At the same time, early-stage nLPHD responds well to chemotherapy alone or combined modality therapy. One example of the former approach is a report entailing 55 pediatric patients with low-stage nLPHL treated with cyclophosphamide/vinblastine/prednisone (CVP), with 11 cases treated after initial surgical relapse. The 40-month freedom from treatment failure and OS for the entire cohort were 75.4% and 100%, respectively. On the other hand, excellent results with combined-modality therapy were reported with the VAMP combination plus LDRT in a series of 33 patients having a 100% 10-year survival and EFS.[108] The COG has validated this watchful waiting approach after surgery with its AHOD03P1 study. A total of 52 patients with stage IA disease underwent surgery only if disease was confined to a single lymph node. Twelve relapses have been localized and all were successfully salvaged with three cycles of AV-PC (Adriamycin, vincristine, prednisone, and cyclophosphamide) and no radiotherapy. The current 2-year EFS estimate among

these patients treated without chemotherapy is 81.6%.[207] A separate cohort of 127 patients with stage II or stage I with multiple nodes were treated upfront with AV-PC for three cycles. The vast majority of patients had a CR and were observed, whereas 12 patients with residual disease received low-dose IFRT. Nine additional patients with local relapse after surgery were also included in this scheme in which the 4-year EFS is estimated at 86.8%.[207]

TREATMENT OF RELAPSED AND REFRACTORY DISEASE

The generally excellent outcome in pediatric HL has limited opportunities to evaluate salvage therapy programs. Most relapses in patients with HL occur within the first 3 years, but some patients may relapse as long as 10 years after initial diagnosis.[208] Treatment and prognosis after relapse depends on the primary therapy, initial stage, and duration of remission (time of relapse). Harker-Murray et al have reviewed the literature on retrieval therapy for HL and have suggested a favorable to intermediate risk cohort of patients with early-stage disease without initial B symptoms and at least a 1 year remission duration to define a group for whom conventional chemotherapy with selective use of RT may be reasonable.[209] Indeed, such an approach may salvage 40% to 50% of children relapsing after a sustained remission (1 year or longer); however, adverse effects of treatment, including second malignancies, may reduce ultimate survival.[210-212] Patients who demonstrate refractory disease, or recurrence within 1 year after completing therapy, respond poorly to conventional salvage therapy, as do patients with multiple relapses. These high-risk patients have a better chance of achieving a durable remission if they are consolidated with myeloablative therapy followed by hematopoietic cell transplantation (HCT).

For higher risk relapses, a combination of ifosfamide/vinorelbine for pediatric patients in first relapse was studied by the COG (AHOD00P1 trial). This regimen showed a good overall complete or partial response rate of 78% and achieved good stem-cell mobilization for future autologous stem-cell transplant.[213] For patients who relapse after transplant or are upfront refractory to chemotherapy, a combination of a gemcitabine/vinorelbine has also studied by the COG, documenting a response rate of 76%.[214]

OS rates in children and adolescents with relapsed HL treated with high-dose chemotherapy and hematopoietic transplant range from 30% to 60%. Because of the higher transplant-related mortality associated with allogeneic transplantation, autologous HCT is preferred for patients with relapsed HL. However, recent investigations of reduced-intensity allogeneic transplantation have demonstrated acceptable rates of transplant-related mortality.[215-217] Nonmyeloablative conditioning regimens most often use fludarabine or low-dose total-body irradiation to provide a nontoxic immunosuppression and establish a graft-versus-lymphoma effect.

