have been so many papers involving so many patients. In an encyclopedic review of recent series, Sheehan et al identified 25 separate reports published between 2002 and 2013 concerning SRS for nonfunctioning pituitary tumors alone.[30]

A representative series, that is also the largest published experience, would be the multicenter retrospective study of the North American Gamma Knife Consortium.[31] Among 512 patients with nonfunctional pituitary adenomas, 94% had prior resection and 7% had prior fractionated radiotherapy, the median age at the time of SRS was 53 years. Most patients had some degree of baseline pre-SRS hypopituitarism. The median SRS dose to the tumor margin was 16 Gy. The actuarial rate of tumor control, assessed radiographically, was 95% and 85% at 5 and 10 years post-SRS, respectively. New or worsened hypopituitarism after SRS was noted in 21% of patients, most commonly manifest as thyroid or cortisol deficiencies. Prior fractionated radiotherapy and higher tumor dose were associated with a higher risk of endocrinopathy. New or progressive cranial nerve deficits occurred in <10% of patients. In multivariate analysis, decreasing age, increasing volume, prior fractionated radiotherapy, and prior pituitary axis deficiency were predictive of new or worsening cranial nerve dysfunction. No patient died as a result of tumor progression. The authors concluded that SRS is effective and well-tolerated for recurrent or residual nonfunctional pituitary adenomas. A marginal dose of 16 Gy to 18 Gy, lower if needed to constrain the maximum point dose to the optic pathway structures below 10 Gy to 12 Gy, appears a reasonable consideration in this setting.

Functioning pituitary adenomas are also commonly treated with SRS, and likewise there have been dozens of studies published since 2000.[30] A key difference in both clinical goal and follow-up evaluation is that the intent is to achieve endocrine normalization that is evaluable by serum or other assay. Table 23-1 includes a summary of the five largest series of SRS for Cushing disease or acromegaly published since 2007. Note that the doses employed are typically higher than for nonfunctioning tumors; prescription doses on the order of 20 Gy to 25 Gy are considered reasonable. Also, there is typically a delay of 1 to 2 years after SRS before the endocrine remission is achieved. Limited data suggest that it might be advantageous to discontinue pharmacological suppression of pituitary hormonal secretion at the time of SRS, possibly because the octreotide reduces the metabolic activity and proliferative activity within tumor cells, allowing opportunity for repair of radiation damage.[40]

AVM

Steiner et al at the Karolinska Institute are credited with the first use of SRS in the management of an AVM.[41] A dose of 25 Gy was prescribed in an effort to obliterate the fistulous point of a sizeable AVM. Success was achieved, and since then. SRS has emerged as an important modality in the treatment of AVM. Numerous centers have reported clinical outcomes in large series, not infrequently including 500 or more patients.[30] Representative series from the University of Pittsburgh and the University of Virginia document an obliteration rate in the range of 70% or higher with a low risk of serious toxicity, with doses in the range of 20 Gy to 25 Gy for small lesions (<4 cc), and somewhat lower doses for larger lesions.[42,43] In the latter analysis, factors associated with a favorable outcome included no prior hemorrhage, AVM in a noneloquent location, and AVMs with a volume of less than 4 cc. When the target volume exceeds 10 cc to 12 cc, consideration is given to a staged treatment regimen, whereby portions of the lesion are treated to a dose of 16 Gy to 18 Gy, followed by a break of 4 to 6 months, and then SRS to another portion.[44]

Meningiomas and Other CNS Tumors

SRS can play an important role in the management of intracranial and skull-based meningiomas. Although most are benign low-grade tumors, these neoplasms may develop in locations that can cause symptoms indirectly via mass effect on eloquent areas such as the brainstem or motor cortex or can directly cause pain and threaten cranial nerve functional compromise if located along the skull base. Numerous single-institutional experiences have been published on this

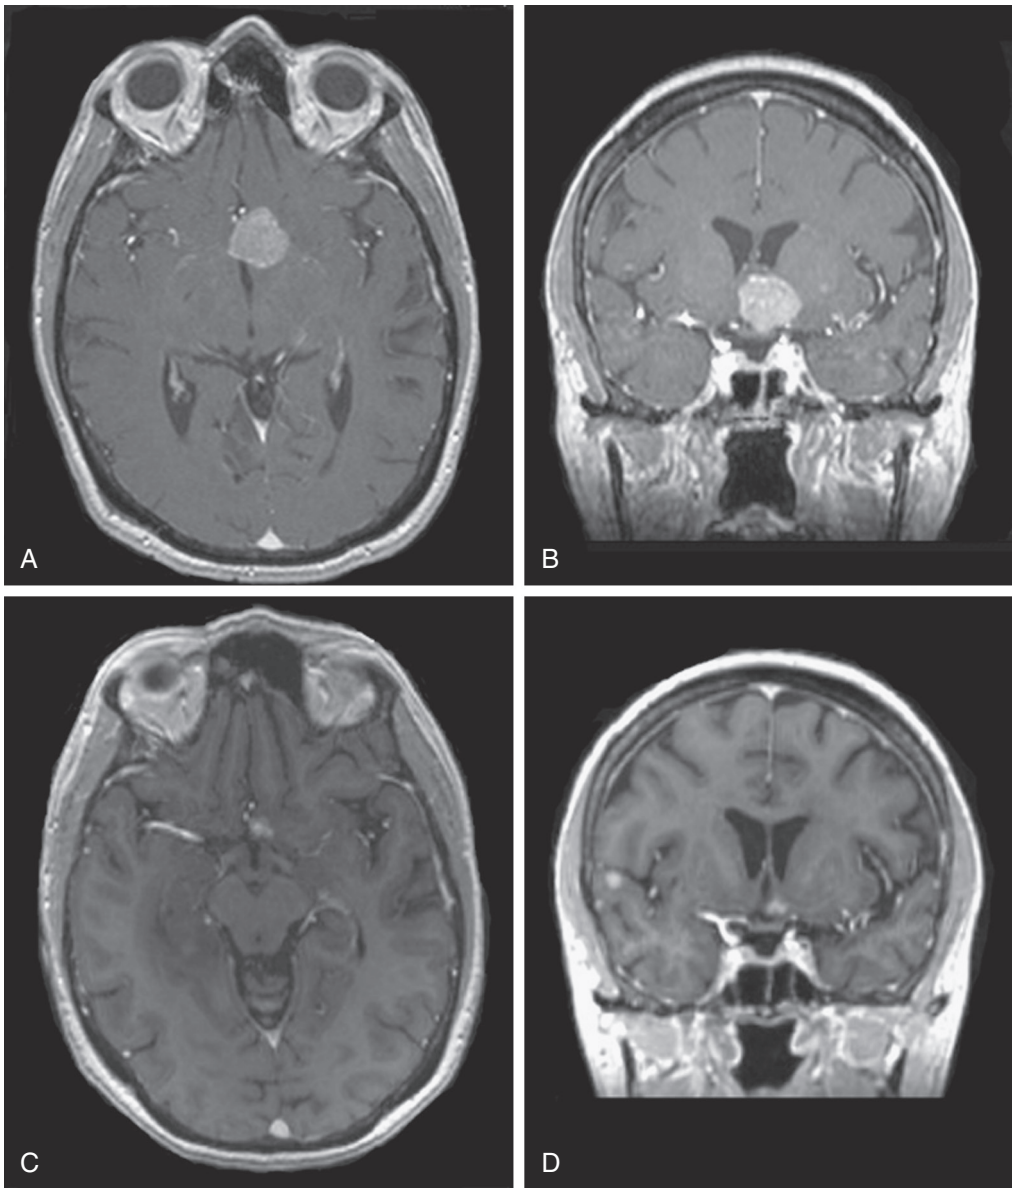

Figure 23-2 The patient is a 54-year-old woman with a history of metastatic non–small cell lung cancer. She underwent stereotactic radiosurgery (SRS) to treat a left perioptic brain metastasis. The tumor was treated in a single session with a margin dose of 16 Gy and a maximum point dose to the optic pathway of 12 Gy. The metastatic lesion is shown on the pre-SRS postcontrast axial **(A)** and coronal **(B)** magnetic resonance imaging (MRI). Six months later, the patient's visual fields and acuity were stable. Her tumor had markedly regressed as demonstrated by the follow up postcontrast axial **(C)** and coronal **(D)** MRIs. Of note, **D** shows a new metastatic lesion in the right Sylvian fissure region that was later treated with SRS.

TABLE 23-1 Summary of Selected Recent Series of Stereotactic Radiosurgery (SRS) for Cushing Disease or Acromegaly

First Author [Reference]	Number of Patients	Mean or Median Follow-Up, Months	Mean or Median Margin Dose, Gy	Endocrine Remission (%)
SRS for Cushing Disease				
Castinetti[32]	40	54.7	29.5	42.5

indication for SRS. A representative example is the most recent update of the Mayo Clinic experience, in which Pollock et al reported on 251 patients treated between 1990 and 2008.[45] The mean patient age was 59 years. Most of the tumors were located in the skull base or tentorium. The mean treatment volume was approximately 8 cc, and the mean tumor margin dose was 16 Gy. After a mean follow-up of more than 5 years, only 3 patients had manifested in-field tumor progression. There was radiographic evidence of tumor size decrease in more than 70% of patients, and no patient died of radiation-related complications. No radiation-induced tumors were observed.

Santacroce et al reported a large European multicenter experience of SRS for meningiomas in 2012.[46] A total of 15 centers contributed data to the retrospective analysis. The median tumor volume was 4.8 cm^3, and median dose to tumor margin was 14 Gy. The median imaging follow-up was 63 months. Similar to the Mayo Clinic experience, the volume of treated lesions was noted to decrease in 58% of cases and remained unchanged in another 34.5%, for a crude local control rate of 92.5%. Tumor control was higher for imaging-defined tumors, female gender, and for skull base compared to convexity tumors.

Prescription dose selection is often influenced by tumor location. For lesions near the cerebellopontine angle, a marginal dose on the order of 13 Gy to 14 Gy is generally advisable,[47] especially considering the need to respect adjacent normal tissue dose constraints. The QUANTEC recommended limit for maximum point dose to the brainstem is 12.5 Gy.[27] For locations where critical structures are not dose-limiting, a marginal dose in the range of 15 Gy to 16 Gy is reasonable.

SRS can also play a role in an assortment of less common indications. This includes recurrent hemangiopericytomas[48-50] and recurrent high-grade glioma,[51,52] among others. Acoustic neuromas (also called vestibular schwannomas) are also commonly treated with SRS[53]; an example case is shown in Figure 23-3.

Brain Metastases

By far the most common current indication of SRS is in the management of brain metastases. In this regard, there are abundant retrospective and also numerous prospective clinical studies.

Because a patient who develops one or more brain metastases is then known to have a risk of manifesting other lesions later, one clinical question that has been asked often asked is whether adjuvant whole brain radiation therapy (WBRT) provides clinical benefit by eradicating occult micrometastases in the brain present at the time of diagnosis with brain metastases. Table 23-2 contains a summary of the four randomized studies performed in the last decade that compared the outcomes of patients who had initial SRS or surgical resection (S) followed by observation or WBRT.[54-57] In addition to the criteria shown in the table, in each study, eligibility typically required good performance status and stable systemic disease. The SRS dose employed was in the range of 18 Gy to 25 Gy. The lack of survival benefit with the addition of WBRT is generally explained by the success of salvage therapy for subsequent brain relapse, which effectively equalizes the chance for durable survival. Additionally, in the study by Chang et al at the M. D. Anderson Cancer Center, the primary endpoint was cognitive decline, and the trial had to be stopped early because of excessive neurocognitive toxicity 4 months after treatment in the WBRT arm. Likewise, in the European Organization for Research and Treatment of Cancer (EORTC) study, a secondary analysis of Health-related Quality of Life (HRQOL) revealed that patients in the observation only arm reported better HRQOL scores than did patients who received WBRT.[58] The differences were statistically significant and clinically relevant, especially during the early follow-up period. Taken together, these studies support a strategy of initial S or SRS for patients with limited brain metastases, followed by close surveillance and salvage therapy later as needed.

Another question commonly asked with regard to SRS for brain metastases is whether there is an upper limit of lesions above which SRS is not appropriate and WBRT should be employed instead. Although the diagnosis-specific graded prognostic assessment index includes number of lesions as a component for certain histologies, it does not address how those patients are ideally managed.[58a] Numerous recent reports have indicated that a patient's prognosis, when treated by SRS, is predominantly driven by performance status and other factors and not the number of lesions. For example, in the M. D. Anderson experience reported by Likhacheva et al, a total of 251 patients underwent SRS for initial treatment of brain metastases.[59] SRS was used as the sole management for most patients but was combined with salvage treatment with SRS, WBRT, or resection on about one third of cases. The median number of brain metastases was 2 (range, 1 to 9). The median overall survival (OS) was 11.1 months. On multivariate analysis, statistically significant predictors of OS were

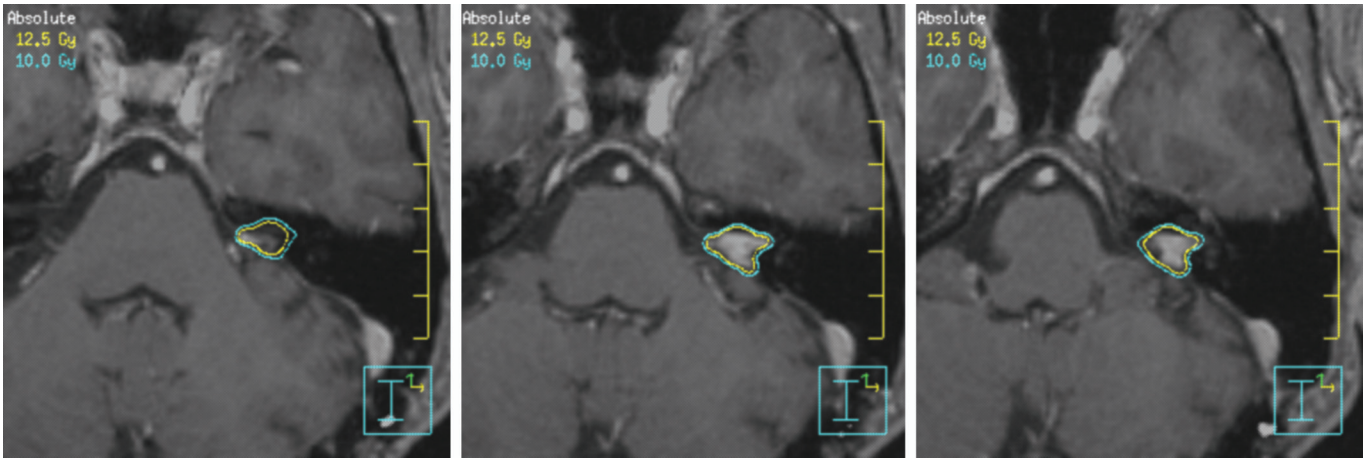

Figure 23-3 Three selected axial cuts through a vestibular schwannoma showing the resulting conformal treatment plan using four different isocenters. The gadolinium contrast enhanced thin slice T1-3D-SPGR MRI data set has been fused to the underlying stereotactic computed tomography (CT) to visualize the vestibular schwannoma. The 12.5-Gy treatment isodose line and the 10-Gy isodose line are shown.

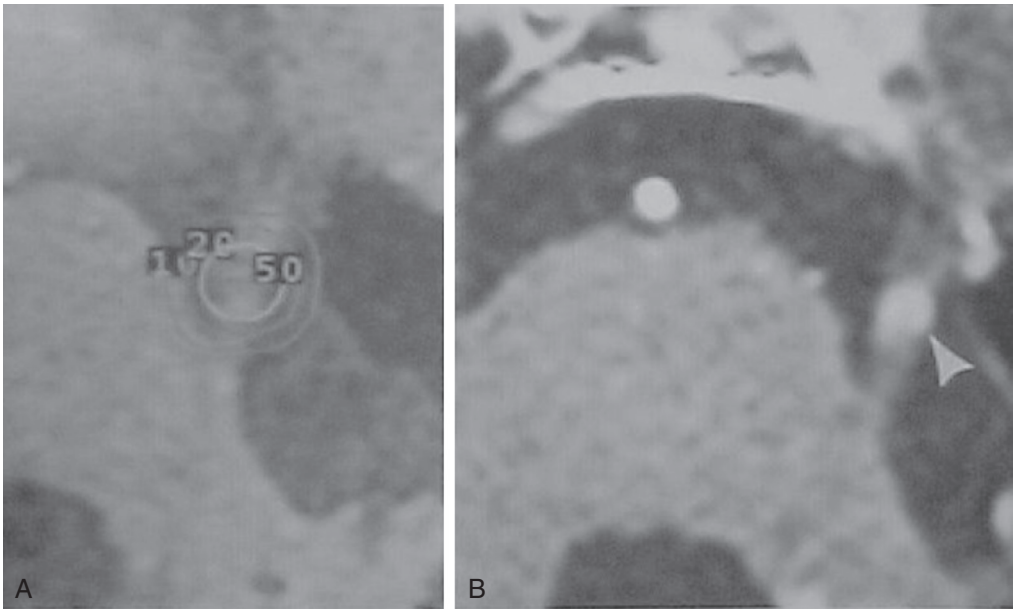

Figure 23-4 **(A)** Typical Gamma Knife radiosurgery dose distribution for trigeminal neuralgia targeted at the root entry zone of cranial nerve V (CN V). The prescription dose is typically 70 Gy to 90 Gy prescribed to the 100% isodose line. **(B)** Magnetic resonance imaging (MRI) 6 months after radiosurgery demonstrating radiographic changes on CN V.

TABLE 23-2 Randomized Studies of Stereotactic Radiosurgery (SRS) versus SRS or Surgery (S) Plus Whole Brain Radiation Therapy (WBRT) for Patients with Brain Metastases

First Author [Reference]	Eligibility	Number of Patients	Median OS (mo.) No WBRT	Median OS (mo.) + WBRT	Comment
Aoyama[51]	1-4 lesions <3 cm diameter	132	8.0	7.5

presence of extracranial disease, total tumor volume greater than 2 cc, age ≥60 years, and diagnosis-specific graded prognostic assessment. The number of brain metastases was not predictive of OS or distant brain failure.

Other data indicating that there does not appear to be a number of brain metastases above which SRS is contraindicated are recently reported Japanese experiences. The Japanese Leksell Gamma Knife (JLGK) Society undertook a prospective study of SRS without WBRT (JLGK 0901) to establish evidence that such a treatment strategy is feasible for 5 to 10 brain metastases. A preliminary report showed that the overall survival for patients with 5 to 10 brain metastases was almost the same as that of patients with two to four brain lesions.[60] More recently reported analyzes are confirmatory.[61]

Functional Disorders

Although a variety of functional disorders have been treated with SRS over the years, the currently most common and widely accepted functional indication for SRS is for medically refractory pain from trigeminal neuralgia.[62] The typical dose given is 70 Gy to 90 Gy prescribed to a point located near where the fifth cranial nerve exits the brainstem (Figure 23-4). In a representative study from the University of Maryland, 112 patients were treated with SRS to a median prescription dose of 75 Gy (range, 70 Gy to 80 Gy).[63] Among 95 who were compliant with follow-up surveys, the median follow-up was 5.6 years (range, 1 year to 10 years). Before SRS 88% of patients had inadequate control or severe pain on medication, whereas the remainder described some pain but controlled on medication. After SRS 64% reported no pain and no requirement for medications, 5% had no pain but were still on medication, 12% had some pain controlled on medication, and the rest still had inadequate pain control. The median time to response was 2 weeks (range, 0 weeks to 12 weeks), and the median response duration was nearly 3 years. The actuarial rates of freedom from treatment failure at 1, 3, 5, and 7 years were 60%, 41%, 34%, and 22%, respectively. Response duration was significantly better for those who had no prior invasive treatment versus those in whom a previous surgical intervention had failed (32 versus 21 months, $p < 0.02$).

CONCLUSIONS

SRS is an established method of ablating brain metastases and AVMs as well as treating certain benign intracranial neoplasms and trigeminal neuralgia. Careful patient selection is important and is best done within the context of a multidisciplinary team approach involving the radiation oncologist, neurosurgeon, and other caregivers involved in the patient's management. With proper attention to technique and an especially thoughtful respect for normal tissue dose tolerances, SRS achieves a clinically valuable result in the majority of patients and has a low risk of serious toxicity.

CHAPTER

24 Stereotactic Body Irradiation: Extracranial Tumors

Brian D. Kavanagh and Robert D. Timmerman

The success of stereotactic radiosurgery (SRS) for intracranial lesions spawned interest in applying the same principles of narrowly focused high-dose per-fraction irradiation in the management of selected extracranial tumors. The transition included an initial effort to design and implement a surgically placed rigid frame for spine immobilization,[1] but soon thereafter noninvasive means to target lung, liver, and other non-brain lesions were developed.[2,3]

Stereotactic body radiation therapy (SBRT) is the current American Medical Association Common Procedural Terminology (CPT) name applied in the United States to describe the management and delivery of image-guided high-dose radiation therapy with extracranial tumor-ablative intent within a course of treatment that does not exceed five fractions. Other labels that have been used in the past include extracranial stereotactic radiosurgery and various vendor-created nicknames, and a moniker that has been used in recent years is stereotactic ablative radiotherapy, which emphasizes the ablative potential of the treatment and has an appealingly onomatopoetic acronym (SABR). For simplicity the acronym *SBRT* will be used throughout.

In this chapter we review technical considerations, radiobiological implications, and normal tissue dose constraints for SBRT. Clinical outcomes after SBRT for common indications will be presented. The radiation physics of SBRT are discussed in a separate chapter in the textbook (Chapter 7).

SAFETY CONSIDERATIONS AND TECHNICAL ASPECTS OF STEREOTACTIC BODY RADIATION THERAPY

Relative to cranial SRS, the major additional practical hurdle that must typically be overcome to target an extracranial tumor with SBRT accurately and precisely involves accounting for breathing-related motion, present to some extent for nearly all cases apart from largely immobile spine and paraspinous tumors. Periodic breathing motion displacements have been both quantified and, if necessary, controlled with equipment and procedures used for simulation/planning and consistently applied toward treatment. Positioning errors (e.g., misalignment) either during a treatment or between treatments would also otherwise require expansion of targets. Numerous linear accelerator manufacturers now offer SBRT-ready treatment delivery systems that integrate a high performance linear accelerator with one or another form of image guidance technology, thus ensuring proper target relocalization and beam alignment. Collectively, these SBRT systems and procedures allow the use of considerably smaller fields compared with conventional radiation therapy without missing the target.

The American Society for Radiation Oncology (ASTRO) has issued guidelines on SBRT,[4] and the American Association of Physicist in Medicine (AAPM) Task Group 101 report expanded and augmented the ASTRO guidelines.[5] More recently, ASTRO also produced a white paper on quality and safety in SRS and SBRT.[6] In addition to describing the personnel and training requirements, the reports highlight key features of the quality assurance (QA) measures necessary to ensure the safety of the procedure.

The complete process of care for a patient receiving SBRT involves a multistep process that can involve patient immobilization, motion assessments (and motion-management if necessary), planning computed tomography (CT) image acquisition, analysis and processing of any four-dimensional image sets, fusion of the planning images with relevant diagnostic image sets, target delineation, dosimetric planning, patient-specific quality assurance testing, patient setup on the treatment couch, acquisition of guidance images to allow target relocalization, deployment of any motion-managing techniques or devices, proper initialization and commencement of the patient's unique beam and/or arc sequence, real-time monitoring of the integrity of the treatment delivery process, and the patient's stability and tolerance. At each step along the way are opportunities for systematic errors, miscalibrations, miscalculations, and any number of operator mistakes.

Regarding the possible purely technical sources of errors such as impaired performance of gantry motion or incorrect registration of pretreatment cone beam CT scans with the planning images in the image guidance software, careful initial commissioning and subsequent regular maintenance checks of individual components of the system are mandatory. Additionally, it is strongly recommended that there be end-to-end testing that incorporates all of the linked component parts to ensure that the additive impact of numerous small errors do not accumulate to a clinically relevant systematic targeting error whereby the planning target volume is not properly irradiated for any combination of reasons. The possibility of human error can never be completely eliminated. However, as noted in the chapter on stereotactic irradiation of central nervous system tumors, steps to reduce the chance of errors include the use of checklists and the development of a general culture of safety in which communication flows freely and nonjudgmentally among colleagues, with the common goal of quality patient care.[7]

SBRT requires proper patient repositioning, target localization, and management of breathing-related motion. Commercially available immobilization devices include several types of body frames with external fiducial markers, but these or any frameless system must always be used with accompanying image guidance that involves ultrasound, kV radiographs, CT scan, or magnetic resonance imaging (MRI) to verify the location of internal targets relative to the beams to be used (Figure 24-1). Because SBRT treatment sessions take more time than conventional external beam treatments, patient comfort is an important issue to lessen the chance that the patient might shift his or her position between the time of image guidance and treatment delivery.

Breathing motion management can be accomplished in one of several ways. Motion-dampening techniques involve light to moderate abdominal compression coupled with thoughtful patient coaching intended to transfer the predominant breathing forces from primarily abdominal (diaphragmatic contraction) to primarily chest wall (external intercostals, scalene, and sternocleidomastoid contraction). In this way, breathing forces

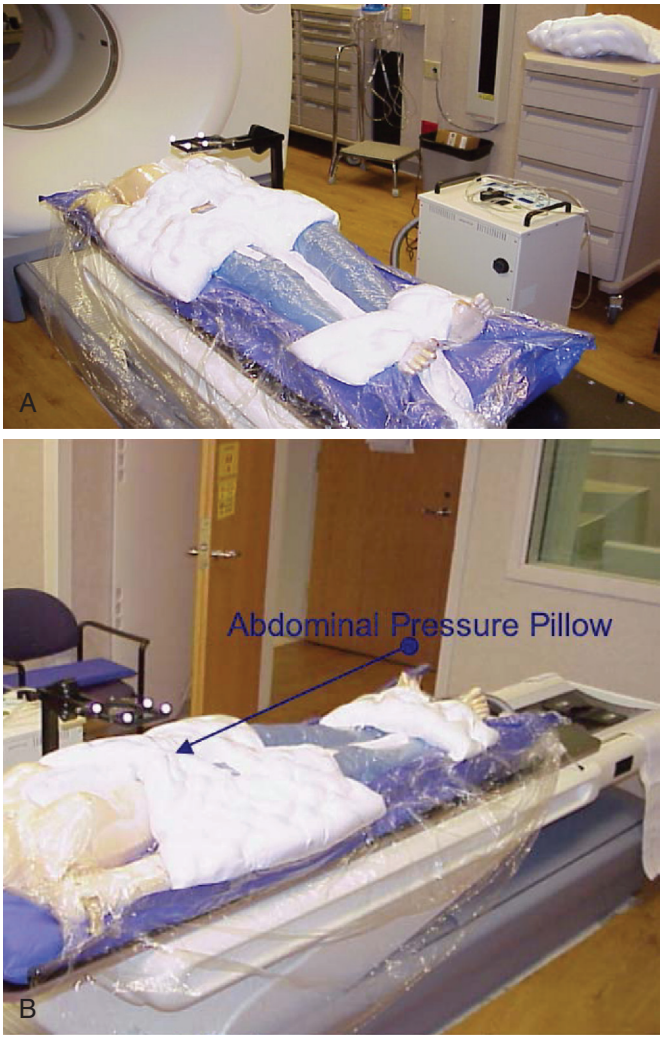

Figure 24-1 An example of a patient immobilization device for SBRT.

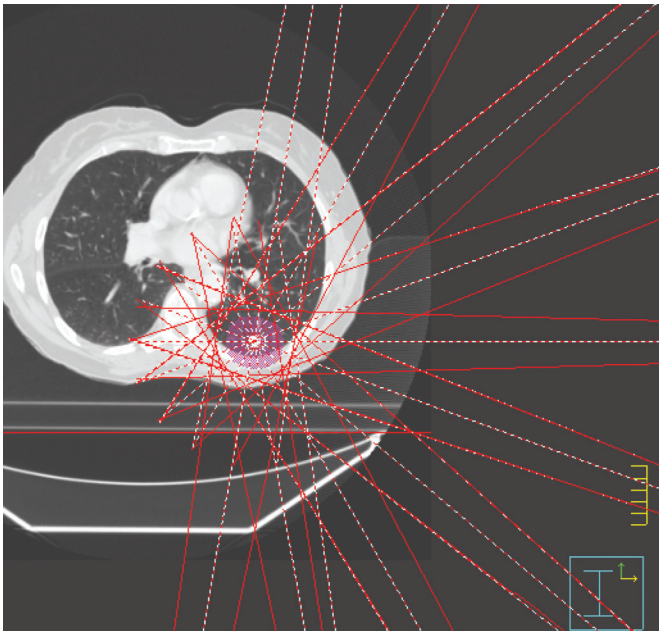

Figure 24-2 Typical beam arrangement and dose distribution for SBRT to a peripheral stage I lung cancer.

that otherwise put a tumor into motion with larger displacements are reduced while still facilitating an adequate tidal volume. Also within this category are coached breath hold maneuvers to "freeze" the tumor in space by drawing in and holding a constant tidal volume (e.g., deep inspiration) and holding that volume while the radiation beam is engaged. Gating systems may be used for SBRT in the same manner as for conventionally fractionated radiotherapy: the movement of external surface markers is correlated with phases of the breathing cycle, and beam output is triggered only when the markers are located within a preselected segment of the breathing cycle, implying tumor location within the expected range of motion. Tracking or "chasing" systems move the radiation beam to follow the movement of the tumor. Both breath hold and gating methods have a duty cycle whereby the beam is turned on and off for periods of time, thus lengthening the total treatment time. To some degree these motion management techniques can be used in conjunction (e.g., abdominal compression and gating) to reduce the overall target displacements or duty cycle.

Most clinical implementation of SBRT thus far has involved high-energy photons as the source of therapeutic radiation. However, charged particles could also be used. There is no absolute standard or consensus class solution for the combination of beam or arc angles best suited for any given clinical situation, and each case can present idiosyncratic challenges. In general, though, to achieve a tightly focused high-dose distribution within the planning target volume (PTV) and rapid dose fall-off outside the PTV, a combination of multiple (often 7 to 10) noncoplanar beams or multiple arcs is often required (Figure 24-2). Intensity modulation across the individual beams or arc segments can be incorporated within SBRT, but it is important to bear in mind that as for cranial SRS, it is typically advantageous to allow for a dose hotspot to accumulate inside the PTV to steepen the dose falloff outside the target, exploiting the natural gradient of the lateral beam penumbra to some extent in this regard. One notable exception to this practice would be in the case of prostate SBRT, where it is important to avoid a hot spot in the region of the urethra.

CLINICAL RADIOBIOLOGY AND NORMAL TISSUE DOSE CONSTRAINTS

The emerging knowledge about high-dose per-fraction irradiation is reviewed in more detail in the chapter on stereotactic irradiation of CNS tumors. Briefly, the mathematical models established to describe the relationship between radiation dose and biological effect in tumor and normal tissue that are generally reliable for conventionally fractionated radiotherapy are less stable in the setting of high-dose per-fraction irradiation. The linear quadratic model tends to overestimate the in vitro cytotoxicity of doses on the order of 8 Gy to 10 Gy or higher, and yet there is added uncertainty with regard to the in vivo effects of doses in this range because of the suspected extra effect of endothelial cell apoptosis, which can lead to tumor cell death via an early antiangiogenic mechanism as well as likely more late-fibrosing vascular effects. Given these caveats concerning traditional radiobiological models, for the purpose of predicting the effect of SBRT on tumors and normal tissues, it is best to rely whenever possible on empiric observations that relate dose or dose-volume parameters to directly observed rates of tumor control or normal tissue toxicity.

SBRT Dose versus Tumor Control

There are numerous reports that support the concept of a dose-tumor control relationship over the range of doses that have been explored for lung and liver SBRT. For example, McCammon et al reviewed the records of 141 consecutive patients with 246 lung or liver lesions treated with three-fraction SBRT regimens.[8] Lesions treated to a nominal dose of 54 Gy or greater had a 3-year actuarial local control rate of 89.3% compared with 59.0% and 8.1% for those treated to 36 Gy to 53.9 Gy and less than 36 Gy, respectively.

Similarly, Olsen et al reviewed the records of 130 patients who underwent definitive lung cancer SBRT to a single lesion, receiving 18 Gy × 3 fractions for peripheral tumors (n = 111) and either 9 Gy × 5 fractions (n = 8) or 10 Gy × 5 fractions (n = 11) for tumors that were central or near critical structures.[9] The observed local control after 1 or 2 years were, respectively, 75% and 50% for 9 Gy × 5, 100% and 100% for 10 Gy × 5, and 99% and 91% for 18 Gy × 3. No difference in local control or overall survival (OS) was found between the 10 Gy × 5 and 18 Gy × 3 groups, but treatment with 9 Gy × 5 was the only independent prognostic factor for reduced local control on multivariate analysis.

In yet another study that was particularly robust because of the structured dose escalation within a prospective trial, Rule et al treated patients with hepatic metastases in three consecutive dose-escalation cohorts: 30 Gy in three fractions, 50 Gy in five fractions, and 60 Gy in five fractions.[10] Twenty-seven patients, 9 in each cohort, with 37 lesions were enrolled and treated: 17 men and 11 women; median age 62 (range 48 to 86) years. The most common site of primary disease was colorectal cancer. The 2-year actuarial local control rates were 56%, 89%, and 100% for the 30 Gy, 50 Gy, and 60 Gy cohorts, respectively. There was a statistically significant difference for local control between the 60 Gy and 30 Gy cohorts (p = 0.009) but not between the 60-Gy and 50-Gy cohorts (p = 0.56) or the 50-Gy and 30-Gy cohorts (p = 0.091). Thus, taken together, the results of these studies support that SBRT doses in the range of 50 Gy to 54 Gy or higher in three to five fractions provide superior local control rates than less aggressive regimens for liver and lung lesions.

Normal Tissue Dose Constraints

There is a growing literature of reports characterizing SBRT dose-effect relationships in normal tissues, notably for liver, lung, and intestinal tissue. In an effort to analyze these data in aggregate to search for consistent trends across series, the AAPM has supported a working group initiative involving dozens of volunteers charged with cataloging all of the published SBRT studies that include clinical information, treatment details, and rates of toxicity. Although the results of this effort might eventually illuminate correlations not appreciated when only smaller numbers of patients in individual reports are considered, there are already strong indicators of effects that are routinely observed after high-dose per-fraction irradiation above given thresholds of dose or volume, some considered clinically harmless and others associated with toxicity.

One feature of the normal tissue effect of liver SBRT consistently observed within the first few months after SBRT is a zone of hypodensity observed on follow-up CT scans corresponding to the volume that received approximately 30 Gy in three to five fractions. This phenomenon, first described by Herfarth et al following single dose liver SBRT,[11] is related to a local veno-occlusive effect.[12] There is no clinical consequence associated with the finding per se, and it will resolve over time, but the Herfarth effect can obscure the assessment of tumor response within the first few months after liver SBRT. Of greater utility for this purpose would likely be a positron emission tomography (PET) scan, but here it should be appreciated that it will take months for the full effect of treatment to mature and lower the standardized uptake value (SUV) of target lesions.[13]

For conventionally fractionated radiotherapy, it has been observed that the risk of significant radiation-induced liver disease (RILD) characterized by ascites, anicteric hepatomegaly, and elevated liver enzymes is well correlated to the mean liver dose.[14] Fortunately, RILD is an exceedingly rare complication after liver SBRT because the mean dose to uninvolved liver parenchyma is generally well below what has been given in the past using conventional techniques. Indeed, normal tissue complication probability (NTCP) models established for conventional fractionation have not reliably predicted toxicity after liver SBRT, typically overestimating the risk.[15]

The QUANTEC (Quantitative Analyses of Normal Tissue Effects in the Clinic) summary recommendations for liver SBRT given in a three fraction regimen are to constrain the mean normal liver dose (liver minus gross tumor volume) to less than 13 Gy for primary liver cancer and less than 15 Gy for metastases and to ensure that at least 700 mL of normal liver receive less than 15 Gy.[14] This latter recommendation is based on a so-called *critical volume model*. Relevant for organs of parallel structure, this construct requires recognizing how much volume of the organ is essential and must be protected from functional ablation. The estimate for liver that at least 700 mL should receive less than 15 Gy during a three-fraction SBRT course was originally derived from a combination of prior reports of outcomes after partial hepatectomy documenting approximate minimum volumes required and good faith estimates of the effects of that dose of radiation extrapolated from prior reports of conventionally fractionated treatment.[16]

Analogous to the Herfarth reactions after liver SBRT are observations of lung inflammation and fibrosis in and near the zone of high dose irradiation after lung SBRT. Diot et al studied post-SBRT follow-up CT scans of 62 patients who received lung SBRT prescribed to a median dose of 54 Gy (range, 30 Gy to 60 Gy) in three to five fractions. The surrogate marker of parenchymal injury was an increase in Hounsfield Units (HU), presumed here to represent postinjury scar tissue. Across a range of follow-up intervals, the HU values linearly increased with dose until 35 Gy and were constant thereafter. For 3, 18, 24, and 30 months, the rate of HU increase with per dose was consistent; however, at 6 months the rate was similar below 20 Gy but then doubled above this threshold, suggesting a phase of peak post-SBRT inflammation that subsides at later time points. These observations largely validated the quantitatively similar contemporaneous work of Palma et al, who also noted an independent effect on promoting lung fibrosis with larger PTV.[17]

Radiation pneumonitis, characterized clinically as cough, fever, shortness of breath and chest pain, and associated radiographically with a geometric alveolar infiltrate corresponding to irradiated volumes, is an uncommon event after lung SBRT. In the Radiation Therapy Oncology Group (RTOG) 0236 study in which patients with medically inoperable early stage lung cancer were treated with SBRT to a nominal dose of 60 Gy in three fractions (recalculated as 54 Gy in three fractions when accounting properly for tissue heterogeneity), the incidence of grade 3 radiation pneumonitis was 4%, with no grade 4 or 5 radiation pneumonitis.[18] A subsequent analysis of the same study documented no clinically significant changes in pulmonary function after treatment.[19] For a large cohort of patients treated at the M. D. Anderson Cancer Center, Chang et al found on multivariate analysis that only the mean dose to ipsilateral lung (lung minus gross tumor volume) was a significant predictor of grades 2 to 3 radiation pneumonitis after lung SBRT,

with a sharp increase in incidence when this metric exceeded approximately 9 Gy.[20] It has also been noted that tumor location might have a substantial influence on risk of toxicity, with a higher rate of severe toxicity observed for centrally located tumors in the initial Indiana University experience.[21]

The intestinal tract is a thin-walled structure that is susceptible to injury from high-dose per-fraction irradiation. For the major segments of the gastrointestinal tract studied to date (esophagus, duodenum, and rectum), the most significant predictor of post-SBRT late toxicity is a dose-volume metric whereby toxicity is triggered when the amount of tissue receiving a certain dose exceeds a threshold volume.[22-24] For example, in the esophagus, after a single fraction exposure, there is an escalated risk of grade 3 or higher toxicity if the volume receiving 12 Gy exceeds approximately 4 cc[22]; similarly, the risk for duodenal toxicity, grade 2 or higher, escalates sharply if the volume receiving a single fraction of 15 Gy exceeds approximately 9 cc.[23] In an analysis of a dose escalation study of prostate SBRT, the risk of grade 3 or higher late rectal toxicity was significantly elevated when the volume of rectal wall receiving 50 Gy exceeded 3 cc.[24]

CLINICAL INDICATIONS AND OUTCOMES

Lung Cancer

An important unmet medical need provided the impetus for much of the early development of SBRT. Until the advent of SBRT, a patient with medically inoperable stage I lung non–small cell lung cancer (see Chapter 44) would derive rather limited clinical benefit from conventionally fractionated radiotherapy (CFRT). The Surveillance, Epidemiology, and End Results (SEER) registry indicated a median survival of a little more than a year is typical without any radiotherapy, extending to approximately 21 months with CFRT, with an expected 3 year OS on the order of 30%.[25] The challenge for these patients was that CFRT did not achieve a high rate of local control and was poorly tolerated in a patient population especially susceptible to pulmonary toxicity. The typical single-institution analysis from centers of excellence revealed 3-year local control rates of approximately 50%, with consistently disappointing median survival of less than 2 years.[26,27]

Breakthrough improvements relative to this baseline were achieved in studies performed contemporaneously in separate multiinstitutional studies on two continents. In the Nordic Group study from Europe and the RTOG study from North America, SBRT was employed to treat patients with medically inoperable early stage lung cancer to a dose of 45 Gy to 54 Gy in three fractions, achieving a local control of more than 90% and a 3-year OS of approximately 60%.[18,28] These results are roughly twice what was typically achieved historically with CFRT, establishing a new standard of care in this setting.

In addition to its well-established role in medically inoperable early stage lung cancer, SBRT has gained traction as an acceptable approach for a variety of other indications. Primary prostate, pancreas, and hepatocellular cancers may be well treated with SBRT. Additionally, SBRT can serve as a noninvasive means of ablating oligometastatic tumor deposits in the lung and liver as well as controlling challenging para-spinal tumor deposits.

Prostate Cancer

King et al have reported tumor control outcomes and prospectively collected patient-reported quality of life effects in 1100 patients who had been enrolled in prospective trials and registries of SBRT for prostate cancer[29,30] (see also Chapter 53). The median follow-up was 3 years and 194 patients remained evaluable at 5 years. After a median dose of 36.25 Gy in four to five fractions, the 5-year biochemical relapse free survival rate was 95%, 83%, and 78% for patients with Gleason Score 6, 7, and 8, respectively, and 95%, 84%, and 81% for low-, intermediate-, and high-risk patients, respectively. A temporary decline in self-reported urinary and bowel function was observed within the first 3 months after SBRT which returned to baseline status or better within 6 months and remained so beyond 5 years. A decline in sexual quality of life was observed predominantly within the first 9 months, with no significant impact from androgen deprivation or patient age. SBRT for prostate cancer is less costly than other forms of radiation therapy.[31,32] However, an analysis of the experience of early adopters of this technology suggested there the rate of genitourinary toxicity after SBRT for prostate cancer might be slightly higher than for CFRT,[32] and so continued analyses of ongoing prospective studies will be important to understand what metrics are important for optimizing the quality of care in this setting.

Gastrointestinal Cancers: Pancreatic and Hepatocellular

Regarding the use of SBRT for locally unresectable pancreatic cancer, in an early Danish study, a large volume of bowel received a high dose (30 Gy or higher in three fractions), leading to substantial toxicity.[33] Learning from that experience, investigators from numerous institutions have reported the safe administration of SBRT to tightly focused fields around the primary pancreatic tumor, often sandwiching cycles of chemotherapy around the SBRT with minimal interruption of the chemotherapy, achieving survival and toxicity rates that compare favorably with CFRT[34-36] (see also Chapter 48).

Yet another domain in which SBRT has been explored is the primary treatment of hepatocellular cancer (HCC) (see also Chapter 49). Here, as for the other primary cancers noted previously, SBRT is an appealingly noninvasive therapy. SBRT can be administered either as definitive therapy or as a bridge to liver transplant.[37] In the Indiana University experience, 60 patients with liver-confined HCC were treated with SBRT to doses adjusted according to pretreatment liver function.[38] For Child-Pugh (CP) class A patients, the majority of patients received a prescription dose of 48 Gy in three fractions; in contrast, for CP class B patients, the dose was reduced to 40 Gy in five fractions. With a median follow-up time of 27 months for the 60 patients treated (36 CP A, 24 CP B), the 2-year local control, progression-free survival, and OS were 90%, 48%, and 67%, respectively. Twenty-three patients underwent transplant a median of 7 months post-SBRT. There was no grade 3 or higher nonhematologic toxicities, although 20% of patients experienced a progression in CP class within 3 months of treatment. This latter toxicity was similar to what was noted by the Princess Margaret Hospital group in their prospective studies.[39] In a large Japanese retrospective study, patients treated with SBRT had CP A or B status and a single primary or recurrent HCC lesion 5 cm or less in maximum diameter.[40] The prescribed dose was 40 Gy for CP A and 35 Gy for CP B, given in five fractions, with a dose reduction if more than 20% of the liver received more than 20 Gy. A 5-Gy dose reduction was required if the proportion of the liver receiving ≥20 Gy exceeded 20%. For the entire cohort of 185 patients (n = 48 in the 35-Gy group; n = 137 in the 40 Gy-group), the 3-year local control and OS rates were 91% and 70%, respectively.

Oligometastases

Ever since Hellman and Weichselbaum coined the term *oligometastases* and suggested a role for conformal radiotherapy in

this context,[41] there has been steadily increasing interest in ablating limited foci of metastatic disease radiotherapeutically or by other local intervention. A full discussion of this topic is beyond the scope of the present chapter, but there are numerous reviews summarizing the canon of literature that documents durable disease-free survivorship following surgery, radiotherapy, or other local ablative modality for many patients with limited deposits of metastatic disease.[42,43] A recent example of one of the evolving paradigms in which this approach appears to have a role is in the setting of oligoprogressive disease in a patient on therapy with a novel targeted agent, where the strategy is to "weed the garden" of resistant clonogens while extending the patient's access to an agent that is still providing systemic benefit. Gan et al described the use of local ablative therapy for patients with anaplastic lymphoma kinase-positive lung cancer receiving crizotinib.[44] Among 33 patients who progressed while taking crizotinib, those with progression outside the central nervous system (n = 14) received SBRT or equivalent local ablative therapy. The 6- and 12-month actuarial local lesion control rates with SBRT were 100% and 86%, respectively. Crizotinib was continued after local ablative therapy. The use of local ablative therapy allowed a longer duration of the use of crizotinib. Patients continuing to take crizotinib for >12 months versus ≤12 months had a 2-year OS of 72% versus 12%, respectively ($p < 0.0001$).

CONCLUSIONS

SBRT has emerged as a technology with the potential to benefit cancer patients in many ways. SBRT has an established role as a standard therapy for medically inoperable early stage lung cancer and is a viable alternative to surgery and other forms of radiation therapy for numerous other malignancies. There remain opportunities to refine the technical aspects of treatment delivery as well as our understanding of the ideal patients to treat.

CHAPTER

25 Metastatic Disease: Bone, Spinal Cord, Brain, Liver, and Lung

Kenneth Y. Usuki, Michael T. Milano, Marc David, and Paul Okunieff

Local tumor control is now achieved with modern combined modality therapy. Metastatic disease therefore dominates the survival outcomes of patients with cancer. Metastases to the bone commonly cause pain, whereas those to the lung, liver, and brain cause organ dysfunction with substantial changes in quality of life. Metastases to any of these organs can lead to a shorter life. Although palliative care comprises a large part of the clinical practice of oncology, studies show that cancer pain is often inadequately managed.[1,2]

Among painful metastases, osseous metastases[3] remain the most common cause of intractable pain in patients with cancer. Bone is the third most common site of metastases after lung and liver.[4] Metastases usually become apparent after the diagnosis of the primary tumor, but in up to 23% of patients they are the presenting problem. Bone pain results in immobility, anxiety, and depression and severely impacts a patient's quality of life. Thus, treatment of bone pain is a high priority.

Brain metastases are a devastating site of metastatic disease. Most patients with brain metastases succumb to metastatic disease within a few months.[5,6] Relatively few are candidates for open surgery, which can carry the risk of severe sequelae. The advent of radiosurgical techniques and high-quality magnetic resonance imaging (MRI) of the brain has greatly changed the outcomes for some patients with brain metastases. Patients can have improved duration of cognitive performance, with some enjoying prolonged survival.[6] The success of this approach is limited to patients with tumors in favorable regions of the brain. Among patients with lung cancer, the actuarial incidence of brain metastases can exceed 70%.[7,8] Other cancers can also have high rates, including 19% of women with metastatic breast cancer. Regarding therapy, local therapies such as surgery or radiosurgery are often supplemented by elective whole brain irradiation in patients with more than one lesion.[9]

Liver metastases are common in many cancers, and like brain metastases are usually associated with a limited median survival. Liver metastases occur in 40% to 70% of patients with progressive colorectal cancer and in a similar range of patients with progressive breast cancer or progressive lung cancer.[10,11] Treatment for liver disease, like pain, is often difficult and therefore inadequately managed. More recently there has been an effort to treat liver metastases using localized therapies. These include stereotactic radiation techniques, radiofrequency ablation, hyperthermia, and embolic therapy in addition to resection. There has been satisfactory success with many of these treatments, which appear to be improving patient outcomes. International consensus increasingly favors stereotactic liver irradiation as a local treatment for liver metastases.[12,13]

BONE METASTASES

Table 25-1[14] shows the prevalence of skeletal metastases in several autopsy series. The marked variation may be attributed to differences in the thoroughness of the pathologic examination of the skeleton. Bone scintigraphic surveys have, in general, reported higher rates of bone metastases. In a study by Tofe et al,[15] bone scans of 1143 patients with a nonosseous primary tumor were examined; 61% of the patients had an abnormal bone scan finding, and 33% had breast, lung, or prostate primary cancer.

In a prospective series of hospital patients with bone metastases, the tumors carrying the highest risk of bone metastases were those originating in the prostate (32.4%), breast (21.9%), kidney (16.4%), thyroid (11.7%), lung (10.9%), and testes (10.2%).[2] The incidence of patients developing bone metastases by primary site is shown in Table 25-2.[15]

The distribution of skeletal metastases from breast cancer is shown in Table 25-3. Similar distributions have been noted from prostate, lung, and breast primary cancers.[16-19]

Pathophysiology

Tumor cells gain access to the systemic circulation, primarily through the capillary system, but some gain access through the lymphatics; only a few of these cells are able to successfully establish a metastatic focus.[20] Indeed although circulating tumor cells are common,[21,22] they do not reliably portend metastases and when included in American Joint Committee on Cancer (AJCC) staging are considered M0-like in choice of therapy. The process of developing a hematogenous metastasis from a primary tumor includes many steps; steps that are rarely achieved by any individual circulating tumor cell.[23] The tumor must dissociate from the primary mass, gain access to the circulation, survive the immune system and circulatory shear forces, identify a host organ, and develop an exit passage to that organ. Once it enters an organ it must retain reproductive potential, proliferate, generate a vasculature, and grow. The molecular expression profiles that dictate which tumor cells can produce a metastasis, at what frequency, and in which organs are of great research interest.[24]

Cancer cells metastasize to bone mostly via hematogenous spread. Skeletal blood flow accounts for only 4% to 10% of the cardiac output,[25] and some authors believe that the incidence of skeletal metastases is higher than expected based on perfusion alone. A mechanism explaining the high incidence has been described by Weiss.[26] The microstructure of the hematopoietic marrow renders it particularly vulnerable to tumor cell accumulation and ultimate invasion. Nutrient arteries to the bone tend to subdivide into capillaries as they near the endosteal margin of the bone. These capillaries become continuous with a rich venous sinusoidal system, with a capacity six to eight times that of the osseous arterial system. More important, the circulation comes to a near standstill at this point, allowing tumor cells more time to invade the matrix.

To sustain growth, a colony of tumor cells needs to obtain its own vascular supply once it has been established. A hypothesis is that a tumor angiogenesis factor attracts

TABLE 25-1 Prevalence of Skeletal Metastases at Primary Site

Primary Site	Prevalence (%)
Breast	47-85
Prostate	54-85
Thyroid	28-60
Kidney	33-40
Bronchus	32-40
Esophagus	5-7
Other gastrointestinal	3-11
Rectum	8-13
Bladder	42
Cervix	0
Ovaries	9
Liver	16

Data from Galasko CSB: Incidence and distribution of skeletal metastases. Clin Orthop 210:14–22, 1986.

TABLE 25-2 Incidence of Bone Metastases According to Primary Site

Primary Site	No. of Patients	Patients with Bone Metastases (%)
Breast	6423	17
Prostate	144	16
Esophagus	451	6
Lung	589	5
Bladder	172	5
Rectum	274	4
Thyroid	107	4
Uterine cervix	1981	3
Uterine corpus	509	3

endothelial cells to a small tumor colony that would otherwise be dependent on local tissue circulation and incapable of further invasion.[27] The production of such tumor angiogenesis factor may be partly blocked by the immune responses, presumably mediated through lymphocytes. Therefore, an established micrometastasis may attract vasculature required for growth several years later. This theory may explain the late appearance of metastases long after definitive treatment of the primary.

Some tumors, notably of breast, prostate, lung, renal, and thyroid, produce and secrete humeral mediators that stimulate osteoclast activity. These include transforming growth factor, platelet-derived growth factor, tumor necrosis factor, prostaglandins, procathepsin D, interleukins, parathyroid hormone-related protein, and granulocyte-macrophage colony-stimulating factors.[28,29]

The distribution of metastases in the skeletal system is not uniform. Bone metastases tend to involve the axial skeleton more often than the appendicular skeleton. Considering the distribution of marrow in the axial and appendicular skeleton, this higher predilection argues for specific bone marrow-derived growth factors that fertilize the soil of the bone for tumor growth.[25]

Diagnosis

Laboratory

The biochemical parameters include alkaline phosphatase, urinary hydroxyproline, and the urinary hydroxyproline-creatinine ratio lack specificity, and are of no value in the diagnosis of skeletal metastases.[30,31]

Imaging

Skeletal scintigraphy is usually the first-line imaging technique used for detecting skeletal metastases. A bone scan is more sensitive than plain radiographs and has the advantage of examining the entire skeleton. Most lesions evoke an osteoblastic response, which shows up as an increased tracer uptake.[32] Occasionally, metastases may show up as areas of decreased uptake. This may be observed in rapidly growing lesions, when bone destruction far exceeds new bone formation, or secondary to an infarction. Highly vascular metastases, such as those from a renal primary cancer, may be seen on the early vascular phase of the bone scan. Metastases not detected by a bone scan include tumors that do not evoke an osteoblastic response such as myeloma, some lymphomas, and very small deposits.[33]

Widespread metastatic disease may be misinterpreted as a normal scan with symmetric uptake. In these situations, a reduction in urinary excretion of isotope and faint or absent renal uptake with decreased bladder activity are clues of an abnormal scan.[34]

Most skeletal metastases develop in the medulla and involve the cortex later on; therefore, plain radiographs are generally insensitive.[34] Within the spine, the vertebral body is affected first, although the radiologic findings of pedicle destruction are noted first.[35]

Computed tomography (CT) scanning has been found to differentiate between metastases and degenerative joint disease, even though the two coexist, and the latter is a common cause of increased uptake on a bone scan. Muindi et al[36] reported that 50% of patients with breast cancer with a positive bone scan and a normal radiograph had obvious skeletal metastases on a CT scan, 25% had a benign cause, and 25% had a negative CT. None of the patients with a CT scan that was negative for metastases subsequently experienced metastases. CT scan is also valuable in evaluating soft-tissue involvement and can be combined with myelography for

detecting extradural tumor spread in patients unable to undergo MRI.

More recently, MRI has been described as the method of choice for examining the spine. It is more sensitive than a bone scan for detecting early metastases within the medulla, but both T1- and T2-weighted images are required.[37] It is the procedure of choice when neural compression is suspected[31] because it is less invasive than CT myelography, and a small incidence of acute deterioration of neurologic function has been reported by CT myelography.[38] When cord impingement is suspected, imaging of the entire spine should be considered because approximately 10% of patients have multiple levels of cord impingement.[39] It is also used in discriminating between benign and malignant vertebral collapse. In the future whole-body MRI could emerge for metastasis screening.[40] Disadvantages of an MRI include its high cost, exclusion of patients with metal implants, patients with severe claustrophobia, and inferior visualization of the cortex compared with a CT scan. Treatment response using MRI and CT can be difficult to evaluate.

Positron emission tomography (PET) with 18F-fluoride or 2-fluoro-deoxy-D-glucose (FDG) is used for the initial staging of many malignancies and is helpful in the diagnosis of bony metastasis. 18F-fluoride is a bone-imaging agent and forms fluoroapatite in osteoblastic cells. Uptake of 18F-fluoride is higher than for 99Tc used for bone scintigraphy.[41] This sensitivity can lead to inadvertant overdiagnosis of bone metastases, but can be useful for diagnosis, tumor localization, and assessment of treatment response. FDG is a tumor-imaging agent that uses the higher glycolysis activity in the tumor cells.[42] FDG-PET scan compared to bone scintigraphy shows a similar high sensitivity (range from 74% to 95%) but a higher specificity (range of 90% to 97%).[43-47] Limitations include traumatic, infectious, and inflammatory processes that can also accumulate glucose. Accumulation of FDG requires the tumor to have an adequate metabolic rate. Neoplasms, like prostate adenocarcinoma, are not consistently seen using PET scans.[48,49] PET images provide poor anatomic imaging but are extremely useful when employed with a concurrent CT or fused MRI image.[41,50,51]

Biopsy

Bone biopsy is not necessary routine. It is helpful in patients with no history of malignancy, in patients with a solitary lesion (in whom a more aggressive treatment approach may be indicated), and in patients with more than one suspected primary lesion.

Treatment

The primary goal of therapy is to improve quality of life. To achieve this goal, we need to decrease or eliminate pain and improve or maintain skeletal function. The complexity, duration, and cost of therapy should be low, and complications should be avoided.

Treatment recommendations must be individualized. A key consideration is patients' overall prognosis. This assessment should be based on an understanding of the natural course of the specific disease. Although the survival of patients with bone metastases is generally poor, potential long-term survivors must be identified. Long-term survivors require a more durable relief of pain, but they are also at more risk for a late, treatment-related complication. The Radiation Therapy Oncology Group (RTOG) trial[52] studied longevity among patients with bone metastases. The median survival in patients with solitary and multiple bone metastases was 36 and 24 weeks, respectively. Patients with breast and prostate primaries survived significantly longer (30 weeks to 73 weeks), whereas patients with lung cancer died within a median of 12 weeks to 14 weeks. Patients with renal cell carcinoma with solitary metastasis are also likely to be long-term survivors. Kjaer[53] monitored 25 such patients for 10 years to 14 years. The median survival was 4.3 years, with 5-year overall survival (OS) of 36%, and 10-year OS of 16%.

Pharmacologic Treatment

Systemic therapy remains the mainstay of treatment for metastatic disease, including bone metastases. For asymptomatic bone metastases not at immediate risk of fracture, disease-appropriate systemic therapy including chemotherapy, hormonal therapy, and biologic therapy is indicated. Patients may also benefit from bisphosphonate therapy.

Bisphosphonates

The discovery of compounds inhibiting calcium phosphate precipitation in plasma and urine led to an interest in the use of bisphosphonates as therapeutic agents. The inhibitory activity was attributed to inorganic pyrophosphate, but the use of this agent was limited because of its rapid hydrolysis when given parenterally. Subsequent research led to the development of pyrophosphate analogs resistant to endogenous phosphatases, now known as bisphosphonates.

Bisphosphonates inhibit osteoclast-mediated bone resorption. The exact mechanism is likely multifactorial, including direct biochemical effects on the osteoclast, prevention of osteoclast attachment to the bone matrix, and inhibition of differentiation of osteoclast precursors and recruitment.

Four Phase II trials of intravenous pamidronate every 2 weeks to 4 weeks as the sole treatment of osteolytic bone metastases in breast cancer reported similar results.[54-57] Relief of pain was noted in approximately 50% of patients, and approximately 25% showed radiographic evidence of bone healing. Similar results for bone pain have also been reported in patients with prostate cancer.

In more recent studies, one Phase II[58] and one Phase III[59] showed equivalence between zoledronic acid and pamidronate. Rosen conducted a three-arm study for patients with bone lytic or mixed disease from either breast cancer or multiple myeloma.[59] One thousand six hundred forty-eight patients received intravenous pamidronate 90-mg zoledronate in 4 mg or 8 mg every 3 weeks for 13 months. The primary endpoint was the incidence of a skeletal event and secondary endpoints were pain relief and performance status (ECOG). All treatment groups showed equivalence with a similar frequency of skeletal events at 12 months and with pain scores decreased by an average of 0.5 on a scale of 5. This randomized trial led to modification of the ASCO 2003 and the Cochrane Breast Cancer Review Group update recommendations on the use of bisphosphonates in breast cancer.[60,61] Both boards now recommend either pamidronate 90 mg intravenously (IV) over 2 hours or zoledronate acid 4 mg IV over 15 minutes for patients with an abnormal bone scan and abnormal imaging by plain radiographs on CT scan or MRI. Bisphosphonates have not yet been formally tested in patients with early, asymptomatic bone metastasis.

Zoledronic acid has also been used in prostate cancer to treat blastic metastasis.[62] Saad et al randomized 643 patients to placebo or to zometa 4 or 8 mg IV infusion every 3 weeks for 15 months. Results show a reduction in skeletal-related events from 44% to 33% with a significant p value of 0.021. Pathological fractures were reduced from 22% to 13% (p = 0.015). Onset of the events occurred at a median time of >420 days (median not reached) in the group receiving zometa and at 321 days in the placebo group. Time to disease progression or survival was similar in both groups. The need for local field radiation was not significantly different in the two groups.

Zometa has also been evaluated for the treatment of bone metastases from other disease sites; 773 patients with lung, renal, head and neck, thyroid, and unknown primaries received either a placebo or zometa 4 or 8 mg.[63] Skeletal events including hypercalcemia were significantly reduced from 47% to 38% ($p = 0.039$) and the median time to the first event was longer in the zometa group (225 days versus 155 days, $p = 0.023$).

Although zoledronic acid is well tolerated, the treating physician is advised to monitor serum creatinine before each administration. Caution is also advised for patients receiving concomitant aminoglycoside or loop diuretic because of an increased risk of hypocalcemia. Ruggiero published a retrospective review of 63 patients on bisphosphonates who suffered osteonecrosis of the jaw[64]; 57% received pamidronate and 21% zoledronic acid. Surgical treatment was required. Oral agents, such as clodronate, have low bioavailability (2%) and produce gastrointestinal side effects.

Analgesics

The optimal management of pain begins with careful assessment of the degree of pain, site, functional limitations, and concurrent neurologic symptoms.[65] The World Health Organization (WHO) analgesic ladder for cancer pain management provides guidelines for analgesic use.[66]

Step I. Nonopioid with or without adjuvant therapy
Step II. Opioid for mild to moderate pain plus nonopioid with or without adjuvant therapy
Step III. Opioid for moderate to severe pain with or without nonopioid with or without adjuvant therapy

Step I nonopioid analgesics include acetaminophen, aspirin, and other nonsteroidal antiinflammatory drugs (NSAIDs). The dose of acetaminophen should not exceed 4 g/day. Step II opioids include codeine, dihydrocodeine, hydrocodone, oxycodone, and propoxyphene. Step III opioids include morphine, oxycodone, hydromorphone, and fentanyl.

Attention should be paid to selecting the appropriate analgesic, dose, route, and schedule. Continuous, slow-release medications are generally preferred over short-acting medications. The latter can be effectively used for breakthrough pain. Allowing pain to recur between doses causes unnecessary suffering and may allow tolerance to develop. When prescribing oral opioids, the dose is about two times that of the subcutaneous dose and three times that of the intravenous dose. For patients unable to take oral medications, suppositories and transdermal patches are good options. When combining drugs, it is important to use drugs that act at different levels of the pain pathway (Figure 25-1). The combined effect can be additive and at times synergistic.

The pain of bone metastases is generally only partially responsive to opioids.[67] Many osseous metastases produce prostaglandins that induce osteolysis. NSAIDs alleviate pain by inhibiting the synthesis of prostaglandins. Corticosteroids prevent the formation of arachidonic acid (the precursor of prostaglandins) from cell membrane phospholipids. The use of NSAIDs or corticosteroids combined with morphine is usually effective.

Corticosteroids can be used when pain is caused by nerve compression. They decrease edema and reduce the pressure on the nerve. Pain relief can be achieved within 48 hours. Corticosteroids can be used as a temporary measure before a more definitive decompression is achieved with radiotherapy or surgery.

Side effects associated with the use of opioids include nausea, vomiting, constipation, urinary retention, dysphoria, mental clouding, tolerance, and addiction. Nausea and vomiting are usually self-limiting and resolve during the first week. Side effects should be anticipated, prevented, and managed aggressively.

Surgery

Surgery should be considered for patients with pathologic fractures or impending fractures (Figure 25-2). In the former situation, fixation can reduce pain and expedite healing. In the latter, prophylactic fixation may prevent a fracture, thereby eliminating the functional loss and reducing the risk of nonunion of a fracture.

To understand the role of surgery better, we need first to elaborate on the biomechanics of pathologic fractures. Cortical defects weaken bone, especially in the setting of torsional stress. The two general categories of cortical defects are (1) stress riser, a defect with dimensions less than the diameter of the bone, and (2) open-section defect, a discontinuity of dimensions greater than the diameter of the bone.[68] By creating a nonuniform distribution of stresses in bone, stress risers can decrease bone strength by 60% to 70%.[69] An open-section defect has a greater impact on decreasing shear and torque-loading resistance. The volume of bone able to resist the load is significantly decreased compared with a closed section. A 90% reduction in load to failure and energy storage to failure is noted in torsion testing of the human adult tibia with open section.[70] Torsional or rotational forces occur in various daily movements such as getting out of a chair. Bone is weakest during torsion. A single quarter-inch hole made for a bone biopsy can decrease torsional strength by 50%.[71]

The nature of the metastatic lesion affects the overall bone strength. Both lytic and blastic lesions dramatically alter bone elasticity; lytic lesions reduce bone strength more than blastic lesions. Irregular lesions are not necessarily more detrimental to the bone than smooth lesions, but elongated lesions drastically reduce bone strength.[72]

The distribution of pathologic fractures is shown in Table 25-4. Several series have examined various criteria predicting the risk of a pathologic fracture. Keene et al[73] evaluated 2673 patients with breast cancer in an attempt to predict pathologic fracture of the femur using clinical and radiologic criteria. Only 26 (13%) of 203 patients with evaluable proximal femur metastasis had pathologic fractures. They were unable to correlate lesion size and risk of pathologic fracture. No other risk factor was identified. The authors concluded that plains radiographs are insufficient diagnostic tools for identifying high-risk lesions. Of note is that this study was limited to single anteroposterior (AP) films.

Mirels[75] designed a score system to predict the risk of a pathologic fracture (Tables 25-5 and 25-6). Of 78 patients, 51 experienced a fracture and 27 did not. The mean score for the nonfracture group was 7 versus 10 for the fracture group. This system provides a useful tool to evaluate patients for prophylactic fixation. Patients with a score of 10 to 12 should undergo surgery. Patients with scores of 7 or less are not likely to benefit from such therapy. In patients with a "gray zone" score, the status of surrounding bone and lifestyle (old, osteoporotic woman vs young athlete) should be considered.

The following guidelines may help make a decision regarding prophylactic fixation. Because each patient has unique circumstances, these guidelines cannot replace sound clinical judgment on the part of the attending physician.

1. Life expectancy is longer than 3 months.
2. Patient is medically fit to tolerate major surgery.
3. Procedure planned is expected to expedite mobilization.
4. Quality of bone both proximal and distal to the lesion is adequate to support any fixation device.
5. There is cortical bone destruction of 50% or more.
6. Lesion measuring 2.5 cm or larger is located in the proximal femur.
7. There is pathologic avulsion fracture of the lesser trochanter.
8. Stress pain persists after irradiation.

The following principles govern the surgery of impending fractures:

1. Maximum effort is made to avoid disrupting the surrounding soft tissue to preserve the periosteal blood supply. This is of particular importance in these patients because the endosteal circulation has usually been disrupted by the metastatic deposits.
2. Highly vascular lesions (metastasis from renal cell carcinoma, for instance) should be considered for possible embolization before open curettage.
3. Defects that include the entire circumference of the cortex should be plugged by acrylic cement at fixation to reduce the biomechanical risks associated with stress risers or open-section defects.
4. When large, thin-walled lesions exist, the intramedullary nailing techniques should be augmented by direct reinforcement of the lesion using methyl methacrylate. This will enhance fixation of the distal long bone, particularly with regard to the torsional stability, and will also prevent shortening of the bone.

Pathologic fractures of the humerus commonly occur in the diaphysis followed by the proximal humerus. Fractures of the diaphysis can be fixed using an intramedullary interlocking device, such as a Brooker-Wills nail, which provides excellent strength and effective resistance against varus, torque, and distraction forces.[76] Proximal humerus fractures commonly require a prosthesis. These patients usually achieve a limited flexion and abduction of about 90 degree to 100 degree and enjoy good overall function, joint stability, and pain relief.[68]

Fixation of the femoral neck–intertrochanteric area can be achieved with the use of a compression hip screw and side plate. Fractures involving the femoral neck may be better treated with prosthetic replacement because they are rarely amenable to internal fixation.[77] Subtrochanteric, femoral shaft, and supracondylar femoral lesions are amenable to internal fixation, but large cortical lesions may benefit from an intramedullary acrylic cement filling.

The common problem encountered in acetabular lesions is the failure to appreciate the extent of bone lysis radiographically. Extensive destruction of bone may render efforts to reinforce such lesions with bone graft fruitless. Pathologic fractures of the acetabulum should be managed by total hip arthroplasty.

The spine is the most common site of skeletal metastases. The vertebral body is typically affected first, although pedicle destruction is noted first radiographically. In the absence of a

blastic lesion, 30% to 50% of the vertebral body needs to be destroyed before any destruction can be noted on a radiograph. Vertebral metastases are often asymptomatic. Symptoms are usually a result of one of the following: (1) an enlarging mass within the vertebral body that breaks through the cortex and invades the paravertebral soft tissues, (2) a mass compressing or invading local nerve roots, (3) a pathologic fracture, (4) spinal instability secondary to a pathologic fracture (in particular when the posterior elements are involved), and (5) spinal cord compression.

An aggressive surgical approach to spine metastases is usually not warranted.[78] Spinal stabilization is a major surgery involving multiple risks and prolonged recovery. Most patients with spinal metastases do not have progressive spinal instability or neurologic involvement and can be treated with radiation, hormones, chemotherapy, or temporary bracing. Even patients with vertebral body compression fractures can be treated with temporary bed rest and soft bracing. Indications for surgical intervention include (1) progressive spinal canal impingement and cord compression by a radioresistant tumor or a recurrence after maximum tolerable radiation dose to the intended area; (2) bone or soft-tissue detritus extruded into the canal as a result of progressive spinal deformity, with or without spinal instability; (3) progressive spinal deformity; (4) progressive kyphotic deformity associated with posterior disruption and shear deformity; and (5) solitary metastases of a histology that is unlikely to be controlled long term with tolerable doses of irradiation.

Vertebroplasty of bone metastasis was first described in 1987 and consists of direct injection of the affected vertebra with cement. Polymethylmethacrylate (PMMA) is active through several pathways and produces pain relief in 80% of the patients.[79] The procedure is done under intravenous sedation or general anesthesia. Pain-receptors destruction is achieved with exothermic reaction of the polymonomer and compressive effect on small nerves. Vertebroplasty effects are not modified by external-beam radiation (EBRT) and PMMA conserves its properties despite radiation[79] Vertebroplasty and radiation are complementary, both providing pain relief, the former providing more structural benefit of weak bones, and the later offering more durable tumor control of larger tumors.

Radiotherapy

Local Field Radiotherapy

The vast majority of patients can be managed successfully with EBRT. A large body of clinical evidence documents the effectiveness of such therapy.[80] The optimal dose and fractionation schedule is still not resolved. A summary of the major prospective clinical trials that addressed these issues is provided in Table 25-7. The results of these studies should be interpreted with caution because the inherent heterogeneity within the randomization groups may have precluded detection of significant differences, even when such differences could have existed. The use of different pain scoring systems (physician based versus patient based) and different handling of concomitant use of analgesics, chemotherapy, or hormonal therapy precludes meaningful comparison of the results of these studies.

Between 1974 and 1980, the RTOG conducted a large national study to determine the effectiveness of five different dose fractionation schedules.[52] A total of 1016 patients were entered, 266 into a solitary metastasis stratum and 750 into a multiple metastasis stratum. The former were randomly assigned to treatment with 40.5 Gy in 15 fractions or 20 Gy in 5 fractions. The latter were assigned to 30 Gy in 10 fractions, 15 Gy in 5 fractions, 20 Gy in 5 fractions, or 25 Gy in 5 fractions. A quantitative measure of pain, based on severity and frequency of pain and the type and frequency of pain medications used, was devised to evaluate response. Overall, 89% of patients experienced at least minimal relief, 83% achieved partial relief, and 54% obtained complete relief. There were no significant differences between the treatment arms in both strata. The initial pain score was found to be a useful predictor; patients with high scores were less likely to respond and less likely to experience a complete response. Patients with breast and prostate cancer were significantly more likely to respond than those with lung or other primary lesions. Patients completing their treatment as planned had a significantly higher rate of complete response than those who did not. Although some pain relief was experienced almost invariably within the first 4 weeks, complete relief was first reported later than 4 weeks after the start of treatment in about 50% of patients. The

median duration of minimal and complete pain relief was 20 and 12 weeks, respectively. There were no significant differences in the duration of pain relief between the different arms. The authors concluded that all treatment dose schedules were equally effective.

Blitzer[87] performed a reanalysis of the RTOG study. Using a stepwise logistic regression, he examined the effect of the number of fractions, the dose per fraction, and solitary versus multiple metastases on the probability of attaining complete pain relief and the need for retreatment. This multivariate technique allowed patients with solitary and multiple metastases to be analyzed together. The number of fractions was the only variable that was significantly associated with outcome. There was no correlation of the time-dose factor (TDF)[88] with outcome. It was concluded that the more protracted schedules resulted in improved pain relief.

The concept of TDF has long been replaced by the linear quadratic model. Using this model, and assuming an α/β of 10 for tumor, we calculated the biologically effective dose (BED) for the various schedules tested by the RTOG. Figures 25-3 and 25-4 depict pain response and freedom from retreatment as a function of BED, respectively. The solid lines are the regression functions, and the dotted lines represent the 95% confidence intervals. The results suggest that schedules with higher BED resulted in better pain relief and reduced the need for retreatment.

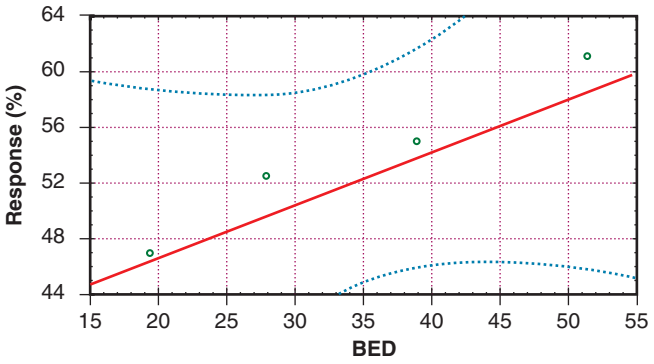

Figure 25-3 Pain response as a function of biologically effective dose (BED) by means of linear regression analysis. Response = 39.1 + 0.38 × BED; $r = 0.74$; $P = 0.15$. The *solid red line* indicates the regression function, and the dotted blue lines indicate 95% confidence intervals.

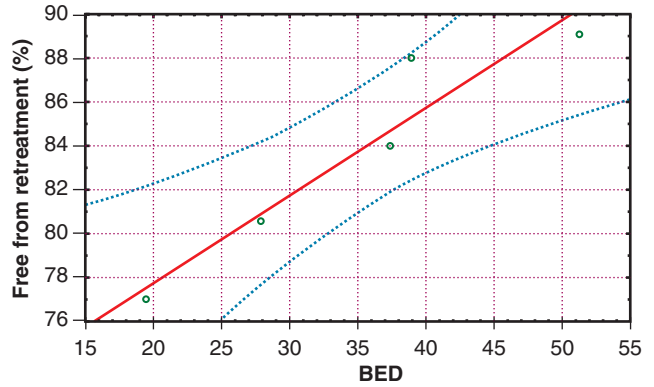

Figure 25-4 Freedom from retreatment as a function of biologically effective dose (BED) by means of linear regression analysis. Response = 69.7 + 0.4 × BED; $r = 0.95$; $P = 0.05$. The *solid red line* indicates the regression function, and the dotted blue lines indicate 95% confidence intervals.

Price et al[81] randomized 288 patients to receive either 8 Gy in one fraction or 30 Gy in 10 daily fractions. Pain was assessed using a daily questionnaire completed by the patient at home. No differences were found in the probability of attaining pain relief, speed of relief, or duration of relief between the two arms.

Hoskin et al[82] randomized 270 patients to receive either 4 Gy or 8 Gy in one fraction. Pain (assessed by the patient) and analgesic usage were recorded before treatment and at 2, 4, 8, and 12 weeks. At 4 weeks, the response rates were 69% for 8 Gy and 44% for 4 Gy ($p < 0.001$). The duration of the effect was independent of dose.

Additional studies have evaluated single- and multiple-fraction regimens. A Danish randomized trial of 241 patients showed no significant difference with regard to pain relief or quality of life after receiving either 8 Gy in a single fraction or 20 Gy in five fractions.[89] Wu et al performed a meta-analysis of 16 trials including 5455 patients[90] and proclaimed equivalence between single and multiple fractions. Van der Linden et al recently published a reanalysis of a Dutch Bone Metastasis Study that included 1171 patients.[91] This study randomized patients to either single 8 Gy or 24 Gy in six fractions. Mean time to retreatment was shorter (13 weeks versus 21 weeks) with a single fraction. It was also more frequent: 24% after a single fraction and 6% after 6 fractions ($p = 0.001$). An initial high pain score also influenced the need for retreatment.

Treatment Techniques

The target volumes for EBRT should be defined after review of all appropriate diagnostic studies. Attention should be paid to soft-tissue masses, which are often associated with bone metastases and at times responsible for the observed symptoms. Such lesions are best assessed by CT or MRI. The target volumes are treated with appropriate margins. Depending on the treatment site and volume, suppression of the bone marrow should be anticipated. In patients for whom chemotherapy is planned, treatment volumes should be kept to a minimum to preserve marrow reserves. Because many patients have repeated courses of therapy, all previous ports and radiation records must be reviewed. To minimize late radiation damage, overlap of radiation fields should be avoided. Depending on the clinical circumstances, overlapping retreatment may be appropriate in patients with short life expectancy.

Hemibody Irradiation

Most patients with bone metastases have multiple sites of involvement. As many as 76% of patients receiving therapy to a local field require additional treatment for pain at other sites within 1 year.[92] Historically, wide-field radiotherapy was used to address this problem. Although large-field radiation is less commonly used is the era of systemic therapy, it remains a treatment option. A summary of results of this form of therapy is provided in Table 25-8. Response rates are similar to those observed with local-field radiotherapy, but the onset of relief is more rapid, occurring often within 24 hours of treatment. Hemibody irradiation (HBI) is mentioned here for completeness but is rarely employed. It may require hospitalization for hydration and premedication with steroids and antiemetics and tends to be associated with substantial morbidity. Most patients experience acute gastrointestinal toxicity, with nausea, vomiting, and diarrhea persisting for 24 to 48 hours. Myelosuppression is commonly observed but is rarely of clinical significance. Radiation pneumonitis is rare at doses below 7 Gy to the lungs.

The RTOG conducted a Phase III study to evaluate the efficacy of HBI in addition to local-field irradiation.[92] A total of 499 patients were randomized to receive either HBI or no

TABLE 25-8 Wide-Field Radiotherapy for Painful Osseous Metastases

further therapy after completion of local-field irradiation to a symptomatic site. Entry was stratified by extent of metastatic disease (solitary or multiple) and the targeted hemibody area (upper, middle, or lower). Local-field irradiation consisted of 30 Gy in 10 fractions. HBI consisted of 8 Gy in 1 fraction given within 7 days of completion of the local field. Partial transmission blocks were used to reduce the dose to the lungs to 7 Gy. Time to disease progression, time to new disease, and time to new course of therapy were significantly longer in the HBI arm. Progression of disease was faster in patients with involvement of the upper and middle hemibody (compared with lower hemibody) and in patients with multiple metastases (compared with solitary tumor). As expected, toxicity was significantly higher in the HBI arm, but there were no fatalities and no occurrences of radiation pneumonitis. Although an impact of HBI on clinically occult metastatic disease was demonstrated, the long-term benefit was relatively small. The ultimate progression rates were not significantly different between the arms, and at 1 year 60% of the patients in the HBI arm had to be retreated.

Stereotactic Radiosurgery of the Spine

The spinal column is a common site of metastatic spread where pernicious disease progression threatens the spinal cord. Although conventional palliative fractionated radiotherapy has proven to be effective in both pain relief and short-term local control, the dose is limited by the close proximity of the spinal cord. As treatment improves and metastatic patients survive longer, progression of spine disease after fractionated radiation therapy becomes a serious issue. Stereotactic radiosurgery (SRS) allows for the delivery of a single, ablative dose fraction of radiation using highly conformal techniques with enhanced targeting accuracy. Generally, the delivery of two to five fractions of radiation, using the same techniques, is referred to as stereotactic body radiation therapy (SBRT). SBRT and SRS offer advantages over traditional fractionated therapy. Including the convenience of one to five treatments versus several days of treatment for patients with limited life expectancy in significant pain, improved long-term local control that is less histology dependent, and a safe effective radiation retreatment modality.

The ability to safely deliver ablative doses of radiation depends on accurate localization and immobilization. Using MRI imaging, a planning CT scan, and in some situations spinal myelogram and PET scan, accurate identification of anatomical dosing gradients is achieved. During treatment, image guidance using the bony vertebra as a high fidelity fiducial for both the lesion and the spinal cord may be used. Immobilization of the bony vertebral body structure may be achieved using gravity in the supine position, usually combined with a variety of other immobilization techniques. Modern treatment planning achieves a sharp dose gradient that allows the technique to achieve an ablative dose of radiation to the PTV while reducing significant dose delivery to critical structures, most importantly the spinal cord, but also the esophagus, lungs, kidney, bowel, and bone marrow of adjacent vertebral bodies.

SBRT or SRS technique can be used as the sole initial treatment for spinal metastatic disease, particularly in tumor histologies that are known to have a poor response to traditional fractionated palliative radiation technique, patients with oligometastatic disease, and patients with a long life expectancy. SRS can also be used as a boost treatment after the delivery of conventional radiation (generally prescribed to 20 Gy to 40 Gy in 2.5 Gy fractions to 4 Gy fractions), postoperatively as adjuvant treatment,[98] and as salvage treatment in patients previously irradiated (generally >3 to 6 months prior) for spine metastases.

Spinal SRS is most ideally performed on intravetebral body lesions without extension into the canal allowing for distance between the PTV and the spinal cord. If there is posterior cortical compromise of the vertebral body by the lesion, conventional fractionated radiation therapy should be considered in radiosensitive histologies. Radioresistant histology patients with limited systemic disease should be considered for surgery followed by radiation.

Generally with SRS/SBRT technique, the pain control and local tumor control is on the order of 85%.[99-104] Garg et al[105] showed local control for single fraction SRS in previously unirradiated tumors to be 88% at 18 months. There appears to be a dose response, with greater palliation with prescribed isocenter doses of ≥14 Gy.[106] Although traditional palliative spine radiation fields encompass the involved vertebral body plus a vertebral body above and below, SRS and SBRT generally treat only the involved vertebral body or a portion of the involved vertebral body. This typically equates to the anterior vertebral body with or without the posterior elements and pedicles in those with more posterior extension. In a study from Henry Ford Hospital (Detroit, MI), subsequent metastases to adjoining vertebral bodies after SRS was rare (~5%) and associated with progression of disease elsewhere.[100] In a study from M. D. Anderson Cancer Center (Houston, TX), in-field failures occurred in ~25% of recurrences, and roughly half of the recurrences were in the epidural space, which was attributed to underdosing this region to maintain spinal cord dose constraints. Patients also failed in other regions not included in the treatment volume (of any given patient) including the pedicles, posterior elements, and pre- and paravertebral regions.[98] The presence of paraspinal disease and using SRS doses <16 Gy increased risk of marginal recurrence is discussed in a paper by Koyfman el al.[107] Recent clinical data has shown spine SRS and SBRT to be tolerable, albeit with limited patient follow-up,[108] because patients with spine metastases generally have a poor survival, even those with solitary spine metastases.[109] It appears that myelopathy and radiculopathy rarely occur.[63,108] For single-fraction SRS, most institutions try to achieve a spinal cord maximum dose below 10 Gy.[57] In the University of Pittsburgh experience of spine SRS in 393 patients with 500 lesions, for which the cord maximum was kept below 8 Gy, no acute or late neurotoxicity was observed, and no late toxicity was reported after a follow-up of 3 to 53 months (median, 21 months).[100] In Garg et al[105] the dose to the spinal cord was limited to no greater than 0.01 cm^3 of the spinal cord receiving >10 Gy and the spinal cord plus 2 mm was limited to receiving 12 Gy. These constraints yielded limited toxicity with only 3% of patients suffering grade-3 neurotoxicity with some patients' prescription doses as high as 24 Gy. Sahgal et al[110] looked at dose-volume histogram results for nine cases of spine SBRT, treated at multiple institutions, where radiation myelopathy was

reported and compared them with a cohort of 66 spine SBRT patients without radiation myelopathy. They found a risk of radiation myelopathy of 5% or less when limiting the thecal sac Pmax volume to 12.4 Gy in a single fraction, 17.0 Gy in two fractions, 20.3 Gy in three fractions, 23.0 Gy in four fractions, and 25.3 Gy in five fractions. Several institutions have demonstrated that spinal cord maxima of 12 Gy[102] to 20 Gy[108,111] are tolerated in some patients, though from a multiinstitutional pooled analysis, radiation myelopathy has only been documented to occur after exceeding a fractional dose maximum of 10 Gy to the spinal cord.[112] From this study, dose-volume parameters such as maximal dose and mean and median dose to 0.1 mL to 5 mL of spinal cord significantly correlated with the risk of radiation myelopathy. From the RTOG 0631 study (which is a randomization of spine SRS delivered with 16 Gy versus conventional radiation delivered in one fraction of 8 Gy), spinal cord dose constraints are: 10% and 0.35 mL of spinal cord <10 Gy, and 0.035 mL <14 Gy, with the spinal cord volume defined as 5 mm to 6 mm above and below the target, based on T2- and T1-weighted MRI.

The use of SRS is attractive in the setting of progression after conventional fractionated radiation for spine metastases. With a repeated course of standard fractionated radiation, there is concern about exceeding residual cord tolerance, while affording inferior local control versus SRS. A study of spinal cord tolerance in a rhesus monkey model by Ang et al[113] suggested that the spinal cord has remarkable ability to recovery from previous radiation when treated 1 to 3 years later. Mahadevan et al[114] showed SBRT salvage after normal fractionated palliative radiation was effective. The dose used was 8 Gy × 3 = 24 Gy when the tumor did not touch the spinal cord and 5 Gy to 6 Gy × 5 = 25 Gy to 30 Gy when the tumor abutted the cord. The cord surface received up to the prescription dose. In this group, 93% of patients had stable or improved disease, whereas 7% of patients showed disease progression. With 65% of patients gaining significant pain relief, there was no significant toxicity other than fatigue. A spine SRS/SBRT retreatment study by Sahgal et al[110] looked at patients from multiple institutions, given salvage SRS/SBRT, with one to five fractions, at least 5 months after conventional palliative radiotherapy. They compared dose volume histograms of patients who developed radiation myelopathy to patients who did not develop radiation myelopathy. They found that a thecal sac Pmax nBED of 20 Gy to 25 Gy 2/2 appears to be safe provided the total Pmax nBED does not exceed approximately 70 Gy 2/2, and the SBRT thecal sac Pmax nBED comprises no more than approximately 50% of the total nBED.

The use of SRS/SBRT for spinal metastatic tumors is increasing. Standard field palliative radiation has been a standard option in the treatment of spinal metastatic lesions where the dose delivered was limited by the sensitivity of the spinal cord and surrounding critical structures. Spinal SRS emerged with modern techniques of improved localization, immobilization, and dose gradients within a treatment plan. This relatively new radiation modality affords patients with metastatic spine lesions a safe, effective, and convenient therapy.

Systemic Radionuclide Therapy

The first report on the use of systemic radionuclides for the treatment of bone metastases was published by Pecher more than 50 years ago.[115] Using this modality, all involved osseous sites can be addressed simultaneously. Selective absorption into bone metastases limits irradiation of normal tissues and increases the therapeutic ratio. Administration as a single intravenous injection in the outpatient clinic is a further advantage for many patients.

Systemic radionuclides should be considered in the following circumstances:

1. In patients with widely metastatic disease, as adjuvant to EBRT
2. In patients with pain but without a predominantly painful site, as a first-line therapy
3. There is no evidence of imminent epidural cord compression, pathologic fracture, or mechanical instability
4. In patients with good marrow reserve with a white blood cell count of greater than 2400 and a platelet count of greater than 100,000
5. Patients for whom the value of future marrow toxic chemotherapy is limited.

Historically, phosphorus-32 was the first radionuclide to be widely used in the treatment of bone metastases,[116] although this isotope is now rarely used for bone disease as a result in part of myelosuppression with pancytopenia and an increased incidence of acute leukemia.[92] Phosphorus-32 has since been replaced by newer, less toxic radionuclides (Tables 25-9 and 25-10).

Strontium 89. Strontium 89 decays by beta emission to yttrium 89 with a half-life of 50.6 days. The average beta energy is 1.46 MeV. Chemically similar to calcium, strontium 89 is quickly taken up into the mineral matrix of bone. The fraction of strontium 89 retained is proportional to the metastatic tumor burden and varies between 20% and 80% of the administered dose.[126] Accumulation is preferred in and around metastatic deposits, where active bone formation takes place, which is likely adjacent to but not in the site of malignancy.[126-128] Once incorporated into the metastatic lesion, strontium 89 is not removed metabolically and remains deposited for as long as 100 days.[126] Accurate tumor dosimetry is difficult and usually based primarily on the location of tracer accumulation. Estimates of the total dose absorbed within the metastatic lesion vary between 0.9 cGy and 231 cGy per megabecquerel (MBq), with the typical mean total dose at 23 cGy/MBq and high doses usually corresponding to superscans.[127-130] Typical doses are 1.5 MBq/kg, leading to a nominal tumor dose of 20 Gy to 25 Gy. Elimination is through the kidneys, and careful disposal of urine is needed for 7 days to 10 days after administration. Extra care is advised for incontinent patients. Because strontium 89 emits extremely little gamma radiation, the patient is not a radiation hazard to family members or hospital staff.

The efficacy of strontium 89 has been well documented in dose-seeking studies.[118,119,126,130-134] Laing et al[118] reported on the

results of a dose-escalation study. The optimal dose was found to be 1.5 MBq/kg with no appreciable increment in efficacy above this dose. Of 83 patients treated with at least 1.5 MBq/Kg, 75% had partial relief of pain and 22% were rendered pain free. Pain relief began 10 days to 20 days after treatment and peaked at 6 weeks. Response was maintained for a median of 6 months (range, 4 months to 15 months). The RTOG conducted a dose escalation study and concluded that the maximum tolerated dose of strontium 89 is 6.5 mCi (approximately 3.4 MBq/kg).

Toxicity of strontium 89 is mainly hematologic. Platelet depression is dose dependent and can be prolonged. Most patients have a 20% to 50% drop in their counts after doses of 3 mCi to 4 mCi (1.5 MBq/kg to 2 MBq/kg). Grade 3 toxicity is rare. Other adverse effects include a transient increase in bone pain in up to 10% of patients and rarely facial flushing. The pain flare occurs 1 week to 2 weeks after treatment, may last a few days, and usually heralds a favorable response.

Porter et al[135] reported the results of the Trans-Canada study. This trial evaluated the efficacy of strontium 89 adjuvant to local-field EBRT in patients with hormone-refractory prostate cancer. A total of 126 patients were randomized to local-field radiotherapy (20 Gy in 5 fractions or 30 Gy in 10 fractions) followed by placebo or by strontium 89 (10.8 mCi). Overall and complete responses (relief of pain at the index site) were higher in the treatment arm, but the differences did not reach statistical significance. At 3 months after treatment, 58.7% and 34% of patients in the treatment arm and control arm, respectively, were free of new painful metastases. The median time to further radiotherapy was 35.3 weeks and 20.3 weeks in the treatment and control arms, respectively. Hematologic toxicity was, as expected, higher in patients treated with strontium 89.

Samarium 153. Samarium 153 is a man-made radionuclide that emits beta particles of 0.81 MeV (20%), 0.71 MeV (30%), and 0.64 MeV (50%) and gamma photons of 103 keV (28%). It has a relatively short half-life of 46.3 hours and, consequently, a relatively high dose-rate. Samarium 153 has been chelated to a phosphonate, ethylenediaminetetramethylene (EDTMP), to produce a bone-seeking complex. About 50% of an intravenously administered dose is retained in bone.[136,137] Absorbed dose in bone and red marrow has been estimated at 2.5 cGy/MBq and 0.57 cGy/MBq, respectively.[137] In a Phase I/II clinical trial,[124] the maximally tolerated dose (MTD) was determined to be 2.5 mCi/kg. The principal toxicity observed was hematologic; maximum myelosuppression occurred at 3 weeks to 4 weeks. A flare of bone pain occurred in 12% of patients. The overall pain relief rate was 74%, with a median duration of palliation of 2.6 months. In responders, relief was obtained promptly within 7 days to 14 days of treatment. Response rates were significantly higher with 2.5 mCi/kg than with 1.0 mCi/kg.

Rhenium 186. Rhenium 186 emits beta particles of 1.07 MeV and a 137-keV gamma ray and has a short half-life of 3.8 days. Like samarium 153, it has been complexed to a bone-seeking phosphonate, hydroxyethylenediphosphonic acid (HEDP). Retention in bone is about 50% of the injected dose; the rest is excreted through the kidneys into the urine.[121] Rhenium 186 has been studied in a small number of patients with metastatic cancer of the prostate, breast, colon, and lung.[122] After administration of 33 mCi to 35 mCi, 75% to 80% of patients experienced pain relief, most often within 2 weeks.[121-123] The therapeutic efficacy of rhenium 186 has been confirmed in a double-blind, crossover comparison with placebo.[123] Myelosuppression begins 2 weeks after treatment, peaks at 4 to 6 weeks, and resolves by 8 weeks.[122] A pain flare occurs in 10% of patients 2 days to 3 days after treatment and resolves within 1 week.

Choice of Radiotherapeutic Approaches

In the United States, the usual approach to painful osseous metastases includes fractionated EBRT to index painful sites. Asymptomatic sites are less commonly irradiated. Patients with multiple lesions will commonly receive radionuclides in addition to EBRT to cytoreduce occult metastases and reduce the need for future local radiation. Radionuclides alone and hemibody radiation are less common in the United States, although the latter is often used in Europe and Canada. The advent of improved external-beam targeting technologies and the earlier discovery of patients with limited metastases have spawned efforts for local targeting of bone metastases. The utility of these high-dose treatments to achieve improved tumor control with reduced marrow and other toxicity is under investigation.[138]

SPINAL CORD COMPRESSION

Malignant spinal cord compression occurs in 5% of all patients with malignant disease and in approximately 20% of patients with metastases to the vertebral column.[139] More than 95% of spinal cord compressions are the result of extramedullary malignancy, most commonly secondary to involvement of the vertebral column anterior to the spinal cord, less frequently by tumors posterior to the spinal cord, and occasionally by invasion of the epidural space. Thankfully, the frequency of severe spinal cord compressions leading to paralysis and incontinence is decreasing with the availability of high-quality MRI technologies.[140]

Any tumor that metastasizes to the bone can eventually result in a cord compression. Most commonly seen primaries include lung, breast, prostate, kidney, lymphoma, myeloma, sarcoma, and unknown primaries.

Clinical Manifestation and Patient Evaluation

The majority of patients present with pain, motor loss, autonomic dysfunction, and sensory loss.[141] Pain is often radicular for weeks or months before the onset of neurologic symptoms, offering ample time for early diagnosis. Autonomic dysfunction may occur early and manifest as hesitancy and urgency. Weakness usually precedes sensory loss; incontinence, paraplegia, and paralysis are late effects. Pain was the initial symptom in 96% of the patients but is a poor indicator of spinal-epidural involvement.[142] In contrast, 75% of patients with major neurologic involvement have involvement of the epidural space.

Diagnosis

Early diagnosis is essential because recovery of neurologic function is related to the degree of loss. A careful history and physical examination focusing on neurologic assessment with a high index of suspicion in patients with known malignancy is key to early diagnosis. MRI is the diagnostic study of choice. Distortion of the theca by extradural lesions and soft-tissue abnormalities can be easily identified.[142,143] In case of compression fracture, protrusion of the vertebral body or tumor into the spinal canal is seen clearly, as is the impingement of nerve roots and neural foramina.[144] Approximately 10% of patients have multiple sites of cord compression and perhaps benefit from imaging of the entire spine.

Treatment

A multidisciplinary approach is recommended to treat spinal cord compression. High-dose steroids should be administered after a clinical diagnosis. An initial dose of 20 mg of dexamethasone (Decadron) followed by 4 mg four times daily improves pain and neurologic symptoms in most patients. Steroids should be tapered gradually after completion of radiation. Patients receiving dexamethasone should be placed on H_2 blockers and monitored for hyperglycemia, hypertension, and electrolyte imbalances.

A randomized trial comparing laminectomy followed by radiation versus radiation alone in the treatment of spinal epidural metastasis showed no significant difference in the effectiveness of treatment in regard to pain relief, improved ambulation, and improved sphincter function.[145] Although most cases of spinal cord compression can be managed with steroids and radiotherapy, patients without a histologically proven cancer, radioresistant tumors, previously radiated sites, or mechanical instability should be seen by a neurosurgeon for a laminectomy (Figure 25-5).

In a multiinstitutional randomized study[146] of patients with symptomatic spinal cord compression from vertebral metastases, 50 patients were randomized to receive decompressive surgery followed by radiation and 51 were randomized to receive radiation alone (30 Gy in three Gy fractions for both arms). The study was closed early because of the superiority in outcomes of surgery plus radiation versus radiation alone. Compared to patients receiving radiation alone, following surgery and radiation, significantly more patients were able to walk, patients retained the ability to walk significantly longer, significantly more patients regained the ability to walk, and the need for corticosteroids and analgesics was significantly reduced. Patients undergoing surgery also had a significantly longer survival time. Table 25-11 summarizes the results from this landmark study.

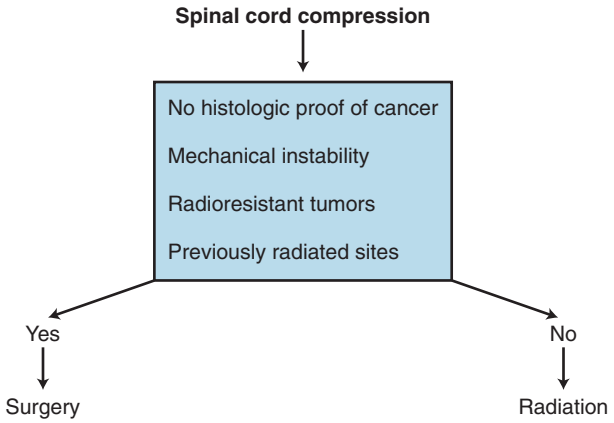

Figure 25-5 Treatment algorithm for spinal cord compression.