IFRT to sites of recurrent disease should be considered in the setting of HCT. In a Stanford report, patients with stages I to III disease at relapse who received autologous bone marrow transplantation and IFRT had a 3-year freedom from relapse of 100% and OS of 85%, compared with 67% and 60%, respectively, for patients not receiving IFRT.[218] For patients not previously irradiated, IFRT was associated with an improved freedom from relapse of 85% and OS of 93%, in contrast to 57% and 55%, respectively, for those previously irradiated. Morbidity was similar to those not irradiated, although RT may have contributed to the peritransplant death of two patients. Other reports on the use of consolidative RT suggest a benefit and low to moderate morbidity, although these are mostly adult data which suffer from inherent selection and publication biases.[219-224] Central issues relating to the use of IFRT are the dose, target volume, and timing with respect to the transplant. RT doses are generally 15 Gy to 25 Gy, in 1.5-Gy to 2.0-Gy fractions. This variation relates to potential normal tissue toxicity as well as the consideration for higher radiation doses in patients with an identifiable tumor that demonstrates radiation responsiveness. RT volume can vary and include treatment to all sites of initial disease, recurrent disease, persistent disease following salvage chemotherapy, persistent disease following the preparative regimen for transplant, or all nodal sites. Unless protocol-specific therapy is directed, individual considerations for such decision making are necessary at this time. IFRT can be administered before the high-dose chemotherapy program to place patients in a minimal disease state. Alternatively, RT can also be administered after the high-dose chemotherapy program to decrease the overall potential for disease progression and avoid RT-related peritransplant morbidity such as esophagitis, pneumonitis, cardiomyopathy, and veno-occlusive disease. Possible disadvantages of this approach include the loss of the pretransplant cytoreductive effect and the theoretical carcinogenic effect of RT on the newly proliferating hematopoietic system.

New agents for HL are being evaluated in the relapse setting. In particular there is great excitement with the anti-CD30-drug conjugate, Brentuximab Vedotin, that has shown excellent activity in early clinical trials.[225] This type of targeted therapy hold promise for greater efficacy with less toxicity as it is carefully combined with other agents. Clinical trials incorporating this agent in upfront therapy for both adults and children with HL are under way or being planned.

Treatment Algorithms

Table 74-6 summarizes recommendations for risk-adapted treatment approaches. Because patients with localized favorable disease presentations can achieve long-term disease-free survival using regimens that minimize alkylators, doxorubicin-based chemotherapy such as ABVD or ABVE is preferred for this group.[96,98,105,110] However, alkylating agents or etoposide can be added to the regimen without compromising disease outcome if the clinician prefers to restrict anthracycline chemotherapy exposure to preserve cardiac function.[50,51,101] Combined-modality treatment approaches including low-dose IFRT have historically produced excellent results in children with favorable localized disease and reduce cumulative chemotherapy doses. However, there is an increasing trend to try to use response-based programs to reduce or eliminate the use of radiotherapy in patients with a rapid early response with a goal of lessening the burden of late effects of therapy.

Combinations such as ABVE-PC or older ABVD/MOPP-type hybrid regimens with the addition of etoposide still provide the most effective chemotherapy strategies for children and adolescents with intermediate- or high-risk disease presentations.[50,51] In older regimens reporting good long-term outcomes, low-dose RT is administered following chemotherapy to areas of bulk disease, or nodes (usually the regions harboring the involved nodes) present at diagnosis. However, the use of dose-intensive regimens such as ABVE-PC allows rapid responders to significantly decrease their exposure to RT. This is rapidly evolving into a new standard for pediatric HL. At the same time this type of abbreviated, dose-dense regimen that induce rapid tumor response may permit reduction of cumulative chemotherapy doses below threshold levels associated with significant long-term toxicity.[68]

TABLE 74-6 Recommendations for Treatment Approach in Pediatric Hodgkin Lymphoma

Clinical Presentation	Stage	Recommended Treatment Approach
EARLY (low risk)		**RECOMMENDED THERAPY**
<3-4 nodal regions; no B symptoms, bulk, or extranodal extension from contiguous nodal disease	IA, IIA	2-4 cycles noncross-resistant chemotherapy without alkylators plus low-dose IFRT (15 Gy-21 Gy); in highly favorable patients with no extranodal disease and less then 3 sites, abbreviated chemotherapy with a CR on interim assessment or at completion of therapy may allow for deletion of RT **IN CLINICAL TRIAL SETTING ONLY** 2-4 cycles of chemotherapy alone if there is negative PET2; or such chemotherapy followed by ISRT or RT limited to initial bulky sites or residual disease sites (15 Gy-21 Gy)
INTERMEDIATE		**RECOMMENDED THERAPY**
≥3-4 nodal regions; bulky lymphadenopathy (mediastinal ratio ≥33%; peripheral lymph node mass ≥6-10 cm)	IA, IIA, IIB* IIIA, some IIIB	4-6 cycles (3-5 compacted, dose-intensive cycles) noncross-resistant chemotherapy. Low-dose RT (15 Gy -21 Gy) is reserved for patients with slow response, incomplete response, or residual disease or masses. **IN CLINICAL TRIAL SETTING ONLY** 4-6 cycles (3-5 compacted, dose-intensive cycles) noncross-resistant chemotherapy alone if there is negative PET2; or such chemotherapy followed by ISRT or RT limited to initial bulky sites or residual sites of disease (15 Gy-21 Gy)
ADVANCED (HIGH risk)		**RECOMMENDED THERAPY**
Stage II patients with fever or weight loss and/or bulk*; any patient with advanced stage (not all stage III would be high risk)	IIB* IIIB IV	6 cycles (4-6 compacted, dose-intensive cycles) of noncross-resistant chemotherapy plus low-dose IFRT (15 Gy-21 Gy) **IN CLINICAL TRIAL SETTING ONLY** 6 cycles (4-6 compacted, dose-intensive cycles) of noncross-resistant chemotherapy plus low-dose IFRT (15 Gy-25 Gy) restricted to (1) sites of initial bulky disease, (2) PET2 positive disease, or (3) residual masses