TABLE 25-11 Treatment Results for Spinal Cord Compression

Variable	Radiation Alone	Radiation and Surgery	*p* Values
All patients			
Able to walk after treatment	29/51 (57%)	42/50 (84%)	0.001
Retained ability to walk	median 13 days	median 122 days	0.003
Maintenance of continence	median 17 days	median 156 days	0.016
Maintenance of muscle strength	median 72 days	median 566 days	0.001
Dexamethasone dose	median 4.2 mg	median 1.6 mg	0.0093
Morphine dose	median 4.8 mg	median 0.4 mg	0.002
Survival time	median 100 days	median 126 days	0.033
Initial ambulatory patients			
Maintained ability to walk	26/35 (74%)	32/34 (94%)	0.024
Retained ability to walk	median 54 days	median 153 days	0.024
Initial nonambulatory patients			
Regained ability to walk	3/16 (19%)	10/16 (62%)	0.010
Retained ability to walk	median 0 days	median 59 days	0.024

Treatment outcome is dependent on pretreatment function. In a study of 137 patients with malignant spinal cord compression, 81% of patients who were ambulatory pretreatment remained ambulant, whereas only 16.5% of those who were nonambulant before treatment became ambulant after treatment. Pain improved after treatment in 73% of the patients regardless of their ambulatory status.[139] This was confirmed by Zelefsky et al in a retrospective review of 42 patients.[147] They also reported that the presence of a compression fracture of greater than 50% at the level of the spinal cord compression was associated with poor response on refluoromyelography (RFM). Sixty-seven percent with severe compression fractures had no response on RFM versus 11% without compression fracture ($p = 0.01$).

Irradiation Technique and Doses

The depth of the tumor mass can be determined by MRI. If the MRI is unavailable at the time of simulation, a lateral film taken at simulation can help determine the prescription depth. The width of the field is dependent on the extent of the soft-tissue mass as determined by the MRI.

Treatment fields are dependent on the site of involved spinal cord. The cervical spine is usually treated using opposed laterals to avoid the oral cavity. For the thoracic spine, a posterior field alone can be used. When treating the lumbar spine or when the target appears to be more midline, a parallel opposed anteroposterior/posterior-anterior (AP/PA) beam arrangement may be preferred. For either the thoracic or lumbar spine, acceptable alternative techniques include paired posterior obliques or PA and paired laterals. For nonemergent cases, wherein there is sufficient time for treatment planing, IMRT or arcing technique can produce reduced normal tissue consequences, particularly in the neck and thoracic regions where esophageal irradiation can be symptomatic.

The dose of irradiation used for the treatment of spinal cord compression is dependent on both the histopathologic findings and the clinical situation (ambulatory versus nonambulatory, solitary versus multiple metastases, systemic therapy options and efficacy, etc.). The typical dose is 30 Gy in 10 fractions over 2 weeks or 20 Gy in 5 fractions. If life expectancy exceeds a few months, a more protracted regimen (35 Gy to 40 Gy in 3 to 4 weeks) is reasonable with regard to the issue of spinal cord tolerance.

BRAIN METASTASES

Brain metastases are the most common intracranial brain tumor and a common complication of systemic cancer. The incidence ranges from 20% to 40% of all patients diagnosed with cancer.[148] Cancers known to generate systemic disease are the most common primary tumors involved: lung, breast, colon, and melanoma. Current improvements in systemic therapy have improved survival significantly for several cancers but may leave untreated tumor cells beyond the blood-brain barrier and increasing the incidence of brain metastasis in some solid tumors. More precise diagnostic tools, such as MRI, also have an impact on the increasing discovery of brain metastases.

The prognosis of brain metastases is poor and the impact on the patient's quality of life is important as a result of the functional neurologic deficits associated. Symptom management is successful in most patients and efforts can be concentrated on improving the outcome of the patients.[148]

Arterial hematogenous spread results in tumor emboli growth at the gray-white junction[149]; the most common neuroanatomical sites are the cerebral hemispheres (80%), the cerebellum (15%), and the brainstem (5%),[150] with this distribution approximately mirroring blood flow volumes. However, data shows that the distribution of intracranial metastases based solely on the model of arterial embolization and blood volume does not likely depict the full biological basis of spatial distribution of brain metastases. It has been found that patients with non–small cell lung cancer lesions are more likely to be located in the parieto-occipital lobes and cerebellum. Breast cancer lesions have a greater probability to be located in the cerebellum.[151] Multiple metastases are more common than single metastasis and the contribution of MRI to this statistic has reached 80% to 90%.[148]

Presenting symptoms are various and require that any new neurologic symptom be investigated in a patient known to have cancer. Symptoms reflect increasing intracranial pressure and focal neurologic deficit—headache, nausea, lateralized weakness, seizures, modified higher neurologic function. In most patients, the cancer is already diagnosed, but in as many as 20%, it may be the first manifestation; histologic confirmation is then necessary.

Contrast-enhanced MRI is the diagnostic modality of choice. The radiologic differential diagnosis includes primary brain tumor, inflammatory lesion, abscess, and brain infarction or hemorrhage. CT may also be used, but it is less specific and warrants MRI confirmation in the case of a single metastasis. Patchell et al[152] reported a false-positive rate of MRI of 11%, confirmed by histology.

Treatment

Palliative treatment of brain metastases requires rapid control of the symptoms, which are decreasing the patient's quality of life. Collaboration with colleagues in neurology is preferable. Pharmacologic treatment includes corticosteroids and antiepileptic drugs, although antiepileptic drugs should not be used prophylactically in patients without prior seizure.[153] Rapid regression of cerebral edema is the first step and can be achieved with intravenous corticosteroids. Optimal dosage is unknown, but the general practice is to administer a loading dose of Decadron (8 mg to 32 mg) followed by oral medication (4 mg four times a day).[154] Side effects are numerous, and a tapering dose schedule should be planned as symptoms improve. As a single modality, corticosteroids achieve poor survival results of 1 month to 3 months.

Treatment depends on several prognostic factors; Gaspar et al[155] have evaluated results of RTOG trials to produce a recursive partitioning analysis. Pretreatment and treatment-related variables were analyzed. Class 1 (Karnofsky Performance Status [KPS] >70, age <65 years, and controlled primary tumor) patients have a better median prognosis of 7 months. Class 2 (KPS <70, age >65 years, or uncontrolled primary tumor) patients have a median prognosis of 4 months. Class 3 (KPS <70, age >65 years, and uncontrolled primary tumor) patients have a median of 2 months. Other factors, such as histology of the tumor and the number and size of metastases, are important in the initial evaluation. Treatment options are evolving and now include whole brain radiotherapy (WBRT), surgical resection, and radiosurgery (linear accelerator or gamma knife).

Patients with a single brain metastasis in recursive partitioning analysis (RPA) Class 1 are treated aggressively with either surgical resection or SRS with or without WBRT. Multiple metastases from any RPA class receive standard WBRT alone. Patients with up to three metastases in Class 1 or 2 may be considered for local modality surgery or SRS.

Whole Brain Radiotherapy

WBRT is the treatment of choice for many patients because of the high incidence of multiple metastatic brain sites.[148,154,155] The goal of WBRT is to limit tumor progression, sterilize

microscopic disease preventing future brain metastasis[156] and to limit corticosteroid dependency. Classically, WBRT is thought to have some response in around 50% of patients and is histology dependent with small cell and breast cancers being the most sensitive. Renal cell and melanoma histologies are thought to be the most resistant. A study by Nieder et al[157] showed complete remission was observed in 37% of metastases from small-cell carcinoma, 35% of those from breast cancer, 25% of those from squamous-cell carcinoma, and 14% of those from nonbreast adenocarcinoma. The rate was 52% for metastases <0.5 cm^3 and 0% for those >10 cm^3. Sneed et al[158] showed WBRT for patients with unresected brain metastases results in symptomatic response in about 50% of patients and improvement in median survival from 3 months to 6 months compared to historical controls. The optimal dose of radiation is unknown, but in clinical practice, the range is 20 Gy in 5 fractions over 1 week to 40 Gy in 20 fractions over 4 weeks.[148]

Complications of treatment include alopecia, transient worsening of neurologic symptoms, and otitis. Continuing use of corticosteroids during WBRT may limit the incidence of most side effects. Long-term side effects such as memory loss, dementia, and decreased concentration are possible in survivors but are not expected to materialize in the majority of poor prognosis patients.

At our institutions, WBRT is becoming less commonly employed in patients with one to three metastatic lesions. Studies by Aoyama et al[156] and Chang et al[159] have shown that WBRT does not add to survival in this subset of patients and may even be detrimental, compared to SRS alone as shown in the study by Chang et al. The authors attributed this finding to patients treated with WBRT receiving less salvage treatment and less systemic therapy. In the Chang et al[159] study, there was a greater risk of significant decline in learning and memory function at 4 months in the SRS with whole brain group compared to SRS alone.

Because of this association of WBRT and cognitive decline, RTOG 0933, a single-arm Phase II study, looked at hippocampal sparring WBRT, using IMRT technique, compared to a historical control of WBRT without hippocampal avoidance. The dose received by the entirety of the hippocampus did not exceed 10 Gy, and the maximum dose did not exceed 17 Gy. The results showed that avoidance of the hippocampus during WBRT is associated with memory preservation at 4 months and 6 months. Only 4.5% of patients had progression in the hippocampal avoidance region.[160] The RTOG is planning a study of hippocampal sparing prophylactic cranial irradiation in patients with small cell lung cancer. Further study is needed to define the role and optimization of WBRT in the modern era.

Technique of WBRT

The patient is undergoing simulation for palliative treatment and therefore should be conscious and cooperative. Agitated or unresponsive patients should be stabilized before this step to decrease the risk of injury. Simulation is done in a supine position with a head rest, and immobilization is achieved with a custom mask or at least tape between the forehead and table. CT simulation requires the use of a mask.

Portal films with the gantry at 90 degrees and 270 degrees will give parallel-opposed lateral fields. The collimator should be rotated to allow the inferior border to parallel the base of skull. The field borders should go beyond the skull anterior, superior, and posterior bony limits by 2 cm to allow dosimetric homogeneity. The inferior border can be set from the bony canthus to the C1 to C2 intervertebral space and should cover the base of skull with a 1-cm margin. CT simulation is now commonly used with the same parameter but allows for a custom-block design to avoid irradiation of the lens and facial structures. All fields are treated daily. Megavoltage energy of 4 MV to 6 MV is used.

Surgical Resection

The role of surgery has evolved over the past decade. Three randomized controlled trials comparing WBRT alone versus surgery plus WBRT in patients with a single brain metastasis have been published.[152,161,162] Two demonstrated a survival advantage of the combined modalities over WBRT alone (Table 25-12). All three trials addressed the issue of single metastasis, and one cannot extrapolate the results to multiple lesions. The negative results of Mintz contradict those of others, but this trial also contained a large crossover rate, poor KPS patients, lower complete surgical resection rate, and lower WBRT dose.[162] These trials established the increased effectiveness of combination therapy of WBRT and surgical resection. Patchell et al[163] examined the effectiveness of postoperative WBRT after complete resection in patients with a single brain metastasis. They found that although whole brain did not improve survival in this group of patients it did improve local control at the site of resection, decreased the risk of general brain recurrence and decreased the risk of dying from neurological causes.

Radiosurgery

Numerous papers have been published showing the efficacy of SRS with excellent survival and local control in patients with one to three brain metastases. SRS does not require WBRT[163] to achieve excellent local control at the metastatic site, likely because of the penumbra dose beyond the periphery of the metastatic lesion sterilizing microscopic disease. In our institution, surgical resection of a single brain metastasis is trending toward being reserved for symptomatic tumors resistant to steroid treatment, larger lesions more than 4 cm where giving an ablative dose of radiation using a stereotactic technique would be deleterious and establishing diagnosis of metastatic disease when indicated.

Stereotactic radiosurgery is an accepted alternative to resection in patients with limited metastatic lesions that meet size criteria. SRS may be offered to patients with one to three brain metastases and 4 cm or less in size.[164-179]

TABLE 25-12 WBRT Alone or Plus Surgical Resection in the Management of Brain Metastases

Trial	Treatment	Radiotherapy Schedule	*n*	Median Survival (mo)	*p* Value
Patchell[152]	Biopsy + WBRT	36 Gy/12	23	4.2	<0.01
	S + WBRT	36 Gy/12	25	10	
Vecht[161]	WBRT	40 Gy/10 bid	31	6.5	NA
	S + WBRT	40 Gy/10 bid	32	10.8	
Mintz[162]	WBRT	30 Gy/10	43	6.3	0.24
	S + WBRT	30 Gy/10	41	5.9	

S, *Surgery;* WBRT, *Whole brain radiotherapy.*

RTOG 9508 study randomized 333 patients with 1 to 3 brain metastases to WBRT (37.5 Gy in 2.5 Gy fractions) versus WBRT plus SRS within 1 week of completing WBRT.[168] All metastases were ≤4 cm in size and only one metastasis could be >3 cm. The dose was dependent on the lesion size based on the RTOG 9005 Phase I study 2: 24 Gy to lesions ≤2 cm, 18 Gy for lesions >2 to ≤3 cm, and 15 Gy to lesions >3 Gy to ≤4 cm. In both RTOG 9005 and RTOG 9508, the prescription dose covering the gross tumor was the 50% to 90% isodose line, equating to central doses of 1.1 to 2 times the prescription dose. The RTOG 9508 trial demonstrated a significant survival advantage with the use of SRS in patients with a single unresectable metastasis, with a median survival of 4.9 months versus 6.5 months ($p = 0.0393$). The addition of SRS resulted in improved performance status and reduced extent of steroid use. The authors conclude that SRS should be used for patients with an unresectable solitary metastasis and considered for patients with one to three metastases.

SRS alone (without WBRT) in patients with one to three unresectable brain metastases is an alternative approach that remains actively investigated.[180,181] In retrospective studies, the 1-year local control rate is generally on the order of 80% to 95% with WBRT with SRS,[165,170,172,174,175,177] versus 80% to 90% with SRS alone.[172,177-179] At 2 years, the local control is on the order of 80% to 85% versus 50% to 70%. Thus, WBRT does lower the risk of brain failure, and the equivalence in survival likely reflects the need for more salvage therapy in the patients who underwent SRS only. In a study published by the University of Alabama (Birmingham, AL), the risk of new brain metastases in 100 patients treated with SRS alone was significantly correlated to the number of brain metastases (hazard ratio [HR] of 3.3 in patients with >3 metastases, $p = 0.004$), poorly controlled extracranial disease (HR of 2.16, $p = 0.04$), and melanoma histology ($p = 2.14$, $p = 0.02$).[182] Retrospective data suggest similar local control, overall survival, and neurologic death with SRS alone versus resection with WBRT.[183,184] Interestingly, in some series the reported local control with SRS is greater than that after resection,[185,186] probably reflecting the radiosurgical penumbra dose around the tumor periphery that treats microscopic disease.[187]

A multiinstitutional, pooled retrospective analysis examined 569 patients treated with SRS alone compared to SRS with WBRT.[167] Among the patients treated with SRS alone, 37% underwent salvage therapy at a median of 5.7 months after SRS versus 7% after a median of 8 months following WBRT with SRS. This study did not differentiate between salvage for local failures and distant central nervous system (CNS) failures. Survival was not significantly different (~8 month median survival in both arms). In a randomized study from M. D. Anderson Cancer Center (MDACC; Houston, TX), 58 patients were randomized to receive SRS alone versus SRS plus WBRT.[159] Patients treated with SRS alone had a significantly inferior 1-year tumor control (67% versus 100%, $p = 0.012$) and distant brain tumor control (45% versus 73%, $p = 0.020$), but had a significantly improved 1-year survival (63% versus 21%, $p = 0.003$), with a >2 HR of death from neurologic causes as well as systemic causes. Postulated reasons for the improved survival of the SRS-only group is the earlier administration of systemic therapy as well as the high rate of salvage therapy (87%) for brain metastases.

Avoiding WBRT can potentially prevent acute and late toxicity from WBRT and allow WBRT to be used as salvage therapy if needed. During WBRT, patients acutely experience alopecia and may develop skin erythema and mild desquamation. Less commonly, otitis media may develop. More concerning is the late toxicity from WBRT, occurring months to years after radiation, which may be relevant in the population of patients with a solitary metastasis who have a potential for cure. Late toxicity includes cataract formation, dry eye, and neurocognitive defects such as memory loss and dementia.[188-190] The extent to which WBRT causes neurocognitive defects is not well reported.[191] Neurocognitive decline may in part be because of the poor function of many patients who present with brain metastases and the general deterioration of patients whose cancer progresses.[192,193] In the randomized study of SRS versus WBRT with SRS from Japan, there was not a significant difference in the posttreatment change in neurocognitive function between the two study groups, although those patients in the SRS-alone group experienced a more rapid decline in neurocognitive function, presumably as a consequence of brain failure (local failure or distant brain failure).[194] Patients treated with WBRT did experience a continued decline in neurocognitive function, as a result of tumor recurrence or effects from WBRT. In the previously discussed trial from MDACC, Chang et al employed the most sophisticated cognitive testing to date in a randomized trial. The trial was prematurely closed because of the significantly greater likelihood of decline in learning and memory function for patients undergoing WBRT with SRS versus SRS alone.

LIVER METASTASES

Liver metastases are a common cause of morbidity and mortality. They can occur in patients with tumors of many common cancer types, are difficult to treat, and often lead to short survival periods. The liver is also protected from some cytotoxic agents because of its natural detoxification function and its relative hypoxic state. In contrast to the 80% perfusion of the normal liver by the portal venous system, most liver tumors obtain blood flow almost exclusively through the hepatic arterial system. This phenomenon necessitates novel interventional radiological techniques. Likewise, advances in imaging have allowed for more definitive anatomic localization of liver metastases, leading to new minimally or noninvasive treatments for these tumors.

Clinical Manifestations and Patient Evaluation

Common symptoms of liver metastasis include nausea, vomiting, changes in bowel habits, distension, and bloating associated with ascites, jaundice, and pain as a result of distension of the liver capsule. Some patients experience petechia, night sweats, and weight loss.

Diagnosis

Most liver metastases are discovered with routine metastatic surveys. Biphasic and triphasic helical CT is the optimal method for the detection of liver metastases. During the portal venous phase of the scan, the tumor is hypointense because of its dependence on hepatic arterial perfusion, while tumors can be enhanced on arterial phase images. Approximately 90% of lesions greater than 1 cm are detected by portal phase images alone; approximately 10% more lesions are detected when the arterial images are used in combination.[195] These imaging characteristics are also useful for distinguishing metastatic disease from many other benign small lesions commonly seen in the liver, including cysts and hemangiomas.[196] An MRI can also help detect liver metastases; however, MRIs are expensive, can have motion artifacts, and have less well-defined tumor borders. They are generally employed when a patient has a contraindication to a contrast CT scan, or when a CT is inconclusive. MRI can distinguish solid hepatic metastasis from fatty change, cysts, and hemangiomas. On T1-weighted images, hepatic metastases have low-signal intensity, whereas on T2-weighted images tumors have inhomogeneously

high-signal intensity. Other methods of tumor detection include ultrasound and incidental detection during procedures done for benign diagnoses.

Treatment

Most treatments for liver metastases are systemic. Liver metastasis can respond well to chemotherapy and hormone therapy, but most remissions are short-lived. The response to these treatments can be mixed, with some tumors progressing while others subside. Aggressive local treatments for liver metastases can also provide substantial benefits. Although liver transplantation is not recommended, resection of lesions can lead to long-term survival, particularly among patients who respond to chemotherapy.[197,198] Benefits for patients who respond to chemotherapy occur even among those who were initially unresectable because of nodes, number or location of lesions, or lesion size.[198] Generally, resections are limited to patients with disease in a single lobe peripheral to the portal region. This limitation is also true for many other localized techniques, including radiofrequency ablation and cryotherapy.

Chemoablation has arisen as an effective form of therapy. In this invasive radiological technique, the artery feeding the tumor is infused with chemotherapy, usually after an injection of contrast material defined by the tumor vasculature, followed by vascular ablation to trap the drug and asphyxiate the tumor.[199-203] Chemoablation is suitable for patients with a limited number of tumors and for whom vascular access is possible.

Irradiation Technique and Doses

Radiation techniques for liver metastases include whole liver radiation, stereotactic liver radiation, and selective internal radiation-therapy methods. Radiotherapy is often used to palliate liver-capsule pain and treat patients with chemotherapy-resistant disease. In addition, it can be used on patients with poor liver function, who have an expected survival of more than 3 months.

Whole Liver Irradiation

Normal liver has poor tolerance to EBRT if the entire liver is irradiated, and clinical liver failure can arise from low to moderate doses of whole-liver radiation (20 Gy to 30 Gy in 1.8- Gy to 2-Gy fractions). Higher doses have not been shown to be superior to lower doses. Care is taken to avoid exposure of the kidneys. Radiation has not had a significant role in the treatment of liver metastases in most institutions. It should be noted, however, that the risk for radiation-induced liver disease (RILD) is low if the whole liver dose is restricted to 30 Gy or less in fractions of 2 Gy or less.

Liver radiation for metastatic disease can be of palliative benefit, as found in an RTOG Phase II trial of 100 patients in whom palliation of pain was noted in 55%.[204] Survival for more than 6 months was significantly correlated with colorectal primary, good initial performance status, and lack of extrahepatic metastases. Median survival however even when these criteria are employed is only 4 months to 4.5 months.[205] Addition of chemotherapy provides little if any additional benefit.[206] Bydder used 5 Gy × 2 fractions and found improvement at 6 weeks in abdominal pain (63%), distention (30%), night sweats (63%), and nausea (44%). This abbreviated treatment provided results similar to those seen with more protracted courses and may be recommended for patients with poor performance status.[207]

Selective Internal Irradiation (SIRT)

Liver metastases can be treated with one of several embolization techniques, in which microscopic spheres (microspheres) are administered via the liver's arterial supply. Specific techniques include "bland embolization" in which the microspheres are not embedded with cytotoxic agents, transarterial chemotherapy embolization (TACE) in which the microspheres are embedded with chemotherapeutic agents, and SIRT in which the microspheres are embedded with radioactive Yttrium-90 (Y-90). It remains controversial as to which embolization technique is preferred for any given patient. Y-90–labeled microspheres have also been used in the treatment of hepatocellular carcinoma.[208]

Specifically, radioembolization is a highly conformal method of delivering radiation using the radioactive, beta emitter, isotope Y-90 embedded in a glass or resin microspheres. An interventional radiologist delivers these microspheres using the hepatic artery and the microsphere size allows it to become embedded in the tortuous vasculature of metastatic liver tumors. The high stopping power of the beta particle (maximum energy 2.28 MeV, average energy 0.94 MeV) allows for an average penetration range of about 2.5 mm in soft tissue. SIR-Spheres, a Y-90 labeled biocompatible resin microspheres (20 micrometers to 40 micrometers in diameter), is the only Y-90 radioembolization product approved in the United States for the treatment of unresectable liver metastases from primary colorectal cancer.

A study from Northwestern University (Chicago, IL) investigated 137 patients who underwent 227 administrations of Y-90–labeled microspheres for chemotherapy refractory liver metastases.[209] Fifty-nine percent of patients had >4 tumors. Most patients (>80%) had <25% of the liver involved. For all lesions in all patients, 87% experienced a biologic response. Toxicity was acceptable. Fifty-one patients had colorectal cancer; their median survival was about 15 months. Another study from Northwestern University demonstrated the safety and efficacy of Y-90–labeled microspheres in patients with liver metastases.[210]

In an early study from Australia of mostly patients with hepatic colorectal metastases, the combination of a single injection of Y-90–labeled microspheres plus regional hepatic artery chemotherapy was substantially more effective in increasing tumor responses and progression-free survival than the same regimen of hepatic artery chemotherapy alone. Clinical tumor response, carcinoembryonic antigen (CEA) level, and survival were all significantly improved with the addition of Y-90–labeled microspheres.[211] In another study by the same group, adding Y-90–labeled microspheres to systemic therapy yielded improved response rates and acceptable toxicity.[212] A Phase III trial published in 2010 comparing protracted intravenous fluorouracil infusion with or without Y-90 resin microsphere radioembolization for liver-limited metastatic colorectal cancer refractory to standard chemotherapy showed that Y-90 microspheres plus fluorouracil is well tolerated and improves time to liver progression 2.1 versus 5.5 (p = 0.003).[213] A pooled analysis combined 19 studies that specifically investigated patients receiving Y-90–labeled microspheres for liver metastases from colorectal cancer. The reported median survival ranged from 10.8 months to 29.4 months.[208]

Liver metastases from neuroendocrine tumors also appear to be effectively treated with Y-90–labeled microspheres. In the study from Northwestern University, 19 patients had neuroendocrine carcinomas. Among these patients, the median survival was 26 months and the 2-year survival was 69%.[209] In a multiinstitutional report, 148 patients with liver metastases from neuroendocrine tumors underwent 185 administrations of Y-90 microspheres.[148] After treatment, 23% had stable disease, 61% partial response, 3% complete response, and 5% progressive disease. The 2-year survival was ~75% and the median survival was ~70 months. In another multiinstitutional study, 42 patients underwent Y-90 microspheres for liver

metastases from neuroendocrine tumors.[214] Greater than 90% achieved stable disease or a partial response. The median survival was on the order of 2 years. In an Australian study, 34 patients with liver metastases from neuroendocrine tumors were treated with Y-90 microspheres. Radiologic liver responses were observed in 50% of patients and included 6 (18%) complete responses and 11 (32%) partial responses; the mean overall survival was 29 months. Symptoms from the tumor were improved in 50%. The differences in survival between these studies demonstrate a heterogeneous patient population. Also, the survival without Y-90–labeled microspheres treatment cannot be determined in these patients, with a condition that is often slowly progressive. Only one of these studies addressed the potential of Y-90 microspheres treatment to alleviate symptoms from carcinoid tumors.

Evidence is accumulating supporting Y-90 use for hepatic metastatic tumor treatment in a wide variety of primary cancer histologies including breast, pancreatic, lung, renal, esophageal, ovarian, and intrahepatic cholangiocarcinoma.[215,216] Because of the expense and the limited data at this time, Y-90 is usually reserved for unresectable liver dominant metastatic hepatic disease with a projected life expectancy of at least 3 months. The prework-up of this procedure is relatively intensive and includes a pretreatment planning angiogram, microsphere angiography of the liver, and a 99m-Tc macroaggregated albumin scan that demonstrates lung shunting or flow to the gastrointestinal tract. A consensus statement addressing patient eligibility for Y-90–labeled microspheres states, "Patients considered for radioembolization therapy would include those with (1) unresectable hepatic primary or metastatic cancer, (2) liver-dominant tumor burden, and (3) a life expectancy of at least 3 months … Contraindications for radioembolization therapy may include (1) pretreatment 99m-Tc macro-aggregated albumin (MAA) scan demonstrating the potential of ≥30 Gy radiation exposure to the lung or flow to the gastrointestinal tract resulting in extrahepatic deposition of 99m-Tc MAA that cannot be corrected by catheter embolization techniques, (2) excessive tumor burden with limited hepatic reserve, (3) elevated total bilirubin level (≥2 mg/dL) in the absence of a reversible cause, and (4) compromised portal vein, unless selective or superselective radioembolization can be performed. Patients with prior radiotherapy involving the liver should be carefully reviewed on a case-by-case basis. It is unclear whether capecitabine chemotherapy treatments represent a contraindication to Y90 treatment.[217]

SBRT

Because the liver's regenerative powers make localized high-dose radiation achievable with minimal toxicity, SBRT has become popular for patients with a limited number of metastases and minimal extrahepatic tumors.[12,13,218,219] As with most SBRT approaches, respiratory arrest or gating is preferred, but four-dimensional CT has also achieved good results. Large and portal lesions can be treated safely, and most studies show local control rates of more than 70%.[218,219] No clear dose response has been measured, but all radiation doses and schedules have produced similar results.

Liver Tolerance

Although lethal RILD can occur when the median liver dose exceeds 37 Gy in standard fractionation, little or no toxicity is seen when more than 50% to 70% of the liver is maintained under 30 Gy.[220,221] Patients primarily report decreased appetite and gastritis; moreover, patients with cirrhosis may experience exacerbation of hepatitis, and those with subdiaphragmatic tumors can have asymptomatic right pleural effusions. After radiation, tumors often become hypointense on CT scans, and surrounding hepatic damage may correspond to the 37-Gy isodose line. These radiographic changes can be confused with tumor progression because tumors reach a maximum size at 6 weeks to 3 months after irradiation and recover at 6 months to 9 months. The contralateral lobe of the liver commonly hypertrophies to compensate for the lost liver mass; however, total liver volume usually maintains normal levels.

LUNG METASTASES

Disease can occur in the parenchyma and in mediastinal or hilar nodes. Metastases in the lung bases are more common than in upper regions.[11] Although peripheral lesions are often asymptomatic, central tumors can cause airway obstruction. Other signs and symptoms include cough, respiratory discomfort, shortness of breath, superior vena cava syndrome, and in severe cases hemoptysis or dysphagia. High-speed helical CT allows for high-precision detection of lung tumors smaller than 1 cm. Malignancy can be confirmed using PET/CT for glucose-avid tumor types, including colorectal, lung, and breast cancers.

Treatment

Standard treatment for pulmonary metastases is systemic chemotherapy. Tumor response to chemotherapy can be substantial, but it is usually short lived and oftentimes results in eventual recurrence. Minimally invasive surgical techniques paired with advanced imaging of the lung have made it possible to remove many small lesions. Although rarely employed for adult cancers, resection by open or minimally invasive techniques is commonly used for many childhood malignancies.[222,223] As with liver metastases, radiofrequency ablation and radiosurgical techniques are also employed.

SBRT

Use of pulmonary SBRT for metastasis to the lung has greatly increased with the advent of imaging technologies capable of identifying very small metastatic tumors. The more widespread availability of PET/CT has improved our ability to distinguish these small tumors from benign nodules. The incremental gain for patients, as with metastectomy, has been difficult to prove; still, as with surgical approaches, local control rates are consistently higher than 80% or 90%. New metastases in the lungs are also commonly low, and quality of life is improved with maintenance of pulmonary function. Additionally, most studies show increased long-term and disease-free survival, which indicates the potential for a cure.

The ability to give hypofractionated ablative doses of radiation relies on decreasing the size of the planned treatment volume to spare normal tissue from damaging penumbra. In the lung, the most severe limitation of a parsimonious PTV that covers the lesion is respiratory motion. Several methods for increased PTV accuracy include real-time imaging of the lesion during respiration, gating, and methods to decrease the severity of motion (breath hold, quiet breathing, real-time breathing feedback, and diaphragmatic immobilization). Radiation doses range from 30 Gy to 66 Gy given in 3 fractions to 10 fractions to 48 Gy to 60 Gy given in 10 fractions to 12 fractions.[224-227] Despite the wide variation in dose and fractionation, the results have been uniformly excellent with high control rates. Higher fraction sizes do not necessarily produce higher control rates for metastases, but grade-3 to grade-5 toxicity is most common with larger fraction sizes and central tumor locations.[225] In Rusthoven et al's[227] report on patients, with one to three metastases with a cumulative diameter under 7 cm, who were given 48 Gy to 60 Gy in 3 fractions: 63 lesions were treated in 38 patients with a local control rate of

96% at 2 years and 8% grade 3 and no grade 4 toxicity. Okunieff et al[224] report local failures in 8 of 125 lesions (local control rate of 94%) treated and followed for a minimum of 1 year. Tumors were up to 7.7 cm, and the dose was 50 Gy in 10 fractions. The progression-free survival progression-free survival (PFS) was 16% at 2 years. Grade-3 toxicity was seen in only 2% of patients; there was no grade-4 toxicity.

Most patients have already failed several courses of standard chemotherapy before being offered SBRT. Nevertheless, excellent tumor control with minimal toxicity and unexpectedly high rates of PFS suggest that SBRT improves morbidity and mortality.

Overview

Minesh P. Mehta

Since the last edition of this book, significant advances in neurooncology have been made that have changed the standard of care for several central nervous system (CNS) neoplasms, and these are reviewed in detail in the following chapters. The purpose of this overview is to present the "headlines" relative to these major practice events, which will then set the stage for the reader to delve into greater detail in the ensuing chapters.

SPECIFIC TUMORS: GLIOMAS AND LYMPHOMA

For *glioblastoma*, despite a name change from the prior glioblastoma multiforme (GBM), few true advances in survival prolongation have been identified. Two major efforts, focused at dose-intensifying temozolomide and incorporating antiangiogenic strategies, have failed to prolong survival. However, for recurrent glioblastoma, antiangiogenic agents have become well-established in practice, and newer technologies such as alternating electric field devices are emerging as options. More importantly, an explosion of molecularly driven knowledge has opened up several avenues, for example, the recognition that the benefit of temozolomide in methyl-guanine methyl transferase (MGMT)-unmethylated tumors might in fact be a reflection of undetected methylated tumors; that some subsets of GBM might actually benefit from antiangiogenic strategies (based on preliminary analysis); and the rapidly emerging investigation of immune checkpoint inhibitors and vaccine-based strategies. Management of elderly patients with GBM, always a major challenge, is also being rapidly refined, with the understanding that as far as single agent therapy alone is being contemplated, temozolomide might be superior to radiotherapy for methylated tumors, with the converse being true for the unmethylated tumors.

For *anaplastic gliomas*, the role of combined modality chemoradiation has now become truly established with the recognition of a major benefit in overall survival with procarbazine/CCNU/vincristine (PCV) plus radiotherapy especially in the 1p19q co-deleted tumors. Further, it appears that the survival benefit seen with concurrent chemoradiation in the 1p19q non codeleted anaplastic oligodendroglioma might in fact be limited to the cohort of patients with mutated isocitrate dehydrogenase (IDH), and in fact IDH mutations might supplant 1p19q analysis in this context. In practice, this has posed a major conundrum, because of practitioner preference for temozolomide, which is currently being compared to PCV in a randomized trial, with only limited prospective data supporting the use of temozolomide in this context. More importantly, even though there are no categorical data to support such an approach, there is an emerging trend to withhold radiotherapy from some of these patients, driven in large measure because the long-term survival of these patients raises the specter of delayed radiotherapy toxicities. However, advances in the realm of intensity-modulated radiotherapy (IMRT) have now convincingly demonstrated improved cognitive sparing and such techniques are rapidly being adapted in practice. The significant increase in the number of proton centers is also allowing greater access to this technology, which is also associated with clear dosimetric advantages, the clinical benefits of which remain to be categorically demonstrated.

For *low-grade gliomas*, chemotherapy historically had no role; recent results from seminal trials conducted by the Radiation Therapy Oncology Group (RTOG) and other North American cooperative groups with long-term follow-up now provide convincing evidence of major survival benefit from combined chemoradiation, compared to radiotherapy alone for all patients older than the age of 40, and for patients who are subtotally resected, irrespective of age. This survival benefit also comes from PCV chemotherapy, and limited data supporting similar possible outcomes are beginning to emerge when PCV is replaced with temozolomide. Whether radiotherapy could be withheld or not remains an investigational question and data from a recently completed prospective randomized European Organisation for Research and Treatment of Cancer (EORTC) trial will likely provide the answer in the near future. The role of molecular fingerprints determining the extent of benefit and identifying appropriate subsets is being unraveled, and as would be expected, MGMT, 1p19q, IDH, and several others are being intensively interrogated. Clearly, for most gliomas, therefore, the landscape appears to be shifting in favor of combined chemoradiation, and especially in the context of molecular subtyping to identify tumors most likely to benefit.

For *lymphomas* of the CNS, major survival gains have been made with high-dose methotrexate-based regimens, and biological agents such as rituximab in conjunction with chemotherapy are rapidly being incorporated into practice based on the results of two recent clinical trials.

IMAGING

Despite the superb detail provided by today's high-resolution high-field magnets, a major limitation of magnetic resonance imaging, especially for infiltrative neoplasms, is definition of the true extent and range of spread, something that no established imaging technique comes even close to estimating with precision. The unusual phenomena of pseudo-progression, and more recently, pseudo-response, rarely seen outside the

CNS continue to pose a further diagnostic conundrum, and new and more sophisticated biologically based imaging is being developed for this purpose.

The success of local therapies such as surgery and radiotherapy is comprehensively dependent on accurate estimation of tumor extent. As several studies have now demonstrated, current imaging is simply inadequate for this, especially for detecting microscopic infiltration, which in CNS neoplasms can assume extremely complicated patterns, such as along fiber tracts, along subependymal planes, through the cerebrospinal fluid, by exhibiting "skipping" and "multifocality," and more recently the presumed phenomenon of "cooption."

PRIMARY THERAPY: SURGERY AND IRRADIATION

The surgical challenges in the CNS remain immense. Unlike other anatomic sites, the concept of "redundant" tissue simply does not exist in the brain and spinal cord, and therefore, every surgical procedure is technically risky, and en bloc oncologically complete resections with wide margins are almost impossible. Before the advent of pre- and intraoperative neuronavigation with three-dimensional (3D) navigating capabilities, intraoperative microscopes, the availability of brilliant illumination, improved instrumentation and techniques for hemostatsis, as well as neuroanesthetic advances, aggressive resections with an intent to remove all visible tumors were infrequently undertaken. The consequences of this were multiple. Many tumors remained "imaging and clinical diagnosis," for example, skull-base meningiomas, vestibular schwannomas, brainstem gliomas, and presumed pineal germ cell tumors. Inclusion of these tumors, with uncertain diagnosis, as well as uncertain clinical behavior, makes interpretation of generalized treatment results inaccurate. Further, a tendency toward "small" biopsies was common, adding to diagnostic uncertainty. And most importantly, although level 1 evidence is sparse, an increasing body of literature suggests that more complete resections are important for almost all CNS neoplasms, a trend that has clearly increased in practice in the last decade. Agents to guide complete resection through tumor-specific visualization have already been approved in Europe and remain under investigation in the United States; their advent could be practice changing.

Advances in radiotherapeutic techniques over the last two decades have had a major impact in neurooncology. Because the majority of cell populations within the CNS have a low mitotic index, and proliferate slowly, they are the prototypical "late-responding tissues" of conventional radiobiologic literature. Consequently, the effects of CNS radiation are sometimes not apparent for years, and even then, the historic approach has assumed that "all brain is equally sensitive," with a nascent appreciation of compartment and cell-type specific radiosensitivity. This, too, is changing rapidly, and the advent of 3D conformal, stereotactic, IMRT, image-guided radiotherapy (IGRT), and proton solutions now offers unique opportunities for altering the therapeutic index in CNS tumors. Some elegant and practical examples include the avoidance of the optic apparatus during stereotactic radiosurgery (SRS) to prevent blindness, cochlear sparing with IMRT in children with medulloblastoma to spare hearing, minimizing the dose to the hypothalamic-pituitary axis to avoid endocrinopathies, the emerging hypothesis of compartmental stem cell sparing to retain neurogenesis and hence memory, etc. The recent QUAntitative estimates of Normal Tissue Effects in the Clinic (QUANTEC) analysis provides a new dataset for normal tissue tolerance, and although still limited in scope, it is substantially improved over what was available just 3 years ago for the treating physician. This should help standardize dose-selection practices.

SUMMARY

In the series of detailed chapters that follow, a team of internationally acclaimed authors, infused with this newfound enthusiasm in neurooncology, review the issues I have highlighted in considerable detail. This will provide the treating physician with an up-to-date resource that is practical, comprehensive, and thoroughly referenced, which we hope will ultimately serve our patients' needs.

CHAPTER

26 Low-Grade Gliomas

Paul D. Brown, Michael D. Chan, Edward G. Shaw, and Martin J. van den Bent

EPIDEMIOLOGIC AND ETIOLOGIC FINDINGS

The estimated annual incidence of low-grade gliomas in the United States is 2000 cases. Etiologic factors are unknown. These tumors are seen with increased frequency in patients with types 1 and 2 neurofibromatosis.

PATHOLOGIC FINDINGS

The most common pathologic types include pilocytic astrocytoma (World Health Organization [WHO] grade I), diffuse fibrillary astrocytoma, oligoastrocytoma, and oligodendroglioma (WHO grade II).

BIOLOGIC CHARACTERISTICS

Combined 1p and 19q deletions are associated with a superior outcome and are most common in oligodendrogliomas. *TP53* mutations are more common in diffuse astrocytomas and are mutually exclusive from 1p/19q co-deletions. *IDH1* mutations occur in the vast majority of low-grade gliomas and are found both in tumors with *TP53* mutations and in tumors with 1p/19q codeletions.

CLINICAL MANIFESTATIONS AND PATIENT EVALUATION

The mean age at presentation is 37 years. Most patients do not have any signs of their disease (i.e., they are neurologically "intact"). The most common symptom is seizure.

Age is the most powerful clinical prognostic factor for survival. Children have a significantly better outcome than adults. Other prognostic factors associated with better overall or progression-free survival (PFS) rates include oligodendroglioma histology, normal mental status, and smaller tumor size.

The imaging features vary by pathologic type. Pilocytic astrocytomas are well circumscribed and contrast enhancing. Diffuse fibrillary astrocytomas are poorly circumscribed and typically nonenhancing, best seen on a T2-weighted or fluid attenuated inversion recovery (FLAIR) magnetic resonance imaging (MRI) scan.

PRIMARY THERAPY

Maximum surgical resection is associated with a more favorable outcome.

In pediatric low-grade gliomas, observation is recommended after gross total resection. After subtotal resection or biopsy, treatment (radiation therapy, chemotherapy) is usually deferred until symptomatic or imaging progression.

In adults, after gross total resection of a pilocytic astrocytoma, observation is recommended. After gross total or subtotal resection (or biopsy) of a low-grade glioma, irradiation may be given postoperatively or deferred until progression occurs.

The recommended radiotherapy (RT) dose is 45 Gy to 54 Gy in 25 fractions to 30 fractions, treating the MRI-defined tumor volume with a 2-cm margin.

Early results from one large randomized clinical trial suggest disease and outcomes are similar for either temozolomide or RT for 1p/19q-deleted tumors although RT may have a superior PFS for 1p-intact tumors; however, the period of follow-up in this trial is immature and not yet adequate to make definitive treatment recommendations.

Long-term follow-up of a large randomized clinical trial of 251 patients with less than gross total tumor resection or older than 40 found significantly better PFS and overall survival (OS) for those treated with RT followed by procarbazine, CCNU, and vincristine (PCV) compared to those treated with RT alone (RTOG 98-02). These results confirm a benefit for RT followed by chemotherapy for select low-grade glioma populations.

RECURRENT DISEASE

Several challenges constrain recommendations in this setting. It is difficult to differentiate recurrence from radionecrosis by clinical symptoms or signs alone or by conventional MRI or positron emission tomography (PET). Further, at recurrence, consideration must be given to the possibility that these tumors could have transformed to malignant gliomas, which are treated differently.

Low-grade gliomas are a pathologically and clinically diverse group of uncommon central nervous system (CNS) tumors that occur primarily in children and young adults. The prognosis is principally affected by patient age and pathologic type of tumor. Studies assessing proliferation and molecular genetics may provide additional insight into prognostic groups that are at higher risk for developing recurrence and therefore may benefit from adjunctive treatments such as radiation therapy and chemotherapy. In general, more extensive resection is associated with better prognosis. The optimal timing of irradiation is best determined by weighing all prognostic factors, favoring "early" (or postoperative) irradiation for high-risk patients and delaying irradiation for lower-risk patients. The importance of chemotherapy in the treatment of low-grade glioma is growing based on a number of clinical trials.[1]

In this chapter, a comprehensive overview of low-grade glioma is provided with an emphasis on adults. Topics covered include epidemiology, etiology, pathology, biology, clinical manifestations, patient evaluation, management (including surgery, radiation therapy, and chemotherapy), and toxicity.

EPIDEMIOLOGY AND ETIOLOGY

Annually in the United States, it is estimated that 23,130 CNS tumors will be diagnosed,[2] of which approximately 20,000 will arise in the brain.[3] Of these, approximately 2000 will be low-grade gliomas.[4]

Etiologic factors for low-grade gliomas are largely unknown. Low-grade astrocytomas have been associated with von Recklinghausen disease (type 1 neurofibromatosis) and type 2 neurofibromatosis.[3] In addition, a direct link has been made between subependymal giant cell astrocytoma, an uncommon pathologic type of low-grade astrocytoma, and tuberous sclerosis.[5]

PATHOLOGY

Pathologic Classification

Historically, low-grade gliomas have been considered a homogeneous group of neoplasms associated with a more favorable natural history.[6] In reality, they are a diverse group of tumors found throughout the CNS, the outcome of which depends on a number of anatomic, pathologic, biologic, host, and treatment factors.

Table 26-1 summarizes the current World Health Organization (WHO) classification of primary CNS tumors as it applies to low-grade gliomas.[7] Grade I tumors must be separated from grade II tumors because they have a different molecular background. These tumors are well circumscribed, are considered benign, and if completely resected, they are typically cured. The pilocytic astrocytomas, which comprise nearly all of the grade I cerebral astrocytomas, tend to be better circumscribed and rarely transform.[8] Although pilocytic astrocytomas occur more commonly in the cerebellum of children (juvenile pilocytic astrocytoma), they also occur in the cerebral hemispheres and in particular near the optic pathway.

The diffusely infiltrative low-grade astrocytomas (WHO grade II) are the most common and include astrocytoma, oligodendroglioma, and mixed oligoastrocytoma.[7] Grade II gliomas are diffusely infiltrating tumors and are capable of undergoing anaplastic transformation with an incidence as high as 80%.[8,9] Remaining are the uncommon low-grade glioma variants, including the pleomorphic xanthoastrocytomas, subependymal giant cell astrocytomas, and others, which are briefly discussed later in the chapter.

TABLE 26-1 Low-Grade Gliomas* Included in World Health Organization (WHO) Classification of Gliomas

Type	WHO Grade
ASTROCYTIC TUMORS	
Subependymal giant cell astrocytomas	I
Pilocytic astrocytomas	I
Pleomorphic xanthoastrocytomas	II
Pilomyxoid astrocytoma	II
Diffuse astrocytoma	II
OLIGODENDROGLIAL TUMORS	
Oligodendrogliomas	II
OLIGOASTROCYTIC TUMORS	
Oligoastrocytomas	II

Grading Systems

The concept of dividing astrocytomas into discrete grades associated with a distinct clinical prognosis dates back to the mid-1920s and early 1930s to the work of Bailey and Cushing, who recognized a subset of astrocytomas that had a more favorable outcome than glioblastoma.[10] There have been many grading systems (e.g., Kernohan, St. Anne-Mayo, and Ringertz systems) in the past, which assess nuclear abnormalities, mitoses, endothelial proliferation, and necrosis. Currently, the most widely used and accepted grading system is the WHO system.[7] WHO grade I lesions are well circumscribed and have low proliferative potential, with the possibility of cure following surgery alone. Grade II neoplasms are infiltrative, as a rule recur, and tend to progress to higher grades of malignancy (e.g., grade II astrocytoma transforms to grade III anaplastic astrocytoma) despite initial low-level proliferative activity. All histopathological grading schemes are limited by their need to separate gliomas artificially into three or four groups, when in actuality they exist along a biologic continuum and the diagnoses are subject to considerable interobserver variation.[11] For the present, this somewhat outdated method is still used in both therapeutic decision making and prognostication, but it is fully anticipated that in the near future reiterations of the WHO grading system will incorporate imaging and genetic testing.

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

Since the 1990s, our understanding of the biology of low-grade gliomas has increased. This has included studies of tumor proliferation, and both cytogenetic and molecular genetic studies.

Studies of Proliferation

Tumor proliferation can be assessed with Ki-67 labeling. A large review on Ki-67 labeling revealed increasing values of Ki-67/MIB-1 labeling index with increasing grade of malignancy.[12] The MIB-1 labeling index differentiates diffuse astrocytomas (WHO grade II) from anaplastic astrocytomas (WHO grade III) and glioblastoma (GM) tumors. Similar findings have been reported in oligodendrogliomas.[13] Although the MIB-1 labeling index is a clear prognostic factor in low-grade glioma, the absence of agreed-on low versus high cut-off values and interobserver variation between various institutions prevents its routine use.

Genetic and Other Molecular Studies

About 50% to 60% of astrocytomas have *TP53* mutations, and this figure may be even higher in gemistocytic astrocytoma.[14,15] In contrast, low-grade oligodendrogliomas typically have combined loss of 1p/19q, and the genotype is actually an unbalanced t(1;19)(p10;q10) peri-centromeric translocation.[16] *TP53* mutations and 1p/19q codeletions are mutually exclusive, and most mixed oligoastrocytomas carry either the typical oligodendroglial 1p/19q codeletion or a *TP53* mutation, suggestive of an astrocytic lineage.[17] Therefore, at the molecular level, mixed oligoastrocytomas are not true mixed tumors but are of either astrocytic or oligodendroglial lineage.

The recently identified *IDH1* mutations (an enzyme that participates in the citric acid cycle) occur in 70% to 80% of low-grade gliomas, both in tumors with *TP53* mutations and in tumors with the 1p/19q loss.[15,18] The current data and the absence of the acquisition of *IDH1* mutations over time suggest that the *IDH1* mutation is an early event in the tumorigenesis

of *IDH1*-mutated tumors[19] and distinguishes primary from secondary glioblastoma.[18]

Methyl-guanine methyl transferase (MGMT) is a DNA-repair enzyme that removes alkyl groups from the O_6 position of guanine in DNA and therefore repairs damage induced by alkylating agents (e.g., temozolomide). MGMT promoter methylation in IDH-mutated tumors is highly associated with the CpG Island methylated phenotype (CIMP) that is induced by the metabolic alterations induced by IDH mutations.[20] It is currently unclear if MGMT promoter methylation can be used for treatment decisions in low-grade gliomas; recent data suggest that MGMT promoter methylation may have different significance in IDH-mutated versus IDHwt tumors.[21] Lastly, a concept of "triple negative" low-grade glioma is emerging, low-grade astrocytomas without either IDH mutations, TP53 mutation, or 1p/19q co-deletion. Of all grade II diffuse glioma these tumors tend to have the worst survival.[22]

The PI3K/mTOR pathway is activated in most adult low-grade gliomas, with methylation of the promoter region of the PTEN gene in one third of patients.[23] One study observed that p14(ARF) hypermethylation and MGMT hypermethylation constitute distinct molecular pathways of astrocytoma progression, with more frequent progression in p14(ARF) hypermethylation cases.[24]

Prognostic and Predictive Molecular Factors

Molecular and cellular biologic characterization of low-grade gliomas may help to predict which patients are more likely to require earlier and more aggressive therapy. Conversely, it may help to determine which patients may be observed initially, withholding treatment until the time of disease progression. To date, molecular findings are still infrequently used for clinical decision making primarily because most lack prospective validation. Today, most of the observed findings are primarily prognostic and are not predictive for outcome to specific treatments. For example, the presence of IDH1 mutations have a major favorable prognostic impact in low-grade astrocytomas but does not affect outcome with temozolomide treatment.[15,25] However, recent studies show that molecular profiling holds more prognostic information in low-grade glioma compared to classical histology.[25] Moreover, the upcoming molecular analyses of recently completed large Radiation Therapy Oncology Group (RTOG) and European Organisation for Research and Treatment of Cancer (EORTC) Phase III studies on low-grade gliomas are expected to change the prognostic nature of these molecular features to predictive factors, similar to the recent developments in anaplastic glioma.