IFRT, *Involved-field radiotherapy;* INRT, *involved-nodal radiotherapy;* PET2, *PET scan after second cycle of chemotherapy used as indicator of rapid early response.*
**Patients with stage IIB disease have been variably treated as intermediate or unfavorable risk. Some studies use associated factors, e.g., weight loss, bulk disease, extranodal extension, for further risk stratification.*

CHAPTER

75 Rare Pediatric Tumors

Luke E. Pater and John Breneman

INCIDENCE

Hepatic tumors: 1.6 per million; male predominance.

Germ cell tumors: 3% of childhood malignancies; female predominance.

Juvenile nasopharyngeal angiofibroma: 0.05% of head and neck tumors.

Pleuropulmonary blastoma: Extremely rare.

Hemangioma and lymphangioma: Hemangiomas: 1% of infants; lymphangiomas: 0.01% of infants.

Diffuse, small, round cell tumor: Extremely rare; primarily affects young males.

Langerhans cell histiocytosis: 1 million to 5 per million; slight male predominance.

Nasopharyngeal cancer: 1% of pediatric cancers; 2:1 male predominance.

BIOLOGIC CHARACTERISTICS

Hepatic tumors: Fetal-type hepatoblasts with sinusoidal hematopoiesis; typically alpha-fetoprotein positive.

Germ cell tumors: Vary widely from undifferentiated germinomas to benign well-differentiated teratomas.

Juvenile nasopharyngeal angiofibroma: Mixed endothelial-lined vessels and fibrous stroma; β-catenin mutations seen in 75%.

Pleuropulmonary blastoma: Mixed blastemal and sarcomatous elements with cystic and solid morphologies. Solid variants behave more aggressively.

Hemangioma and lymphangioma: Abnormal dilated blood or lymph vessels.

Diffuse, small, round cell tumor: Small, round blue cells with collagen dense stroma.

Langerhans cell histiocytosis: Dendritic histiocytes; CD207, S-100, and CD1a positive.

Nasopharyngeal cancer: Mostly lymphoepithelioma; Epstein-Barr virus related.

STAGING

Hepatic tumors: Right upper quadrant ultrasonography, magnetic resonance imaging/computed tomography (MRI/CT) of liver, CT of chest, alpha-fetoprotein level.

Germ cell tumors: Ultrasonography of primary tumor, CT of chest, abdomen, and pelvis; alpha-fetoprotein, β-human chorionic gonadotropin, and lactate dehydrogenase levels.

Juvenile nasopharyngeal angiofibroma: Angiography and CT or MRI of the head.

Pleuropulmonary blastoma: CT of the chest, abdomen, and pelvis; MRI of the brain.

Hemangioma and lymphangioma: CT or MRI of affected site; angiography in selected cases.

Diffuse, small, round cell tumor: CT with intravenous and oral contrast enhancement.

Langerhans cell histiocytosis: Skeletal survey, chest radiography, CT, bone scintigraphy.

Nasopharyngeal cancer: Nasopharyngoscopy, positron emission tomography (PET)/CT, MRI, blood chemistries, and dental and endocrine evaluation.

PRIMARY THERAPY

Hepatic tumors: Neoadjuvant chemotherapy and surgery; overall survival (OS) is about 65% for hepatoblastoma and 25% for hepatocellular carcinoma.