The presence of the 1p/19q codeletion also confers a favorable prognosis, with slower growth rates, compared with non–codeleted low-grade gliomas.[26,27] In a study of patients with low-grade glioma enrolled on two North Central Cancer Treatment Group (NCCTG) protocols, the median OS time and 5-year OS were 13 years and 96% in oligodendroglioma patients with 1p/19q codeleted tumors versus 10.8 years and 70% in those without codeletion.[16] For oligoastrocytomas, the median OS and 5-year OS were 11 years and 90% for 1p/19q codeleted tumors and 8.3 years and 62% for tumors without the 1p/19q codeletion. Several studies noted improved outcome with chemotherapy of 1p/19q codeleted tumors as opposed to 1p/19q intact (oligodendroglial) tumors.[28]

CLINICAL MANIFESTATIONS AND PATIENT EVALUATION

In this section, information is reviewed on the clinical presentation and imaging of supratentorial low-grade gliomas based on the literature.[29]

Clinical Presentation

Low-grade gliomas are generally a disease of patients in their 20s, 30s, or 40s, with a mean age at presentation of 37 years. Cases have been reported in patients as young as 7 months and as old as 78 years. Low-grade gliomas are more common in men than in women by a ratio of 1.4:1.

The symptoms of low-grade gliomas are shown in Table 26-2. The most common symptom is seizure, occurring in two thirds of patients. Focal seizures are more common than generalized ones. Generalized tonic-clonic, simple partial, and complex partial seizures occur in 43%, 23%, and 34% of patients, respectively. Seizures are particularly common in patients with tumors located in the temporal and frontal lobes, insula, and perirolandic cortex.[30] Headache and weakness occur in approximately one third of patients. The remaining symptoms occur in 15% or fewer patients. The median duration from onset of symptoms to diagnosis is between 6 and 17 months, with a range of 1 day to 17 years.

Neurologic signs associated with low-grade gliomas have not been as rigorously reported in the literature. Focal neurologic deficits are related to the tumor location. About 50% of affected patients have a normal neurologic examination. The frequency of other signs at presentation is as follows: sensory or motor deficit, 42%; altered mental status, 23%; papilledema, 22%; aphasia, dysphasia, or decreased memory, 20%; focal deficit, 15%; altered consciousness, 8%; and motor deficit, 8%. Neurologic function is considered normal or mildly symptomatic or impaired in 63% of patients, moderately symptomatic or impaired in 25% of patients, and severely symptomatic or impaired in the remaining 12%. Less than 5% of low-grade gliomas are discovered incidentally (generally because of work-up of head trauma). These tumors appear to have improved outcomes compared to symptomatic tumors.[31]

Prognosis by Clinical Presentation

Age, gender, symptoms, signs, and neurologic function have all been significantly associated with survival in univariate and multivariate analyses from a number of retrospective studies in the literature. Both preoperative and postoperative neurologic function and performance status are correlated with outcome.[32] Brown et al conducted an analysis of baseline (before radiation therapy) Mini-Mental State Examination (MMSE) scores collected in patients with low-grade glioma on a prospective, intergroup clinical trial and found that the

TABLE 26-3 Survival of Children with Low-Grade Astrocytoma

Series	No.	Age (yr)	5-yr OS (%)	10-yr OS (%)
Pollack et al[35]	71	≤18	95	93
Youland et al[36]	351	<20	95	90
Merchant et al[33]	78	<20	99	96

No., *Number;* OS, *overall survival;* yr, *year.*

presence of an abnormal baseline MMSE score (26 or less) was a strong predictor of worse outcome. Patients with an abnormal baseline MMSE score had worse 5-year PFS (27% versus 60%) and OS (31% versus 76%) compared with those with a normal score.

After grade, the most powerful predictor of survival in patients with low-grade glioma is age, with much better survival rates in pediatric patients compared with adults. Table 26-3 shows the survival rate of children with low-grade astrocytoma. In a Phase II trial of 78 pediatric patients with low-grade glioma treated with RT (54 Gy), the 5- and 10-year OS were 99% and 96%, respectively.[33] For adult patients with low-grade astrocytoma, there is also an association between age and survival. Those younger than 40 years of age have a better survival than older patients.[34]

Of all the neurologic symptoms associated with low-grade astrocytoma, seizures, particularly when preceding the diagnosis by 6 months or more and in the absence of other neurologic symptoms, are associated with a better prognosis. In one series, the 5-year OS was 47% in patients presenting with seizures, 33% in those with headaches, 20% in those with altered mental status, and 0% when stupor was the presenting symptom.[37] In another series, the 5-year OS was 64% in patients with low-grade glioma who had seizures versus 14% in those without seizures.[38] Recent evidence suggests that low-grade gliomas presenting with seizures as first symptom may correlate with the presence of *IDH* mutations.[39]

Patients who present with a history of chronic epilepsy resulting from an underlying cerebral neoplasm are frequently found to have a low-grade astrocytoma. These patients are usually children or young adults (30 years of age or younger) whose seizure disorder and underlying tumor are often cured by a complete resection.[40]

Imaging of Low-Grade Gliomas

Table 26-4 shows the imaging characteristics of supratentorial low-grade astrocytomas based on multiple series in the literature.[41] On computed tomography (CT), the typical low-grade astrocytoma is lobar in location, involves the frontal or temporal lobes, is larger than 5 cm in diameter, and is nonenhancing. Because of the infiltrative nature of low-grade astrocytomas, the CT appearance of a typical nonenhancing tumor is a poorly defined area of low attenuation (Figure 26-1, *A*).

MRI (see Figure 26-1, *B*) provides superior visualization. FLAIR and both T2- and T1-weighted images (without and with contrast) provide anatomic detail that is useful in defining the extent of the tumor and in planning for surgical and radiation therapy. An understanding of these imaging-based anatomic-histopathologic relationships is important for both the neurosurgeon and the radiation oncologist. Removal of the poorly defined area of low attenuation (increased T2 or FLAIR signal) in a functionally intact area of brain (Figure 26-2) may lead to significant neurologic morbidity.

The radiographic features of low-grade gliomas have been correlated with prognosis in a number of retrospective series.

‡Only two series presented data on mass effect.[43,44]

Although the presence of contrast enhancement on a CT or MRI scan in nonpilocytic low-grade gliomas would seemingly be associated with a worse prognosis because of presumed higher-grade elements or malignant transformation, data from prospective trials have not found the presence of contrast enhancement to be a predictor of outcome.[45,46] This may be related to the type of enhancement. Nodular enhancement as opposed to faint, patchy enhancement appears to be related to decreased survival times.[47] Other imaging findings, such as tumor size greater than 5 or 6 cm, or tumor crossing the midline (Figure 26-3), have been consistently associated with worse outcome.[34,45] Although the relationship between enhancement and prognosis has been controversial in the literature, two series assessing the likelihood of malignant transformation in low-grade gliomas based on the presence of enhancement have demonstrated a statistical association between enhancement and earlier malignant transformation.[48,49]

Imaging alone cannot reliably distinguish between grade II astrocytomas and oligodendrogliomas, though there are some imaging characteristics that may suggest that a tumor has an oligodendroglial component. Oligodendrogliomas are the most frequent primary brain tumor to calcify and have calcifications in 70% to 90% of cases.[50] They also tend to have cortical involvement and heterogeneous signal. There is also emerging evidence that oligodendroglioma and astrocytoma may have distinct signatures on perfusion MRI as the relative cerebral blood volume (rCBV) was found in one study to be significantly higher in low-grade oligodendroglioma than in low-grade astrocytoma.[51]

Pignatti et al[34] developed a prognostic scoring system using imaging, patient, and tumor characteristics derived from the

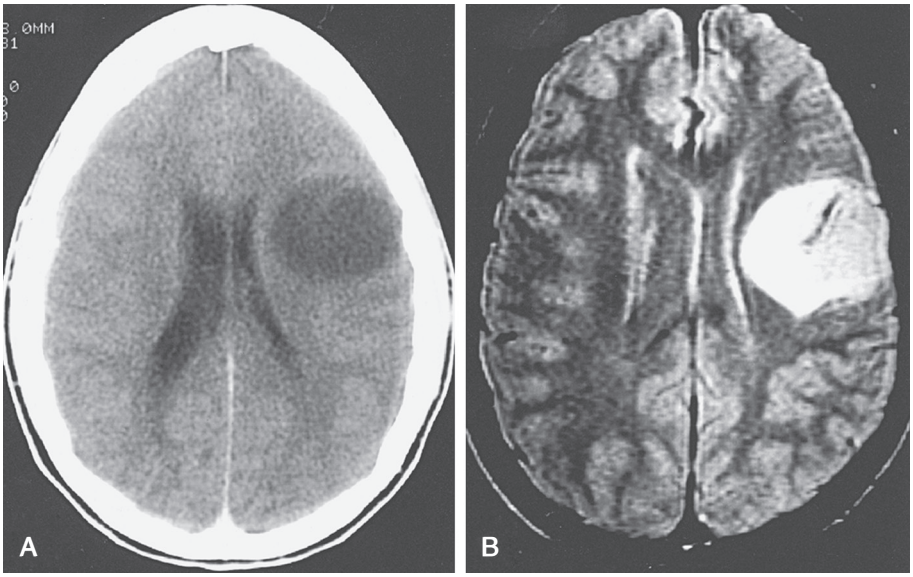

Figure 26-1 Postcontrast CT **(A)** and a noncontrast MRI **(B)** of an adult with a nonenhancing posterior left frontal WHO II astrocytoma.

databases of two large Phase III adult low-grade glioma trials (EORTC trials 22844 and 22845). By means of Cox regression analysis, they identified and validated the following negative risk factors: age 40 years or older, astrocytoma histology subtype, largest diameter of the tumor of 6 cm or more, tumor crossing the midline, and presence of neurologic deficit before surgery. The total number of unfavorable factors present was found to be useful in predicting outcome. The presence of two of these factors or fewer identified a low-risk group (median survival, 7.7 years), whereas three risk factors or more identified a high-risk group (median survival, 3.2 years). A more recent meta-analysis of the four available large Phase III studies using only data on centrally confirmed low-grade astrocytoma found that both PFS and OS were adversely influenced by the presence of baseline neurological deficits, a shorter time since first symptoms (<30 wk), an astrocytic tumor type, and tumors larger than 5 cm in diameter. Age was no longer of prognostic significance.[52]

PRIMARY THERAPY

Observation

The decision to observe a patient with low-grade glioma has been justified in the literature for several reasons. These reasons include the relatively favorable natural history of the disease, the lack of proven benefit for invasive interventions such as surgical resection or radiation therapy, and the potential morbidities of treatment. Patients who are observed should be monitored at regular intervals (e.g., every 6 months) to detect radiologic progression before new signs and symptoms occur.

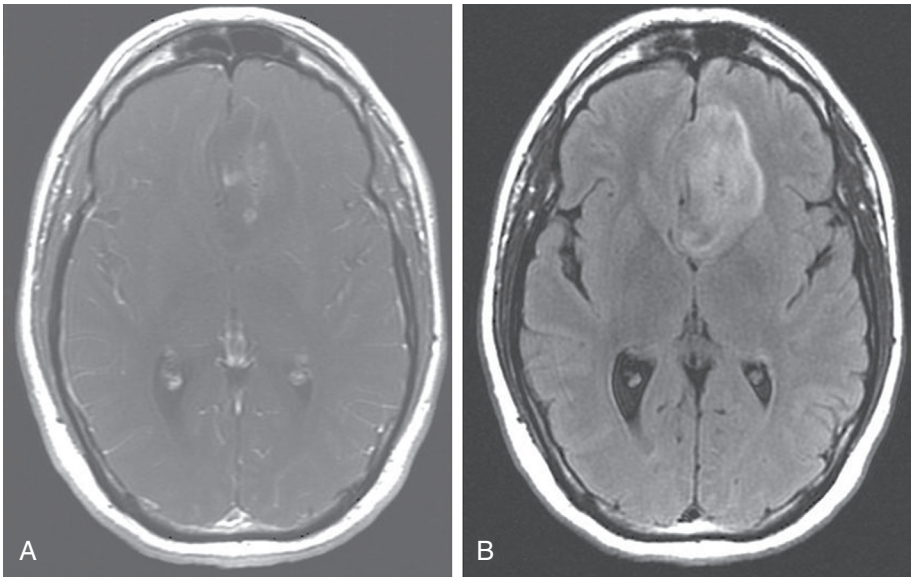

Figure 26-3 Postgadolinium T1-weighted **(A)** and FLAIR **(B)** MRI scans of an adult with a WHO II oligoastrocytoma of the left frontal lobe with midline involvement.

A *to* ***D,*** *Adapted from Shaw EG: The low-grade glioma debate. Evidence defending the position of early radiation therapy. Clin Neurosurg 42:488-494, 1995.*

Despite the favorable survival rates observed in certain subsets of patients with low-grade gliomas, the natural history of all pathologic types of supratentorial low-grade gliomas, including the pilocytic astrocytomas (WHO grade I), diffuse astrocytomas, oligoastrocytomas, and oligodendrogliomas (WHO grade II), is significantly worse than that of an age- and sex-matched control population, for which the expected survival rate is greater than 95% (Figure 26-4).[53] Based on this observation, some have argued that all such patients should undergo maximal safe surgical resection followed by

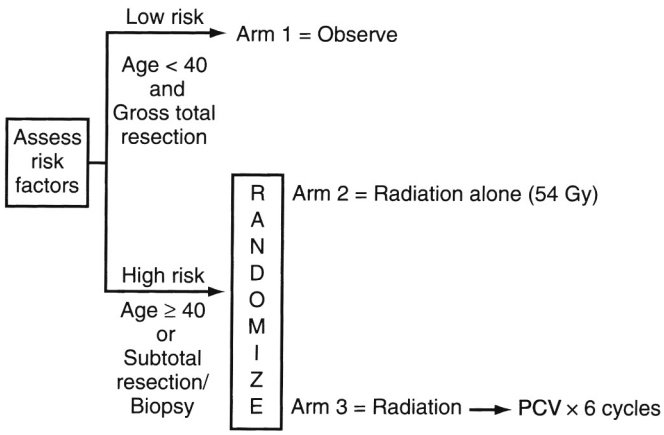

Figure 26-5 Schema of the Radiation Therapy Oncology Group Intergroup Low-Grade Glioma Trial 98-02. PCV, procarbazine, CCNU, and vincristine.

postoperative radiation therapy or chemotherapy, although a survival benefit for treatment, with either aggressive surgery, chemotherapy, or radiation therapy has not been demonstrated in prospective clinical trials.

The RTOG Phase II portion of protocol 9802 (Figure 26-5) prospectively observed 111 patients with low-risk (age younger than 40 years and neurosurgically defined gross total resection) low-grade gliomas.[46] In this "low-risk" population, the 5-year OS was 93%. Astrocytoma histology, residual tumor of 1 cm or more according to MR imaging, and preoperative tumor diameter of 4 cm or more were found to be predictive of a poorer PFS. In patients with all three unfavorable prognostic factors, the 2- and 5-year rates of PFS were 60% and 13%, respectively. In patients with none of the three unfavorable prognostic factors, the 2- and 5-year rates of PFS were 100% and 70%, respectively. These data suggest that observation is a reasonable strategy for the most favorable subset (<1 cm residual tumor, preoperative tumor diameter <4 cm, and oligodendroglioma histology) of younger patients after a gross total resection (GTR).

An EORTC Phase III trial (22845) of 311 adults with supratentorial low-grade gliomas randomized patients to either observation with radiation therapy at progression (which should be considered a delayed RT arm because two thirds of the patients in the observation group received RT at the time of progression) or initial radiation therapy using 54 Gy to localized treatment fields.[54] The 5-year rate of PFS was significantly better for patients receiving initial radiation therapy (55% versus 35%). However, the median OS was not affected (7.4 years versus 7.2 years). In patients who were progression free at 2 years, there were no differences with respect to cognitive deficits, performance status, and headache. These data suggest that observation is a reasonable strategy in adults with asymptomatic supratentorial low-grade glioma.

Surgery

The key surgical issues in the management of supratentorial low-grade gliomas are twofold. The first issue is whether to perform a biopsy on a patient whose clinical presentation and imaging studies suggest a low-grade glioma, and the second is extent of resection.

Although one series in the literature suggests that the survival rate of patients irradiated for presumed low-grade glioma is comparable to that of patients irradiated for histologically verified low-grade astrocytoma,[55] the possibility of inappropriate management in up to 50% of cases[56] diagnosed by imaging underscores the need for histologic verification if a therapeutic intervention is planned. For instance, patients with higher-grade astrocytomas typically receive high-dose external beam radiation therapy in addition to alkylating agents (e.g., temozolomide), whereas GTR without adjuvant radiation therapy constitutes curative treatment for a ganglioglioma.

Extent of Resection

A number of retrospective studies have suggested a benefit for greater extent of resection recognizing the inherent bias associated with extent of resection and tumor location (e.g., more favorable "lobar" lesions are resectable and unfavorable brainstem lesions are unresectable) that makes any definitive conclusions about extent of resection dubious.[57] Nonetheless, some retrospective trials have attempted to further assess this issue.

Investigators from the University of California San Francisco (UCSF) measured tumor volumes based on FLAIR imaging in 216 patients with low-grade gliomas.[58] Patients with at least 90% extent of resection had an 8-year OS of 91% whereas patients with less than 90% extent of resection had an 8-year OS of 60%. After adjusting for age, Karnofsky performance status (KPS) score, tumor location, and tumor subtype, OS and PFS outcomes were both predicted by postoperative tumor volume. One limitation of this study was the relatively short follow-up (median, 4.4 years).

A long-term follow-up (median, 13.6 years) study from the Mayo Clinic reviewed 314 adult patients with low-grade gliomas and found on multivariate analyses significantly improved OS and PFS rates with GTR or nearly GTR. Almost 50% of patients after GTR or nearly GTR were free of recurrence 10 years after diagnosis.[59]

Prospective trials have also found a benefit for greater extent of resection. The Phase II portion of RTOG 9802 (see Figure 26-5) prospectively observed 111 low-risk cases after neurosurgically defined GTR.[46] Review of the postoperative MRI emphasized the importance of postoperative imaging to confirm the extent of resection because a substantial minority of patients had residual disease (32% with 1 cm to 2 cm of residual disease and 9% with more than 2 cm of residual tumor). The crude incidence of tumor recurrence was 26% with a residual tumor of less than 1 cm, 68% with a residual tumor of 1 to 2 cm, and 89% with a residual tumor of more than 2 cm.

Although there are no randomized trials that directly assess the impact of maximal tumor resection in low-grade gliomas, a review of the literature suggests a benefit for maximal *safe* tumor resection, recognizing the importance of achieving this with as little morbidity as possible.[60-62]

External Beam Irradiation

The key external beam irradiation (EBRT) issues in the management of supratentorial low-grade gliomas are timing of radiation (postoperative versus at time of recurrence) and the appropriate dose and treatment volume. The timing of radiation therapy has best been addressed by the Phase III randomized trial EORTC 22845[54] and the RTOG intergroup trial 98-02,[46] as previously reviewed.

Radiation, however, has several other beneficial effects besides the potential delay in tumor recurrence. In a small series of 25 patients with medically intractable epilepsy resulting from an underlying cerebral low-grade glioma, 19 (76%) achieved a significant reduction (>50% decrease) in seizure frequency after RT.[63] In the EORTC Phase III randomized trial 22845, there were no differences in seizure control at baseline,

but at 1 year there were significantly fewer seizures in the irradiated group (25%) than in the observation group (41%).[54]

It has been suggested that radiation therapy may either increase or decrease the likelihood of malignant transformation or may delay its onset. However, in the EORTC Phase III randomized trial 22845, there were no differences in the malignant transformation rate (observation group, 66% versus 72% in the irradiated group) between the study arms at the time of progression.[54] These data imply that irradiation neither increases nor decreases the likelihood of malignant transformation, suggesting that dedifferentiation is a biologic phenomenon observed in low-grade gliomas independent of the treatment.

EBRT Dose-Volume Considerations

Regarding the potential benefit of higher doses of radiation therapy compared with lower doses, two prospective randomized clinical trials (EORTC 22844 and NCCTG 86-72-51) failed to show improved outcome with higher radiation therapy doses.[45,64] The EORTC trial randomized 379 patients to receive moderate-dose (45 Gy) or higher-dose (59.4 Gy) radiation therapy and found no difference in survival rates between the two doses but did find worse quality of life in the higher-dose arm with lower levels of functioning (i.e., emotional and leisure time functioning) and a more extensive symptom burden, including fatigue, malaise, and insomnia.[65] The NCCTG trial compared 50.4 Gy with 64.8 Gy and also failed to demonstrate a difference in survival rates between the two doses. Taken together these trials (along with EORTC 22845) support moderate doses in the range of 45 Gy to 54 Gy using localized fields.[54]

Several series analyzing failure patterns in irradiated patients with low-grade hemispheric gliomas suggest that when tumor progression occurs, it almost always is at the site of the primary tumor within the treatment volume, which implies that partial brain irradiation is appropriate. This was confirmed in the prospective dose-response trial NCCTG 86-72-51 with 92% of failures occurring in the treatment field, 3% within 2 cm of the treatment field, and 5% more than 2 cm beyond the treatment field.[45] These data support the appropriateness of partial brain irradiation.

Other Radiation Modalities

Several other radiation modalities (e.g., stereotactic radiosurgery, proton therapy) have been used selectively in patients with low-grade gliomas with growing interest especially in proton RT. Because proton RT reduces the amount of radiation to the normal surrounding brain it is hoped this will decrease late toxicity. To date only small studies have been conducted and more clinical trials are needed to evaluate the efficacy and safety of protons in this setting.[66]

Chemotherapy

Several Phase II chemotherapy studies have shown efficacy of both temozolomide and PCV chemotherapy in both newly diagnosed and in progressing low-grade gliomas[67-73] (Figure 26-6). The studies on newly diagnosed tumors show that the response assessment may be difficult, and that most cases have radiologically stable disease or a minor response as their best response to chemotherapy (at times, even despite clinical improvement and improved seizure control).[67] As a result, the PFS appears to be a more informative endpoint than objective response rate in unenhancing tumors.[74]

Trials that investigated recurrent tumors with enhancing disease report high response rates both in relapsing oligodendrogliomas and astrocytomas even in the absence of 1p/19q deletion.[72,73] For example a study of 58 patients with dedifferentiated low-grade astrocytomas treated with temozolomide found a response rate of 50% and 6- and 12-month rates of PFS in 67% and 25% of patients, respectively.[75]

The potential role of chemotherapy in newly diagnosed low-grade glioma is better defined based on the results of two large Phase III chemotherapy studies. RTOG intergroup trial 98-02 (see Figure 26-5) randomized patients with low-grade gliomas at high risk for recurrence (age of 40 years or older or subtotal resection/biopsy) between radiation therapy alone or radiation therapy followed by six cycles of PCV.[1,76] With a median follow up of 12 years the patients in the RT and PCV arm had significantly longer median PFS (10.4 years versus 4.0 years, $p = 0.002$) and OS (13.3 years versus 7.8 years, $p = 0.03$) compared with the radiotherapy alone arm. These

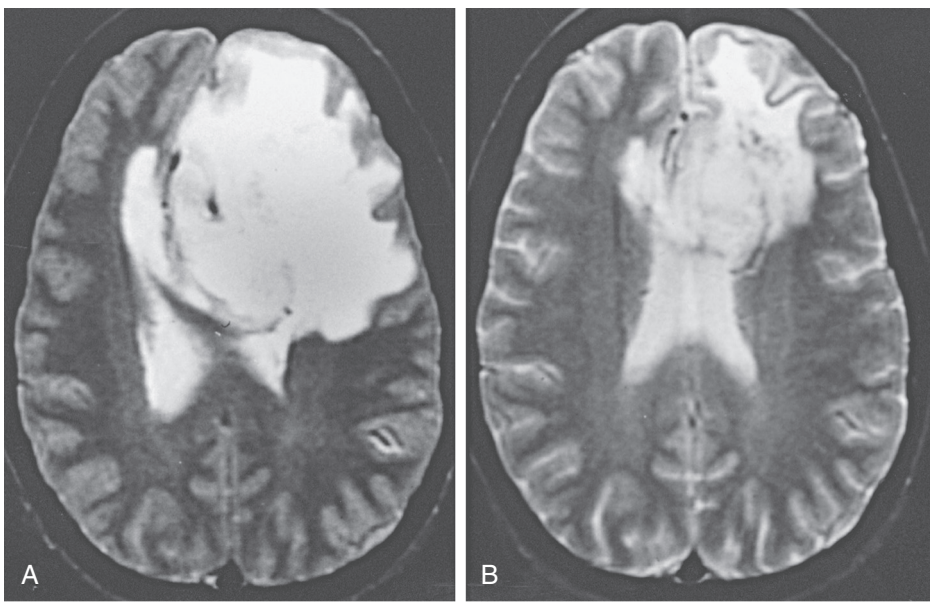

Figure 26-6 Prechemotherapy **(A)** and postchemotherapy **(B)** T2-weighted MRI of a young adult with a WHO II oligodendroglioma of the left frontal lobe.

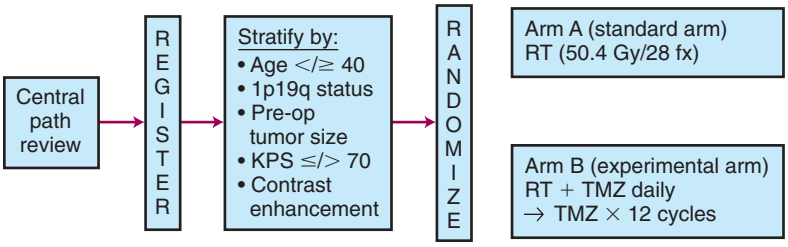

Figure 26-7 Schema of the Eastern Cooperative Oncology Group Intergroup Phase III trial E3F05 of radiation therapy with or without temozolomide for symptomatic or progressive low-grade gliomas. *fx*, Fraction; *KPS*, Karnofsky performance scale; *RT*, radiotherapy; *TMZ*, temozolomide.

results confirm a benefit for RT followed by PCV for selected low-grade glioma populations.

An EORTC trial addressed the role of temozolomide in newly diagnosed patients with high-risk low-grade gliomas.[77] This trial, with PFS as the primary endpoint, randomized patients with progressive disease, uncontrolled seizures despite anticonvulsants, or neurologic symptoms to either standard radiation therapy or daily low-dose temozolomide. Initial results suggest that in 1p-intact tumors RT may confer an improved PFS (p = 0.06), whereas in 1p-deleted tumors temozolomide may be equivalent to RT. At the time of the first report, OS data were still immature. Further follow-up reports of this study must confirm whether a strategy to treat with early chemotherapy and delay administration of RT will translate into better long-term cognitive functioning. An intergroup Phase III trial (Figure 26-7) with similar eligibility criteria and stratification factors investigated the efficacy of combined chemoradiation with temozolomide compared with RT alone although the results of this trial are not yet available. Of note a RTOG Phase II study of RT plus concurrent and adjuvant temozolomide for high-risk low-grade gliomas did find improved OS compared to a historical control of RT alone.[78]

FAVORABLE LOW-GRADE GLIOMA VARIANTS

One group of primary CNS tumors with a distinctly more favorable prognosis than WHO grade II low-grade gliomas includes the pilocytic astrocytomas (WHO grade I) and the other low-grade glioma variants, such as pleomorphic xanthoastrocytomas, subependymal giant cell astrocytomas, and subependymomas. Three other primary CNS tumors of neuronal or mixed neuronal-glial origin are often grouped with the low-grade glioma variants because of their similar presentation and favorable prognosis, including the gangliogliomas, central neurocytomas, and dysembryoplastic neuroepithelial tumors. Other than the pilocytic astrocytomas, which make up approximately 20% of supratentorial low-grade gliomas and 80% of cerebellar gliomas,[41] the other six variants are uncommon, accounting for approximately 1% or less of primary CNS tumors. From an imaging standpoint, they are typically well circumscribed, enhancing, and sometimes cystic or calcified, or both.[7]

Pilocytic Astrocytomas

Pilocytic astrocytomas typically occur in children and young adults, with common locations being the cerebellum, optic pathways, hypothalamus/third ventricle, and cerebral hemispheres. They are the most common primary brain tumor occurring in patients with type 1 neurofibromatosis.[79,80] The 10-year OS rate is 80% or greater, independent of location in the brain, although rarely, they behave more aggressively.[8] In patients undergoing GTR, the 10-year disease-free survival and OS approach 100%.[8]

For patients who have subtotal resection, particularly children, a reasonable strategy is observation with close follow-up because there is no apparent survival benefit for routine postoperative radiation therapy, and a second surgical procedure accomplishing GTR appears curative.[81] Radiation therapy is usually reserved for symptomatic subtotally resected or unresectable tumors, usually in the setting of tumor recurrence. This paradigm was tested and proved to be successful in an NCCTG prospective clinical trial of 20 adults with supratentorial pilocytic astrocytomas observed after gross or subtotal resection or treated with irradiation after biopsy.[8] The 10-year rate of PFS and OS was 95%. When pilocytic astrocytomas require irradiation, the recommendation is to treat localized fields (enhancing tumor with a 4-mm to 5-mm margin using image-guided radiotherapy [IGRT]) with moderate doses (45 Gy to 54 Gy). Radiosurgery (e.g., 13 Gy or 15 Gy marginal dose) has also been used in the treatment of pilocytic astrocytoma, although it is most frequently used in the salvage setting after prior fractionated RT.[82,83] The recurrence rate seems to be higher with radiosurgery when compared to fractionated RT, which may be as a result of patient selection, dose inadequacy, or margin inadequacy.

Pleomorphic Xanthoastrocytomas

Pleomorphic xanthoastrocytomas occur in children and young adults, usually presenting with seizures caused by an underlying tumor in the cerebral cortex (temporal lobes), sometimes with adjacent meningeal and, rarely, craniospinal leptomeningeal involvement. Despite their pleomorphism, these tumors often behave in an indolent manner.[7] An analysis of BRAF V600E mutation in 1320 CNS tumors found BRAF mutations in several tumor types (e.g., pilocytic astrocytoma, ganglioglioma) with an especially high frequency (66%) in pleomorphic xanthoastrocytoma, possibly providing a new therapeutic window for BRAF-targeted therapies although this will require future clinical trials.[84] Treatment recommendations depend on the grade of the astrocytic component. When GTR has been achieved of a pleomorphic xanthoastrocytoma that contains a low-grade diffuse astrocytoma (WHO grade II), observation is appropriate, although local tumor recurrence, sometimes with malignant transformation, can occur. Indications for radiation therapy (doses and treatment fields are similar to those of the more common forms of WHO grade II low-grade gliomas) include pleomorphic xanthoastrocytomas that contain an anaplastic astrocytoma or glioblastoma (WHO grades III/IV), symptomatic subtotally resected or unresectable tumors, or recurrent tumors, particularly if their astrocytic component dedifferentiates.[85]

Central Neurocytomas

Central neurocytomas contain neuronal elements that are usually mature. They are classified as WHO grade II tumors. By definition, they arise in the ventricular system (although an extraventricular neurocytoma with similar clinical behavior

is described in the fourth edition of the WHO classification), usually as large tumors in the lateral ventricular system, and they rarely have been reported to disseminate craniospinally. The typical age at presentation is the late 20s, although these tumors can occur in children or adults.[7] Subtotally resected tumors have been reported to respond to radiation therapy.[86]

A review of 45 patients with central neurocytoma treated with various combinations of surgery, radiation therapy (median dose, 55.8 Gy), and chemotherapy found a 10-year OS of 83%.[86] The 5-year local control rate was 100% for patients who received radiation therapy compared with 51% for those who did not ($p = 0.045$); however, there was no difference in 5-year OS, likely because of the effectiveness of salvage irradiation. Therefore, patients are observed after GTR with consideration of observation after subtotal resection of typical neurocytomas. Patients with unresectable tumors, recurrent tumors, or select patients with subtotally resected tumors (especially, "atypical neurocytomas") are usually offered radiation therapy postoperatively. A systematic review of radiosurgery identified 64 central neurocytomas with a tumor control of 91% at a mean follow-up of 59 months after radiosurgery (median marginal dose 12 Gy to 16 Gy).[87] Although this review was limited by small patient numbers, radiosurgery appears to be an effective treatment for highly selected patients with recurrent or residual disease.

Other Favorable Variants

Gangliogliomas consist of neoplastic ganglion (neuronal) cells and neoplastic glial (astrocytic) cells. They can occur in children and adults, although most are present in the first two to three decades of life. Gangliogliomas can develop anywhere in the CNS, but they tend to occur in the supratentorial brain, most often in a temporal location, and enhance on MR images with contrast medium. Like pleomorphic xanthoastrocytomas, the glial component can be a low-grade tumor (WHO grade I) or a higher-grade tumor (WHO grade III).[7] A review of 402 patients found no local control or survival benefit with postoperative RT after GTR but did find improved local control (but not survival) after subtotal resection for both low and high-grade tumors.[88] Treatment principles are similar to those of pleomorphic xanthoastrocytoma from both a surgical and radiotherapeutic standpoint.[89]

Dysembryoplastic neuroepithelial tumors, like gangliogliomas, also contain a mixture of neuronal and glial elements, although the neuronal component is mature and the glial component is well differentiated and has astrocytic or oligodendroglial tissue. As such, the tumors are classified as WHO grade I tumors. Typically, these tumors occur in a temporal location, are characteristically multinodular, and arise during the first two decades of life. Treatment principles are similar to those of pilocytic astrocytomas from both a surgical and radiotherapeutic standpoint, although irradiation is rarely necessary.[7]

Subependymal giant cell astrocytomas (SEGA) occur in patients with tuberous sclerosis, often during the first two decades of life but sometimes later.[5] Characterized by large astrocyte-like cells, they are classified as WHO grade I tumors, like the pilocytic astrocytomas. Typically, they arise in an intraventricular or periventricular location (e.g., lateral ventricles, foramen of Monro) and on MR images appear as intraventricular enhancing masses. Treatment recommendations parallel the pilocytic astrocytomas; that is, GTR is considered curative.[90] However the role of RT for symptomatic progression or relapse has been diminished even more with the recognition that tuberous sclerosis is associated with constitutive activation of mammalian target of rapamycin (mTOR). Prospective placebo-controlled trials[91] have shown the efficacy and safety of mTOR inhibitors (e.g., everolimus) in the treatment of SEGA, even in the long term.[92]

Subependymomas are also classified as WHO grade I ependymal tumors. They contain both low-grade astrocytic and ependymal-like cells, and they usually arise in an intraventricular location (lateral or fourth ventricles, particularly in and around the foramen of Monro) in adults near the age of 50 years. Treatment recommendations parallel those of pilocytic astrocytomas, both surgically and radiotherapeutically. Subtotally resected and recurrent tumors have been reported to respond to radiation therapy.[93]

RECURRENT DISEASE AND PALLIATION

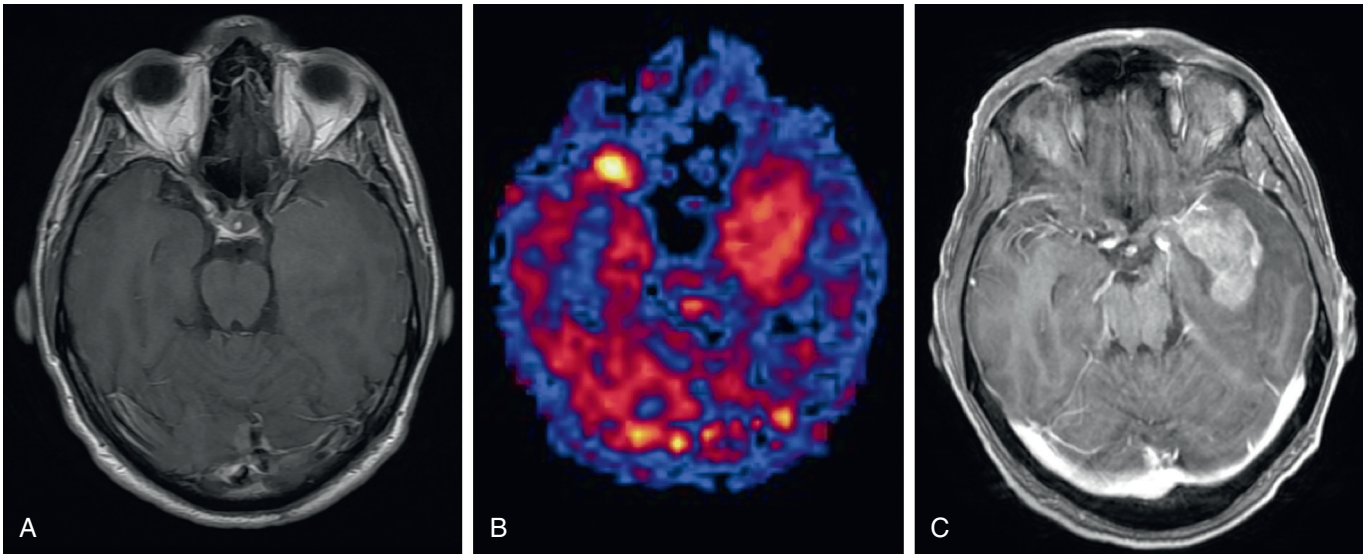
The vast majority of patients with a low-grade diffuse glioma die of their disease. As such, at some point in his or her illness, the typical patient with a low-grade glioma likely has the combination of progressive neurologic symptoms and signs in the face of neuroimaging evidence of tumor recurrence. Most of the time the lesion progresses at the original site, but uncommon patterns of treatment failure can occur in patients with recurrent low-grade gliomas such as infiltration across the deep, dense white matter tracts of the brain. Leptomeningeal failure has also been reported, though this is more likely to occur in the pediatric low-grade glioma population.

At the time of progression, often (in up to 70% of patients) the lesion has dedifferentiated to a higher grade of malignancy.[54] This is revealed on the MRI scan by areas of enhancement, which can be preceded for 6 months to 12 months by a local increase in regional cerebral blood volume (e.g., Figure 26-8). The clinical and radiographic features of a high-grade tumor recurrence can be difficult to distinguish from radiation necrosis by conventional MRI. Advanced imaging techniques such as PET,[94] single-photon emission CT,[95] MRI spectroscopy,[96] perfusion and diffusion-weighted MRI[97] may prove to be more useful in this regard (Figure 26-9), though there is not yet a consensus as to the most accurate imaging technique for distinguishing transformation from treatment-related imaging changes. As such, tissue must be obtained, although even pathologic findings can be difficult to interpret.

In Forsyth et al,[98] 51 previously irradiated patients (40 of whom had Kernohan grade 1 or grade 2 astrocytoma, oligoastrocytoma, or oligodendroglioma) underwent stereotactic biopsy for suspected recurrence. Pathologic examination revealed the presence of tumor only in 30 biopsies (59%), tumor plus necrosis in 17 biopsies (33%), radionecrosis in three instances (6%), and one case of a radiation-induced sarcoma (3%). In patients in whom tumor was found, it was of a high grade in 63%. Median survival time after biopsy was 10 months in patients with tumor only, a finding significantly worse than the 22-month median survival time in those with tumor plus necrosis. No deaths occurred among the patients whose biopsies showed radionecrosis alone.

In general, survival after tumor recurrence is poor. In one series, patients with recurrent low-grade astrocytoma after treatment with surgery and postoperative irradiation were treated with temozolomide and had a 1-year OS of 60%.[75] Typically, survival in patients with recurrent oligodendroglioma showing a 1p/19q codeletion will be better. In the series Leighton et al[99] conducted before the 1p/19q era, the median survival time after recurrence was 39 months for all patients, 16 months for those with recurrent low-grade diffuse astrocytomas, and 60 months for those with recurrent low-grade oligodendrogliomas.

Treatment options for recurrence include surgery, reirradiation (e.g., EBRT, brachytherapy, stereotactic radiation



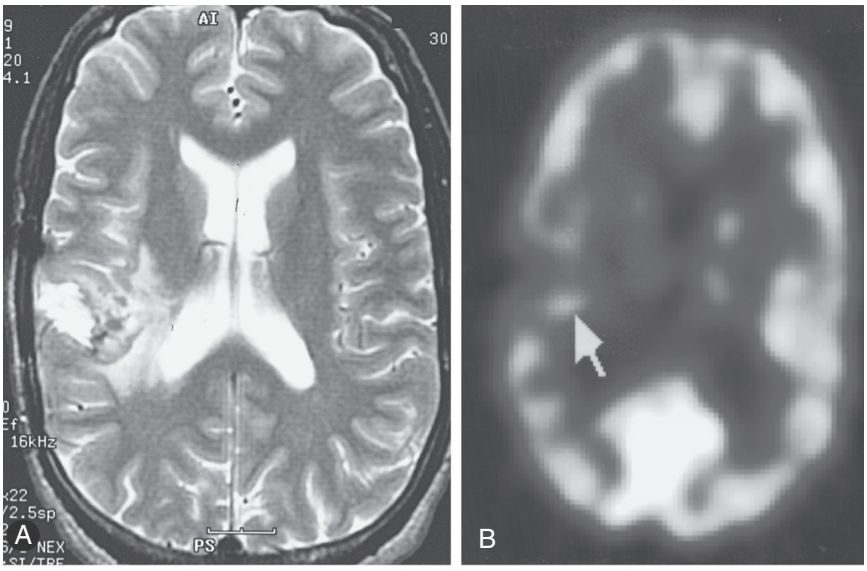


Figure 26-8 **A,** Axial T1-weighted MRI of diagnostic imaging of WHO grade II diffuse astrocytoma demonstrating nonenhancing mass in the left medial temporal lobe. **B,** Axial arterial spin labeling MRI of the same patient acquired simultaneously with image A and showing increased perfusion in the left temporal lobe mass. **C,** Axial T1-weighted MRI performed at 6-month interval showing increased enhancement in the left temporal lobe. Subsequent biopsy demonstrated malignant transformation to WHO grade IV glioblastoma.

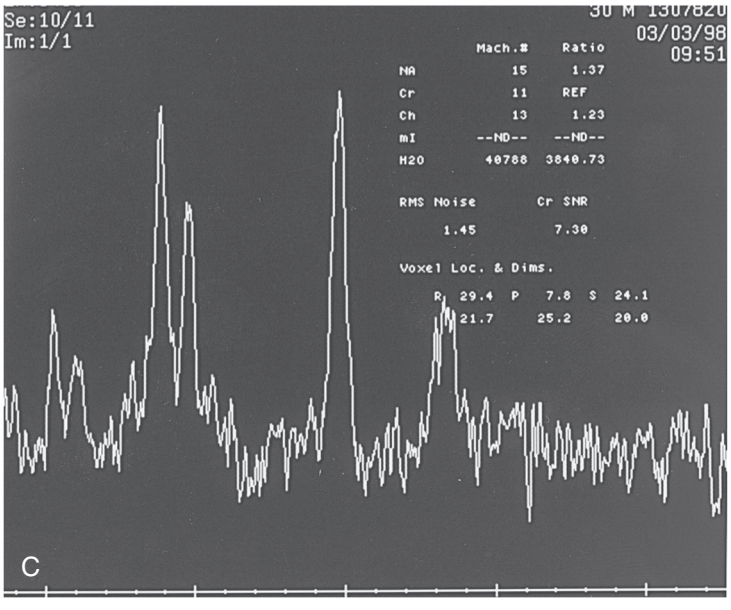

Figure 26-9 Postgadolinium T1-weighted MRI of a young adult with a WHO grade II oligoastrocytoma after subtotal resection, 50.4-Gy external beam radiation therapy, and 18 Gy given in a single fraction in stereotactic radiosurgery for recurrent disease at the medial edge of the resection cavity. **A,** An area of increased contrast enhancement at the site of the stereotactic radiosurgery. **B,** Positron emission tomography using fluorodeoxyglucose showed increased uptake at the site of the contrast enhancement *(arrow).* However, MRI spectroscopy **(C)** was more suggestive of radiation necrosis because the choline-to-creatine ratio was less than 2 and the lactate peak was elevated. Subsequent biopsy demonstrated radiation necrosis.

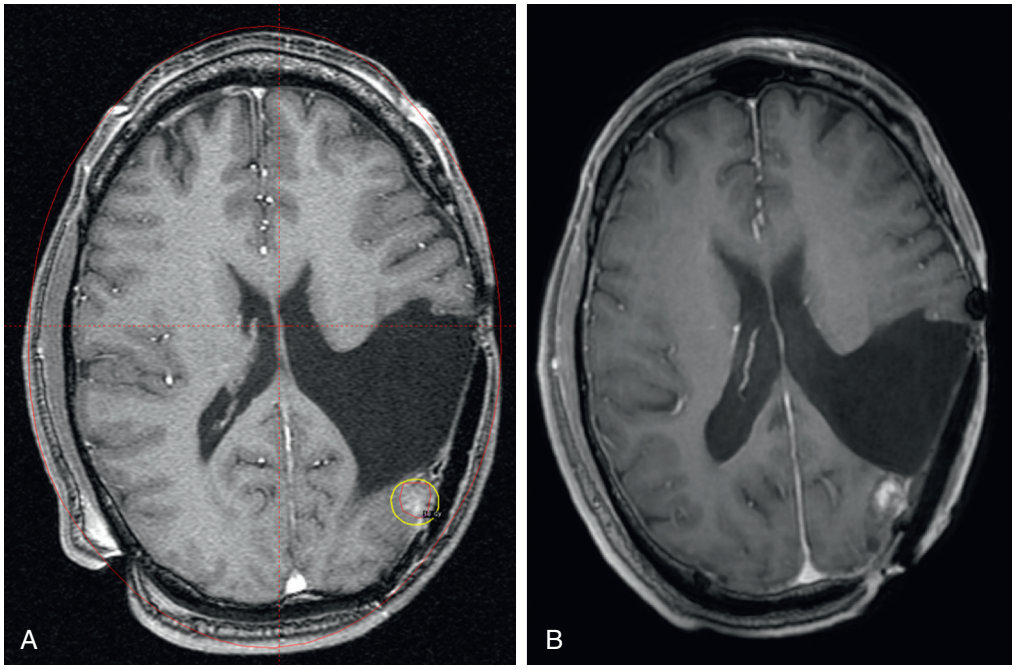

Figure 26-10 **A,** Axial T1-weighted MRI depicting treatment plan for single fraction radiosurgery of multiply recurrent WHO grade II oligodendroglioma treated with 18 Gy to the 50%. **B,** Axial T1-weighted MRI depicting 10-year follow-up imaging confirming long-term local control of previously treated lesion.

therapy, radiosurgery) and chemotherapy (or second-line chemotherapy). Patients must be managed on an individual basis, depending on the timing of the relapse, previous treatments, and accessibility for clinically significant surgery. In one series, 63 patients with recurrent low-grade gliomas were treated with a second course of conventionally fractionated RT (median dose 36 Gy in 2 Gy fractions) in which the enhancing and FLAIR abnormality was encompassed within the RT volume.[100] From time of reirradiation, median survival and PFS were 23 and 12 months, respectively. Hypofractionated reirradiation has also been reported for recurrent low-grade gliomas.[101]

A concern for stereotactic radiosurgery (SRS) as a treatment option for recurrent low-grade glioma is the likely infiltrative nature of these tumors and the limitations of SRS to a smaller treatment volume. There have been several reported series of salvage SRS, and although durable local control is not the rule, there likely exists a population of patients that may benefit from this modality. In a University of Pittsburgh SRS series, PFS was 81.5% at 5 years after SRS for patients with recurrent grade II oligodendroglioma.[83] In a separate SRS series from the same institution in patients with recurrent grade II astrocytoma, only 54.1% remained progression free at 5 years.[102] Figure 26-10 depicts a patient treated with SRS for a nodular resection cavity recurrence of grade II oligodendroglioma along with a 10 year follow-up MRI documenting continued local control.

Salvage chemotherapy appears to have a modest effect after failure of low-grade glioma that has progressed beyond either prior RT or prior first-line chemotherapy. Retrospective series appear to suggest that neither PCV nor temozolomide have significant activity after a low-grade glioma has failed the other regimen as first-line therapy.[103,104] The EORTC is currently assessing the efficacy of adding bevacizumab to temozolomide in a randomized Phase II study in progressive non 1p/19q codeleted grade II and grade III tumors.

IRRADIATION TECHNIQUES AND TOXICITIES

EBRT Volume Considerations

Because the vast majority of treatment failures after partial brain irradiation occur in the field, treatment of the tumor plus a margin of normal tissue is considered the standard of care. With the identification of tumor cells up to several centimeters beyond the margin of the tumor identified by T2-weighted MRI,[105] the appropriate irradiation volume should include the MRI extent of tumor as defined by T2-weighted or FLAIR MR images with a 2-cm to 3-cm margin. A 2-cm margin may be acceptable if some form of IGRT is used (Figure 26-11).