Germ cell tumors: Surgery alone for teratomas or stage I tumors; others get surgery plus chemotherapy. Cure rate is more than 90%.

Juvenile nasopharyngeal angiofibroma: Surgical resection controls approximately 70% of tumors.

Pleuropulmonary blastoma: Surgical resection; cure obtained in 80% of type I tumors and 45% of types II and III tumors.

Hemangioma and lymphangioma: Surgical resection; local control achieved in most patients.

Diffuse, small, round cell tumor: Surgical resection; cure is uncommon.

Langerhans cell histiocytosis: Varies by extent of disease.

Nasopharyngeal cancer: Radiotherapy (RT) with OS of 51% to 95% and relapse-free survival of 36% to 91%

ADJUVANT THERAPY

Hepatic tumors: Cisplatin-based chemotherapy.

Germ cell tumors: Cisplatin/etoposide/bleomycin (PEB) chemotherapy for three to four cycles.

Juvenile nasopharyngeal angiofibroma: Consider RT with 36 Gy to 40 Gy.

Pleuropulmonary blastoma: Chemotherapy with ifosfamide/vincristine/dactinomycin (Actinomycin-D)/doxorubicin (IVADo) or similar regimen.

Hemangioma and lymphangioma: None.

Diffuse, small, round cell tumor: Chemotherapy with alkylating regimen and whole-abdomen irradiation.

Langerhans cell histiocytosis: Surgery, chemotherapy, RT, or corticosteroids.

Nasopharyngeal cancer: Neoadjuvant or adjuvant chemotherapy.

THERAPY FOR LOCALLY ADVANCED DISEASE

Hepatic tumors: Neoadjuvant chemotherapy, surgery, possible liver transplantation; consider RT if unresectable.

Germ cell tumors: Neoadjuvant chemotherapy plus surgery.

Juvenile nasopharyngeal angiofibroma: RT with 36 Gy to 40 Gy controls approximately 80% of tumors.

Pleuropulmonary blastoma: Neoadjuvant chemotherapy with delayed resection. Consider RT with 44 Gy.

Hemangioma and lymphangioma: Surgery, embolization, corticosteroids.

Diffuse, small, round cell tumor: Neoadjuvant chemotherapy, surgical debulking.

Langerhans cell histiocytosis: Low-dose RT or chemotherapy.

Nasopharyngeal cancer: Most disease is locally advanced and treated with chemoradiation.

PALLIATION

Hepatic tumors: Chemotherapy or RT.

Germ cell tumors: Consider RT or additional chemotherapy.

Juvenile nasopharyngeal angiofibroma: Consider diethylstilbestrol or flutamide. Cytotoxic chemotherapy may be effective.

Pleuropulmonary blastoma: RT for brain metastases and symptomatic bone metastases.

Hemangioma and lymphangioma: Consider RT with 10 Gy to 25 Gy for life-threatening conditions.

Diffuse, small, round cell tumor: RT for symptomatic disease.

Langerhans cell histiocytosis: Low-dose RT or chemotherapy.

PRIMARY LIVER TUMORS OF CHILDHOOD

Etiology and Epidemiology

Primary malignant liver tumors (PMLT) in children are rare malignancies representing ~1% of pediatric cancers. They are comprised almost entirely of hepatoblastoma (HBL) and hepatocellular carcinoma (HCC). In people younger than 20 years old, 67% of PMLTs are HBL and 31% are HCC.[1] Age-adjusted rates show a slight male-to-female predisposition for both HBL and HCC.[1,2] HBL has been associated with prematurity, low birth weight, fetal alcohol syndrome, use of maternal oral contraceptives, Beckwith–Wiedemann syndrome, hemihypertrophy, and familial adenomatous polyposis.[3-8] HCC is strongly associated with hepatitis B virus (HBV) as well as α_1-antitrypsin deficiency, hereditary tyrosinemia, extrahepatic biliary a tresia, Fanconi anemia, ataxia-telangiectasia, Sotos syndrome, glucose-6-phosphatase deficiency, congenital hepatic fibrosis, Byler disease, and Wilson disease.[3,9]

Biologic Characteristics and Molecular Biology

There is no familial clustering of HBL, though genetic syndromes are associated with approximately 15% of cases.[10] Familial adenomatous polyposis coli (FAP) with the heritable mutation of the adenomatous polyposis coli (APC) gene has been associated with risk of HBL[11,12] as have been Beckwith–Wiedemann, Sotos syndrome, and Simpson–Golabi–Behmel syndrome. Trisomy 18 has been observed in HBL, particularly in females and patients with multifocal tumors. Other cytogenetic findings in HBL include gains of chromosomes 2, 8, or 20 and loss of 18.[13-16] Mutations of β-catenin and phosphatidylinositol-3-kinase have been reported in sporadic cases,[17,18] as well as differential expression of imprinted genes and altered methylation of gene promoters.[19-21]

HBV is associated with nearly all cases of HCC in areas endemic for HBV.[22] Molecular hybridization reveals incorporation of viral DNA into both malignant and adjacent benign liver cells. The time to development of HCC in children after HBV infection is known to be shorter in children than in adults.

Pathology and Pathways of Spread

HBL is an embryonal tumor thought to arise from a hepatocyte precursor cell, and accounts for 60% to 75% of PMLTs of childhood.[23,24] Two subtypes are recognized; epithelial and mixed, with epithelial type further divided into fetal, embryonal, macrotrabecular, small-cell undifferentiated (SCU), and cholangioblastic variants. The SCU variant has a particularly poor prognosis and is often viewed distinctly for treatment decisions. Within the mixed type, stromal and teratoid variants are identified.[25]

There is a strong relationship between HCC and preexistent hepatic disease or cirrhosis. Fibrolamellar HCC is a variant found in approximately one third of pediatric HCC and typically in cases without preexisting liver disease.[25] This variant has sometimes been reported to have a higher rate of resectability and improved clinical outcome, though this was not supported by the Pediatric Intergroup Hepatoma INT-0098 results.[26]

Clinical Manifestations, Patient Evaluation, and Staging

The majority of children with PMLTs present with a painless right upper quadrant abdominal mass. Additional findings may include abdominal enlargement, pain, anorexia with associated weight loss, nausea, emesis, fever, and jaundice.

Initial evaluation consists of abdominal ultrasound with characteristic findings of a solid intrahepatic mass. Subsequent evaluation should include dual-phase CT of the abdomen and pelvis or axial and coronal MRI with gadolinium at arterial, portal venous, and equilibrium phases. CT of the chest is also required because lung metastases are present in approximately 20% of HBL cases and 30% of HCC cases. Bone scan is reserved for symptomatic patients.[27-29] Laboratory evaluation includes: complete blood count (CBC), differential, platelets, urinalysis, electrolytes including calcium, phosphate, magnesium, creatinine, ALT/AST, bilirubin and total protein/albumin. Alpha-fetoprotein (AFP) is elevated in approximately 90% of patients with HBL and between 60% and 80% of patients with HCC.[28,30] AFP levels less than 100 ng/mL have been associated with poor prognosis.

PMLTs of childhood are typically staged using the Children's Oncology Group Staging system (Table 75-1) and the PRETEXT surgical staging system (Figure 75-1). The PRETEXT staging is based on the number and relative locations of involved liver segments on preoperative imaging. The left lobe of the liver consists of a lateral sector (segments 2 and 3) and a medial sector (segment 4), whereas the right lobe is divided in an anterior sector (segments 5 and 8) and a posterior sector (segments 6 and 7). The number of affected liver

TABLE 75-1 Children's Oncology Group Staging System for Hepatoblastoma

Stage	Description
I	Completely resected localized tumors
II	Grossly resected tumors with microscopic residual tumor
III	Unresectable tumors (measurable residual tumor or abdominal lymph node involvement)
IV	Distant metastases

From Schnater JM, Kohler SE, Lamers WH, et al: Where do we stand with hepatoblastoma? A review. Cancer 98:668–678, 2003.