EBRT Dose and Technique Issues

As previously outlined, three prospective randomized clinical trials (EORTC 22844, EORTC 22845, and NCCTG 86-72-51) support moderate RT doses in the range of 45 Gy to 54 Gy.[45,54,64] In an effort to improve conformality and possibly better spare normal structures, many centers use intensity-modulated radiation therapy (IMRT), especially in select situations such as tumors involving the inferior temporal lobes or tumors with irregular or complex shapes. However, a disadvantage of IMRT is the increased dose heterogeneity because in low-grade gliomas, much of the target is an admixture of tumor cells and normal brain tissue.[106] As an example, if IMRT is used with a prescription of 54 Gy in 30 fractions, this may result in heterogeneity of 10% or more in the target. This increased heterogeneity results in an increased daily dose per fraction and an increased total dose such that the biologically equivalent dose approaches that of the high-dose arm in NCCTG 86-72-51 (e.g., 64.8 Gy) and therefore increases the risk of radiation necrosis.[45] Selecting a slightly lower dose (e.g., 50.4 Gy) is a reasonable strategy because even with

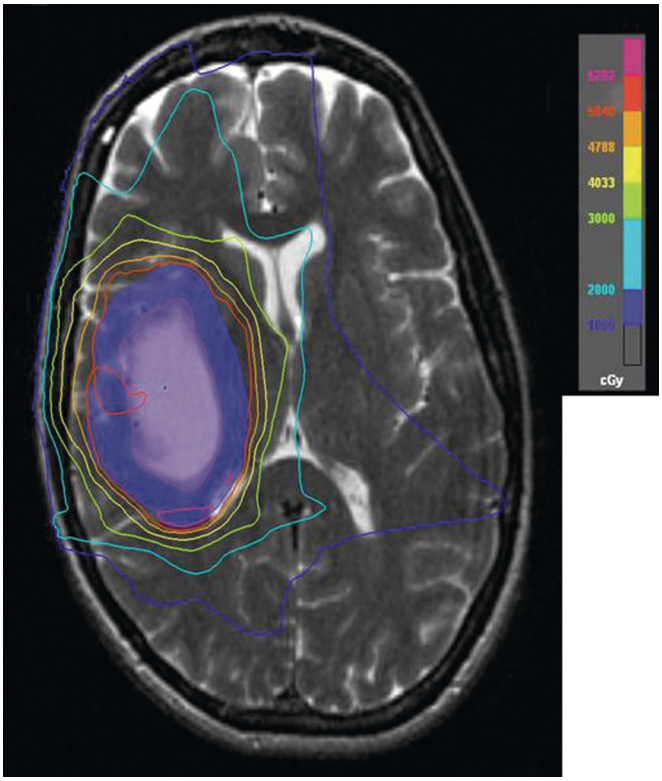

Figure 26-11 Fractionated stereotactic radiotherapy (50.4 Gy in 28 fractions), using daily image-guided radiotherapy (IGRT), in the treatment of a WHO grade II oligoastrocytoma involving the posterior insular cortex and superior temporal gyrus.

heterogeneity of 10% the hot spots are within the range of what is considered to be a low risk of radiation necrosis. Accordingly, a dose of 50.4 Gy was chosen for the current intergroup low-grade glioma trial (E3F05) (see Figure 26-7). Because modern IMRT techniques tend not to have this degree of dose heterogeneity, the issue will likely become less significant with better treatment planning techniques.

Toxicities of Radiation Therapy

A spectrum of radiation-induced toxicities can occur in patients receiving therapeutic brain irradiation. These range from cognitive sequelae, the pathogenesis of which is likely white matter injury, to overt radiation necrosis, which is probably a consequence of vascular injury.[107] The incidence of overt radiation necrosis after irradiation for a cerebral low-grade glioma is approximately 3% based on data from surgical series in which reoperation data were reported.[43,108] This is consistent with findings from NCCTG 86-72-51 (50.4 Gy versus 64.8 Gy), in which the 2-year actuarial incidence of severe, life-threatening, or fatal radionecrosis was 1% at 50.4 Gy and 5% at 64.8 Gy.[45] Examples of the clinical presentation, imaging changes, time course, management, and outcome of the spectrum of severe or worse radiation toxicities seen in patients with cerebral low-grade gliomas are shown in Figures 26-12 to 26-14.

Prospective Quality-of-Life and Neurocognitive Analyses

Several studies have focused on the neurocognitive effects of radiation therapy in patients who are long-term recurrence-free survivors, most of whom were irradiated for supratentorial low-grade gliomas. To assess the toxicity of irradiation, it is also important to understand the neurologic and cognitive dysfunction that results from having a cerebral low-grade glioma.[109] To assess the impact of early intervention on quality of life (QOL), investigators from the University Medical Center Utrecht matched 24 patients with suspected low-grade gliomas (based on imaging and clinical history) to 24 patients with proven low-grade gliomas, who had undergone early surgery, and 24 healthy controls.[110] Both patient groups scored worse on QOL and cognitive function scales than healthy control subjects. Unoperated patients with suspected low-grade gliomas scored better on most items than patients who had undergone surgery and had tissue with proven low-grade gliomas. This study suggests that observation is a reasonable option for a select population. In addition, this study emphasizes the need for baseline (i.e., before surgery or RT) cognitive testing because the tumor itself causes cognitive deficits.

Because there is no convincing evidence that early radiation therapy improves OS, deferring irradiation until there is evidence of symptomatic tumor growth is an acceptable practice. The primary rationale for delaying irradiation is to reduce the risk of radiation-induced neurocognitive damage. Some retrospective studies have found increased neurocognitive difficulties after cranial radiation therapy. However, these studies have several deficiencies[109] although the most serious is the lack of baseline neurocognitive testing because the brain tumor itself is often the primary cause of cognitive difficulties. In contrast, a number of studies have prospectively performed extensive neuropsychological testing on adult patients with low-grade neoplasms before (baseline) and after radiation therapy (up to 6 years after radiation therapy) and have not found significant neurocognitive deficits when compared with either baseline[111,112] or a cohort of patients with low-grade brain neoplasms not treated with irradiation[113,114] (Table 26-5). For example, in NCCTG 86-72-51, a subset of 20 of the 203 adult study patients who received either 50.4 Gy or 64.8 Gy underwent psychometric testing before and up to 5 years after localized radiation therapy.[112] No significant loss in general intellectual function, new learning, or memory was seen. However, four patients, all in the 64.8-Gy arm, had a mild decline in one or more of the domains (immediate verbal memory, learning, and spatial problem solving) assessed. Therefore the weight of evidence indicates a low incidence of neurocognitive difficulties after focal, conventionally fractionated (1.8 Gy to 2 Gy) radiation therapy using modern techniques to deliver moderate doses in adults.[109]

In children, the risk of cognitive injury after irradiation appears to be most closely associated with younger age (i.e., developing brain) at the time of treatment and secondarily with the volume of brain irradiated.[115] The effects of surgery and other therapies for these tumors are also associated with a risk of cognitive injury, which can make assessments after RT difficult.[116,117] To better assess the cognitive impact of RT in children St Jude Children's Hospital evaluated late effects in 78 patients with low-grade gliomas after treatment with more *modern* techniques (54-Gy conformal EBRT with a 10-mm clinical target volume margin).[115] Through 5 years of follow-up for the entire group (baseline testing after surgery and serial evaluations), only a decline in spelling scores was clinically significant. Thirteen of the patients had neurofibromatosis 1 (NF-1) and were found to have worse function at baseline compared with other pediatric patients with low-grade gliomas. In addition, the patients with NF-1 had worsening function over time whereas patients without NF-1 had stable function over time. Age had a significant impact on cognitive function over time, such that a 10-point decline in IQ 5 years after irradiation would be expected for a child age

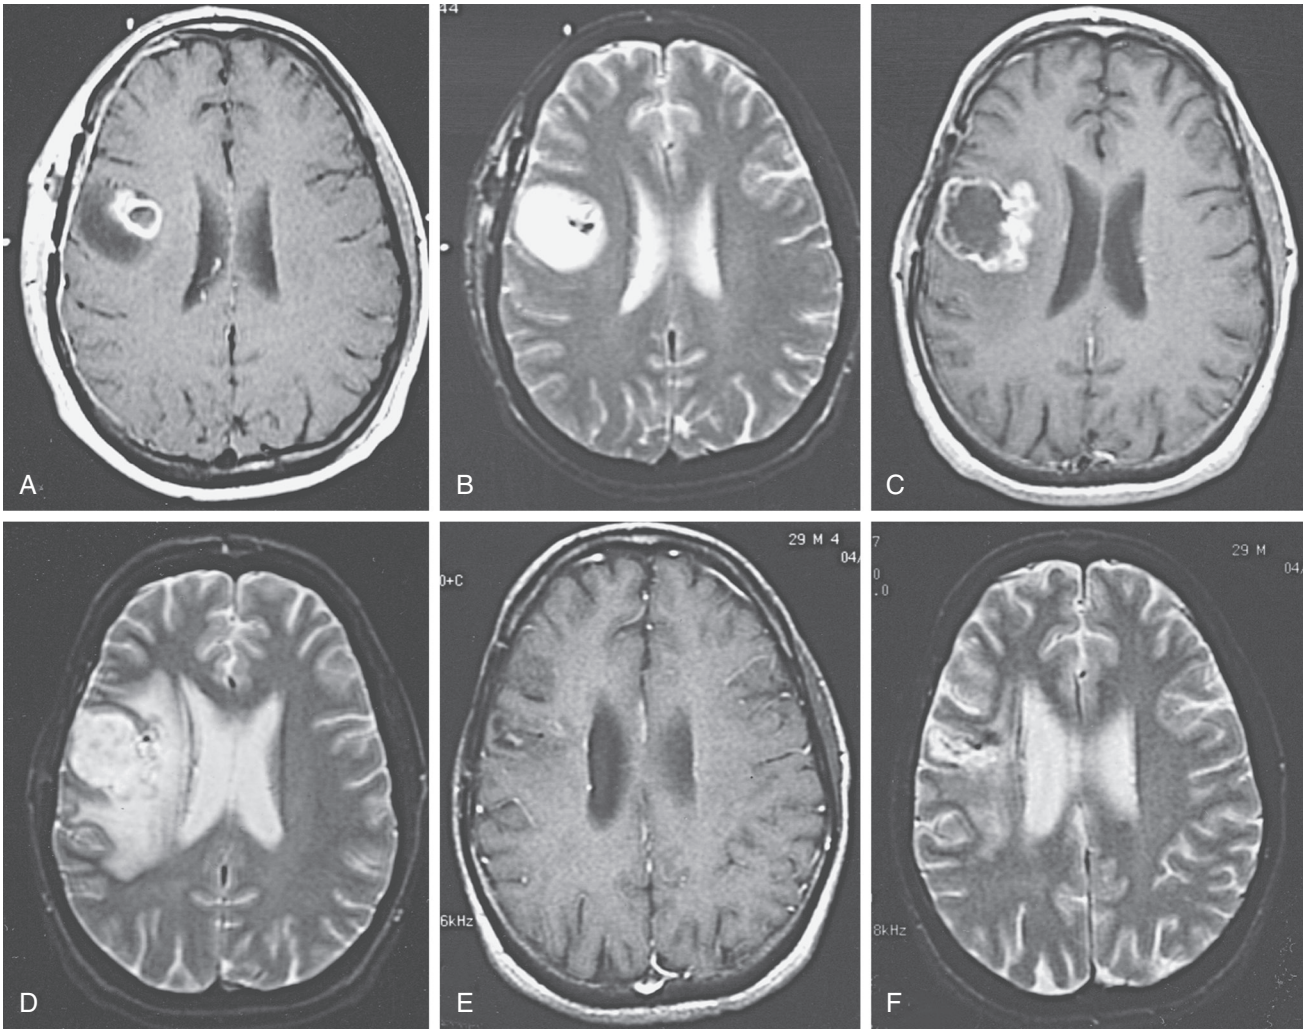

Figure 26-12 Preirradiation, postgadolinium T1-weighted **(A)** and T2-weighted **(B)** MR images of an adult with a WHO grade II oligodendroglioma of the right frontotemporal lobes. Seven months after 64.8-Gy external beam radiation therapy, the patient developed headaches. Postgadolinium T1-weighted **(C)** and T2-weighted **(D)** MR images are shown. The differential diagnosis considered recurrent tumor and radiation necrosis. After a brief course of oral corticosteroid medications, the imaging abnormalities resolved, a finding supporting the diagnosis of transient radiation necrosis. Postgadolinium T1-weighted **(E)** and T2-weighted **(F)** magnetic resonant images are shown.

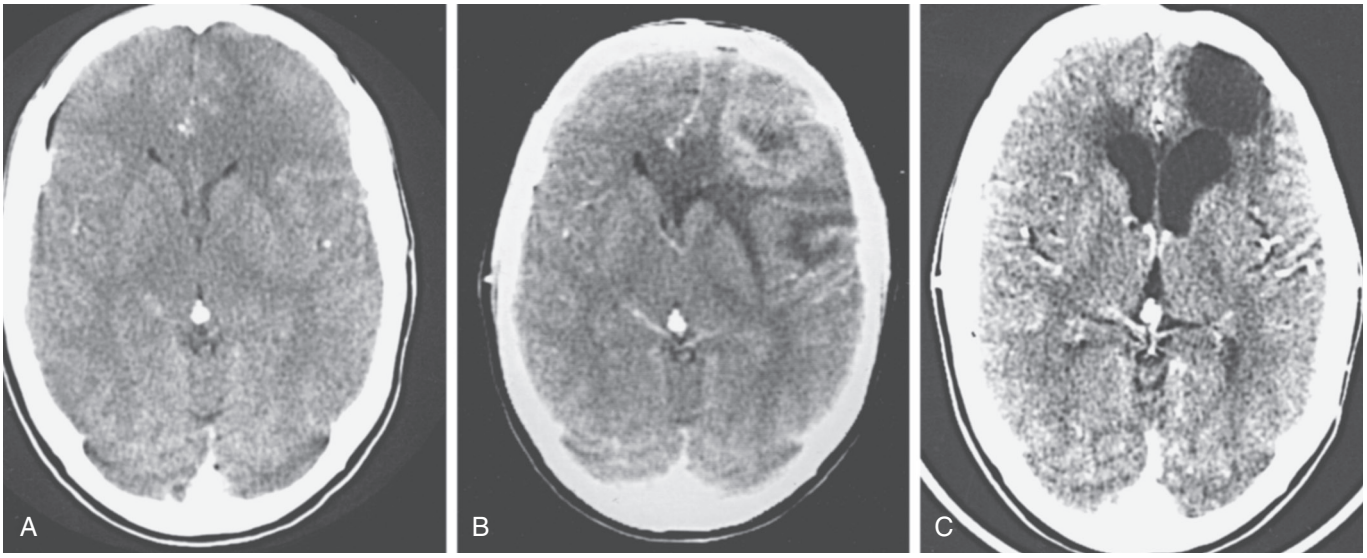

Figure 26-13 Contrast-enhanced CT demonstrates the progress of a left frontal WHO grade II astrocytoma in an adult patient. **A,** Before 64.8-Gy external beam radiation therapy. **B,** After irradiation, the patient had headaches. **C,** Eighteen months after gross total resection of what proved to be a combination of radiation necrosis and persistent low-grade astrocytoma, the patient had no evidence of further radiation necrosis or tumor.

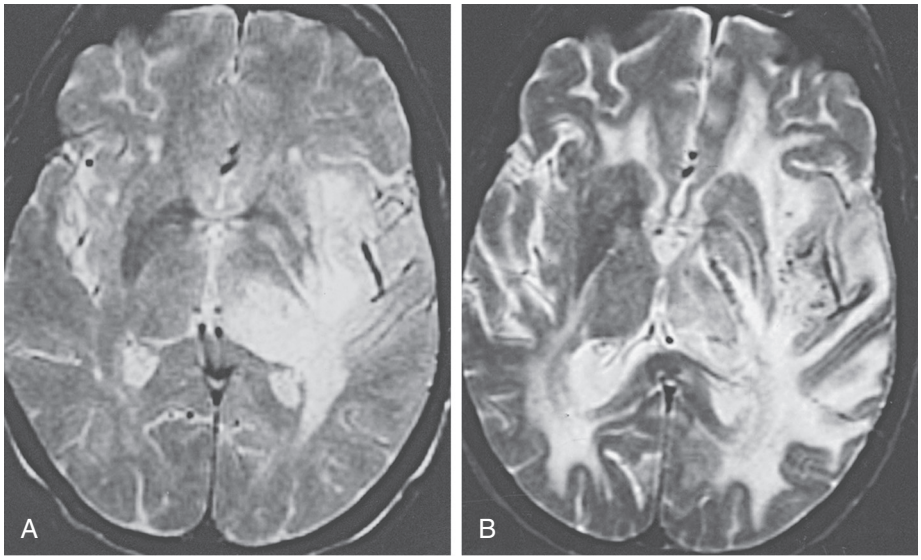

Figure 26-14 **A,** T2-weighted MRI scan of an older adult with an infiltrative, poorly defined WHO grade II astrocytoma the epicenter of which was in the left temporal lobe. Six months after completing 64.8-Gy external beam radiation therapy, the patient developed a significant decline in cognitive function and overall performance status. **B,** Repeat MRI showed dramatic white matter changes. The patient subsequently died, and an autopsy showed radiation necrosis with a persistent low-grade astrocytoma.

TABLE 26-5 Prospective Trials with Baseline and Serial Cognitive Testing in Adults with Low-Grade Neoplasms

Author	Histology (No. with RT)	RT: Total Dose/ Fraction (Gy)	Mean FU (yr)	Neurotoxicity after RT
Vigliani et al[114]	LGG, AA (17)	Focal RT 54/1.8	4	No; transient decline in RcT
Armstrong et al[111]	LGG, pituitary, pineal, meningioma (26)	Focal RT mean 54.6/1.8-2	3	No; mild decline in visual memory after 5 yr
Torres et al[113]	Meningioma, LGG, GBM, ependymoma, adenoma (15)	Focal RT mean 54/1.8	2	No; decline in memory and attention only if tumor progression
Laack et al[112]	LGG (20)	Focal RT 50.4/1.8 or 64.8/1.8	3	No; mild decline in 64.8-Gy arm in immediate verbal memory, learning, and spatial problem solving

AA, *Anaplastic astrocytoma;* CGE, *cobalt Gray equivalent;* FU, *follow-up;* GBM, *glioblastoma multiforme;* LGG, *low-grade glioma;* NFS, *neurologic function scores;* RcT, *reaction time;* RT, *radiation therapy.*

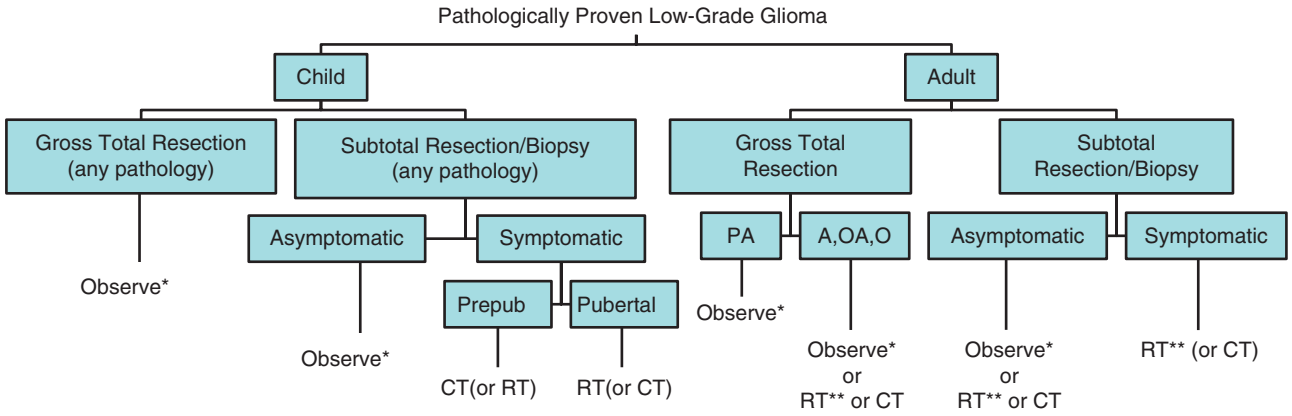

Figure 26-15 Treatment algorithm for low-grade glioma. *Treatment is deferred until the time of symptomatic or imaging progression. Appropriate treatment at the time of progression may include surgery, chemotherapy, or radiation therapy. ** For patients with less than gross total tumor resection or older than 40 consider radiotherapy followed by procarbazine, CCNU, and vincristine. *A*, Astrocytoma; *CT*, chemotherapy; *O*, oligodendroglioma; *OA*, oligoastrocytoma; *PA*, pilocytic astrocytoma; *RT*, radiation therapy.

5 years at the time of irradiation. Each year of increasing age significantly reduced the decline in IQ. The authors noted that cognitive function was largely preserved after conformal RT using modern techniques, but RT should be delayed if possible for younger patients.

CONCLUSIONS, TREATMENT ALGORITHM, AND FUTURE POSSIBILITIES

Low-grade gliomas are a heterogeneous group of CNS neoplasms, and their natural history depends primarily on pathologic type and tumor size. A treatment algorithm for low-grade gliomas is provided in Figure 26-15. Despite having been considered "benign," most of these tumors behave in an aggressive manner, even after surgery and radiation therapy.

Prospective trials confirm the role of chemotherapy for select low-grade glioma populations. Long-term follow-up of RTOG 98-02 (high-risk patients with less than gross total tumor resection or older than 40) found significantly better PFS (10.4 years versus 4.0 years, $p = 0.002$) and OS (13.3 years versus 7.8 years, $p = 0.02$) for those treated with RT followed by PCV chemotherapy compared to those treated with RT alone.

Translational research, including studies of proliferation, cytogenetics, and molecular genetics, will provide much needed insight for the next generation of biologically based therapies.

CHAPTER

27 High-Grade Gliomas

Andrew B. Lassman, Diana Matceyevsky, and Benjamin W. Corn

INCIDENCE

There are approximately 68,000 new cases of brain tumors diagnosed in the United States each year. Gliomas now account for nearly 80% of malignant brain tumors. Glioblastoma (GBM) is the most common primary malignant brain tumor.[1]

BIOLOGIC CHARACTERISTICS

A better prognosis is associated with grade III tumors (as classified by the World Health Organization [WHO]) when compared with grade IV tumors (i.e., GBM) and for oligodendrogliomas when compared with astrocytomas. A better response to therapy and higher rates of survival are associated with oligodendroglial tumors manifesting 1p19q codeletions and IDH mutations. Methylation of the promoter for the *MGMT* gene predicts for increased sensitivity to DNA alkylating agents such as temozolomide and is prognostic for overall survival (OS) in patients with GBM, especially older patients.

STAGING EVALUATION

Optimal imaging is carried out with contrast-enhanced magnetic resonance imaging (MRI). Computed tomography (CT) scans are primarily used as an infrastructure for radiation treatment planning before fusion with MRI images. On the first postoperative day, an MRI study should be obtained to evaluate the extent of resection and as a basis for radiation treatment planning.

PRIMARY THERAPY AND RESULTS

The standard of care for the definitive treatment of newly diagnosed GBM in patients aged 18 years to 70 years is the delivery of approximately 60 Gy of fractionated partial brain radiotherapy following maximal safe surgical debulking. Irradiation (most commonly administered with conformal strategies) should be accompanied by concurrent temozolomide chemotherapy. Adjuvant temozolomide is also administered for at least 6 months following the end of radiotherapy unless disease progression occurs.

Temozolomide has not been established as a component of standard therapy for newly diagnosed WHO grade III gliomas; ongoing trials are investigating this issue.

Prospective randomized trials could not define a role for either brachytherapy or radiosurgery in the initial management of high-grade gliomas.

LOCALLY ADVANCED DISEASE AND RECURRENCE

Bevacizumab has been approved for salvage of failures following definitive therapy for GBM. If chemotherapeutic options are not available in the setting of recurrence, creative radiotherapeutic strategies (e.g., radiosurgery, intensity-modulated radiation therapy [IMRT], brachytherapy) may be considered.

High-grade gliomas are almost universally fatal. Although recently discovered combined-modality approaches have prolonged survival, many patients succumb relatively quickly, and cure remains elusive for the majority.

New protocols have recently emerged after decades of limited progress in the management of these tumors. New chemotherapeutic drugs, such as temozolomide, have found application in GBM. Bevacizumab is effective in recurrent disease and prolongs radiographic disease control in first-line regimens. In the future, molecular profiling may also allow tailoring of specific treatment to the patients most likely to benefit.

ETIOLOGY AND EPIDEMIOLOGY

Most malignant brain tumors are high-grade gliomas, and most of these are GBM, a WHO grade IV tumor. The remainder are WHO grade III tumors such as anaplastic astrocytoma, anaplastic oligodendroglioma, and anaplastic oligoastrocytoma. Men are more commonly affected than women. The peak incidence occurs in the age range of 65 years to 75 years, and the median survival time is inversely proportional to age; these findings have prompted a redoubling of efforts in elderly subpopulations.[1]

There has been concern for cancer development following exposure to electromagnetic fields, but definitive evidence is lacking. More recently, the use of cellular telephones has been studied extensively in Europe,[2] but its importance as a risk factor has not been established. In terms of chemical exposure, nitrosamines have long been regarded as culpable, but causality is far from proven.[3] Brain tumors have also been linked with previous exposure to therapeutic ionizing radiation.[3] However, the absolute risk is low.

Most gliomas are sporadic, but genetic susceptibility is suspected based on the occurrence of multiple brain tumors in families with germline mutation of the *TP53* suppressor gene and patients with neurofibromatosis type I as well as the rare patients who have been diagnosed with Turcot's syndrome. A heritable syndrome contributes to less than 5% of GBMs.[4]

PREVENTION AND EARLY DETECTION

No viable strategy for screening or early detection of glial tumors has been developed. There is also no convincing evidence demonstrating either improved survival when high-grade gliomas are found early, or a clear rationale for prophylactic strategies to reduce the incidence of these aggressive tumors.[3]

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

Investigators around the world are searching for the molecular biologic characteristics of gliomas in an effort to improve therapy. For example, work by the Cancer Genome Atlas Research Network[5] and others[6,7] suggests that at least three molecular subclasses of GBM exist with potential therapeutic and prognostic implications. Mouse modeling has also demonstrated the oncogenic importance of abnormalities in receptor signaling (e.g., epidermal growth factor receptor [EGFR] and platelet-derived growth factor receptor [PDGFR]), signal transduction cascades (e.g., RAS and AKT), and cell cycle regulation.[8]

In the early 1990s, it was recognized that deletion of the short arm of chromosome 1 (1p) and the long arm of chromosome 19 (19q) occurs in most oligodendrogliomas.[9] Codeletion of 1p and 19q is prognostic for longer survival,[10-12] although until recently controversy existed as to whether this finding should alter therapy.[13] It is now recognized that an unbalanced chromosomal translocation underlies 1p/19q codeletion,[14,15] but the specific genes involved and their mechanism of action remain elusive. More recently, mutations in the isocitrate dehydrogenase 1 and 2 *(IDH1* and *IDH2)* genes, occurring most often in low-grade gliomas but also in a minority of WHO grades III and IV tumors have been described,[16,17] and are prognostic for longer survival.[12,16,18,19] Methylation of the *MGMT* promoter (see the section on chemotherapy) is emerging as a potential but imperfect predictive and prognostic factor in the treatment of newly diagnosed GBMs.

With the exception of 1p19q codeletion in anaplastic tumors, it is not yet clear how to best incorporate molecular data into the treatment of individual patients. Detailed discussions of the biologic characteristics of glioma and their clinical relevance are beyond the scope of this chapter and can be found elsewhere.[20]

PATHOLOGY AND PATHWAYS OF SPREAD

The WHO classification system[21] is derived in part from the correlation between pathologic findings and survival rates observed by Bailey and Cushing[22] and published in the early 1900s. In current parlance, *low grade* refers to WHO grades I to II tumors and *high grade* to WHO grades III to IV tumors (Figure 27-1). However, the WHO grade I gliomas (e.g., juvenile pilocytic astrocytomas) are biologically different tumors from the others, infrequently occur in adults, and may be amenable to surgical cure. *Anaplastic* in the context of gliomas refers to WHO grade III tumors such as anaplastic astrocytomas, anaplastic oligodendrogliomas, and anaplastic oligoastrocytomas. GBM is a WHO grade IV astrocytoma, although the most recent WHO classification scheme does account for other rare subtypes, including GBM with oligodendroglial components.

WHO grades II to IV gliomas are characterized by a tendency to directly infiltrate adjacent brain tissue. Lesions with direct access to the corpus callosum may extend across the midline and configure themselves in a classic "butterfly pattern" (Figure 27-2). MRI underestimates the extent of invasive disease, and the diffusely infiltrative nature of these tumors makes complete removal of all tumor cells impossible. This "misleading appearance of enucleability" was described more than 80 years ago.[22] Leptomeningeal spread occurs occasionally (Figure 27-3). Hematogenous and lymphatic spread are exceedingly uncommon.[23]

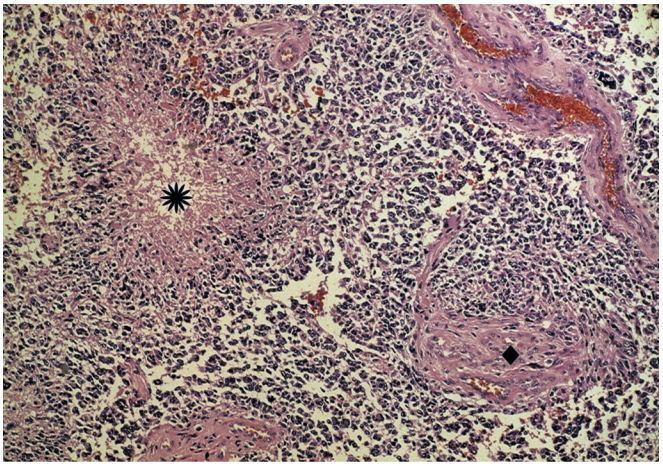

Figure 27-1 Highly cellular astrocytic glioma with foci of microvascular proliferation *(asterisk)* and pseudopalisading necrosis *(diamond)* consistent with glioblastoma.

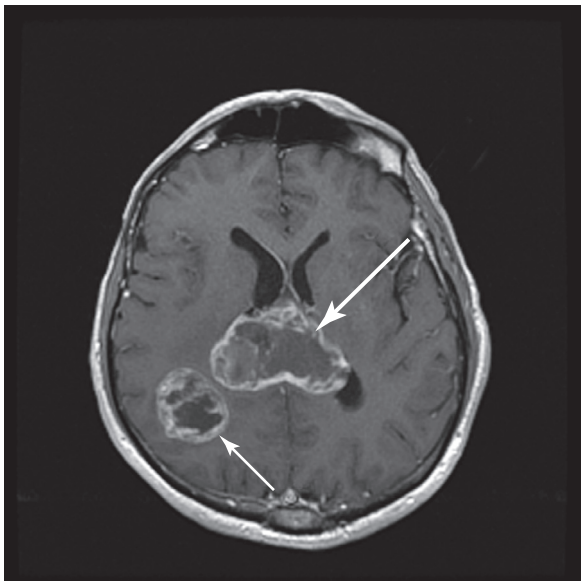

Figure 27-2 "Butterfly" glioblastoma *(long arrow)*; a separate satellite lesion in the right parietal lobe *(short arrow)* is also apparent. The contrast enhancement with central necrosis is classic for a glioblastoma, which was histologically confirmed by biopsy.

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

No specific symptom constellation is pathognomonic of high-grade glioma. Typically, patients present with some combination of headaches, neurologic deficits, nausea, and vomiting, depending on tumor size and location. It is not unusual for patients to present with or subsequently develop seizures. Tissue for pathologic diagnosis can be obtained via stereotactic biopsy, open biopsy, or gross resection in the context of craniotomy. More complete resection improves diagnostic accuracy, provides additional tissue for molecular analyses, and is increasingly thought to improve OS.

The typical imaging appearance of a GBM is a ring-enhancing or heterogeneously enhancing lesion. The differential diagnosis may include stroke, brain metastasis, primary central nervous system lymphoma, demyelination, and even infectious or other inflammatory diseases. If a brain metastasis

is suspected, it is prudent to perform an appropriate extracranial evaluation to identify the primary malignant tumor. If there is a high index of suspicion for primary central nervous system lymphoma, such as in multifocal, periventricular, or homogenously enhancing lesions,[24] corticosteroids should be withheld preoperatively unless herniation is imminent because their use may confound the histologic diagnosis.

Nearly all GBMs demonstrate contrast enhancement. However, up to 10% of anaplastic gliomas will not manifest such a pattern on imaging. Background uptake in the brain (an organ with an inherent avidity for glucose) significantly compromises the use of glucose-based positron emission tomography (PET) as a diagnostic tool for high-grade gliomas.

An algorithm for the evaluation and management of patients with GBM is shown in Figure 27-4.

Figure 27-3 T1 contrast-enhanced sagittal view from a magnetic resonance imaging showing rare leptomeningeal spread from a glioblastoma surrounding the spinal cord.

PRIMARY THERAPY

Prognostic and Predictive Factors

Historically, all high-grade gliomas were lumped together in most clinical trials, thereby confounding results because of maldistribution of patients with differing prognoses. In 1993, Curran et al[25] published a landmark paper describing a prognostic classification scheme based on clinical variables. Data from three Radiation Therapy Oncology Group (RTOG) trials that enrolled nearly 1600 patients with high-grade glioma from 1974 to 1989 were used. This recursive partitioning analysis (RPA) methodology builds decision trees to model predictors by examining all possible "cut points" for all variables included in the model. Patients were segmented into six distinct groups with different survival outcomes. The key variables included patient age, performance status, histologic tumor type (i.e., anaplastic astrocytoma versus GBM), mental status, symptom duration antecedent to diagnosis, extent of resection, neurologic function, and radiotherapy dose. Median survival ranged from 4.6 months for class VI patients to almost 5 years for class I patients, underscoring heterogeneity. The European Organization for Research and Treatment of Cancer (EORTC) demonstrated that the prior RTOG RPA classification remained valid among patients in a more recent Phase III trial.[26] An RPA for anaplastic oligodendroglial tumors has also been proposed.[27]

One of the more controversial factors in the setting of high-grade gliomas has been the extent of surgical resection. Bailey and Cushing observed longer survival following resection in their 1926 publication,[22] as did others in the 1960s.[28] Numerous series since then also support more complete resection as a prognostic factor.[29-33] One of the largest involved more than 400 patients at the M. D. Anderson Cancer Center and demonstrated improved median survival (13 versus 8.8 months; $p < 0.0001$) following at least 98% resection, as defined by postoperative MRI scans.[34] One small randomized study of 30 patients older than 65 years demonstrated improved survival rates following resection versus biopsy alone.[32] Use of 5-aminolevulinic acid fluorescence intraoperatively improves the likelihood of gross total resection,[29] but the effect on survival is debated.

Surgery

Patients can often undergo a craniotomy where the goal is the safe removal of the largest possible volume of tumor to establish a diagnosis and relieve mass effect. High-grade gliomas are not surgically curable because of their extensive infiltration.

If biopsy rather than resection is pursued, choices include stereotactic options with CT or MRI guidance or open craniotomy and biopsy. Some have employed metabolic imaging such as magnetic resonance spectroscopy (MRS) to better select the biopsy sites most likely to contain the most aggressive portions of the tumor, but this is not widely used. Usually, stereotactic biopsy can be performed using either frame-based or frameless neuronavigation systems. The pathologist can review the frozen section to make an immediate preliminary diagnosis and confirm tissue adequacy.

When craniotomy is contemplated, meticulous planning is invested in the scalp incision and flap design. Special care must be taken to preserve the vascular supply of the scalp. The bony opening is devised to be sufficiently large to facilitate resection without needlessly exposing adjacent brain to the risk of injury. After opening the scalp, burr holes are placed and connected with a craniotomy. The bone flap is removed and the dura mater is opened. As a rule, the bone flap is reattached at the end of the resection, although some surgeons prefer not to reattach the bone flap.

Although tumors on the brain surface are immediately visible after exposure, subcortical lesions are harder to discern. Frameless image-guided neuronavigation systems are employed to localize subcortical tumors along with intraoperative ultrasound and MRI. Tumors that are situated near "eloquent" areas of cortex, such as those harboring motor and speech function, are mapped intraoperatively via electrical cortical stimulation to achieve maximal tumor debulking without operative morbidity. Resection of gliomas in the dominant hemisphere is often carried out under local anesthesia with supplementary sedation to allow speech mapping.

Occasionally, tumors may be removed en bloc via circumferential dissection, but more frequently, resection is effected in piecemeal fashion. A cavitational ultrasonic surgical aspirator (CUSA) facilitates removal of a firm, adherent, or calcified tumor.

Patients are routinely monitored in an intensive care unit following a craniotomy. The first MRI is obtained within 24 hours to 48 hours after surgery before postoperative changes set in. The extent of resection can be determined in this manner.

External Beam Irradiation

External beam irradiation (EBRT) has historically been the cornerstone of the therapeutic approach to GBM (and anaplastic astrocytoma) for the past half-century, and its use in brain tumors was already described by the 1920s.[35] In the 1970s and early 1980s, categorical level I data became available from several studies,[36] including prospective Phase III trials conducted by the Brain Tumor Study Group (BTSG)[37,38] (Table 27-1).

The radiotherapeutic approach to high-grade glioma has evolved. Initially, large opposed lateral fields were employed to cover the entire brain volume. In 1989, Shapiro et al[42] published data from Brain Tumor Cooperative Group trial 80-01, in which the randomization was altered during the trial to compare partial brain irradiation with whole-brain radiotherapy (WBRT). No difference in OS or change in the patterns of failure was seen. Accordingly, WBRT is generally not advocated, except perhaps in the scenario of a widespread intracranial process such as gliomatosis cerebri.[43]

Several lines of evidence have influenced the trend to treat the gross tumor volume along with a margin of approximately 2 cm. In a classic paper published in 1980, Hochberg and Pruitt[44] used CT scans to determine that nearly 90% of GBM recurrences occurred within 2 cm of the primary tumor site (although this may be changing with the use of bevacizumab). Wallner et al[45] assessed the patterns of recurrence in 32 patients with unifocal malignant gliomas who were treated with primary surgery and postoperative irradiation. Nearly 80% of patients manifested recurrence or progression within 2 cm of the original tumor. Even when 80 Gy of partial brain irradiation was used in a prospective Phase I trial,[46] 90% of patients failed within the high-dose region.

It has been demonstrated on biopsy and autopsy studies that the abnormality detected on T2 or fluid-attenuated inversion-recovery (FLAIR) images harbors microscopic tumor extension. Accordingly, 45 Gy to 50 Gy is generally delivered, in 1.8-Gy to 2-Gy fractions, to the T2/FLAIR abnormality seen

on the image, followed by a boost to raise the total dose to 60 Gy based on the T1-enhancing abnormality. The MRI abnormalities, however, remain quite nonspecific in terms of histopathologic confirmation, and even when novel strategies such as MRS are used for radiotherapy planning, there can be over or underestimation of the true extent of microscopic spread.[47]

A novel view of target definition has recently been proposed.[48,49] This approach posits that neuroprogenitor cells in the subventricular zone (SVZ) play a role in tumor recurrence. In retrospective analyses of dose distribution among patients with GBM, investigators found that the deposition of high dose (e.g., >40 Gy) in the ipsilateral SVZ was associated with a significantly improved progression-free survival (PFS) and OS in patients who also achieved gross total resection of their tumors. To validate this hypothesis, prospective clinical trials will need to be conducted to determine if cancer stem cells will need to be encompassed when delineating the targets for irradiation of high-grade glioma.

Rationale for Current Total Irradiation Dose

A pooled analysis of three successive randomized trials conducted by the Brain Tumor Study Group (BTSG 66-01, 69-01, 72-01, respectively) generated data to support doses in excess of 50 Gy.[50] A stepwise improvement in survival was observed with doses ranging from less than 45 Gy to 60 Gy, consistent with dose response. A comparison of 70 Gy versus 60 Gy demonstrated no survival or local control advantage for the 70-Gy dose.[51,52] These results established 60 Gy as the standard of care.

Dose escalation has remained an important investigational option because there is still a pattern of failure characterized by local progression or recurrence. There are now multiple techniques for dose escalation, including three-dimensional conformal irradiation, radiosurgery, and brachytherapy, but these have not yielded higher rates of disease control or survival. Increasing the radiotherapy dose or reirradiation with radioprotective or antiangiogenic agents may be a useful strategy in the future.[53]

Altered Fractionation

The RTOG has systematically and rigorously studied hyperfractionation for high-grade gliomas. In RTOG 83-02, patients were randomized to one of four dose arms (64.8 Gy, 72 Gy, 76.8 Gy, or 81.6 Gy) using twice-daily fractions of 1.2 Gy. Initial results suggested the superiority of 72 Gy,[54] but a subsequent Phase III trial demonstrated no improvement.[55] Prados et al[56] used an elegant randomization to assess not only a hyperfractionation schedule, but also to determine the activity of difluoromethylornithine (DFMO), a compound that inhibits sublethal and potentially lethal damage repair. Unfortunately, neither intervention improved survival.

Stereotactic Irradiation

Two provocative small-scale experiences prompted the design of Phase III trials to formally evaluate radiosurgery for high-grade gliomas.[57,58] Loeffler et al[57] reported on 37 patients treated with 59.4-Gy fractionated radiotherapy followed by a stereotactic radiosurgery (SRS) boost to a median dose of 12 Gy. After a median follow-up period of 19 months, a 76% survival rate was reported. Sarkaria et al[58] described 115 patients with high-grade glioma who received conformal radiation therapy and a SRS boost; median survival time was 96 weeks. These results called into question whether they represented a benefit from SRS or simply selection bias.

RTOG 93-05 compared conformal irradiation plus carmustine with or without a SRS boost for newly diagnosed GBM. No differences were observed in terms of OS (median, approximately 13 months in each arm) or quality of life.[59]

SRS may still have a role in the treatment of recurrent disease, particularly if a focal region of recurrence can be defined.[53] However, this has not been tested in prospective trials.

Brachytherapy

Brachytherapy, the use of implanted radioactive material at the site of the tumor offers a mechanism for focal dose escalation. Both permanent and temporary radioactive implants have been used. Early positive results by Gutin et al[60] suggested a potential survival benefit in a Phase II trial. These findings were not reproduced in subsequent randomized trials.[61,62]

Interest in this modality was rekindled when the GliaSite radiation therapy system (Proxima Therapeutics, Alpharetta, Georgia) received approval by the Food and Drug Administration (FDA) in 2001. This intracavitary device is implanted at the time of tumor debulking, and a solution of iodine-125 (^{125}I) is injected into an expandable closed-catheter balloon. A retrospective study suggested reasonable safety and promising efficacy.[63] A Phase I study was conducted.[64] However, the implant induces changes in imaging that complicate determination of disease progression.[65]

Chemotherapy: Concurrent with EBRT, Maintenance, and Other

Early randomized trials of chemotherapy were individually negative, but meta-analysis of these trials showed that 15% to 20% of patients treated with radiation therapy (RT) and nitrosoureas survived at least 18 months versus 5% treated with radiotherapy alone (Table 27-1).[37,38,66,67] Nitrosoureas, especially carmustine, were the most commonly used drugs, although procarbazine was also used extensively.[68] The combination of procarbazine, lomustine (CCNU), and vincristine (PCV)[69] had no clear benefit (yet much greater toxicity) versus carmustine for anaplastic astrocytoma,[70] and this regimen has been largely abandoned for nonoligodendroglial tumors.

Intratumoral delivery of chemotherapy for residual postoperative disease is most commonly in the form of carmustine-eluting (Gliadel) wafers. Patients undergoing wafer implantation during surgery for recurrent GBM survived approximately 2 months longer than patients without wafers in one study ($p = 0.02$).[71] Treatment of newly diagnosed disease also yielded a 2-month prolongation of average survival.[72,73] However, this was not statistically significant when the analysis was restricted to patients with GBM histology. Of note, wafer delivery of carmustine versus systemic administration has not been compared for safety or efficacy. Gliadel does, however, carry an FDA label for implantation during resection of recurrent GBM and newly diagnosed malignant glioma. Attempts to treat residual visible or microscopic disease with other local chemotherapies delivered through implanted catheters and using convection-enhanced migration of drug have generally failed.[74]

Currently, the most widely used chemotherapeutic agent is temozolomide. Whether it is more effective than nitrosoureas has not been investigated, but it is unquestionably better tolerated with significant myelosuppression in less than 20% of patients.[39,40] Temozolomide was first approved for use in the United States in recurrent anaplastic astrocytomas following a phase II study.[75] A randomized study also demonstrated superior efficacy to procarbazine in recurrent GBM.[76]

Temozolomide for newly diagnosed GBM has been studied both when given before RT[77] and when combined with RT in various dosing schedules.[78,79] Its role for newly diagnosed GBM was established by Stupp et al[39,40] on the basis of the EORTC 26981/22981 and NCIC CE.3 trial (Figure 27-4). In

this Phase III multicenter study, 573 patients with newly diagnosed GBM received RT alone or RT with concurrent temozolomide followed by six adjuvant cycles of temozolomide. The patients who received the combined-modality regimen had significantly longer OS and PFS without significantly more toxicity (Table 27-1). The 5-year OS was 10% among those receiving temozolomide versus 2% among those receiving RT alone ($p < 0.0001$).[39] Patients in the most favorable RPA class had a 5-year OS rate of 28% following combined therapy.[39] In a companion paper, Hegi et al[41] reported that methylation of the promoter for the O_6-methylguanine DNA methyltransferase *(MGMT)* gene, which encodes the DNA repair enzyme O_6-alkylguanine DNA alkyltransferase (AGT or AGAT, but now commonly also referred to as MGMT), was correlated with prolonged survival and patients with *MGMT* methylated tumors benefited the most from temozolomide.

MGMT repairs DNA damage induced by temozolomide, and methylation of the *MGMT* promoter silences expression of the protein, thereby accentuating the antineoplastic effects of temozolomide. However, the mechanism by which *MGMT* promoter methylation leads to an improved outcome is more complex. For example, some patients with tumors that did not demonstrate MGMT methylation also benefited from temozolomide although it is increasingly recognized that the initial test probably scored some "methylated" tumors as either "unmethylated" or "unknown."[39-41] Accordingly, it remains unclear whether MGMT analysis should categorically alter treatment, although this situation remains somewhat fluid. In addition, patients with tumors harboring methylated *MGMT* survived longer following treatment with RT alone than patients who did not have tumors harboring methylated *MGMT* treated identically.[39,40] Others reported similar findings in GBM[80] and other malignant gliomas.[81] Moreover, MGMT protein expression by immunostaining does not predict outcome.[82]

Several groups have explored intensifying the temozolomide dosing schedule in an attempt to overcome *MGMT*-mediated resistance.[83,84] The intensified regimens are designed to deplete MGMT activity as suggested by previous studies.[85] RTOG 0525 was a Phase III randomized placebo controlled study that compared standard temozolomide dosing following completion of radiotherapy (150 mg/m^2 to 200 mg/m^2 body surface area days 1 to 5 of 28) versus an intensified regimen (75 mg/m^2 to 100 mg/m^2 body surface area days 1 to 21 of 28). This prospectively validated that *MGMT* promoter methylation is a favorable prognostic factor regardless of treatment.[86] However, "dose-dense" temozolomide was more toxic than standard dosing and did not significantly alter PFS or OS regardless of *MGMT* status.[86]

Therefore, *MGMT* promoter methylation is prognostic but the mechanism remains unclear. In addition, there are now several different methodologies to test for *MGMT* promoter methylation, which may lead to discordant results.[87] It is possible that *MGMT* is a marker of more global hypermethylation and is only one of multiple genes mechanistically involved in resistance to alkylator chemotherapy and prognosis in tumors harboring the recently described Glioma CpG island methylator phenotype (G-CIMP).[88,89]

Another major area of investigation has been the use of vascular endothelial growth factor receptor (VEGFR) signaling inhibitors. Bevacizumab (Avastin) is a monoclonal antibody against VEGF that competitively inhibits binding of the ligand to VEGFR and targets tumor vascularity. It is the most widely studied of these antiangiogenic strategies.

Based on encouraging response rates and prolongation of PFS in recurrent GBM, two major Phase III studies, RTOG 0825 and Avastin in Glioblastoma (AVAglio) sponsored by F. Hoffmann La Roche, were launched nearly simultaneously. Following maximal safe surgical resection, both randomized patients to receive RT and temozolomide plus either bevacizumab or placebo. Although there were subtle differences in trial design with respect to extent of resection (e.g., biopsy-only patients not permitted in RTOG 0825 but allowed in AVAglio, timing of treatment, etc.), both demonstrated prolongation of PFS (median 10.7 versus 7.3 months, $p = 0.007$ for RTOG 0825; median 8.4 versus 4.3 months, $p < 0.001$ for AVAglio).[90,91] However, neither demonstrated a difference in OS (median 15.7 versus 16.1 months, $p = 0.21$ for RTOG 0825; median 16.8 months versus 16.7 months for AVAglio, $p = 0.10$). Both permitted cross-over from placebo to bevacizumab that was offered as part of the study design to participants in RTOG 0825 and permitted but not offered routinely in AVAglio.

These results have not categorically settled the issue of whether bevacizumab should be used for newly diagnosed GBM. In RTOG 0825, the prolongation of PFS did not meet the prespecified statistical level (30% reduction in hazard, $p = 0.004$ required for significance), whereas it did for AVaglio (23% improvement, $p = 0.01$ required for significant difference in PFS). In addition, quality of life measures in RTOG 0825 did not demonstrate a "Net Clinical Benefit," in fact it was worse for those who received bevacizumab, whereas improvement was observed in AVAglio.[90,91] In the context of these results, some practitioners consider using bevacizumab for patients with unresectable large deep tumors with surrounding edema, and especially patients with poor performance status, but such patients would have been excluded from the Phase III trials.

Other antiangiogenic therapies also have not improved survival. For example, the EORTC in collaboration with the Canadian Brain Tumor Consortium conducted the Phase III CENTRIC (CilENgitide in combination with Temozolomide and Radiotherapy In newly diagnosed glioblastoma Phase III randomized Clinical trial) study to evaluate the integrin inhibitor cilengitide that has reported antiangiogenic properties.[92] Based on encouraging Phase II results among the subset of patients with *MGMT* methylated tumors,[93] CENTRIC randomized such patients with newly diagnosed GBM to standard RT and temozolomide with or without cilengitide.[94] Median survival was unchanged (26.3 months in both arms, hazard ratio [HR] 1.02, $p = 0.86$).[94] There was also no significant improvement in PFS (13.5 months versus 10.7 months, HR 0.93, $p = 0.48$) as evaluated by the treating investigator.[94] A study of cediranib for newly diagnosed GBM (RTOG 0837) is ongoing; however, the failure of cediranib to demonstrate meaningful efficacy in recurrent GBM is concerning.

Two studies have evaluated antiangiogenic therapy in particular for patients with *MGMT* unmethylated tumors. The ongoing CORE (Cilengitide in patients with newly diagnosed glioblastoma multifoRme and unmethylated *MGMT* genE promoter) randomized such patients to RT and temozolomide with or without cilengitide. Results are not available yet. The German GLARIUS Phase II trial randomized cases with ummethyalted *MGMT* 2:1 to RT and concurrent bevacizumab followed by maintenance temozolomide for six cycles.[95] The primary endpoint was 6-month PFS determined by central review (generally considered somewhat unconventional), with 80% power to detect an increase from 40% to 60%. Results favored the bevacizumab arm (79.6% versus 41.3%, $p < 0.0001$). Median PFS (9.7 versus 6.0 months, HR 0.3, $p < 0.0001$) and OS (16.6 versus 14.8 months, HR 0.60, $p = 0.031$) also significantly favored the experimental arm.[95] These results require maturation and further validation, but begin to suggest a subgroup of patients who may benefit from addition of bevacizumab containing chemotherapy in lieu of temozolomide for newly diagnosed GBM. Notably, OS did not favor the bevacizumab group in RTOG 0825 or AVAglio,[90,91] but these trials were not intended for comparison.

Anaplastic Gliomas

Anaplastic astrocytomas, anaplastic oligodendrogliomas, and anaplastic oligoastrocytomas represent the most common WHO grade III tumors.[1,21] In anaplastic gliomas, resection appears to improve survival relative to biopsy, as it does for GBM.

Anaplastic Astrocytic Neoplasms

It is generally accepted that RT should be administered postoperatively for astrocytomas. In a German study (NOA-04), early analysis demonstrated that survival was equivalent whether chemotherapy or RT was used first among patients with anaplastic astrocytomas, oligodendrogliomas, and mixed tumors.[12] However, time to progression following RT was longer than after chemotherapy, and initial radiation therapy achieved more complete and partial responses than initial chemotherapy, suggesting the superiority of RT.[96] In addition, the data were relatively immature at initial publication, and longer follow-up may demonstrate the importance of primary RT more fully among anaplastic astrocytomas, or mixed oligoastrocytomas without 1p19q codeletion.

Regarding chemotherapy, Combs et al[97] reviewed the outcome of 191 patients with grade III astrocytic tumors treated at the University of Heidelberg with either RT alone or RT in combination with temozolomide during a 20-year period (from 1988 to 2007). In this retrospective study, no significant advantage in rates of OS or PFS could be attributed to the combination. RTOG trial 9813 randomized patients with anaplastic astrocytomas (or oligoastrocytomas) to RT with concurrent nitrosourea (carmustine or lomustine) or with temozolomide, and results are pending.

The ongoing Concurrent vs. Adjuvant Temozolomide for NON 1p19q co-deleted anaplastic gliomas, also called EORTC 26053-22054 (CATNON) Intergroup trial randomizes patients to receive postoperative RT alone, concurrent temozolomide and RT without adjuvant temozolomide, RT (without concurrent temozolomide) followed by adjuvant temozolomide, or RT with both concurrent and adjuvant temozolomide (Figure 27-5). Although technically this study allows any WHO grade III glioma without 1p/19q codeletion, the majority of the tumors will be anaplastic astrocytomas.

Anaplastic Oligodendroglial Tumors

Long-term follow-up is now available for patients enrolled on RTOG 94-02[10,98] and EORTC 26951.[11,99] In these studies, radiation was compared to radiation with PCV chemotherapy. The RTOG trial entailed administration of chemotherapy before irradiation (intensified PCV[100] for up to four cycles in the combined-modality arm) whereas the reverse sequence (i.e., RT alone versus 59.4 Gy followed by up to six cycles of standard dose PCV) was used in the EORTC trial. With median follow-up in excess of 10 years in both studies, there was a dramatic improvement in OS associated with combined chemotherapy and radiotherapy (irrespective of sequence) among patients with anaplastic oligodendroglioma or anaplastic mixed oligoastrocytoma whose tumors contain allelic loss of chromosomes 1p and 19q, compared with radiation alone. For example, in RTOG 9402, median survival was 14.7 years versus 7.3 years ($p = 0.03$, HR 0.59 for chemoradiotherapy) and in EORTC 26951 median survival was not reached versus 9.3 years ($p = 0.0594$, HR 0.56 for chemoradiotherapy). In addition, patients with *IDH* mutant but not 1p19q codeleted tumors also benefited from chemotherapy, although the magnitude was lower than for those with tumors that harbored both codeletion and *IDH* mutation.[101] Those with *MGMT* promoter methylation[87] or ATRX expression[101] may also benefit regardless of 1p19q deletion status.

The applicability of these findings in an era where PCV is no longer popular remains debatable, especially because temozolomide has almost entirely replaced PCV in routine practice[102] despite the lack of a clear efficacy equivalence. What is clear, however, is that RT alone is inadequate for treatment of patients with codeleted tumors, and likely those with *IDH1* or *IDH2* mutated tumors, regardless of deletion status.

In addition, the role of RT for newly diagnosed anaplastic oligodendroglioma is becoming the subject of controversy because of the tumor's reported sensitivity to chemotherapy,[100] especially tumors with 1p/19q codeletion.[103] Neither RTOG 9402 nor EORTC 26951 used chemotherapy alone, which was recommended by 42% of clinicians (typically with temozolomide)[13] and used in 55% of patients from 2005 to 2007 in a retrospective series of codeleted tumors, without prospective data supporting such usage.[102] The ongoing CODEL (for 1p/19q CO-DELeted tumors) trial now randomizes patients to RT followed by PCV versus RT plus concurrent and adjuvant temozolomide, versus temozolomide alone (Figure 27-6).

The CATNON and CODEL study designs are premised on the belief that the 1p/19q chromosomal status may be more important than the histologic subtype for WHO grade III lesions. However, scientific advances in the interim may outpace the questions posed by these trials as it becomes apparent that *MGMT* promoter methylation[81,87] and *IDH* gene mutation[12,18,101] are also powerful markers of outcome in anaplastic gliomas. There is a clear need to move beyond histologic information (e.g., WHO subtyping) because important advances in prognostication have been made.[104]

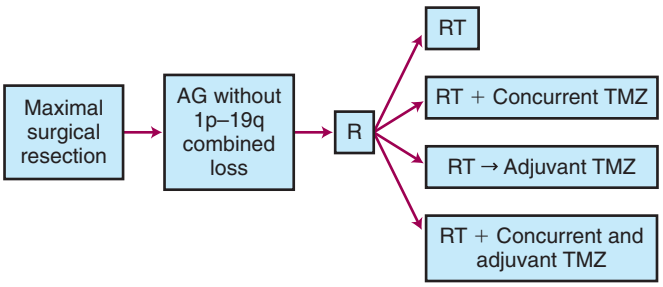

Figure 27-5 Schema from the CATNON study (Intergroup phase III, EORTC 26-53, RTOG 0834). *AG*, Anaplastic glioma; *R*, randomization; *RT*, radiotherapy; *TMZ*, temozolomide.

Special Topics

Toxicities of Radiation Therapy

Acute and late effects of irradiation, including brain necrosis are discussed in a subsequent section on Irradiation Techniques and Toxicities.[45,97,105-107]

Elderly Patients with GBM

More than 44% of GBMs occur in patients older than 65 years of age,[1] but prospective trials often exclude elderly patients.[39,40]

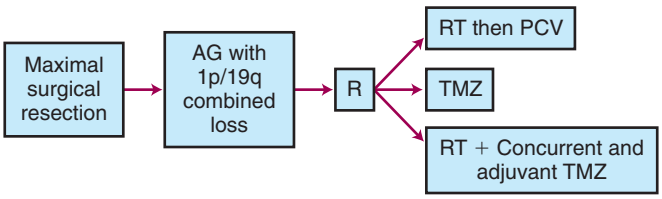

Figure 27-6 Schema from the CODEL trial (NCCTG NO0557/RTOG 0670). *PCV*, Procarbazine; *TMZ*, temozolomide.

Because these patients often have a worse outcome than younger patients, there has been some uncertainty with regard to the aggressiveness of treatment, and the definition of "elderly" is highly variable.

A Finnish randomized study of 30 patients older than age 65 years with imaging consistent with malignant gliomas demonstrated longer median survival following craniotomy than following biopsy (5.7 versus 2.1 months; $p = 0.035$).[32] The Association of French-Speaking Neuro-Oncologists[106] conducted a randomized trial comparing RT alone (50 Gy in conventional fractionation) versus supportive care among patients older than 70 years of age. The trial was discontinued after 85 patients were registered when it became apparent that RT was associated with a statistically advantageous outcome (median survival time, 29 versus 17 weeks; $p = 0.002$).

Efforts to abbreviate the duration of RT have been conducted. For example, a randomized study in patients older than age 60 years demonstrated that 40 Gy in 15 fractions was not inferior to 60 Gy in 30 fractions.[107]

A Phase II study of temozolomide alone in 32 patients older than age 70 years with newly diagnosed GBM demonstrated a response rate of 31%, median PFS time of 5 months and median survival time of 6.4 months, comparable to RT alone.[108,109] A single-arm 77-patient Phase II study for those older than age 70 with poor performance status (Karnofsky Performance Status [KPS] <70)[110] demonstrated median survival of approximately 6 months, with 26% becoming functionally independent (KPS at least 70).[111] Among those with *MGMT*-promoter methylated tumors (13 of 31 tested) median OS was approximately 7 months, and *MGMT* status was a statistically significant prognostic factor.[111]

In the NOA-08 trial conducted by the German Neuro-Oncology Working Group,[112] 373 patients older than age 65 with KPS of at least 60 with anaplastic astrocytoma or GBM (in 89%) were treated following randomization with RT (60 Gy) or an intensive schedule of temozolomide (100 mg/m^2 days 1 to 7 and 15 to 21 of every 28) without RT. If patients did not tolerate treatment or if they demonstrated progression, then cross-over (or surgical intervention) was triggered. Survival was slightly shorter following chemotherapy alone (8.6 months versus 9.6 months), but did not reach the prespecified statistical endpoint for declaring it inferiority (i.e., it was noninferior, based on accepting a certain level of survival loss designated as "noninferior"). Among patients with *MGMT* unmethylated tumors, RT was statistically superior (4.6-month versus 3.3-month event-free-survival). In addition, in *MGMT*-methylated cases, treatment with temozolomide was superior (8.4-month versus 4.6-month event-free survival). Analyzed differently, *MGMT* status did not influence event-free survival following RT (4.6 months regardless of *MGMT* status). However, *MGMT* status clearly and strongly influenced event-free survival following temozolomide alone (8.4 months versus 3.3 months for methylated versus unmethylated). Accordingly, among those with *MGMT*-methylated tumors, RT alone was an inferior treatment to temozolomide, and similarly, temozolomide alone was an inferior treatment to RT in those with unmethylated tumors. Many have presumed by implication that temozolomide in lieu of RT could be considered a reasonable treatment strategy in the elderly, but this supposition does not take into account the fact that results with combination RT and temozolomide are superior in almost all trials, and in the U.S. trials, even patients in their 80s were enrolled. Accordingly, monotherapy should be reserved for patients with poor KPS. Further, the intense schedule of temozolomide was excessively toxic and more standard schedules of temozolomide, commonly used in the United States were not studied in this trial,[112,113] and as eluded to previously, the combination of RT and temozolomide (the standard of care for patients younger than age 70 in Europe, and no age limit imposed in U.S. clinical trials, including enrollment patients, even in their 80s, as long as KPS was >70)[39,40] was not studied. It must further be underscored that NOA-08 had a noninferiority design, which included a definition of inferiority of temozolomide as a greater than 25% difference in survival endpoints, which arguably represents too much latitude and insufficient statistical rigor to allow clinicians to conclude that a new standard of care has emerged, especially given that there are few other comparable scenarios in oncology, where 25% loss of survival is accepted as noninferior.

In a Phase III trial from the Nordic Clinical Brain Tumour Study Group, 291 patients were randomized to standard dose temozolomide, standard (60 Gy) RT, or hypofractionated RT (10 fractions of 3.4 Gy each), and similar to the NOA-08 trial, there was no combined-modality therapy arm.[114] The trial has been criticized for its inclusion criteria of 60-year-olds under the rubric of "elderly" in view of the fact that the median age for the diagnosis of GBM is closer to 65 in the contemporary era.[115] Nonetheless, in an unplanned posthoc subset analysis of patients older than 70 years of age ($n = 123$), standard irradiation was associated with inferior survival in comparison to the other therapeutic arms; there was no difference in outcome between temozolomide and short-course RT, with fewer cytopenic toxicities in the short-course RT arm. The Nordic trial, much like the German study, revealed that *MGMT*-promoter methylation predicted for better outcomes in those treated with temozolomide alone, and once again it must be noted that the trial was not initially powered for this assessment as a primary observation. These trials are still open to interpretation at this juncture. The case could be made that for those patients in whom for reasons of poor performance status or inability to commute for long-course RT, temozolomide alone or short-course RT without temozolomide is an acceptable alternative; for patients who might be at higher risk of infection, short-course RT would induce fewer cytopenic episodes and might actually be preferred over temozolomide. For *MGMT*-methylated tumors in patients for whom daily radiation treatments for 6 weeks or so may impose unacceptable burden, temozolomide alone could be considered. This is not to say that RT is not an effective option for elderly patients, especially for patients with unmethylated-promoter *MGMT*. Indeed, an important next step will be to investigate chemoradiation strategies using a shortened course of irradiation, especially in the elderly poor KPS subset of patients; this is the subject of an ongoing trial by the EORTC and NCI Canada (NCT00482677).

It should also be noted that intravenous temozolomide has recently became available as an option for elderly or otherwise impaired patients who cannot swallow capsules or comply with an oral regimen.[116]

Pseudo-Progression

Pseudo-progression confounds interpretation of imaging performed in the first several months following completion of RT. Descriptions of "pseudo-progression" appeared as early as 1979, when Hoffman et al[117] described patients treated with RT and carmustine. Among patients thought to have experienced disease progression immediately following irradiation, nearly half were shown to have improvement or at least stabilization on subsequent brain imaging.

A report in 2004 described that approximately one third of patients with gliomas stabilized or improved with no change in management.[118] Chamberlain et al[119] reported histologically proven treatment injury rather than disease progression in approximately 50% of patients with symptomatic resectable lesions felt to represent worsening disease

following concurrent RT and temozolomide. The incidence of pseudo-progression has been reported to be as high as 75%, in selected subsets of patients with GBM.[84,120,121] Pseudo-progression rather than "true" progression may also correlate with *MGMT*-promoter methylation,[120] although this has not yet been prospectively validated.

Multiple imaging techniques have been explored to delineate radiographic pseudo-progression from true progression.[120,122-126] However, at this time, histologic analysis is the only validated method of distinguishing the two diagnoses, and even that has its limitations because of sampling issues, and difficulty in interpreting tumor cell viability posttreatment.[127]

It is presumed that the incidence of pseudo-progression is higher following concurrent RT and temozolomide than that following RT alone, although supportive evidence is equivocal.[128] As chemoradiotherapy is now the accepted standard of care for newly diagnosed GBM, no prospective study is likely to study this definitively. One approach to dealing with this issue involves using the MRI study done following RT as a new baseline, unless there is surgical documentation of recurrent disease or clear worsening outside of the RT portal. This remains an area of active study.[129] It is also worth noting that the "stabilization" of the peritumoral vasculature induced by antiangiogenic agents can possibly lead to a reduction in the pseudo-progression event rate, and has sometimes been used to manage florid imaging changes, with or without clinical deterioration.

RECURRENT DISEASE

Chemotherapy

Efforts to treat recurrent disease with single agents, either cytotoxics or molecular-targeted agents, have generally been unsuccessful, at least in part because of the innate resistance, poor drug penetrability, and molecular complexity of the disease.[130] Some studies suggest the key may lie in identifying the patients most likely to respond based on molecular profiling of tumor tissue at recurrence.[131]

An exception is the use of agents that target vascular endothelial growth factor (VEGF) or VEGFRs. Bevacizumab, a monoclonal antibody against VEGF, is the most widely studied of these antiangiogenic strategies.

The "BRAIN" trial was a noncomparative Phase II study for recurrent GBM that randomized 167 patients to either bevacizumab alone or bevacizumab combined with irinotecan,[132] the latter regimen adopted from activity of that combination in colon cancer.[133] The 6-month PFS was 43% with bevacizumab and 50% with bevacizumab plus irinotecan.[132] Similar results were seen in a single-arm Phase II study conducted by the NCI.[134] None of these trials however provided categorical evidence of improved OS.

These results are far superior to those of prior available therapies. For example, the 6-month PFS following carmustine is approximately 15% to 20%.[135] Emerging data from the randomized Dutch BELOB (BEvacizumab vs. LOmustine in glioBlastoma, Or Both) study demonstrate the superiority of bevacizumab (10 mg/kg days 1 and 15 of 28) combined with lomustine (90 mg/m^2 to 110 mg/m^2 every 6 weeks) versus either alone in terms of 6-month PFS (16% for bevacizumab, 13% for lomustine alone, >40% for lomustine with bevacizumab).[136] Based on these results, EORTC 26101 has been redesigned to compare lomustine alone (110 mg/m^2) versus bevacizumab with lomustine (90 mg/m^2), specifically seeking a survival benefit in a Phase III context for recurrent GBM.

Trials of other VEGF/VEGFR inhibitors have been negative. For example, REGAL (Recentin in Glioblastoma Alone and With Lomustine) was a Phase III trial[137] that tested efficacy of Recentin (cediranib), a direct oral pan-VEGFR inhibitor after a prior promising Phase II study.[138] An interim analysis demonstrated median PFS was longer following cedirinib (92 days) or cedirinib and lomustine (125 days) than lomustine (plus placebo, 82 days). However, median OS was not longer with cediranib (8.0 months versus 9.4 months versus 9.8 months), and the PFS benefit did not reach the prespecified improvement goal; accordingly, the trial was declared negative and accrual terminated.[137]

Therefore, despite increased response rates and improved PFS, to date there are no data clearly demonstrating a survival advantage for the use of bevacizumab, and its major potential toxicities include thromboembolic disease, hemorrhagic consequences, and hypertension. In addition, almost all salvage treatments following progression on bevacizumab are ineffective,[41,139] and therefore, the timing of bevacizumab for either first or later recurrence remains controversial. Recent data suggest that deferring bevacizumab to a second or later recurrence does not shorten survival.[140] The potential toxicity, as well as the fear of inducing a more invasive tumor phenotype also tempers enthusiasm for use of this agent in newly diagnosed disease, especially in light of lack of survival benefit from the RTOG 0825[90] and AVAglio trials.[91]

Alternating Electric Fields

Finally, one nonchemotherapy approach has been explored using alternating electric fields, tumor treatment fields (TTF) generated by a current source on the scalp (NovoTTF). This therapy is hypothesized to affect the mitotic spindle and thereby reduce proliferation. A Phase III trial suggested noninferiority when compared to any one of several possible physician-chosen chemotherapy regimens (median survival 6.6 months versus 6.0 months, HR 0.86 [95% CI, 0.66 to 1.12], $p = 0.27$; 6-month PFS 21.4% versus 15.1%, $p = 0.13$) with less toxicity than chemotherapy.[141]

Favoring a role for the device in treatment of glioblastoma, in addition to the similarly of survival and fewer side effects, more responses were seen in the TTF arm, although the difference was not significant and the response rate was low regardless of treatment. These results led to accelerated FDA approval. It should also be noted that 31% of patients received bevacizumab as the comparator chemotherapy during treatment on study, and approximately 20% of patients in both arms had a bevacizumab refractory tumor, suggesting benefit of the device in such patients.

However, it should be noted the trial was formally negative. The primary endpoint was improvement in survival. The statistical design had 80% power to detect a 60% increase in survival (HR 0.63, $p \leq 0.05$), and this was not achieved. The study was neither designed nor powered for a noninferiority endpoint, and the lack of a difference in survival in this study is not necessarily the same as true noninferiority.

In addition, the requirement for device approval is less stringent than for a drug, and the trial design and results have been heavily criticized. For example, there was no placebo device used as a control. One explanation is the questionable ethics of randomizing patients to no treatment whatsoever had the design been chemotherapy compared with NovoTTF compared with placebo device. However, that could have been ameliorated by randomizing patients to a specific chemotherapy (such as a nitrosourea or bevacizumab or both) in combination with either NovoTTF or placebo device.

Therefore, a clear interpretation remains elusive. The device appears reasonably safe, and it may well be that NovoTTF was noninferior to various chemotherapies. However, it is equally plausible that neither the device nor the chemotherapies were

beneficial to the patients. A Phase III study for newly diagnosed GBM (without placebo control) is ongoing, and a trial evaluating survival benefit in bevacizumab refractory GBM is being designed through the RTOG Foundation.

Reirradiation

Focal RT approaches are often employed with limited volume recurrences. In a retrospective analysis of 95 patients with recurrent gliomas treated with the GliaSite device, the median survival time was 36 weeks.[142,143] However, whether this is a function of true benefit or patient selection has not been determined.

Fractionated RT to treat larger-volume recurrent disease has also been employed. Although there has been speculation from animal studies that neural tissue will recover from previous irradiation to a large extent once some time has elapsed (e.g., 1 year to 3 years),[144] no firm data quantify the degree to which one can assume that a "dose discount" exists. It is most likely that the damage from reirradiation is underestimated because the majority of patients do not live long enough to express such damage. A small study showed good short-term tolerance to intensity-modulated radiation therapy (IMRT) delivered in six daily fractions of 5 Gy each.[145] A recent single-arm trial from the Memorial Sloan Kettering Cancer Center (MSKCC) demonstrated reasonable safety and efficacy of combined bevacizumab and reirradiation using IMRT for small recurrent malignant gliomas.[50] No radionecrosis was observed and survival appeared to be prolonged relative to historic controls, suggesting that bevacizumab may not only treat radionecrosis[146] but might protect against it. Another approach was recently reported by investigators from Jefferson Medical College[147] who treated 147 patients with recurrent high-grade glioma to 35 Gy in 3.5-Gy fractions with stereotactic radiation therapy. This hypofractionated stereotactic radiation therapy (HSRT) approach was associated with a median survival time in excess of 10 months.

Based on the promising results from the MSKCC and Jefferson trials, RTOG 12-05 was recently opened for patients with recurrent GBM. The Phase II study, which will enroll approximately 180 patients who are bevacizumab-naive with recurrent disease, compares concurrent bevacizumab plus reirradiation (using a hypofractionated RT schema of 35 Gy in 10 fractions) to bevacizumab alone.

IRRADIATION TECHNIQUES AND TOXICITIES

Whole-brain radiation therapy (WBRT) has been replaced with partial brain techniques by consensus for almost all gliomas. Although the dose computation component of treatment planning requires CT imaging, effective image registration with MRI has made this the modality of choice for contouring. The notion of a dedicated MRI simulator has also been proposed as a valuable adjunct in the radiotherapeutic management of high-grade gliomas.[148] However, treatment plans based only on MRI are not able to take into account tissue electron-density variations, which may lead to slightly inaccurate dose calculations.

Patients are usually simulated after surgical wound apposition is reasonably stable and free of infection (generally, 10 days to 14 days after the operation). An immobilization mask is fashioned to reduce motion during and between fractions. The planning CT scan is extended to encompass the head and neck region to allow sufficient anatomic areas for proper image fusion and generation of high-quality digitally reconstructed radiographs (DRRs) and to permit the introduction of noncoplanar beams; ideally, the slice thickness should match that of the MRI used for fusion.

For high-grade gliomas, especially GBM, T1 contrast-enhanced sequences are used to define the gross tumor volume (GTV) and the T2 or FLAIR sequences plus a margin define the microscopic disease extent, or clinical target volume (CTV), which reflects the bulk of microscopic infiltration. To arrive at a planning target volume (PTV), both organ motion and setup error must be taken into account. Organ motion in the brain is quite minimal during therapy (e.g., <1 mm). The PTV may be further modified to exclude normal tissue in areas where gliomas are unlikely to infiltrate. Bokstein et al[149] recently demonstrated that when anatomic barriers such as the temporal bone can serve as a border to impede tumor spread, failure is likely to be seen in less than 5% of cases even when the customary 2-cm margins are *not added* to the abnormalities seen on MRI (Figure 27-7).

In general, there are two major schools of thought (with numerous institutional variations based on these) that provide guidance for the prescription of the radiation regimen. The RTOG approach is a biphasic technique that includes an initial PTV (PTV 1) followed by a second PTV (PTV 2) that represents the cone down. In the lexicon of the RTOG, the PTV 1 includes the T2 or FLAIR CTV with a margin and is treated to 46 Gy in 2-Gy fractions. The PTV 2 includes the T1-enhancing GTV with a margin and is treated to an additional 14 Gy. The EORTC recommends a single-phase technique using one treatment volume throughout the course of therapy. Table 27-2 shows the partial brain volumes advocated by several cooperative groups for the successive phases of partial brain irradiation.

With the advent of functional imaging tools (e.g., functional MRI [fMRI]) it may be possible to specifically modify irradiation doses to functional brain areas. Figure 27-8 displays a treatment plan wherein the region governing motor control (e.g., finger tapping) is delineated to enable an accounting for dose deposition. In this case, this region in the right hemisphere (i.e., governing tapping by the left upper extremity) is included in the high-dose region but the contralateral side is well spared; a major caveat here is that the dose-response relationships for various functional subvolumes in the brain are largely unknown, and therefore, this

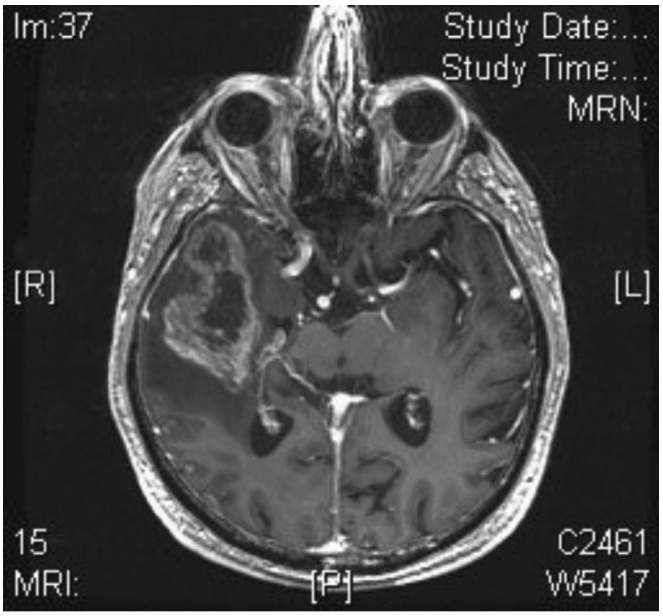

Figure 27-7 Lesion that could be treated without a full complement of margins because of anatomic barrier of the temporal bone.

information is of little practical dosimetric usefulness at this point in time.

In RTOG 08-25, it was noteworthy that approximately 80% of patients, irrespective of treatment arm, received IMRT. Lorentini et al[150] performed meticulous comparison of IMRT and three-dimensional (3D) conformal irradiation among patients treated for GBM. The IMRT plans consistently provided better target coverage than their 3D-conformal counterparts and yielded a statistically significant dose reduction to the healthy brain. The authors suggested that IMRT represents the superior technique when there are more than two regions of overlap between organs at risk (OAR) and the PTV.

Table 27-3 summarizes the tolerance of various OAR according to the new Quantitative Analysis of Normal Tissue Effects in the Clinic (QUANTEC) guidelines. Lawrence et al[151] postulated that the original estimates of Emami et al,[152] suggesting a 5% risk of chronic brain damage at 5 years when one third of the brain is irradiated to 60 Gy, were overly conservative. Instead, they hypothesized (Figure 27-9) that the dose correlated with a 5% risk of damage at 5 years following conventionally fractionated irradiation to the partial brain is 72 Gy, but data regarding subvolume and substructure sensitivity are not included in the QUANTEC assessment.

TABLE 27-2 Radiotherapy Volume Used in Current Clinical Trials

RT Dose	Block Edge Dosimetry Margin*	Source for RT Dose
46 Gy 14 Gy	T2 + 2 cm T1 + 2.5 cm	RTOG
60 Gy†	T1 + 2-3 cm	EORTC
50 Gy 10 Gy	T2 + 2 cm T1 + 2 cm	NCCTG

3D, *Three-dimensional;* EORTC, *European Organization for Research and Treatment of Cancer;* Gy, *Gray;* NCCTG, *North Central Cancer Treatment Group;* RT, *irradiation dose;* RTOG, *Radiation Therapy Oncology Group.*
**Both RTOG and EORTC prescribe dose to block edge (geometric) margin, whereas NCCTG prescribes dose to dosimetry (3D) margin.*
†CENTRIC studies: either RTOG or EORTC volumes and RT doses are used, at individual physician discretion.

There may sometimes be a tendency to overlook structures that, if damaged, would have led to noncatastrophic sequelae. For instance, although it is true that radiation-induced cataracts are easily repairable,[156] avoidance of entrance and exit dose to the eye may be a relatively simple means of preventing not only cataracts but also conjunctivitis and a dry eye, by sparing the lacrimal gland. Similarly, when one contours the ear canals, there is now a greater awareness of the risks of developing otitis externa as well as otitis media.

There are reports of cytopenias arising from cranial irradiation even among patients who have not received chemotherapy.[157] The hypothesized mechanism of this is either irradiation of circulating blood within the radiation portals, injury to marrow in the cranium, or the use of vertex beams that exit through the spinal axis. The latter mechanism has also been invoked to explain radiation-induced fatigue by some investigators.[158]

For tumors located in the temporal lobes, the exit dose to the parotid gland may cause xerostomia. Tumors in such locations may be best treated with IMRT because one of the success stories of the application of IMRT to the head and neck region is indeed the elimination of this bothersome side effect.

Overall, the aim is to achieve the treatment plan that most closely approximates the defined volumes and thereby produces the most conformal plans. Relatively low energy beams (e.g., 6 MV) are typically employed. In contrast to the irradiation of varying organs containing primary tumors, it is

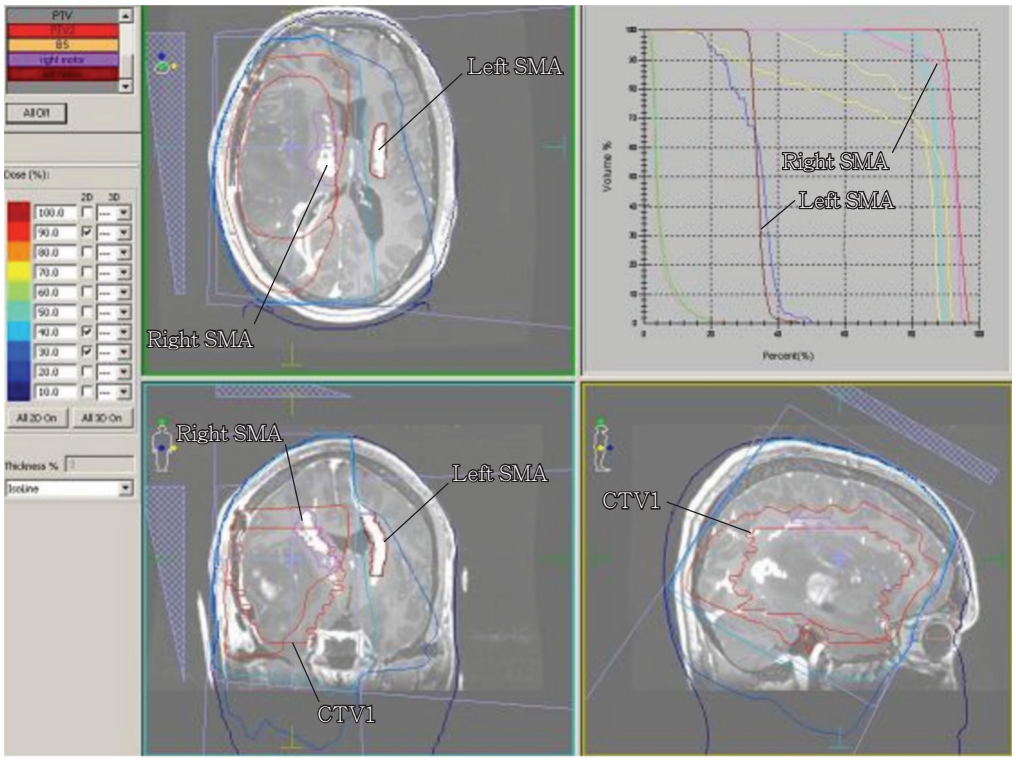

Figure 27-8 Treatment planning based on a functional MRI. Note delineation of the clinical target volume *(CTV)* as well as left and right somatomotor areas *(SMA)* controlling hand movements of the right and left upper extremities, respectively.

TABLE 27-3 Selected Organs at Risk for Treatment Planning of Malignant Glioma

Organ	Dose Limit	Comments
Brain parenchyma[151]	72 Gy	Brain appears to be more sensitive to fraction size > 2 Gy and to twice-daily radiation therapy
Optic apparatus[153]	60 Gy	12 Gy for single-fraction radiosurgery
Brainstem[154]	54 Gy	59 Gy if small volumes (i.e., 1-10 mL)
Parotid gland[155]	20 Gy 25 Gy	Severe xerostomia vis-à-vis sparing of one parotid gland Severe xerostomia vis-à-vis sparing of both parotid glands

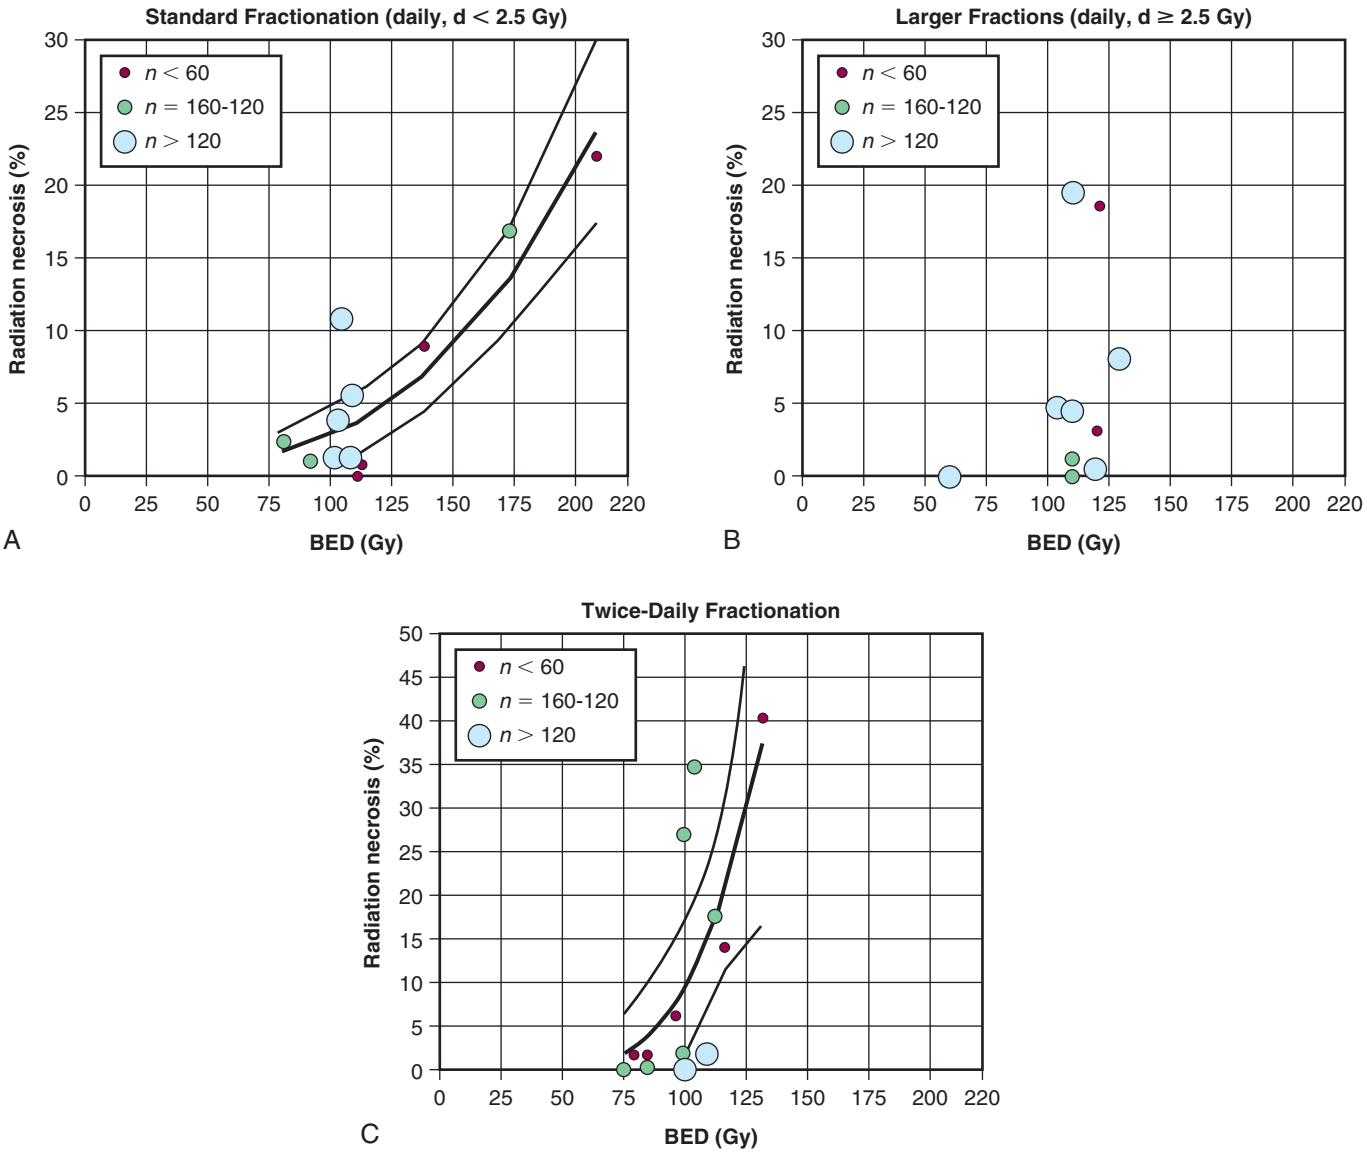

Figure 27-9 QUANTEC data for central nervous system tolerance based on the study in Lawrence et al. Relationship between biologically effective dose (BED) and radiation necrosis after fractionated radiotherapy. The Lawrence figure was done with a nonlinear least-squares algorithm using MatLab software (MathWorks, Natick, Mass.). The nonlinear function chosen was the probit model (similar functional form to the Lyman model). Dotted lines represent 95% confidence levels; each dot represents data from a specific study (Lawrence Table 2); *n* = patient numbers as shown. **A,** Fraction size less than 2.5 Gy. **B,** Fraction size 2.5 Gy or larger (data too scattered to allow plotting of "best-fit" line). **C,** Twice-daily radiotherapy. *Redrawn with permission from Lawrence YR, Li XA, Naqa I, et al: Radiation dose-volume effects in the brain. Int J Radiat Oncol Biol Phys 76:S20–S27, 2010.*

impossible to recommend a single idealized beam arrangement for high-grade gliomas. In this context, the role of proton therapy is being explored to further reduce dose to surrounding tissue distal to the tumor.

Miscellaneous Technique Issues

Despite the absence of level I evidence, IMRT is increasingly used, sometimes to escalate the dose and at other times to spare surrounding tissues or to explore the concomitant boost concept. However, clinical data supporting improved outcomes from IMRT in high-grade gliomas are essentially nonexistent.

Guidelines for tumor delineation and dose selection for WHO grade III gliomas are less well developed. In general, the FLAIR and T2 compartments are regarded as containing microscopic disease and therefore constitute the CTV. The typical dose is 59.4 Gy or 60 Gy in 1.8-Gy to 2-Gy fractions.

Toxicities of Radiation Therapy

Acute radiation morbidity includes fatigue, erythema, alopecia, headache, and rarely, nausea with or without vomiting; these are generally not severe and are usually self-limiting.[45] Some have cautioned that the combination of cranial RT and phenytoin as well as other anticonvulsants could give rise to the Stevens-Johnson syndrome,[159,160] but this dermatologic emergency is an exceedingly rare event, and the causal association between the two has not been established.

Late effects of radiation (e.g., somnolence and, especially, cognitive impairments) are more worrisome and may become manifest many years later.[161] The impact of partial brain irradiation on neurocognitive decline continues to be a hotly debated topic. The confounding factor is always the extent to which there is baseline cognitive impairment or decreased mentation secondary to tumor. Hippocampal sparing may emerge as a method to reduce the risks of neurocongnitive injury as it appears to do in the treatment of brain metastases with WBRT.[162]

Brain necrosis is a serious and uncommon late toxicity, and recently bevacizumab has been explored as a treatment.[146] In a small trial, all patients showed improvement of MRI abnormalities as well as a reduction in corticosteroid requirements following treatment with bevacizumab.[163]

We currently estimate the risk of normal tissue damage based on the most sensitive 5% of the population. Accordingly, we bias our recommendations in a manner that is not germane to most individuals, and preliminary efforts at predicting the likelihood of toxicities based on risk are ongoing.[164,165]

TREATMENT ALGORITHM, CONTROVERSIES, CHALLENGES, AND FUTURE POSSIBILITIES

Treatment Algorithm

For adults up to age 70 years with newly diagnosed GBM, the current standard of care is safe maximal surgical resection (with or without Gliadel wafer implantation) followed by concurrent EBRT (approximately 60 Gy in 30 fractions) with temozolomide and followed by at least 6 months of adjuvant temozolomide (Figure 27-4). For suspected progression that occurs within 3 months of completing RT, the possibility of pseudo-progression should be strongly considered.[166] Relapsed disease may be treated with re-resection, second-line chemotherapy, or experimental therapy in a clinical trial. Reirradiation is also a possibility but is used infrequently. Bevacizumab is approved for relapsed disease, as are carmustine wafers and Gliasite brachytherapy.

For newly diagnosed anaplastic gliomas, RT is typically administered as part of the initial therapy. Some advocate chemotherapy first, especially in 1p19q codeleted anaplastic oligodendroglial tumors.[12,13] Based on randomized trials, RT before and after PCV chemotherapy is clearly superior to RT alone for patients with 1p19q codeleted anaplastic oligodendroglial tumors.[98,99]

Controversies

Treatment for elderly patients (variably defined as older than 60, 65, or 70 years of age, depending on the study) remains controversial. Patients with a good performance status and few comorbidities are often treated according to the same algorithm used for younger patients. However, abbreviated radiotherapy courses appear to be noninferior[107] and are often employed. Temozolomide alone using standard rather than intensified dosing is a reasonable treatment strategy for elderly patients with *MGMT*-methylated tumors based on comparisons to RT alone, specifically in patients for whom combined-modality therapy is a significant challenge.[112,114] Definitive studies of combined RT and temozolomide restricted only to "elderly" patients have not been completed, and whether chemoradiation using a rapid course of RT is superior to RT or temozolomide alone is under investigation, but it must be borne in mind that the U.S. trials included patients even in their 80s when using combined-modality approaches.

Bevacizumab does not prolong survival when added to RT and temozolomide for newly diagnosed GBM.[90,91] Emerging data suggest that combining bevacizumab with nitrosourea therapy may be superior to bevacizumab or nitrosurea alone for recurrent GBM[136] and this is being further tested in Phase III study by the EORTC.

Treatment of anaplastic gliomas is an area of extreme controversy, with astrocytomas often treated as GBMs and a more variable approach used for oligodendrogliomas. Ongoing trials will attempt to define a standard algorithm based on the 1p/19q deletion status.

Challenges

Local control of high-grade gliomas remains a vexing problem. In addition, the increased recognition of pseudo-progression as an entity and the possibility of pseudo-response to antiangiogenic therapy such as bevacizumab[167] complicate matters further. A revised set of consensus criteria were recently developed in part to address some of these issues.[129,166] Certainly, correlative clinical follow-up to provide the proper perspective on the health status of the patient will never be abandoned, because imaging will always represent an imperfect surrogate for survival. Although new developments in diagnostic imaging continue to hold out promise for resolution of the diagnostic dilemmas faced by the neurooncology team, to date even the most sophisticated imaging studies (e.g., FDG PET, MRS) have not provided a consistently reliable solution to these and other vexing problems.

Future Possibilities

Prior dose-escalation trials for GBM, all conducted in the pre-temozolomide era, have been uniformly negative beyond 60 Gy. However, it is conceivable that the notion of dose escalation now needs to be revisited in the backdrop of control of microscopic disease by temozolomide enhancing the effect of focal dose-escalation, as well as the potential radioprotection offered by bevacizumab.[53]

The 5-year OS from the EORTC-NCIC study of patients with GBM treated with RT and temozolomide was approximately 10%, and for patients with favorable prognostic factors it approached 30%.[39] Moreover, a patient who lived more than 20 years following the diagnosis of GBM was described, perhaps the longest documented survivor.[168] He had been treated with surgery and partial brain irradiation with no concurrent or maintenance chemotherapy (59 Gy of 6-MV photons in conventional fractionation delivered via a shrinking-field technique). The authors speculated that the outcome may have stemmed from the fact that he had a favorable molecular profile (e.g., methylated *MGMT* promoter, *PTEN* wild-type, and *p53* positive, which the authors termed "triple positive," similar to the nomenclature of breast cancer). Whether this explained the long survival time is unclear. More importantly, these observations prove that one may strive to create and sustain hope for patients diagnosed with high-grade glioma.

CHAPTER

28 Benign Brain Tumors: Meningiomas and Vestibular Schwannomas

Michael D. Chan, C. Leland Rogers, Bethany Anderson, and Deepak Khuntia

Benign brain tumors are the most prevalent primary brain neoplasms. This chapter focuses on the two most common benign tumors, meningiomas and vestibular schwannomas.

MENINGIOMAS

INCIDENCE

Meningiomas comprise approximately 30% of all primary intracranial neoplasms, rendering them the most frequently reported primary intracranial tumor. The estimated prevalence is 97.5 per 100,000.

PATHOLOGY

The majority of meningiomas are benign (WHO grade I) and progress slowly, but despite this can produce considerable morbidity from local growth, edema, or progression to higher-grade histology. By current WHO standards, approximately 20% of meningiomas are atypical (WHO grade II) and can be difficult to manage long term. Less than 5% are anaplastic (WHO grade III), typically aggressive, malignant tumors.

STAGING EVALUATION

No formal tumor staging system has been adopted.

Meningiomas are optimally imaged by magnetic resonance imaging (MRI), which can be complemented, as needed, by computed tomography (CT) imaging to appraise bone involvement, hyperostosis, or intratumoral calcification. Biologic imaging for meningioma remains in its infancy.

PRIMARY THERAPY

The optimal primary therapy for meningiomas is surgery, which produces excellent results when gross total resection is safely accomplished.

Radiosurgery and fractionated external beam radiation therapy (EBRT) are used in selected patients, especially those with residual or recurrent disease, high-grade disease, or for whom the diagnosis is often based on imaging alone.

ADJUVANT THERAPY

Radiation therapy, either in single or multiple fractions, is often employed postoperatively following subtotal resection of a recurrent benign meningioma, a newly diagnosed or recurrent atypical meningioma, or an anaplastic meningioma.

There is less agreement on the adjuvant use of irradiation following subtotal resection of a newly diagnosed benign lesion, or following gross total resection of an atypical meningioma. In these settings, either immediate treatment or close surveillance are presently defensible.

LOCALLY ADVANCED DISEASE

Surgery, even if incomplete, is an important component of treatment for large, symptomatic meningiomas. Additionally, fractionated EBRT produces excellent long-term local control for large, unresectable or partially resectable, or complex meningiomas. With careful attention to tumor size and anatomy, single or multiple fraction radiotherapy may be used to target residual disease or, in selected cases, as primary therapy.

PALLIATION

Palliation can, on occasion, be the aim of treatment for patients, including those with advanced meningiomatosis, with refractory high-grade or multiply recurrent low-grade tumors that have failed standard treatments. There is a clear need for improved management options for such patients.

Harvey Cushing first used the term *meningioma* to describe tumors originating predominately from the meningeal coverings of the brain and spinal cord.[1] Although not disclosing a cell of origin, meningioma does aptly describe a range of clinically comparable histologic patterns and has endured. Though meningiomas are often approached as benign tumors, studies with long-term follow-up reveal that they are prone to infiltrate locally and to recur.[2] This chapter will consider the available data on intracranial meningiomas in a succinct fashion. For a more detailed review and lengthier bibliography, we refer you to the online version of this chapter.