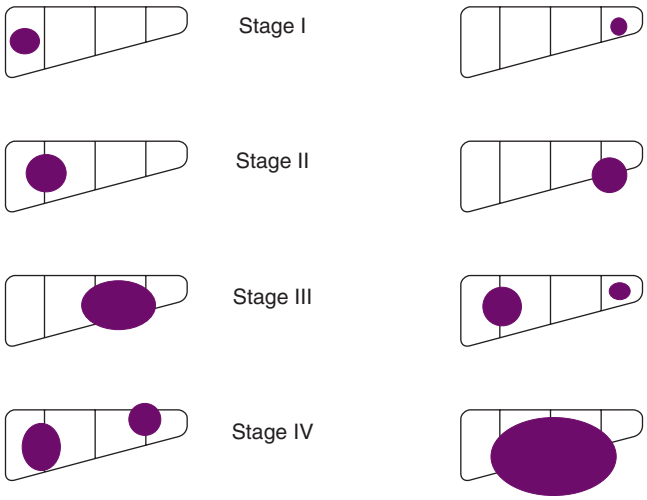

Figure 75-1 PRETEXT surgical staging system for hepatoblastoma. *Adapted from Schnater JM, Aronson DC, Plaschkes J, et al: Surgical view of the treatment of patients with hepatoblastoma. Results from the first prospective trial of the International Society of Pediatric Oncology Liver Tumor Study Group. Cancer 94:1111–1120, 2001.*

sectors determines the PRETEXT category.[27] Staging using the same criteria applied after two to four cycles of chemotherapy is referred to as POST-TEXT. Additional staging notations can be made for involvement of the vena cava or all three hepatic veins (+V), involvement of the portal vein bifurcation or both right and left portal veins (+P), involvement of the caudate lobe (+C), extrahepatic contiguous tumor (+E), and distant metastatic disease (+M).

Primary and Adjuvant Therapy and Results

Surgical resection is the primary treatment modality for PMLTs of childhood and provides the only potential for cure. Approximately half of patients with HBL are able to undergo complete resection at the time of diagnosis. Because HBL is highly chemosensitive, many patients are treated with neoadjuvant chemotherapy, which increases resectability to approximately 75%. Patients with HBL undergoing complete resection have an event-free survival (EFS) of approximately 90%.

The SIOPEL-1 trial reported by the International Society of Paediatric Oncology (SIOP) evaluated the use of four to six courses of preoperative cisplatin and doxorubicin. Eighty-two percent of patients showed at least a partial response and 77% achieved complete resection. The 5-year EFS and OS were 66% and 75%, respectively.[29] The third study of the International Society of Paediatric Oncology Epithelial Liver Tumor Group (SIOPEL-3) randomized patients to cisplatin alone versus cisplatin plus doxorubicin for three cycles preoperatively, followed by two postoperative cycles in children with HBL involving three or fewer liver segments and an alpha-fetoprotein level greater than 100 ng/mL. Outcomes at 3 years were identical: 95% and 93% underwent complete resection in the respective chemotherapy arms, and OS was 95% and 93%, respectively. Grade-3 and grade-4 toxicities were significantly more common in the combination arm.[31]

An analysis of stage I pure fetal histology (PFH) HBL treated with complete surgical resection only on Children's Oncology Group Study P9645 showed all patients free of disease at a median follow-up of 4.9 years.[26]

Children with HCC on the SIOPEL-1 trial presented with more advanced disease and fared significantly worse than patients with HBL. Partial response to neoadjuvant chemotherapy was seen in 49%, and complete resection was achieved in only 36%; 5-year OS and EFS were 28% and 17%, respectively.[28] The Pediatric Intergroup Hepatoma Protocol INT-0098 randomized patients with HCC to postoperative cisplatin/vincristine/5-fluorouracil versus cisplatin and doxorubicin. There was no difference in outcome between the treatment regimens, and the overall 5-year EFS was 17% (75% for stage I, 8% for stage II, and 0% for stage IV).[28] Subsequent SIOPEL studies evaluated a regimen of cisplatin and carboplatin, with no substantial improvement in outcome.[28]

The current COG study reduces chemotherapy for patients with low-risk disease with stage I non-pure fetal histology, non-SCU HBL or stage II non-SCU HBL to two adjuvant cycles of cisplatin, 5-flouorouracil and vincristine (C5V). Intermediate-risk cases with stage I SCU, stage II SCU, or any stage III are given six cycles of C5V + doxorubicin (C5VD).