ETIOLOGY AND EPIDEMIOLOGY

Based on surgical series, approximately 8000 meningiomas are diagnosed each year in the United States. Radiographic and autopsy studies suggest an even greater number of patients with clinically occult tumors.[3-5] A recent epidemiologic study revealed that meningiomas are the most frequently reported primary intracranial neoplasm, constituting about 30% of all brain primaries.[6,7]

The likelihood of developing a meningioma is proportional to age. Pediatric meningiomas are rare but are more likely to

exhibit an aggressive clinical course.[8-12] Meningiomas are most often diagnosed during the sixth to seventh decades of life.[13,14] However, the age-specific incidence continues to rise thereafter, even beyond 85 years of age.[6]

Although there are known associations with certain genetic, environmental, and hormonal risk factors, most meningiomas arise without discernible causation. Genetic factors will be discussed in the "Biologic Characteristics and Molecular Biology" section. Radiation exposure is a well-described environmental etiologic factor for meningiomas. These data stem largely from studies with long-term follow-up of atomic fallout or cranial and scalp irradiation for maladies such as tinea capitis.[15-19] Recent data suggests low-dose exposure, such as seen in dental x-rays, may also increase the risk of meningioma.[20] Indeed, radiation-induced meningiomas are among the most commonly reported secondary neoplasms.[16]

A hormonal role in meningioma induction, or growth promotion is supported by several findings. Meningiomas occur more frequently in females, at a ratio of 2 or 3:1. The incidence appears to increase with hormone replacement therapy, with long-acting oral contraceptives, and with obesity.[3,21-23] Moreover, tumor size or symptoms may progress during the luteal phase of menses or during pregnancy. Despite these observations, the precise role of hormones is unclear. In both sexes, more than 70% of meningiomas express progesterone receptors, up to 40% estrogen receptors, and nearly 40% androgen receptors as well.[3,24]

PREVENTION AND EARLY DETECTION

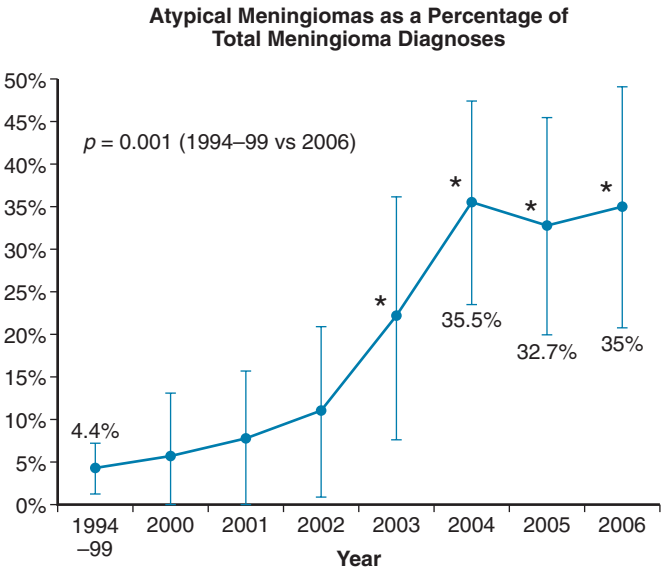
At this time, there are no known preventative interventions, and no evidence in favor of screening. For patients with small asymptomatic, incidentally detected meningiomas, surveillance, with the intent of ruling out aggressive clinical behavior, remains a judicious practice.

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

Meningiomas occur more frequently in certain rare genetic conditions, such as type 2 neurofibromatosis (NF2).[8,25] Mutation in the *NF2* gene on chromosome 22q12 is the most common cytogenetic alteration. Nearly all NF2 meningiomas, most susceptible families, and about half of all meningiomas have alterations of the *NF2* locus.[26,27] Genetic losses of chromosomes 1p, 10, and 14q have been linked with malignant progression or recurrence, but have not yet been validated as independent prognostic markers.[3,26,27] Markers of tumor aggressiveness have been studied.[28-30] MIB-1 expression has been correlated with time to recurrence in some series,[31] but not in others.[32] Tumors lacking *NF2* disruptions but harboring oncogenic mutations in *AKT1* and *SMO* have been identified in therapeutically challenging meningiomas.[33]

PATHOLOGY AND PATHWAYS OF SPREAD

The World Health Organization (WHO) published its most recent grading criteria in 2007.[24] This system describes three grades and 13 histologic subtypes of meningioma (Table 28-1). This has simplified and further objectified the classification of meningioma, and strong associations between grade, relapse-free survival (RFS), and overall survival (OS) have been confirmed in subsequent studies,[24] but even with these improved criteria there remain disparities and interpretive license, particularly regarding the proportion of patients with grade II (atypical) histology. Classically, 5% of meningiomas were identified as atypical.[6] However, Perry et al, on whose work current grading criteria are largely based, found that more than 20% were WHO grade II.[24] Corroborating this proportion, Willis et al regraded patients using modern WHO guidelines and reported 20.4% as atypical.[34] Another recent analysis found that, whereas 4.4% of meningiomas were categorized as WHO grade II from 1994 to 1999, this steadily increased to 35.5% since 2004 (eFigure 28-1).[35]



WHO grade is a dominant prognostic factor.[24,36,37] Compared to a grade I meningioma, a grade II tumor carries a seven- to eightfold increased recurrence risk at 3 to 5 years.[38] Grade III meningiomas are even more aggressive, with a high recurrence risk, and with 5-year OS of 32% to 64%.[3,9,23,39-43]

With reference to pathways of spread, meningiomas most commonly—although not exclusively—arise from dura and spread along dural planes. When located at the skull base, they often spread through skull foramina. Peritumoral vasogenic edema can develop from invasive tumor growth into surrounding brain, but more commonly there is no demonstrable brain invasion. In such cases it is widely accepted that edema results from vascular hyperpermeability, perhaps owing to disruption of the arachnoid membrane and pia mater, or to vasoactive substrates.[44] Regarding meningioma emanating from nondural sites, ventricular primaries are sporadically encountered, and rarely, meningiomas have been

TABLE 28-1 The 2007 World Health Organization (WHO) Criteria for Meningioma Grading

Grade I (Benign)	Grade II (Atypical)	Grade III (Anaplastic/Malignant)
Any major variant other than clear cell, chordoid, papillary, or rhabdoid Does not fulfill criteria for grades II or III	Frequent mitoses (≥4 per 10 hpf) **or** Three or more of the following: • Sheeting architecture • Hypercellularity (focal or diffuse) • Prominent nucleoli • Small cells with high nuclear cytoplasmic ratio • Foci of spontaneous necrosis **or** Additional subtypes/features • Chordoid meningioma • Clear cell meningioma • Brain invasion	Excessive mitotic index (>20 per 10 hpf) **or** Frank anaplasia defined as focal or diffuse loss of meningothelial differentiation resembling: • Sarcoma • Carcinoma • Or melanoma **or** Additional subtypes/features • Papillary meningioma • Rhabdoid meningioma

described originating from a variety of organ sites, including lung.[24,45,46]

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Most data regarding the diagnosis and treatment of meningiomas are based on surgical series. As such, there is an inherent bias toward symptomatic tumors. Symptoms depend largely on the location of the lesion but can be influenced considerably by the presence of edema. Skull-base meningiomas can present with cranial nerve palsies or neuropathies.[47] Sphenoid wing meningiomas may present with seizures.[48]

With the increasing use of contrast-enhanced CT and MRI for head trauma, headaches, and such, the number of incidentally discovered meningiomas has risen. Incidentally discovered meningiomas are often smaller and may show little growth over time.[49-51] Although the clinical behavior of incidental meningiomas is not uniformly predictable, younger age (e.g., <60), larger size (e.g., >25 mm) at detection, male gender, and imaging findings (e.g., absence of tumor calcifications, presence of T2 hyperintensity, or pretreatment edema portend increased progression risk).[49]

Contrast-enhanced MRI is the imaging modality of choice for meningiomas. Tumors at the skull base may also be imaged with CT, to evaluate bony invasion, involvement of skull-base foramina, or hyperostosis. Additionally CT may identify calcifications, a finding predictive of more indolent growth.[3,7] MRI is generally superior for visualization of the contrast-enhanced lesion,[52-55] and MRI T2 signal hyperintensity may presage more aggressive behavior.[51,56,57]

PRIMARY THERAPY

Benign Histology (WHO Grade I)

Surgery

Surgery remains the mainstay, the treatment against which other management options are commonly judged, and the extent of surgical resection correlates with recurrence risk.[2,63,64] In 1957 Simpson reported a series of 265 patients treated surgically, giving rise to the system, still in widespread use, defining the extent of resection.[2] A description of the Simpson grades of resection and their associated crude recurrence rates is found in Table 28-2. Modern series employing current surgical and imaging techniques have generally validated this association.[14,23,65,66]

Surgery remains appropriate therapy for many meningiomas. Convexity meningiomas are often managed with surgery because these can typically be resected completely and without significant morbidity. However, even with convexity tumors, those surrounding or invading major draining veins or venous sinuses can pose considerable difficulty. Gross total resection of tumors involving the skull base is more challenging, but such may also be managed surgically. For meningiomas of the cavernous sinus and other select skull-base sites, close proximity to critical neurovascular structures renders radical resection potentially morbid. Optic nerve sheath meningiomas intricately involve the nerve's vasculature. Resection, which commonly leads to vision loss, is rarely advised, and primary radiation therapy has a favorable track record.

The major risk factors for postsurgical recurrence include tumor grade,[39] prior recurrence,[69] extent of resection,[2] and possibly presence of peritumoral edema.[70] These should be factored into decisions concerning postoperative surveillance versus irradiation.

TABLE 28-2 Simpson's Definitions of "Five Distinct Grades of Operation," With Respective Recurrence Risk*

Grade	Definition of Resection Extent	Recurrence
I	Macroscopically complete removal of tumor, with excision of its dural attachments and any abnormal bone	9%
II	Macroscopically complete removal of tumor, with coagulation of its dural attachments	19%
III	Macroscopically complete removal of tumor, without resection or coagulation of dural attachments, or of extradural extensions (e.g., invaded sinus or hyperostotic bone)	29%
IV	Partial removal, leaving tumor in situ	44%
V	Simple decompression or biopsy	N/A

Modified from Simpson D. J Neurol Neurosurg Psychiat 20:22–39, 1957.
N/A, *Not applicable.*
**Recurrences were identified "in a purely clinical sense to imply the reappearance of symptoms." Dr. Simpson calculated recurrence risk in a crude fashion, often excluding patients who had surgery within the prior 5 years.*

Postoperative Radiotherapy

Adjuvant radiotherapy is generally not recommended following gross total resection of a newly diagnosed grade I meningioma. Radiotherapy has often been used after subtotal resection, although considering the absence of randomized trials, differences in clinical practice are to be expected. Many patients are observed after subtotal resection.[71-73] However, a multitude of retrospective series has reported that radiotherapy improves local control after subtotal resection. Figure 28-1 illustrates long-term (typically 5 to 10 years) PFS outcomes from 35 series with 4389 patients following gross total resection alone, subtotal resection alone, subtotal resection with EBRT or, as will be discussed further, primary radiotherapy (RT).[3,74]

Goldsmith et al reported a series of 140 patients who received RT following subtotal resection and identified a dose-response.[39] Benign subtotally resected tumors had significantly improved PFS (93% versus 65% at 10 years) when a dose greater than 52 Gy was delivered. Moreover, Goldsmith[39,75] and Milosevic[76] found improved outcome with CT- or MRI-based treatment planning (Figure 28-2). A common approach following subtotal resection is 54 Gy in 27 to 30 fractions using CT- or MRI-based planning. It is informative to recognize that some studies evaluating RT after subtotal resection have found superior cause-specific survival (CSS) and possibly even OS compared to subtotal resection alone.[66,69,77]

Recurrent Meningioma

Recurrent meningiomas, including those that remain WHO grade I, display a considerably higher rate of recurrence after surgery alone than do newly diagnosed tumors.[23,66,69,78] Recurrent tumors often retain their original histopathologic grade,[79] nevertheless exhibiting more aggressive biologic behavior. In the setting of recurrence of a grade I meningioma, postoperative RT decreases the rate of tumor progression.[69,78] In a series by Taylor et al, the local control benefit of postoperative RT at time of first recurrence (88% versus 30% at 5 years) translated into an OS advantage (90% versus 45% at 5 years).[69] Miralbel et al reported 78% PFS at 8 years with surgery and postoperative RT after first recurrence compared with 11% with surgery alone.[78] A Phase II trial, which recently completed patient

Biologic imaging has been evaluated for meningioma, and although still considered experimental, may ultimately prove useful in determination of grade and tumor behavior,[58,59] in target delineation for radiation treatment planning,[60,61] and for differentiation of recurrence from treatment-related imaging findings.[62] Current limitations of biologic imaging include lack of specificity of compounds (for instance octreotide-labeled compounds, particularly when tumors are located in or around the sella) and lack of prospective data.

Sughrue et al have challenged the relevance of the Simpson grading scheme in the present era. They found no significant difference in 5-year progression-free survival (PFS) following Simpson grades I through IV resections, with respective 5-year PFS results of 95%, 85%, 88%, and 81% (p = ns).[67] Similar findings hade been reported by Condra and Oya.[57,66] These two studies, although identifying no difference in local control between Simpson grade I to grade III resections, did find shorter PFS with Simpson grade IV surgery.[57,66] In contrast, in a series of 391 convexity meningioma patients reported by Hasseleid et al, significant outcome differences were identified between Simpson grade 1, grades 2 + 3, and grades 4 + 5, supporting the continued applicability of Simpson's criteria.[68]

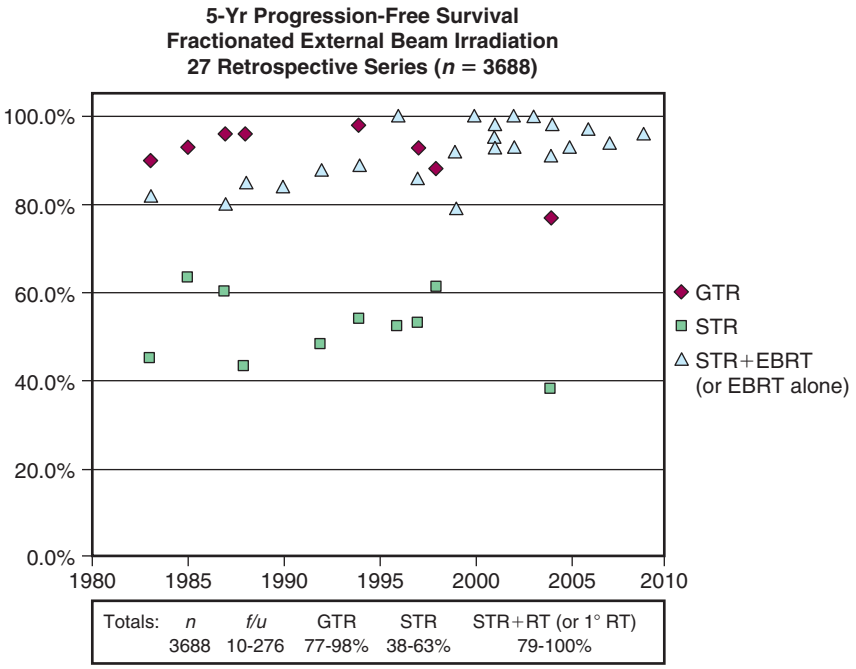

Figure 28-1 Scatterplot comparing 5-year progression-free survival following gross-total resection alone (GTR), subtotal resection alone (STR), and STR plus external beam radiation therapy (STR + EBRT) for patients with meningioma. The *x*-axis is the year of publication. Some of the patients plotted as STR + EBRT were treated with primary EBRT without surgery or histologic confirmation.

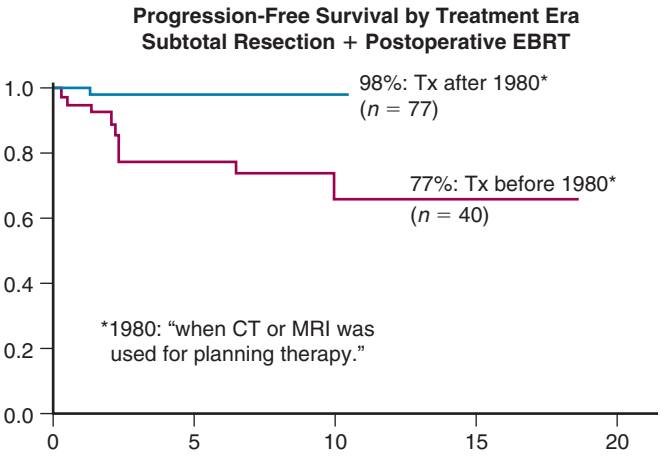

Figure 28-2 Progression free survival of patients with meningioma treated with external beam radiotherapy based on treatment era. Treatment planning techniques changed after 1980 with the advent of computed tomography (CT) and magnetic resonance imaging (MRI). Local control has likely improved secondary to better targeting of the tumor.[39]

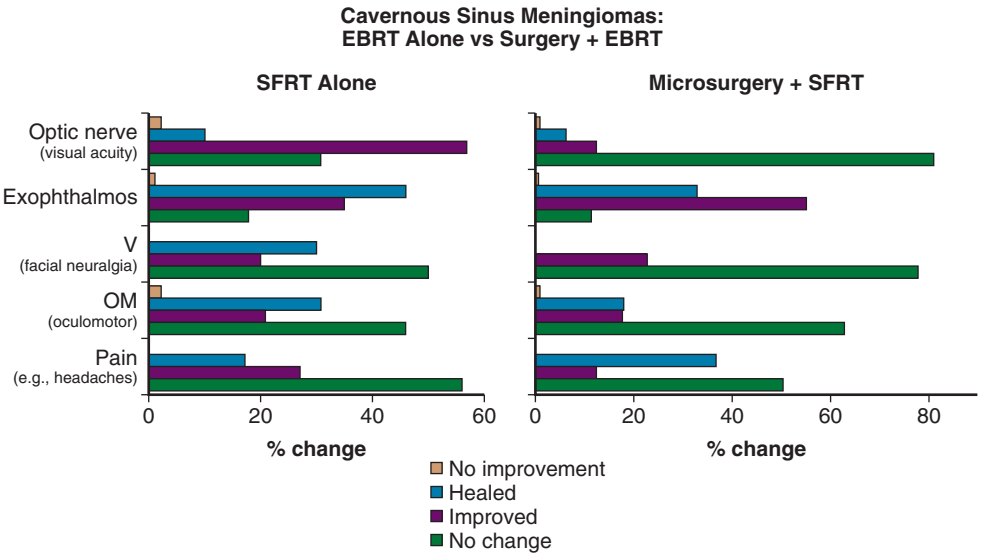
accrual (Radiation Therapy Oncology Group [RTOG]-0539), categorized recurrent grade I tumors into an intermediate-risk cohort treated to 54 Gy in 30 fractions following either gross total or subtotal resection.

Definitive External Beam Radiation Therapy

Early reports of primary RT revealed inferior results, with local control rates on the order of 47%.[80] However, these included patients treated in the 1960s and 1970s, before the advent of current imaging and treatment planning paradigms. Many recent series using conformal techniques have corroborated excellent results from definitive radiotherapy with local control in excess of 90% at 5 to 10 years.[74,81-87] For biopsy-documented or suspected (image diagnosed) grade I meningioma, total doses have ranged from 45 Gy[74] to 57.6 Gy,[88] typically with 1.8 Gy to 2.0 Gy per fraction. The higher cumulative doses were predominately for larger or recurrent meningioma. For most patients doses in the range of 50 Gy to 54 Gy with standard fractionation have produced excellent results with modern imaging-based planning and treatment. Figure 28-3 depicts two examples of tumors appropriate for definitive EBRT. Recently, fractionated stereotactic series have been reported with excellent local control and functional outcome in such regions as the cavernous sinus.[74] eFigure 28-2 shows outcomes of definitive RT as compared with those of combined surgery with RT.



Optic Nerve Sheath Meningioma

Optic nerve sheath meningiomas represent only 1% to 2% of total meningiomas,[89-93] but they pose considerable clinical challenges because of their intimate association with the optic nerve and its vasculature. Historically, treatments included resection or observation, both leaving patients with poor functional outcomes. Accordingly, fractionated EBRT has been increasingly used.

Turbin et al reported 64 patients managed with surgery alone, surgery plus RT, RT alone, or observation. They found that RT alone resulted in excellent tumor control and was the only modality not leading to worsening of visual acuity.[94] Other series have confirmed excellent outcomes, with stabilization or improvement in visual acuity in up to 90%, and with local control exceeding 90%.[92,95-100] Doses of 40 Gy to 54 Gy with fractions of 1.6 Gy to 1.8 Gy have been standard and have produced results more favorable than observation, surgery alone, or surgery plus irradiation.[3,94,95,101] A recent single institution series by Brower et al reported 15 patients treated to a median of 50.4 Gy in 28 fractions and followed for a minimum of 5 years. RFS was 100%, and useful vision was retained in 86% of patients with useful vision prior to RT.[102]

Stereotactic Radiosurgery

Over the past two decades, stereotactic radiosurgery (SRS) has become an acceptable and frequently used modality and is generally considered suitable for meningiomas less than 3 cm to 4 cm in maximum diameter or less than 10 cc in volume, with distinct margins, with little or no surrounding edema, and at sufficient distance from critical normal tissues to permit

eFigure 28-2 Comparison of toxicity profiles of fractionated stereotactic radiotherapy (FSRT) alone versus combined microsurgery and FSRT.

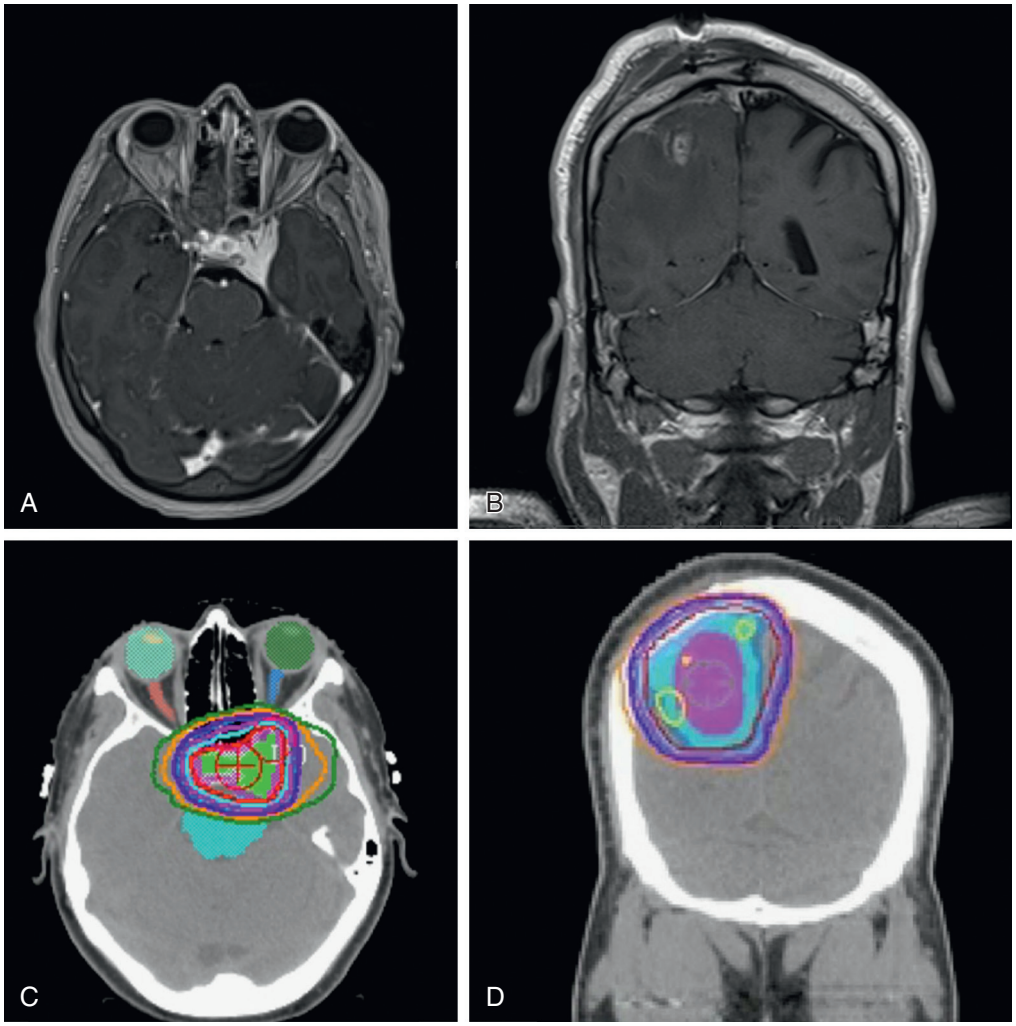


Figure 28-3 Examples of meningioma cases for which fractionated external beam radiotherapy (EBRT) would be indicated. **A,** shows an axial slice of a T1-weighted magnetic resonance imaging (MRI) of a patient with a cavernous sinus meningioma with optic nerve encasement. This patient was treated with fractionated EBRT and exhibited stable useful vision at last follow-up 1 year after therapy. **B,** shows an coronal slice of an T1-weighted MRI sequence of a patient with a resected grade II meningioma of the right frontal convexity with pathology demonstrating brain invasion. **C** and **D,** show the EBRT isodoses for these cases. The cavernous sinus meningioma was prescribed a dose of 52.2 Gy in 1.8 Gy fractions. The convexity grade II meningioma was treated to 55.8 Gy in 1.8 Gy fractions. The lesions remained controlled at 1 and 2 years, respectively.

TABLE 28-3 Comparative Analysis of Results with SRS and EBRT by Grade of Meningioma in Multiple Retrospective Series*

Grade/Treatment	*n*	Mean or Median Follow-up (mo.)	5-year PFS (%)	5-year OS (%)
Gr I—SRS	2281	19-103	75-100	82-100
—EBRT	3588	21-108	79-100	74-97
Gr II—SRS	119	27-48	26-72	40-83
—EBRT	345	32-66	20-68	28-91
Gr III—SRS	39	32-48	0-72	0-59
—EBRT	123	34-59	9-52	28-47

**Five-year progression-free survival (PFS) and overall survival (OS) are compared for all series combined.*

appropriate dose restrictions.[65,103] Long-term local control has exceeded 85% in the majority of studies.[13,104-113] Table 28-3 compares the outcomes for SRS to those of definitive EBRT; this is not a direct comparison, but a compilation of retrospective series reported in the literature, and therefore inherently biased in terms of patient selection. Primary SRS appears to have equivalent local control outcomes to microsurgery with gross total resection for smaller meningiomas,[65,83,114-116] and in certain settings may produce superior results. A recent series by Kano et al demonstrated that there was no benefit from prior microsurgery for patients with cavernous sinus meningiomas.[117]

The University of Pittsburgh's initial publication of long-term outcomes used a median marginal dose of 16 Gy.[103] The rate of new neurologic toxicity was 5%. Since this report, it has become evident that lower single doses may be a sufficient. In the University of Pittsburgh's recent update of 972 patients, the median marginal dose was 14 Gy. Other reports have shown good local control with doses of 12 Gy or 13 Gy.[108,117-119]

Tumor volume has also been shown to predict for success with SRS. DiBiase has reported 5-year disease free intervals of 92% for patients with tumors ≤10 cc versus 68% for larger tumors.[120] Kondziolka et al similarly cited a decreased control rate with larger tumors.[103]

Patients at Higher Risk (WHO Grades II and III)

Atypical Histology (WHO Grade II)

Although there is general consensus on the need for an aggressive combined modality approach for anaplastic or malignant meningioma, considerable controversy exists regarding proper treatment paradigms for grade II meningiomas, particularly following gross total resection.[35,132] WHO grade II tumors carry considerably higher recurrence risk than their grade I counterparts.[3,13,43,66,133-135] Compared to grade I meningioma, recurrences of grade II tumors are seven- to eightfold more likely at 5 years, and there is an increased rate of mortality.[10] Although grade II tumors are often treated with combined surgery and postoperative irradiation, this has not been universally adopted.[40,136,137]

After incomplete resection, postoperative RT is typically recommended. This may be either fractionated EBRT or SRS. A relatively higher dose, as compared to grade I tumors, may be advisable. One study of EBRT demonstrated improved local control with doses exceeding 53 Gy.[39] Studies with proton therapy further inform the issue of total dose. Hug et al published results of 15 patients with atypical meningioma, some treated with combined photons and protons and others with photons alone, to total doses of 40 CGE (cobalt-Gray equivalent) to 72 CGE. Five-year local control was 90% with >60 CGE versus 0% <60 CGE. They noted improved outcome following combined photon and proton therapy, which was felt to be a reflection of higher doses with the use of protons.[42] Boskos et al published outcomes of 24 high-grade meningioma patients (79% WHO grade II), typically treated following incomplete resection. CSS at 5 years was 80% with >60 Gy versus 24% with <60 Gy, and there was a trend toward further improvement with >65 Gy.[138]

Aghi et al analyzed 108 patients following Simpson grade 1 resection of an atypical meningioma. One hundred patients were approached with initial surgery alone, and experienced a 5-year recurrence rate of 41% (eFigure 28-3). Recurrences led to reoperations (mean nearly three per recurrent tumor) and to worse survival. Eight patients received adjuvant fractionated EBRT, mean dose 60.2 Gy to the resection bed with a 1-cm margin. Among this small cohort there were no recurrences.[79] Although several series have demonstrated an advantage to adjuvant EBRT, not all series have shown such an advantage. In some series, survival appears to be worse in patients undergoing RT, possibly reflecting selection bias,[137,139] and results of prospective studies are eagerly anticipated. In the RTOG Phase II trial (RTOG-0539), patients with atypical histology were assigned to receive postoperative RT, 54 Gy in 30 fractions following gross total resection, or 60 Gy in 30 fractions after subtotal resection. The European Organisation for Research and Treatment of Cancer (EORTC) trial used higher doses of 60 Gy in 30 fractions after Simpson grade 1 to 3, or 60 Gy with a 10 Gy boost after Simpson grade 4 or grade 5 surgery.

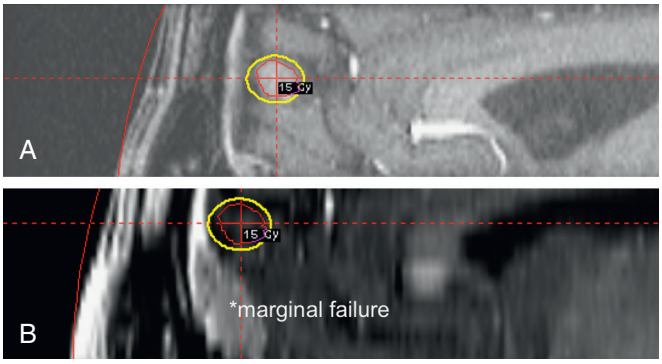

Figure 28-4 Example of a marginal failure after radiosurgery to a high-grade meningioma. **A,** Sagittal slice of T1-weighted magnetic resonance imaging (MRI) obtained during radiosurgical treatment planning; 15 Gy was delivered to the 50% isodose line which encompassed 100% of the meningioma *(red line)*. **B,** Sagittal slice of T1-weighted MRI obtained in follow-up demonstrating new enhancement along the dura adjacent to radiosurgical treatment volume.

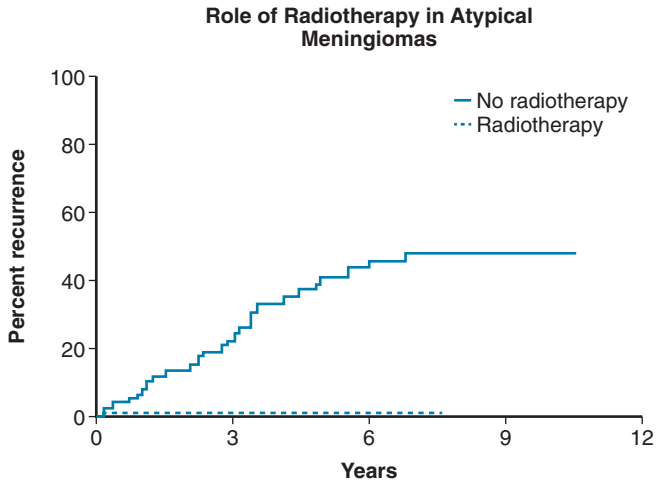
Radiosurgery may also be considered for atypical tumors.[9,43,105,140-142] Stafford et al reported 14 WHO patients with grade II meningiomas treated with SRS, the majority of whom had recurrent tumors. With a median margin dose of 16 Gy, 5-year local control was 68%, compared to 93% for grade I lesions. The 5-year OS for grades I and II were, respectively, 92% and 76%.[13] Kano et al reported improved PFS with a single dose of 20 Gy compared to lower doses (2-year PFS 63.1% versus 29.4%) in a series of patients with recurrent tumors.[141] However, Hakim et al, using a median marginal dose of 15 Gy, achieved 4-year local control of 83%.[105] Moreover, with single fraction SRS, local control within the radiosurgical volume has been acceptable, but marginal failures remain problematic.[141,142] Figure 28-4 depicts an example of a marginal failure after SRS for an atypical meningioma.

Optimal dosing regimens, and choices among varying radiation modalities, are important matters for future study. Dose escalation may have a role for atypical meningioma, particularly following recurrence or subtotal resection, but caution with dose escalation is warranted. Using accelerated hyperfractionated EBRT with or without an SRS boost, Katz found a high rate of complications with no improvement in tumor control.[144] Future research will be strengthened by uniform adoption of WHO grading standards and by studies that clearly distinguish recurrent and de novo patients.

Malignant Histology (WHO Grade III)

Anaplastic meningiomas are rare, 2% to 3% of all meningiomas, with only about 300 newly diagnosed WHO grade III meningiomas in the United States annually.[145] They are aggressive and carry considerably higher recurrence risk and lower survival than their benign counterparts. Five-year recurrence rates in two large surgical series ranged from 72% to 78%.[41,135] Overall survival at 5 years ranged from 32% to 64%, and at 8 years 12%.[146] Failure of local control is often a cause of death.[40,42,76,147]



Patients with WHO grade III tumors are frequently treated with postoperative RT; however, given their relative rarity, this has not been tested in a clinical trial. A series from the Cleveland Clinic reported 13 patients over an interval of 23 years, 3 of whom received RT after initial surgery, and many more as salvage. They suggested that postoperative RT improved median survival (5.4 versus 3.4 years, $p = 0.13$) over surgery

Hypofractionated Stereotactic Radiotherapy

Hypofractionated stereotactic RT is a more recent development, consequential to technologies permitting accurate and repeated patient positioning with less rigid fixation. Recent data suggest that for larger volume tumors (e.g., >5 cc to 10 cc), the use of hypofractionation decreases the likelihood of posttreatment edema as compared to single fraction SRS.[121,122] Larger tumors, particularly those with pretreatment edema, may potentially be treated more safely with hypofractionated RT. Several series have now been reported and show equivalent local control to single fraction SRS or conventionally fractionated EBRT.[121,123-126] The most commonly reported fractionation scheme for treatment of benign meningioma has been 25 Gy in five fractions,[125,126] but more aggressive regimens, such as 24 Gy in three fractions have also been employed.[122]

Incidentally Detected Meningioma

With the increasing use of MRI, the number of incidentally discovered meningiomas has likewise risen. Most patients with incidental meningiomas can undergo a period of serial imaging follow-up and defer definitive therapy until tumor progression occurs. Several series document the natural history of incidental meningiomas.[56,57,127-130] The WHO grade and histologic features of an incidental meningioma are typically unknown, but the majority is likely WHO grade I because benign meningiomas are more common and more likely to be asymptomatic. Risk factors for tumor progression include younger patients, larger tumors at the time of discovery, and noncalcified tumors.[7,56] However, incidental meningiomas generally behave less aggressively and may be observed, withholding treatment until symptoms develop, sustained growth occurs, or concern about encroachment on sensitive structure arise.[131]

eFigure 28-3 Recurrence rates of atypical meningiomas after complete resection based on whether the patient received postoperative radiotherapy.

Huffmann et al treated 15 patients with SRS for atypical meningiomas, using a median prescription dose of 16 Gy.[140] Ten (67%) had recurrent tumors. At 18 to 36 months, 9 were progression-free, for a crude local control of 60%, similar to the 68% reported by Stafford et al.[13] However, in the Huffmann series, 6 of 15 patients (40%) progressed after SRS. Only 1 of the 6 failures was in field, and this occurred after a lower SRS dose of 15 Gy. However, all recurrences were central or marginal. Attia et al[142,143] assessed dose and conformality index (CI = treatment volume ÷ tumor volume) with SRS for residual or recurrent atypical meningioma. The median dose was 14 Gy (range 12 Gy to 18 Gy). Recurrence, defined as within 2 cm of the original tumor margin, developed in 48% of patients at 5 years, at a median of 25 months. CI was a significant predictor of recurrence ($p = 0.038$). Patients who recurred had a mean CI of 1.7 versus 4.6 for those who did not recur. When CI was considered, margin dose >14 Gy was not predictive of tumor control.[121,143] This raises the question whether the higher doses in some studies, for instance Kano et al,[141] might in part be a surrogate for a larger CI.

Skeie et al reported 100 patients with cavernous sinus meningioma, 7 of whom were categorized as grade II.[113] After SRS (mean 12.4 Gy), all seven atypical meningiomas progressed, five within 15 months, whereas only 9% of grade I meningiomas grew. Considering their entire group of 100 patients, larger meningioma volume, lower SRS dose, and suboptimal target coverage were predictive of recurrence. Emphasizing the dire implications of treatment failure, 6 of the 7 recurrent patients with atypical meningioma died of disease at a mean of 25 months after regrowth.[113]

A recent series from the Barrow Neurologic Institute reported no significant improvement in recurrence rate with RT (either SRS or fractionated EBRT) following "aggressive microsurgical resection" of atypical meningioma.[137] It is notable, however, that no patient in this study treated with a gross total resection and postoperative RT experienced recurrence, with actuarial data extending 7 to 9 years. Their median fractionated dose was 54 Gy with 1.8 Gy to 2.0 Gy per fraction, and the mean SRS dose was 14 Gy.[137]

alone.[146] Dziuk et al compared surgery alone to surgery plus RT in 38 patients with WHO grade III tumors. Nineteen (50%) received initial postoperative RT and experienced significant improvement in 5-year disease-free survival, 80% versus 15% for surgery alone ($p = 0.002$).[147] As with grade II tumors, there appears to be a dose-response with grade III meningiomas.[42,138,148,149] DeVries et al found an improvement in local control and survival with greater than 60 Gy.[148] Similarly, Boskos et al reported improved OS with doses exceeding 60 Gy and a trend toward further improvement beyond 65 Gy.[138] Nevertheless, as described previously with atypical meningioma, caution must be used with aggressive dose escalation. One report of accelerated hyperfractionation revealed a 55% rate of grade III to grade V toxicities.[144] The RTOG-0539 trial employed 60 Gy in 30 fractions for patients with malignant tumors (WHO grade III). The EORTC protocol used similar dose and fractionation following Simpson grade 1 to grade 3 resection, but added a 10 Gy in five fraction boost after Simpson grade 4 or grade 5 surgery.

Systemic Therapy

Systemic agents have not had a significant impact on the general management of meningioma to date. Several classes of agents have been evaluated, including hormonal therapy, chemotherapy, immune modulators, and targeted agents. Hydroxyurea has been used for several years, but radiographic responses are uncommon, and rates of progression for atypical and malignant histology have remained high.[158,159]

Because a majority of meningiomas express progesterone receptors, a randomized trial of the antiprogestin, mifepristone, versus placebo was conducted. Mifepristone resulted in increased toxicity but no improvement in response.[160] Several more recent trials employing novel growth factor agents have also been disappointing, with lack of a meaningful response rate or duration.[161,162] There has been recent interest in vascular endothelial growth factor (VEGF) inhibition for recurrent meningioma because of the high rate of VEGF expression and the fact that inhibitors such as bevacizumab may also treat peritumoral edema.[163] Somatostatin may have a measurable response rate in tumors that overexpress this receptor,[164] but more study is needed. There is a critical need for new approaches for patients who have anaplastic tumors, have failed multiple local therapies, or have diffuse and progressive meningiomatosis. It is likely that future investigation will incorporate biologic profiles to individualize and tailor treatment.

IRRADIATION TECHNIQUES AND TOLERANCE

Several methods of target delineation have been described, and there is controversy concerning the optimal method to account for microscopic spread along dura, bone, or into brain. With EBRT, margins as large as 2 cm beyond the gross tumor volume (GTV) have been described using modern imaging.[66] However, margins as small as 1 mm to 2 mm in fractionated stereotactic radiotherapy series have produced good long-term outcome, realizing that the follow-up in many such series is shorter, and the patients selected for such treatment may be inherently different.[81,82] Tight margins may be less applicable to meningiomas beyond grade I. Recent reports of radiosurgery for atypical meningiomas have found that increased conformality predicted for a higher rate of marginal failure.[141,143] In contemporary reports, a clinical target volume (CTV) margin of 1 cm to 2 cm for higher grade meningioma has been more common.

Dural Tail

A dural tail is a nonnodular, linear thickening of the enhancement that may extend from a meningioma on contrast-enhanced MRI. Targeting of the dural tail within the CTV is a subject of controversy. The dural tail was initially thought to result from direct tumor invasion into surrounding dura, though surgical series have found that the dural tail is composed almost entirely of hypervascular dura and is typically an imaging finding, not routinely visualized at surgery.[3,165-168] The Simpson resection grading scale predates MRI. Thus, it does not consider resection of the dural tail. Good results have been obtained from gross total resection alone, without specific attention to it. Furthermore, radiosurgical series have generally not targeted the dural tail.[3,13,103,106] In the recently completed RTOG and EORTC protocols, the dural tail was not targeted within the CTV. We will learn more about this topic from the reports of these trials.

Hyperostosis

Inclusion of hyperostotic bone within the GTV is also worthy of discussion. A Simpson grade 1 resection includes gross total resection of tumor, its dural attachments, and any abnormal bone.[2] Biopsy series have demonstrated a significant rate of bone involvement by meningioma in cases of hyperostosis,[169] and this is associated with a higher rate of recurrence.[170,171] This question needs to be addressed more thoroughly, but it is clearly justifiable to target hyperostotic bone within the treatment volume when this can be accomplished safely.

Toxicities of EBRT

The toxicities associated with EBRT are related to treatment volume and location. Many patients experience fatigue, and some have alopecia. Late toxicities include cataract formation, cranial nerve palsy or neuropathy, and panhypopituitarism can occur.[172,173] Rarely, patients experience symptomatic radionecrosis and may require long-term steroid therapy or surgical intervention.[39] Debus reported a series of 189 patients who received EBRT with modern fractionation schedules, treatment planning, and delivery techniques. The rate of grade 3 toxicities was 2.2%, even less in patients with no preexisting deficit.[81]

Cognitive decline remains a possible late effect, though this is controversial in the setting of partial brain irradiation and smaller treatment volumes.[174] Like most other sequelae, it has site-specific dose-volume relationships.[78,87,175] Temporal lobe dose predicts for cognitive decline,[176,177] and large treatment volumes are more likely to lead to symptomatic decline.[178] The likelihood of radiation-induced cognitive loss rises over time after brain radiotherapy. Cavernous sinus meningiomas, located just medial to the hippocampus, and sphenoid wing meningiomas, lateral to the hippocampus, may carry a higher risk of cognitive decline.[179]

Toxicities of Stereotactic Radiosurgery

The nature of the toxicities of SRS is also dependent on tumor size and location, and most toxicities are related to damage to nerves or to radiation-induced edema. Sensory nerves, such as the optic nerve, are more susceptible to injury than motor nerves. Fraction sizes of 10 Gy or less to the anterior visual pathway carry a 1% to 2% rate of optic neuropathy, but reported rates appear to rise with doses beyond 10 Gy.[13] However, a recent report from Japan suggests that point doses higher than 10 Gy may be acceptable when necessary.[180]

Radiation-Induced Meningioma

Radiation-induced meningiomas may be more clinically aggressive and multifocal.[16,18,150] Multifocal tumors have been reported to occur in 4.6% to 29% of patients with radiation-induced meningiomas,[16,18] compared with roughly 3% of patients with sporadic meningioma.[73] Reports have also suggested a higher incidence of atypia, with WHO grade II or grade III histology from 24% and 38%.[151] The latency between radiation exposure and the development of a secondary meningioma ranges from 2 years to 63 years, though exposure to radiotherapy at a young age,[151] larger radiation fields, and higher doses[152] tend to predict for a shorter latency.

The management of such tumors centers on surgical resection, if possible. Aggressive resection in the setting of previously irradiated tissue, however, poses a risk of wound breakdown and cerebrospinal fluid (CSF) leak. Full-dose re-irradiation has been reported in some cases of recurrent meningioma and can conceivably be accomplished, given the longer latency between treatment courses.[76,153-155] Radiosurgery has also been used.[156,157] Kondziolka described 19 patients with radiation-induced meningioma treated with radiosurgery and reported a control rate of 75% with acceptable toxicity. The advantage of the stereotactic approaches is that they can potentially deliver a curative dose of radiation while sparing the increased cumulative integral dose delivered by conventional EBRT. The disadvantage of a focal approach, however, is the high out-of-field failure caused by meningeal cancerization from the prior radiation,[157] or to microscopic tumor deposits outside the enhancing target.

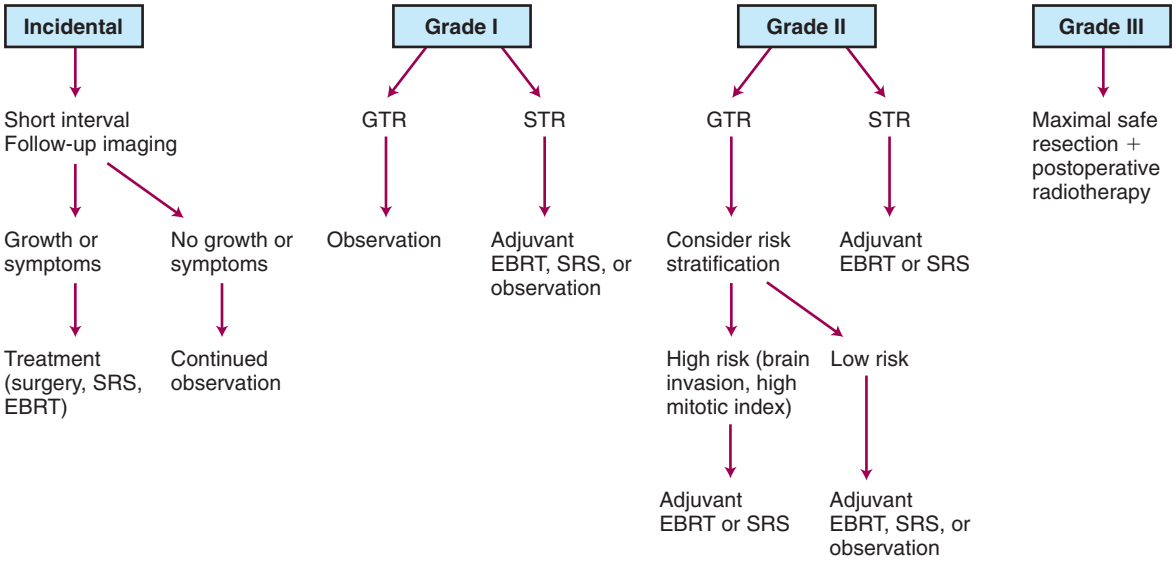


Figure 28-5 **Treatment algorithm for meningiomas** based on grade and operative status.

TABLE 28-4 Meningioma Radiotherapy Suggestions

	Modality	Dose	Fractions	GTV	CTV
Grade I	EBRT	50.4-54 Gy*	28-30	Enhancing tumor on postop MRI	Same as GTV
Grade II	EBRT	54-55.8 Gy	30-31	Enhancing tumor with tumor bed on postop MRI	1-cm expansion on CTV
Grade III	EBRT	59.4-63 Gy	33-35	Enhancing tumor with tumor bed on postop MRI	2 cm expansion on CTV (reduce to 1 cm at 54 Gy)
Grade I	SRS†	12-14 Gy	1	Enhancing tumor	Same as GTV
Grade II	SRS	14-18 Gy	1	Enhancing tumor	Same as GTV
Grade III	SRS	>14 Gy	1	Enhancing tumor	Same as GTV

CTV, *Clinical target volume;* EBRT, *external beam radiation therapy;* GTV, *gross tumor volume;* MRI, *magnetic resonance imaging;* postop, *postoperatively;* SRS, *stereotactic radiosurgery.*

**Good outcomes have been obtained with 45 Gy for optic nerve sheath meningiomas.*

†*SRS, for present purposes assumes single fraction radiosurgery. Good results have been reported with fractionated stereotactic treatments as well, for instance 5 Gy × 5.*[190]

Edema is a more common complication with single-fraction SRS than with standard fractionation EBRT.[3,96,119,181-185] Several risk factors have been identified for SRS-induced edema including higher marginal dose, tumor diameter greater than 4 cc, presence of pretreatment edema, and nonbasal location, including periventricular or parasagittal.[3,56,103,119,182,186,187] One report found that parasagittal meningiomas had a greater than fourfold increased risk of peritumoral edema after SRS.[188]

Response Assessment

No official response assessment criteria are yet available for meningioma, although Response Assessment in Neuro-Oncology (RANO) has formed a working group to address this issue. Because meningiomas are commonly slow growing, they are also commonly slow to respond to RT and will in most cases leave a residual imaging abnormality after treatment. With single-fraction SRS, the University of Pittsburgh reported that within the first four years, 58% of tumors had diminished in size, whereas by 10 years, 88% of tumors had decreased.[189] The University of Heidelberg reported a series of meningiomas treated with fractionated stereotactic radiotherapy in which 70% of patients experienced no change in tumor volume with a median follow-up of 5.7 years.[88]

The rates and time frames of response with nonbenign meningioma have not been thoroughly described. However, grade II tumors have a greater rate of both in-field and marginal failure, and this failure pattern is important in assessing response for grade II or grade III tumors after either fractionated EBRT or SRS.[142]

TREATMENT ALGORITHM, CONTROVERSIES, AND CLINICAL TRIALS

A treatment algorithm is presented in Figure 28-5. Corresponding dose and treatment volume guidelines are contained in Table 28-4. These depict a literature-based approach defined by risk strata. However, many controversies persist. There is substantial debate concerning which patients to observe, which to treat with primary fractionated EBRT or SRS immediately following surgery or indeed instead of surgery, and the selection of patients for postoperative RT. Gross total resection of a benign (WHO grade I) meningioma is considered definitive therapy, but there is less agreement following subtotal resection, or following gross total resection of a grade II meningioma. Subtotally resected grade II meningiomas are frequently managed with irradiation, and all grade III meningiomas demand aggressive treatment, irrespective of resection extent. Despite aggressive management, however, current approaches are insufficient for many high-risk patients. New systemic and biologic agents are needed.