Locally Advanced Disease and Palliation

Patients with high-risk HBL include those with stage IV disease as well as patients with any stage of HBL or initial AFP under 100 ng/mL. The Pediatric Oncology Group study 9345 treated children with unresectable or metastatic HBL with neoadjuvant carboplatin and C5VD, followed by surgery when feasible, or with high-dose cisplatin and etoposide. Thirty-six percent of patients with stage IV disease were able to undergo subsequent resection. For patients able to undergo resection, 5-years EFS was 79%.[32] The recent SIOPEL-4 trial was a single-arm prospective study for high-risk HBL using neoadjuvant dose-dense cisplatin plus doxorubicin. This approach yielded good outcomes with 74% of children able to undergo complete resection and an 83% 3-year OS.[33] Other approaches include orthotopic liver transplantation when disease is unresectable, with documented long-term survival in a limited number of patients.[27,32]

The approach for patients with metastatic disease uses neoadjuvant chemotherapy followed by surgery, if possible, and consideration of metastectomy if local control is achievable. For patients considered for orthotopic liver transplantation, radiographic clearance of metastatic disease must be confirmed before transplant.

Irradiation Techniques

RT is infrequently used in the treatment of PMLTs. Habrand et al used doses of 25 Gy to 45 Gy in conjunction with chemotherapy in a heterogeneous group of 15 patients; 11 with documented HBL, 2 with HCC, and 2 with unknown pathology. Those with inoperable HBL or minimal (<2 cm) disease postoperatively showed a possible benefit of radiotherapy. No benefit was seen for patients with HCC.[34] There are few current indications for hepatic irradiation or treatment beyond palliation to metastatic sites with HBL or HCC. The current Children's Oncology Group HBL study specifically excludes use of RT. It is clear that the RT dose ranges noted previously are less than those now known to be necessary in adults with HCC. Modern techniques of respiratory gating and stereotactic techniques may provide for additional options for RT of pediatric liver tumors in select cases.

Treatment Algorithms, Controversies, Challenges, and Future Possibilities

The cornerstone of treatment for PMLTs is surgical resection. Most children are treated with neoadjuvant and adjuvant platinum-based chemotherapy because of bulky disease. Orthotopic liver transplantation can provide cures for selected patients in whom resection is not possible. Investigational treatments for HBL include chemoembolization, stereotactic

radiosurgery to focal liver lesions, angiogenesis inhibitors, and biologic agents.

PEDIATRIC EXTRACRANIAL GERM CELL TUMORS

Etiology and Epidemiology

Germ cell tumors (GCTs) can be either malignant or benign and are thought to arise from primitive germ cells that fail to undergo complete differentiation. These tumors are found within the ovary and testis, but also among midline structures such as the sacrococcygeal region, retroperitoneum, mediastinum, and the pineal gland. The rationale for their distribution is attributed to embryologic development as cells migrate from the allantoic stock to the genital ridge, coming to rest as the genitalia.[35]

GCTs account for approximately 3% of all pediatric malignancies[35] and are the most common malignancy in neonates.[36] The overall incidence of GCTs is higher in females, but males are more at risk for malignant GCTs.[37] A bimodal age distribution is noted with peaks at 2 and 20 years of age.

Prevention and Early Detection

Several risk factors have been identified for these rare tumors. Intersex disorders of pseudohermaphroditism, androgen insensitivity, and 5α-reductase deficiency are associated with risk of gonadoblastoma, which can transform into GCT.[38] Undescended testis increases the incidence of testicular GCT to 30 to 50 times the incidence in the general population. This risk is even higher for intraabdominal testis.[39-41]

Biologic Characteristics and Molecular Biology

Pediatric GCTs are genetically distinct from adult GCTs. More than 80% of adult GCTs have isochromosome 12p and many of the remaining display amplification of 12p. These are infrequently observed abnormalities in pediatric GCTs,[42-44] where aberrations on chromosome 1 and 6 are more commonly identified.[43,44]

Pathology and Pathways of Spread

GCTs comprise a spectrum of entities from benign to malignant, with elements of multiple histologic types present in 25% of cases.[45] The most common pediatric GCT is the teratoma, which is composed of tissue from more than one embryonic layer. Teratomas can be either mature, consisting of well-differentiated tissues, or immature, consisting of immature elements (most commonly neuroepithelial tissue).