Contemporary Trials

Two cooperative group trials have evaluated the role of RT in the management of meningioma. The EORTC phase II trial (22042-26042) evaluated PFS in patients with grade II and grade III meningioma. It stratified patients based on degree of resection and WHO grade. Patients with Simpson grade 1 to grade 3 resection receive standard postoperative EBRT (60 Gy in 30 fractions), whereas those with lesser resection receive an additional boost (10 Gy in 5 fractions).

The RTOG 0539 trial adopted a risk stratification approach to the postoperative management of meningiomas. Low-risk patients, including gross totally or subtotally resected WHO grade I tumors, were observed. Intermediate-risk patients, including recurrent WHO grade I, and gross totally resected WHO grade II tumors, received postoperative EBRT, 54 Gy in 30 fractions. High-risk patients, with WHO grade III, or subtotally resected or recurrent WHO grade II tumors, received 60 Gy in 30 fractions. Pending the reports from these cooperative groups, these may serve as reason approaches to patients with meningioma.

VESTIBULAR SCHWANNOMAS

INCIDENCE

Vestibular schwannomas occur with an estimated incidence of 0.6 to 0.8 per 100,000 person-years. This is a disease primarily of adults and represents approximately 8% of brain tumors and the vast majority of tumors of the cerebellopontine angle. The exception would be patients with NF2, in which pediatric presentations occur. Bilateral vestibular schwannoma is a pathognomonic feature of NF2.

BIOLOGIC CHARACTERISTICS

Both sporadic and NF2-associated tumors commonly have biallelic inactivating mutations of the tumor suppressor gene *NF2* (chromosome 22q12), which encodes the cytoskeletal protein merlin.

STAGING EVALUATION

The recommended workup includes neurologic examination with careful attention to cranial nerve function, contrast-enhanced MRI, formal audiometric testing, and other testing as clinically indicated.

PRIMARY THERAPY AND RESULTS

Tumors may be managed with microsurgical resection, SRS to 12 Gy to 13 Gy, or fractionated stereotactic radiation therapy (FSRT) using either a standard approach (i.e., 45 Gy at 1.8 Gy per fraction) or a hypofractionated approach (i.e., 20 Gy at 4 Gy per fraction). Local control is more than 90% with all treatment modalities.

Published reports of treatment-related toxicities such as hearing loss, facial neuropathy, and trigeminal neuropathy or neuralgia are generally less frequent with FSRT or expertly performed SRS in appropriately selected patients.

Surveillance MRI scans performed in the first few years after definitive RT may not accurately depict a tumor's ultimate response to treatment because there can be variability in the size and appearance of a schwannoma during this time.

There are no prospective randomized trials to guide treatment decisions, and multidisciplinary evaluation of each patient is an integral component of appropriate management.

INTRODUCTION

Vestibular schwannoma, previously erroneously referred to as acoustic neuroma, is a benign neoplasm originating from the epineural Schwann cells of the vestibular portion of the eighth cranial nerve. Most cases are unilateral and sporadic, although bilateral vestibular schwannoma is pathognomonic for NF2. Although these tumors are rarely fatal, symptoms such as hearing loss, tinnitus, imbalance, and cranial nerve deficits can significantly impair the quality of life. Management options include observation, resection, SRS, or FSRT.

ETIOLOGY AND EPIDEMIOLOGY

The incidence of vestibular schwannoma is increasing and has recently been estimated at 1.2 per 100,000 population per year.[191] More widespread use of intracranial imaging with CT and MRI has contributed to the increased incidence because vestibular schwannomas are identified on MRI in 0.2% of asymptomatic patients.[4] Roughly 85% to 90% of cerebellopontine angle tumors are vestibular schwannomas. Some cases can be attributed to genetic syndromes such as NF2, which pathognomonically presents with bilateral vestibular schwannomas. More than 90% of cases, however, are sporadic and unilateral. Risk factors for the development of sporadic vestibular schwannomas are poorly understood at present, with limited and highly controversial studies suggesting that risk may be increased with cell phone usage,[192] occupational exposure to loud noise (hours), and dental x-rays.[193] The median age of patients at diagnosis is 50 years; however, patients with NF2 typically manifest symptoms by 20 years to 30 years. In one report, it is suggested that in those with 20 or more years of occupational exposure, there is a 10-fold increase in the risk of developing vestibular schwannoma.[194]

BIOLOGIC CHARACTERISTICS

Biallelic inactivating mutations of the tumor suppressor gene *NF2*, located on chromosome 22q12, are commonly found in both sporadic and *NF2*-associated vestibular schwannomas.[195] *NF2* encodes the cytoskeletal protein merlin, which functions in embryonic development, cell adherence, maintenance of cell membrane stability, and cell proliferation. Recently, merlin has been hypothesized to suppress tumorigenesis by translocating to the nucleus to inhibit $CRL4^{DCAF1}$, an E3 ubiquitin ligase.[196] Merlin interacts with a wide variety of cell receptors and signaling pathways, such as EGFR, ERBB2, CD44, Rac, Ras/raf, and Wnt, providing opportunities for investigation of targeted therapies for vestibular schwannoma.[197] VEGF and VEGFR-1 have also been shown to be expressed at high levels in vestibular schwannoma.[198]

PATHOLOGY AND PATHWAYS OF SPREAD

Vestibular schwannomas are histologically similar to schwannomas arising from other cranial and peripheral nerves. Their histologic appearance is characterized by alternating zones of dense and sparse cellularity, known as Antoni A and B areas (Figure 28-6).

Most vestibular schwannomas arise from the superior and inferior branches of the vestibular portion of the eighth cranial nerve, within the internal auditory canal. It is rare for these tumors to originate along the cochlear nerve. Over time, progressive tumor growth may fill the internal auditory canal and extend into the cerebellopontine angle, causing compression of the brainstem and other nearby cranial nerves, most commonly the trigeminal and facial nerves.

The natural history of vestibular schwannoma is typically characterized by gradually progressive growth with gradual sensorineural hearing loss and potentially other cranial nerve deficits. A subset of patients can present with sudden hearing loss. Less than 5% of tumors may regress slightly with surveillance.[199] The average growth rate has been estimated at 1 mm to 2 mm per year for sporadic lesions[199,200] and 3 mm per year for patients with *NF2*-associated lesions.[201] Tumor size and growth rate do not consistently correlate with hearing loss, however. Cystic schwannoma is a well-recognized tumor subtype that tends to behave more aggressively, invading and splaying adjacent cranial nerves. It is rare for malignant degeneration to occur.

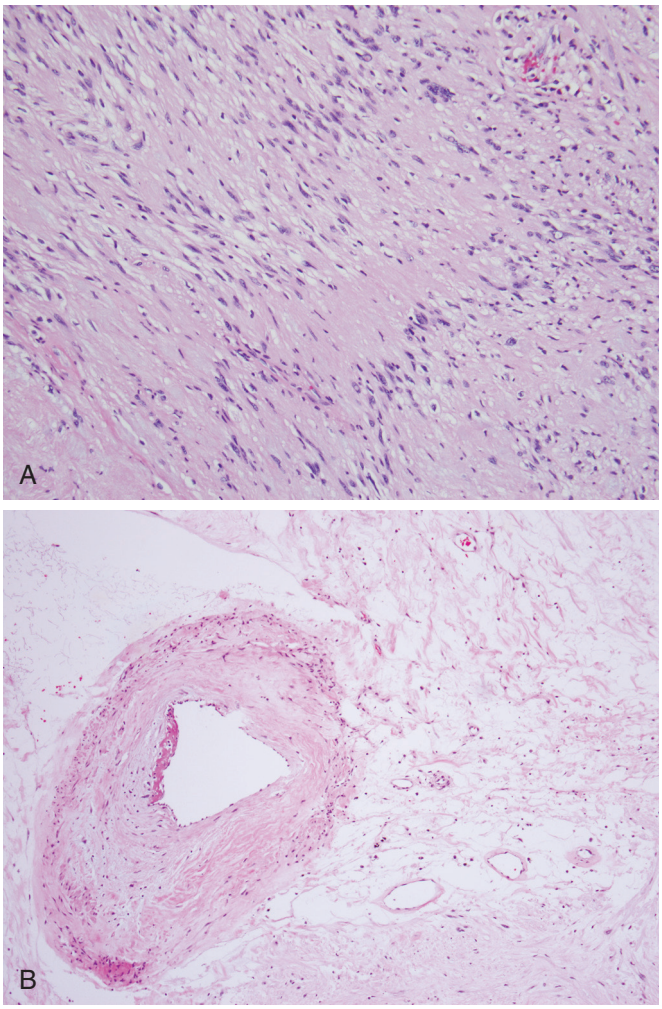

Figure 28-6 Histopathology of vestibular schwannoma. Tumors are well-circumscribed with areas of hyper- and hypocellularity (Antoni A and B areas) and contain thick-walled vessels. **A,** depicts hypercellularity (Antoni A area). **B,** depicts hypocellularity (Antoni B area) adjacent to a hypertrophic blood vessel.

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Vestibular schwannoma is increasingly detected as an incidental finding on MRI or CT performed for other reasons. MRI is the imaging method of choice for visualizing vestibular schwannomas, which typically appear as contrast-enhancing lesions originating within the internal auditory canal on T1-weighted MRI images (see Figure 28-7, *A* and *B*). The extent of tumor may be described using the Koos grading system (Table 28-5).

Symptoms associated with vestibular schwannoma are related to the tumor's size and location with respect to nearby critical structures. When tumors are symptomatic, patients may complain of hearing loss (95% objective, 66% subjective), tinnitus (63%), imbalance or vertigo (61%), facial numbness or pain (17%), facial paresis or taste disturbance (6%), other cranial nerve deficits, or cerebellar dysfunction.[203] Involvement of the cochlear nerve is primarily responsible for hearing loss and tinnitus. Although involvement of the vestibular nerve results in unsteadiness, facial numbness is primarily the result of the trigeminal nerve being affected. In the rare instance of taste disturbance or facial paresthesias, facial nerve involvement is the culprit.

Sensorineural hearing loss classically affects high frequencies preferentially and may therefore be mistaken for noise- or age-related hearing loss. An example of a typical patient's audiogram is shown in Figure 28-8, along with the two mainstream classification systems for audiogram findings specific to patients with vestibular schwannoma, namely the Gardner-Robertson[204] and American Academy of Otolaryngology–Head and Neck Surgery (AAO–HNS)[205] methods. As a rule of thumb, patients whose speech discrimination score is 50% or less at 50 dB or more may not benefit from an approach focused on the preservation of hearing.[206] Each case must be considered individually, however, particularly in patients with bilateral vestibular schwannomas or other causes of contralateral hearing compromise.

Facial nerve function is characterized clinically by the House-Brackmann grading scale (Table 28-6). When clinically indicated, additional studies may be performed, such as facial nerve electromyography, caloric testing, or electronystagmography (Table 28-7).

TABLE 28-5 Koos Staging System for Vestibular Schwannoma

Stage I	Small intracanalicular tumor
Stage II	Small intracanalicular tumor with extension into cerebellopontine angle
Stage III	Larger tumor occupying cerebellopontine cistern without brainstem displacement
Stage IV	Extremely large tumor with marked displacement of brainstem and cranial nerves

Figure 28-8 Pretreatment audiogram of vestibular schwannoma patient showing typical high-frequency sensorineural hearing loss **(A).** Findings are used to classify hearing into varying grades of serviceable or nonserviceable hearing. The Gardner-Robertson[204] system assigned a grade of I to V, with grades I to II representing serviceable hearing **(B).** The American Academy of Otolaryngology–Head and Neck Surgery (AAO–HNS[205]) system assigns a class of A-D, with A-B representing serviceable hearing **(C).**

TABLE 28-6 House-Brackmann Facial Nerve Grading Scale[207]

Grade	Description	Characteristics
I	Normal	Normal facial function in all areas
II	Mild dysfunction	Gross: slight weakness noticeable on close inspection; may have very slight synkinesis At rest: normal symmetry and tone Motion: Forehead: moderate to good function Eye: complete closure with minimum effort Mouth: slight asymmetry
III	Moderate dysfunction	Gross: obvious but not disfiguring difference between two sides; noticeable but not severe synkinesis, contracture, or hemifacial spasm At rest: normal symmetry and tone Motion: Forehead: slight to moderate movement Eye: complete closure with effort Mouth: slightly weak with maximum effort
IV	Moderately severe dysfunction	Gross: obvious weakness or disfiguring asymmetry At rest: normal symmetry and tone Motion: Forehead: none Eye: incomplete closure Mouth: asymmetric with maximum effort
V	Severe dysfunction	Gross: only barely perceptible motion At rest: asymmetry Motion: Forehead: none Eye: incomplete closure Mouth: slight movement
VI	Total paralysis	No movement

MRI, Magnetic resonance imaging.

PRIMARY THERAPY

Because vestibular schwannoma is rarely a life-threatening diagnosis, the primary goals of therapy are local control and preservation of function. Options include surveillance, surgical resection, SRS, and FSRT.

There have been no true randomized, controlled trials published about patients with vestibular schwannoma, and interpretation of single-institution series is limited by differences in factors such as patient selection, treatment techniques, and methods of assessing and reporting tumor control and treatment or tumor-related neurologic deficits. For example, local control may be determined radiographically as a lack of tumor growth, a sign of progressive tumor growth, or a sign of need for further intervention. The natural history of vestibular schwannoma following RT may be characterized by a transient increase in size, often with a necrotic-appearing center (Figure 28-7, *C* and *D*), followed by stability or regression. This type of MRI finding may confound the results of some published SRS series, particularly in early years before this phenomenon was recognized. Hearing deficits are also analyzed in multiple different fashions, including subjectively (typically by querying patients about their ability to use the telephone with the affected ear) or using objective audiometric data. Facial function is typically scored using the House-Brackmann system (see Table 28-6), but investigators differ in their method of defining "significant" facial and other cranial nerve toxicity. Outcomes may also be reported as crude or actuarial rates, adding to the heterogeneity of published case series.

Currently, the choice of treatment modality is based on physician familiarity, bias and choice, patient characteristics (age, symptoms, location, and size of lesions), and the availability of different technologies. Analysis of the Surveillance, Epidemiology, and End Results (SEER) database from 2004 to 2009 revealed that 49% of patients underwent surgery alone, 24% RT alone, 2% both surgery and RT, and 24% did not receive treatment.[191] Observation was the most common management strategy for patients age younger than 10 years and older than 81 years, whereas surgery was most common for patients ages 11 to 70 years. Patients undergoing surgery had significantly larger tumors than those treated with RT (2 versus 1.5 cm, $p < 0.0001$).

Single-Modality Therapy

Surgery

Resection of vestibular schwannoma has been performed since 1894; it can be accomplished through a suboccipital

TABLE 28-8 Surgical Options for Vestibular Schwannoma

Surgical Approach	Indications	Advantages and Disadvantages
Suboccipital (retrosigmoid)	Tumor of any size with attempted hearing preservation	*Advantage:* lower risk of facial nerve injury *Disadvantages:* increased incidence of headache and CSF leak, risk of injury to cerebellum
Middle fossa	Small tumor (≤1.5 cm to 2 cm) involving lateral internal auditory canal with attempted hearing preservation	*Advantage:* hearing preservation rates may be highest *Disadvantages:* increased risk of injury to facial nerve and temporal lobe
Translabyrinthine	Nonserviceable hearing in affected ear	*Advantage:* complete visualization of internal auditory canal minimizes likelihood of incomplete resection *Disadvantage:* hearing sacrifice inevitable

(retrosigmoid or retromastoid), middle fossa, or translabyrinthine approach (Table 28-8). The suboccipital approach is feasible for tumors of any size but poses a risk for CSF leak and headache. The middle fossa approach is most suitable for tumors measuring less than 1.5 cm to 2 cm in size and has the risk for damage to the seventh cranial nerve. Hearing preservation can be attempted with either of these two approaches, although the fundus of the internal auditory canal is incompletely visualized, which can increase the likelihood for incomplete resection. The translabyrinthine approach can be performed for tumors of any size and eliminates this risk but results in inevitable sacrifice of hearing. Recurrence after gross total resection is uncommon.

With suboccipital and middle fossa approaches, published hearing preservation rates for vestibular schwannoma range from 20% to 71%.[208] Factors associated with increased preservation of functional hearing include better preoperative hearing, shorter intraaural and absolute wave V latency on preoperative auditory brainstem response testing, and superior vestibular nerve origin.[208] Better preoperative hearing measured by audiogram and smaller tumor size predict for hearing preservation in some studies but not in others.[208-210]

Other potential side effects of surgery include CSF leakage, facial nerve injury, headache, and meningitis.[206] Preservation of facial nerve function may be more likely for smaller tumors (i.e., <2 cm to 3 cm) and with increasing surgical experience.[211] Function-preserving surgical approaches have been described (i.e., near-total resection leaving a small tumor remnant adherent to structures such as the facial nerve).[212]

Stereotactic Radiosurgery

The first report of SRS for vestibular schwannoma was published by Leksell in 1971. Modern SRS can be performed with the Gamma Knife, linear accelerator, or proton beam techniques. Because of the minimally invasive nature and excellent clinical outcomes achieved with SRS, practice patterns at some institutions are shifting to favor SRS over resection. The ideal candidates have tumors less than 3 cm to 4 cm in size.

Several large, single-institution experiences with SRS for vestibular schwannoma have been reported. Using modern techniques and doses, as will be detailed, local control rates with SRS are generally greater than 90% and significant cranial nerve toxicity rates are less than 10% (Table 28-9).

Published hearing preservation rates are variable; 57% overall in a systemic review of patients treated with an average dose of 16 Gy.[223] Proposed mechanisms of hearing loss following SRS (in the absence of progressive tumor growth) include transient conductive hearing loss resulting from serous otitis media and delayed sensorineural hearing loss because of direct radiation injury to the vestibulocochlear nerve or cochlea, compression of the vestibulocochlear nerve or internal auditory artery from tumor edema, or thrombosis of the internal auditory artery. Patient-related factors that may correlate with increased likelihood of hearing preservation after SRS include age younger than 60 years, tumor volume less than 0.75 cm^3, intracanalicular tumor location, and better pretreatment hearing (class I Gardner-Robertson, speech discrimination score ≥80%, pure tone average <20 dB).[224]

Several retrospective reports have compared outcomes of patients treated with surgery versus SRS[225-228] (Table 28-10), demonstrating that both approaches achieve comparable local control rates of 91% to 100%,[226,228] but SRS produces equivalent or superior functional outcomes. A prospective analysis of 82 patients with small tumors (≤3 cm) eligible for either surgery or SRS at the Mayo Clinic found that patients who chose SRS subsequently had better preservation of normal facial movement and serviceable hearing.[226] A prospective analysis of 91 patients with small vestibular schwannomas (≤2.5 cm) treated with surgery ($n = 28$) or SRS ($n = 28$) at Haukeland University Hospital also showed better facial nerve function and hearing preservation in patients who underwent radiosurgery.[225] A comparison of patients treated with surgery ($n = 110$) or SRS ($n = 100$) published by Régis et al[227] found better preservation of serviceable hearing and facial and trigeminal function with SRS. Finally, a retrospective analysis of 96 patients performed by Karpinos et al[228] showed better preservation of measurable (but not serviceable) hearing and lower rates of facial and trigeminal neuropathy in patients treated with SRS. Tumor size was larger in the surgical group, however.

Fractionated Stereotactic Radiation Therapy

Vestibular schwannomas are slowly proliferating tumors with a low estimated α/β ratio of 2.5 to 4. The hypothesized radiobiologic advantage of FSRT, therefore, is based on reducing late toxicity to surrounding normal structures, such as the cranial nerves and brainstem. Stereotactic localization techniques also contribute to reduction of toxicity by allowing reduction of treatment volumes. Typical candidates are those with tumors too large for radiosurgery or rare patients with malignant schwannomas, although FSRT can certainly be performed for patients with smaller tumors.

Published single-institution outcomes of FSRT are comparable with those achieved with current, moderate-dose SRS, with local control rates greater than 90% and cranial nerve toxicity rates less than 10% (Table 28-11). Serviceable hearing preservation rates may be higher than those achieved with SRS. It will be important to monitor local control rates with increasing follow-up to ensure that they remain high. Combs et al have shown a serviceable hearing preservation rate of 68.6% at 10 years in 116 patients, most of whom were treated

with FSRT; patterns of hearing loss after 10 years were described as similar to those occurring in a healthy aging population.[233]

Four single-institution analyses (one prospective and three retrospective) have compared outcomes of SRS with those of FSRT (see Table 28-10), all of which show equal rates of local control.[229,230] Meijer et al[231] conducted a prospective study of 129 patients with vestibular schwannomas who were allocated to SRS (10 Gy to 12.5 Gy) versus hypofractionated FSRT (20 Gy to 25 Gy at 4 Gy/F to 5 Gy/F) on the basis of dentition, with edentulous patients ($n = 49$) receiving SRS and dentate patients ($n = 80$) receiving FSRT. Toxicity rates were low for both groups, but trigeminal nerve preservation was slightly higher in the FSRT group (98% vs. 92% at 5 years, $p = 0.048$). A review of 125 patients treated with SRS ($n = 69$) or conventional FSRT ($n = 56$) at Thomas Jefferson University also

showed comparable outcomes, with the exception of functional hearing preservation, which was better for patients treated with FSRT.[232] An analysis of 202 vestibular schwannomas treated with SRS (n = 30) versus conventional FSRT (n = 172) at the University of Heidelberg found equivalent outcomes between the two groups, with the exception of patients treated with SRS doses of more than 13 Gy, who had lower rates of hearing preservation.[229] An analysis from the University of Wisconsin compared the outcomes achieved with SRS (n = 48), conventional FSRT (n = 19), and hypofractionated FSRT (n = 37) and found comparable outcomes, with nonsignificant trends toward increased cranial nerve V toxicity in patients treated with hypofractionated FSRT and inferior serviceable hearing preservation with conventional FSRT.[230]

Surveillance

Surveillance may be the best option for elderly patients or those with significant other medical comorbidities and can be considered for patients with small, asymptomatic tumors. Contraindications include brainstem compression, hydrocephalus, and arguably, the desire to preserve hearing.

A systematic review of 903 patients observed by MRI or CT over a mean period of 3.1 years found that 51% of tumors grew and 20% required intervention after a mean time of 2.1 years, primarily because of tumor growth with progressive symptoms.[199] Audiologic data from a subset of 60 patients with serviceable hearing at presentation revealed loss of serviceable hearing in 37%. Analysis of nearly 1000 patients managed expectantly demonstrated an overall hearing preservation rate of 54%.[240] Hearing preservation was more likely in tumors with average annual growth rates of 2.5 mm per year or less (75% versus 32% for faster-growing tumors). The facial nerve preservation rate was higher than 97%. Tinnitus has been shown to worsen with observation, however, while improving with treatment (either surgery or SRS).[241]

Targeted Therapy

Recent advances in our knowledge of the molecular biology of vestibular schwannoma have led to early clinical studies of targeted agents in patients with NF2 with progressive disease. Promising results have been seen with bevacizumab and lapatinib, including both radiographic responses and restored hearing. Other systemic agents currently under investigation include sorafenib, trastuzumab, protein kinase inhibitors, and p21-activated kinase inhibitors.[25]

Combined-Modality Therapy

Combined-modality therapy is rarely indicated in the initial management of vestibular schwannoma. Patients who fail surgical management commonly go on to receive radiation therapy, however, and the opposite is also true.

Management of Vestibular Schwannoma in the Patient with Neurofibromatosis 2

Bilateral vestibular schwannomas, as mentioned previously, occur commonly in patients with NF2, a disorder with an estimated prevalence of 1 in 100,000.[242] Patients with NF2 also have a predisposition to develop other tumors of the central nervous system (meningiomas, ependymomas, astrocytomas, neurofibromas), peripheral neuropathy, ocular findings (retinal hamartomas, epiretinal membranes, cataracts), and skin lesions (plaques and subcutaneous tumors), as recently reviewed by Asthagiri et al.[25] Pretreatment evaluation should therefore include MRI studies of the entire craniospinal axis.

In comparison with sporadic tumors, vestibular schwannomas in patients with NF2 tend to grow more quickly and to more aggressively surround or infiltrate the adjacent cochlear and facial nerves. Functional outcomes after treatment tend to be poorer in this population of patients. For example, in the experience of Combs et al,[235] a diagnosis of NF2 was associated with significantly reduced likelihood of serviceable hearing preservation in patients treated with FSRT (64% for NF2 versus 98% for sporadic tumors).

Mathieu et al[243] recently published the University of Pittsburgh's experience treating 74 vestibular schwannomas in 62 patients with NF2with SRS, with a mean marginal dose of 14 Gy (range, 11 Gy to 20 Gy). The actuarial local control rate was 81% at 10 years to 15 years. The margin dose was significantly related to serviceable hearing preservation on multivariate analysis, and the actuarial serviceable hearing preservation rate was 48% at 5 years in patients treated with a marginal dose of 14 Gy or less. Tumor volume of more than 5 cm^3 and maximum dose of more than 28 Gy predict for the development of other complications, such as facial weakness, trigeminal neuropathy or neuralgia, and vestibular dysfunction. The authors recommend offering treatment only for large symptomatic tumors or tumors manifesting with progressive growth or hearing loss to maximize preservation of function and quality of life.[243] One advantage of earlier intervention may be the potential for sparing function of the cochlear nerve, thereby allowing for future cochlear implantation.

Currently, the use of radiation in the management of vestibular schwannoma in patients with NF2 is controversial. The goal of therapy typically is to preserve function while maintaining quality of life. Many of these patients can simply have their tumors observed. However, patients with decreasing hearing, brainstem compression, or with nerve involvement causing symptoms should have treatment. Typically, surgery

is looked at as the first option. This is partly because of the fear of second malignancies from radiation, though the data on this is sparse.[242,244,245]

IRRADIATION TECHNIQUES AND TOLERANCE

Stereotactic Radiosurgery

Either linac-based or Gamma Knife radiosurgery may be employed to treat intracranial lesions with submillimeter precision. Examples of popular commercial linac radiosurgical systems include Novalis BrainLAB (BrainLAB AG, Feldkirchen, Germany), Radionics XKnife (Integra, Plainsboro, NJ), TomoTherapy (TomoTherapy, Inc., Madison, WI), TrueBeam STX or Edge (Varian Medical Systems, Palo Alto, CA), and CyberKnife (Accuray, Inc., Sunnyvale, CA). Radiosurgery technology is discussed elsewhere in more detail.

High-resolution MRI images should be used during treatment planning, either as the primary dataset or through fusion with a treatment planning CT scan. Care should be taken when relying solely on MRI, however, because spatial distortion may result in targeting errors with resulting compromise in local control.[246] The tumor is best visualized with contrast-enhanced T1 images, whereas the cochlea and semicircular canals are best seen with fast spin echo T2 sequences.

The ideal SRS prescription (marginal) dose is typically 12 Gy to 13 Gy; local control appears to be compromised with doses below this range[219,247] and cranial nerve toxicity increases with higher doses.[221,229,248,249] The incidence of cranial neuropathy may be greater with prescription doses of greater than 12.5 Gy. For example, a recent retrospective analysis by Foote et al[220] found the 2-year incidence of any cranial neuropathy to be 2% with prescription doses of 12.5 Gy or less versus 24% with doses of more than 12.5 Gy ($p < 0.0003$).

Facial, trigeminal, and auditory toxicities have also been shown to correlate with the length of nerve irradiated (represented by the transverse tumor diameter).[249] For example, in the early experience with higher-dose SRS, trigeminal and facial neuropathy rates were, respectively, higher in patients with an extracanalicular tumor dimension of more than 1 cm and a sum of extracanalicular and intracanalicular diameter of more than 2 cm.[250]

Other factors that correlate with increased facial nerve preservation rates include age of 60 years or less, tumor volume of 1.5 cm^3 or less, and marginal dose of 13 Gy or less.[251] Most cranial neuropathies develop within 2 years of SRS, but hearing loss can occur much later.

MRI treatment planning techniques have been found to correlate with reduced facial and trigeminal neuropathy[249] and increased hearing preservation,[247,249] although interera comparisons may be confounded by a tendency to prescribe lower marginal doses in more recent years. Other SRS parameters correlated with improved hearing preservation rates include prescribing a marginal dose of 13 Gy or less,[250] limiting the mean cochlear dose to less than 3 Gy,[252] and maximum dose to less than 4 Gy,[253] and limiting the dose to the cochlear nucleus to less than 10 Gy.[254]

The radiation dose to the brainstem must also be carefully monitored. In 1994, Kihlstrom et al recommended limiting the brainstem dose to 14 Gy or less with SRS, based on the development of adverse radiation imaging effects (ARIE) in 6 of 7 patients who received 14 Gy to 35 Gy for low-grade gliomas of the tectal midbrain.[255] In 2008, Sharma et al[256] demonstrated that ARIE and new neurologic deficits could develop after exposing 0.1 cm or more of brainstem to doses of more than 12 Gy. An example of an SRS treatment plan is shown in Figure 28-9.

Data is now emerging evaluating the use of fractionated proton therapy. Weber et al reported on 88 patients treated with fractionated proton therapy with a median dose of 12 CGE.[257] The 5-year local control rate was 94%. However, only 33% of patients were able to maintain serviceable hearing. As proton therapy utilization increases, it is expected that more literature will emerge to better delineate the benefits of proton therapy in this population.

Fractionated Stereotactic Radiation Therapy

The objective of FSRT is to combine the radiobiologic advantages of conventional EBRT with the reduced normal tissue exposure of SRS. Multiple localization systems have been developed, most of which achieve patient localization through cone-beam CT, megavoltage CT, or infrared light-emitting diodes and are accurate to within 1 mm to 3 mm.

At the University of Wisconsin, FSRT is typically delivered on a linear accelerator with the patient immobilized in an aquaplast head mask (Figure 28-10). To ensure treatment delivery accuracy, pre- and intratreatment continuous, real-time patient localization is carried out using optical guidance. For this purpose a patient specific maxillary bite block is manufactured before CT simulation, to which a fiducial array with passive optical markers is attached. Before the planning CT

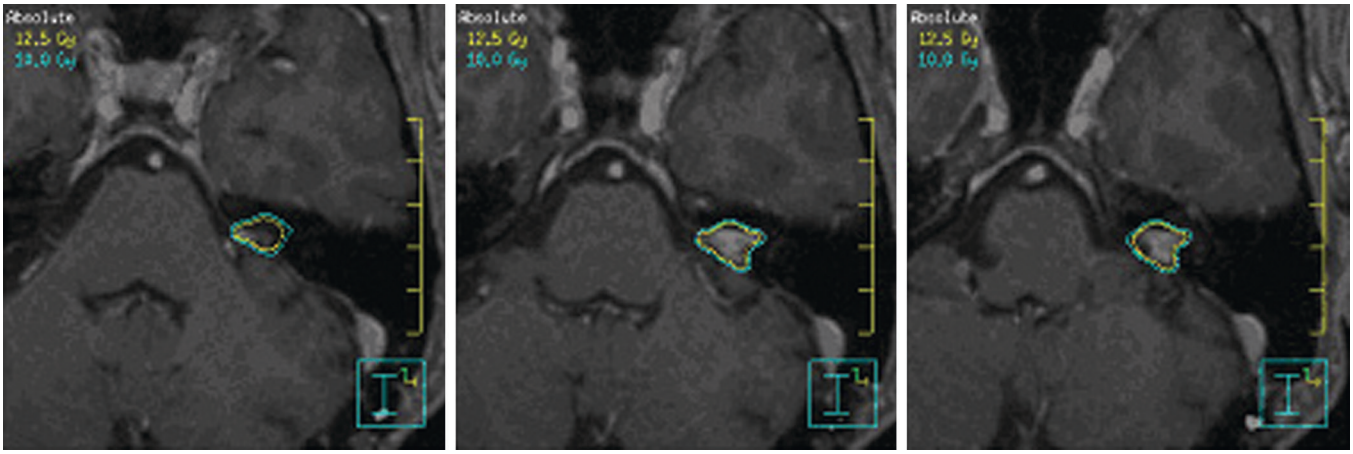

Figure 28-9 Linac stereotactic surgery (SRS) treatment plan delivering 12.5 Gy to a small left-sided vestibular schwannoma using four isocenters.

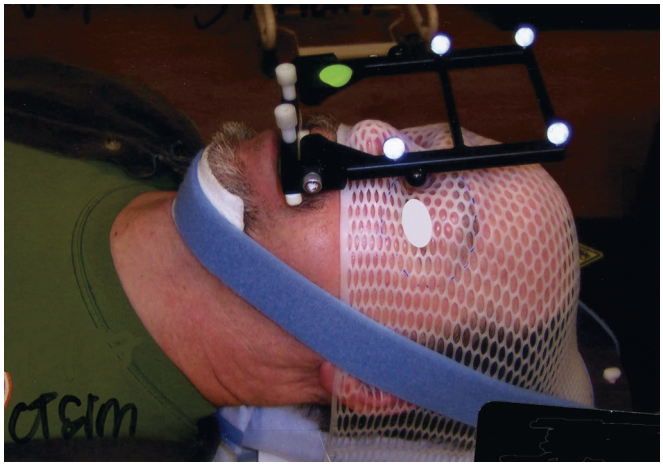

Figure 28-10 Patient immobilization and localization system for fractionated stereotactic radiotherapy (FSRT) at the University of Wisconsin.

and before each treatment fraction the fiducial array bite block complex is inserted, and setup is continuously monitored with optical guidance. If the patient moves out of the predetermined error tolerance band of 0.3 mm or 0.3 degrees of rotation, treatment is interrupted until realignment is achieved.

Common regimens prescribed are on the order of 45 Gy to 50 Gy at 1.8 Gy to 2 Gy per fraction, or 20 Gy to 25 Gy at 4 Gy to 5 Gy per fraction. Compared with untreated controls, 21 patients treated with 54 Gy in 27 fractions to 30 fractions had significantly lower rates of serviceable hearing preservation at 2 years (38% versus 67%).[258] A retrospective analysis of 89 patients treated with FSRT to 46.8 Gy versus 50.4 Gy at 1.8 Gy per fraction found that patients treated to 46.8 Gy were more likely to have preservation of serviceable hearing; however, there was no statistically significant relationship between cochlear dose and serviceable hearing preservation.[259] In contrast, a prospective analysis of 34 patients treated with FSRT to 45 Gy at 1.8 Gy per fraction prescribed to the 90% isodose line found that the dose to the cochlea was the only significant prognostic factor for hearing deterioration.[260] In their experience, the median hearing loss was 10 dB for patients with less than 73.3% of the cochlea exposed to 90% or more of the prescription dose (45 Gy), as opposed to 25 dB for patients with a volume getting 90% of the prescription dose (V_{90}) of 73.3% or more. An example of an FSRT plan is shown in Figure 28-11.

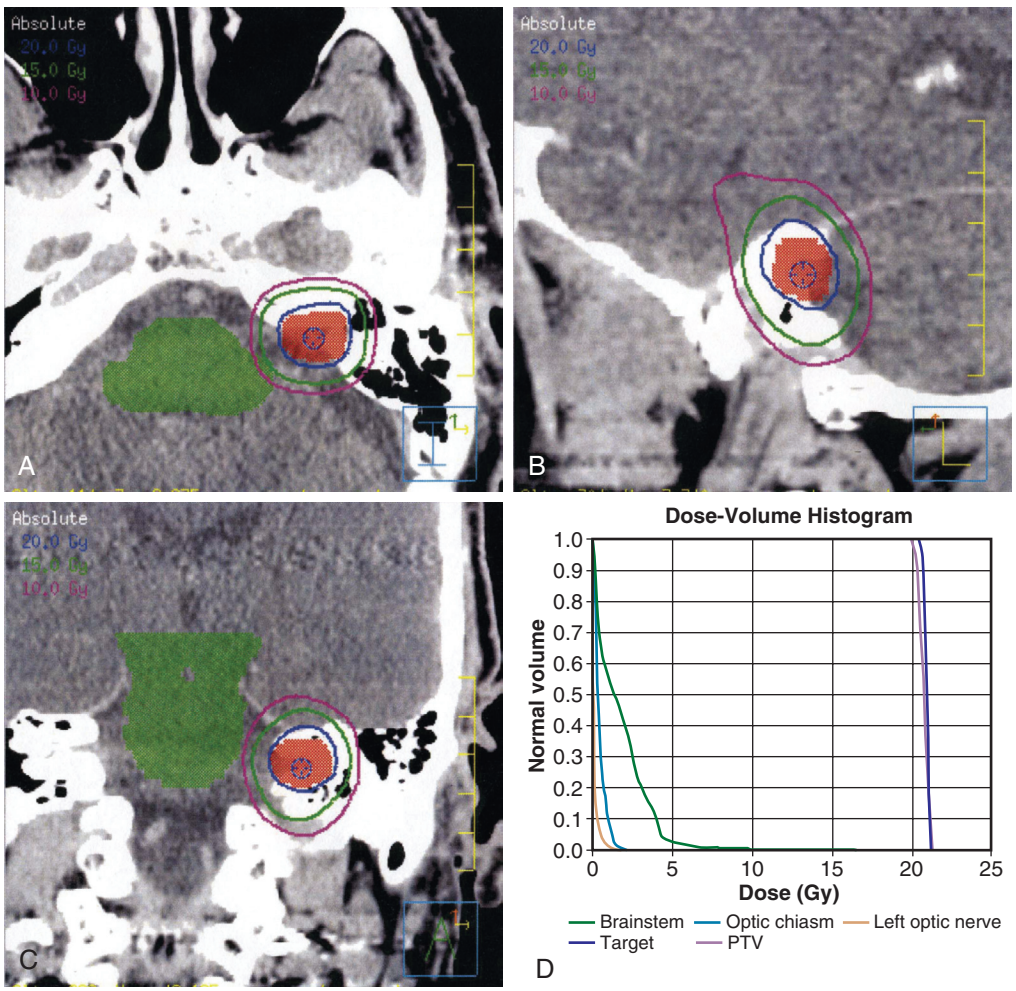

Figure 28-11 Fractionated stereotactic radiotherapy (FSRT) treatment plan delivering 20 Gy at 4 Gy/F weekly to a left-sided vestibular schwannoma. Representative axial (**A**), sagittal (**B**), and coronal (**C**) isodose lines are shown, along with the dose volume histogram (DVH) (**D**) demonstrating good coverage of the gross tumor volume (GTV) and planning target volume (PTV) with minimal dose to adjacent normal structures.

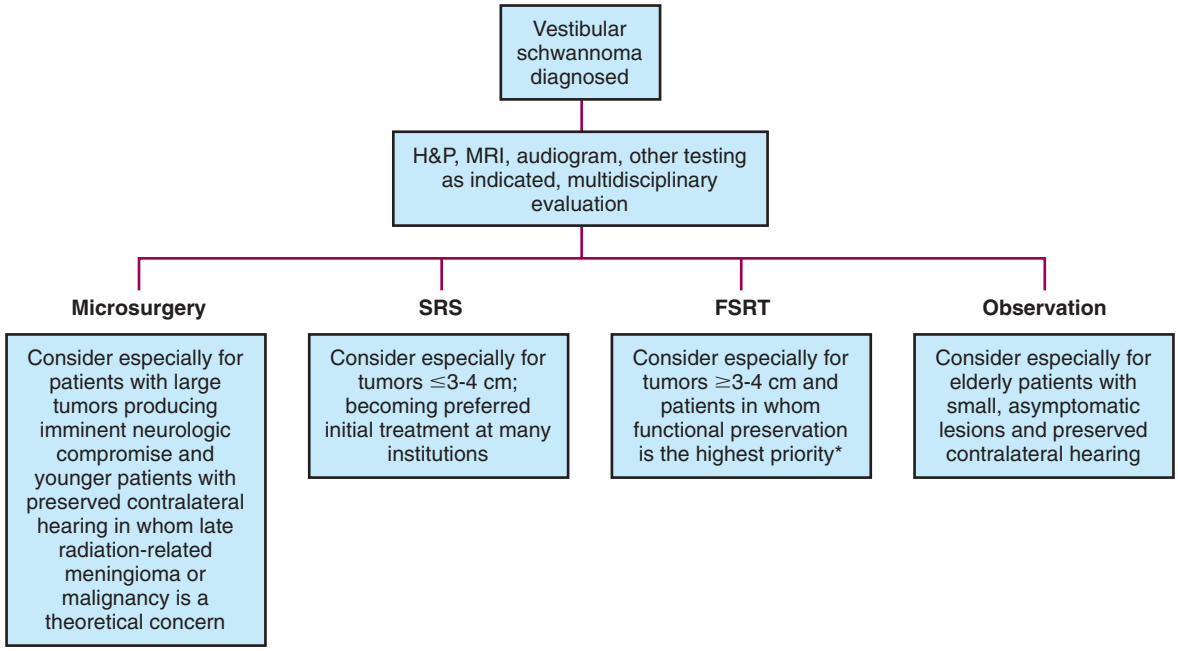

Figure 28-12 Treatment algorithm for vestibular schwannoma. Multidisciplinary evaluation is crucial to ensure that patient-specific factors and institutional strengths that may influence outcomes are taken into consideration.

TREATMENT ALGORITHMS, CHALLENGES, AND FUTURE DIRECTIONS

Patients with newly diagnosed vestibular schwannomas should be evaluated by a multidisciplinary team with expertise in neurosurgery, SRS, and FSRT for discussion of the risks and benefits of treatment, as well as observation (see the treatment algorithm in Figure 28-12). Resection may be performed for virtually any tumor and especially for large tumors causing brainstem compression or hydrocephalus that cannot effectively be managed nonsurgically. Hearing preservation rates may be lower with surgery than with radiation therapy; however, this has never been tested in a prospective randomized fashion. The ideal candidate for SRS is a patient with a small intracanalicular tumor not approaching the brainstem, with marginal doses of 12 Gy to 13 Gy. Conventional or hypofractionated FSRT may be a safer choice for tumors measuring 3 cm to 4 cm or larger and may result in higher hearing preservation rates. Radiation dose to the cochlea should be limited to maximize hearing preservation with either technique. Randomized, controlled trials comparing various treatment options would be valuable.

The cost-effectiveness of various forms of treatment is another important issue to consider. Banerjee et al[261] performed a comparative analysis of the costs incurred through microsurgery versus SRS for vestibular schwannoma. They determined that the mean cost of microsurgery is higher than the mean cost of SRS ($23,788 versus $16,143), but the follow-up costs after SRS tend to be higher because of factors such as increased use of MRI and audiograms, although this reflects practice patterns more than clinical necessity. The authors conclude that SRS is likely to be less expensive than microsurgery from a societal perspective, provided that recurrence rates remain low over prolonged follow-up times.[261]

CHAPTER

29 Pituitary Tumors and Craniopharyngiomas

John H. Suh, Sam T. Chao, Erin S. Murphy, and Robert J. Weil

INCIDENCE

Pituitary tumors represent roughly 10% to 15% of primary intracranial tumors. Based on a meta-analysis, the overall estimated prevalence of pituitary adenoma is 16.7% (14.4% in autopsy series and 22.5% in radiographic series of all patients).

BIOLOGIC CHARACTERISTICS

Most pituitary tumors are benign. They may express or secrete excess hormones and are monoclonal in origin. MAPK and PI3K/Akt signaling pathways appear to have putative roles in pituitary tumorigenesis or continued growth. Genetic predisposition for the development of pituitary adenomas has been described in multiple endocrine neoplasia (MEN) syndromes, Carney syndrome, and isolated familial somatotropinomas. Pituitary carcinomas are extremely rare.

STAGING EVALUATION

Evaluation for patients with pituitary tumors includes a complete history and physical examination, neuroophthalmic assessment, laboratory tests with emphasis on the endocrine profile, and magnetic resonance imaging (MRI) of the brain with emphasis on the sellar and parasellar regions. Although no formal staging exists, these tumors are broadly classified by endocrine dysfunction, anatomic size, and secretory status.

PRIMARY THERAPY AND RESULTS

Primary therapy is optimized by a multidisciplinary approach, including endocrinology, neurosurgery, neuropathology, neuroradiology, neuroophthalmology, otorhinolaryngology, and radiation oncology. Depending on the endocrine abnormality, tumor size, location, and clinical presentation, management strategies can range from observation to surgery, medical management, radiation therapy, or a combination of these options. The primary goals of treatment include preservation or restoration of normal hormonal function, reversal of hypersecretory endocrine abnormalities, and improvement or stabilization of visual changes or neurologic symptoms. The standard surgical approach is transsphenoidal microsurgery.

ADJUVANT THERAPY

Adjuvant medical and radiation therapy options may be used to manage pituitary adenomas. Radiation options include fractionated radiation therapy and stereotactic radiosurgery (SRS), which are both generally used as adjuvant therapies rather than as primary therapies.

LOCALLY ADVANCED DISEASE

Large nonfunctional and some functional pituitary adenomas may require a combination of approaches, such as surgery, medical therapy, and radiation therapy to optimize long-term tumor control.

PALLIATION

Metastases to the pituitary are uncommon and occur most frequently from breast and lung cancer. The majority of metastases involve the posterior pituitary lobe. A short course of radiation therapy is usually effective in controlling these tumors.

CRANIOPHARYNGIOMAS

Craniopharyngiomas are uncommon tumors that are postulated to arise from the embryologic remnants of Rathke's pouch. They are typically slow growing and encapsulated. Although benign in nature, tumor growth and treatment can result in endocrinopathies and visual deficits. Gross total resection (GTR) results in excellent local control but can cause morbidity including hypothalamic dysfunction and visual deficits. Subtotal resection followed by external beam radiation therapy may yield equivalent control with less morbidity. Other options include SRS, intracystic bleomycin, and intracystic phosphorous 32. The 5-year progression free survival is approximately 85%.

INTRODUCTION

This chapter focuses on the etiology, epidemiology, detection, biology, anatomy, pathology, evaluation, and management (specifically the irradiation techniques and associated treatment side effects) of pituitary tumors. Given the diverse presentations of these tumors along with their complex anatomic location and proximity to critical structures such as the optic apparatus, cranial nerves, and internal carotid arteries, a multidisciplinary approach is needed for optimal patient care. Involvement of the endocrinologist, neurosurgeon, otorhinolaryngologist, radiation oncologist, neuroradiologist, neuroophthalmologist, and neuropathologist optimizes management of patients with pituitary tumors. At the end of this chapter, the evaluation and management of craniopharyngiomas will be briefly discussed.

ETIOLOGY AND EPIDEMIOLOGY

Etiology

The etiology of most pituitary tumors is not known. Based on rodent models, two primary modes of pituitary oncogenesis have been suggested.[1] The first model, known as the hyperplasia-adenoma sequence, suggests a hormone-dependent pathway. In this model, dysregulation of hormone or growth factor signaling leads to hyperplasia and tumor formation. For example, there is evidence that implicates overexpression of

transforming growth factor–alpha (TGF–α), fibroblast growth factor (FGF), and fibroblast growth factor receptors (FGFRs) in tumor formation.[2] In the second model, adenomas are believed to arise de novo, without the development of hyperplasia, likely as a result of one or a sequence of genetic alterations, a mechanism supported by some transgenic and knockout animal models.[2] In humans four genes known to be associated with familial pituitary tumor syndromes: multiple endocrine neoplasia (MEN) 1; cyclin dependent kinase inhibitor (CDKN) 1B; protein kinase, cAMP-dependent, regulatory (PRKAR) 1A; and aryl hydrocarbon receptor-interacting protein (AIP).[3]

For patients with MEN1, which is an autosomal dominant disease characterized by tumors of the pancreatic islet cells, parathyroid glands, and pituitary gland, 40% will develop pituitary adenomas, most commonly prolactinomas. Pituitary tumors associated with the MEN1 syndrome demonstrate loss of heterozygosity of chromosome 11q13 (location of the *MEN1* gene), which has also been implicated in malignant progression of some pituitary adenomas.[4] Alterations of *MEN1* do not appear to increase the risk for sporadic pituitary adenomas.[5]

In Carney's complex, a rare inherited condition characterized by endocrine overactivity, schwannomas, abnormal skin pigmentation, and myxomas, the implicated genetic defect is loss of function of PRKAR1A, whose gene is located on chromosome 17q23-24.[6] Additional genetic alterations are found in the McCune-Albright syndrome, a genetic disorder of bones, skin pigmentation, and hormones associated with premature puberty. Activating or gain-of-function *GNAS1* mutations (of the guanine nucleotide-binding protein [G protein], alpha-stimulating activity polypeptide 1 gene on chromosome 20q13.1) are seen in this condition. Patients with McCune-Albright syndrome demonstrate mosaicism, resulting from a postzygotic somatic mutation appearing early in the course of development that yields a monoclonal population of mutated cells within variously affected tissues.

In isolated familial somatotropinomas (i.e., the occurrence of two or more cases of acromegaly in a family without a history of MEN or Carney's complex), germline alterations in the aryl hydrocarbon receptor interacting gene (*AIP* gene) have been identified.[7,8] The syndrome of familial isolated pituitary adenomas (FIPA) accounts for 2% of pituitary adenomas and is associated with mutations in *AIP*, the gene that encodes aryl hydrocarbon receptor interacting protein.[9] The FIPA syndrome is also liked to mutations in *AIP* in 15% to 25% of families, and those affected are typically younger patients with more aggressive tumors[10] *AIP* mutations are usually associated with growth hormone secretion, but prolactinomas, nonfunctional adenomas, Cushing's disease, and other adenoma types can occur.

Finally, heterozygous mutations of *CDNK1B*, which encodes a 196 amino acid protein, the cyclin-dependent kinase CDK1 p27Kip1, can lead in humans to a multiple endocrine syndrome of familial pituitary adenomas and primary hyperparathyroidism, like MEN1, but also including testicular cancer and renal angiomyolipoma. The alterations in *CDNK1B*, located at 12p13, are rare, and lead to the multiple endocrine syndrome known as MEN4.[11]

Epidemiology

Although 10% of normal adults have a pituitary abnormality detectable on MRI, pituitary tumors account for only 10% to 15% of all primary intracranial tumors. The frequency of pituitary adenomas varies greatly, although recent community-based studies from Belgium and the United Kingdom suggest that the prevalence is higher than has been historically noted.[12,13]