Yolk sac or endodermal sinus tumors are highly malignant, occur most commonly in the ovary, testis, and sacrococcygeal region and secrete alpha-fetoprotein. Histologically they show classic perivascular formations called Schiller-Duval bodies. Embryonal carcinomas are composed of large, pleomorphic undifferentiated cells. They often occur in combination with endodermal sinus tumors. Choriocarcinomas are rare tumors composed of malignant cytotrophoblasts and syncytiotrophoblasts. They typically secrete β-human chorionic gonadotropin. All three of these GCT types are highly undifferentiated tumors with the propensity to metastasize to lung, liver, bone, and lymph nodes. In a series of 95 patients with sacrococcygeal endodermal sinus tumors,[45] 15% had positive lymph nodes at diagnosis and 35% had distant metastases.

Tumors of undifferentiated germ epithelium are named according to the site of origin: seminomas originate in the testis, dysgerminomas in the ovary, and germinomas in the brain. Seminoma and dysgerminoma are infrequent in childhood.

Clinical Manifestations, Patient Evaluations, and Staging

Clinical manifestations of GCTs are largely dependent on the location of the tumor. The most common location for pediatric extracranial GCTs is the sacrococcygeal region, and because of their early presentation, they may sometimes be identified by fetal ultrasound. Older children more commonly present with large pelvic masses, with malignant degeneration often seen in children over 6 months to 12 months of age. The ovaries, testes, and mediastinum are also common sites, but GCTs can occur in the retroperitoneum, neck, stomach, and vagina as well. Laboratory evaluation includes complete blood count with differential, urinalysis, tumor markers (AFP, β-human chorionic gonadotropin, lactic dehydrogenase, CA-125), electrolytes, creatinine, bilirubin, ALT, alkaline phosphatase, total protein, albumin, phosphorus, magnesium, and calcium. Diagnostic imaging should include chest/abdomen/pelvis CT or MRI and often bone scan. Tumor marker profiles are indicative of different histologies as noted in Table 75-2.

Sacrococcygeal tumors are staged according to the Altman classification. Type I tumors are predominantly external projecting from the sacrococcygeal region and presenting with distortion of the buttocks. Type II tumors are predominantly external but also have a large intrapelvic component. Type III tumors are predominantly intrapelvic with a small external component, and Type IV tumors are entirely internal with no external or buttock component.[46]

Other GCTs are staged according to their site of origin as defined by the Children's Cancer Group and Pediatric Oncology Group staging system outlined in Table 75-3.

Primary Therapy, Adjuvant Therapy, and Results

Primary therapy is dictated by the resectability of the presenting lesion as well as the histology and thus anticipated response to adjuvant therapy options. For most malignant tumors a multidisciplinary approach combining surgery and

TABLE 75-3 Children's Cancer Group and Pediatric Oncology Group Staging System for Pediatric Germ Cell Tumors

Stage	Description
OVARIAN	
I	Limited to ovary (ovaries), peritoneal washings negative, tumor markers normal after appropriate half-life
II	Microscopic residual or positive lymph nodes (<2 cm), peritoneal washing negative, tumor markers positive or negative
III	Lymph node involvement >2 cm, gross residual disease, biopsy only, contiguous visceral involvement, peritoneal washings positive, tumor markers positive or negative
IV	Distant metastases
TESTICULAR	
I	Limited to testis, tumor marker normal after appropriate half-life, completely resected with high inguinal orchiectomy
II	Transscrotal orchiectomy, microscopic disease in scrotum or high in spermatic cord, retroperitoneal lymph node <2 cm, increased tumor marker after appropriate half-life
III	Retroperitoneal lymph node >2 cm, no visceral of extraabdominal involvement
IV	Distant metastases
EXTRAGONADAL	
I	Complete resection at any site, negative margins, coccygectomy for sacrococcygeal sites
II	Microscopic residual, lymph nodes negative
III	Gross residual or biopsy only, regional lymph nodes positive or negative
IV	Distant metastases

cisplatin-based chemotherapy (often similar to the adult PEB regimen of cisplatin, etoposide, and bleomycin) is standard.

Sacrococcygeal teratomas are approached with the goal to preserve the levator ani musculature and external sphincter using an inverted-V incision. Inadequate surgery has proven deleterious with a 37% local recurrence rate if the coccyx is spared inappropriately.[47]

Ovarian GCTs are chemosensitive and a conservative surgical approach is usually indicated. Resection of the primary tumor sparing the fallopian tumor if possible is combined with collection of ascites and examination and palpation of the peritoneal surfaces, retroperitoneal lymph nodes, omentum, and the contralateral ovary.[48] These fertility-sparring approaches have cure rates of approximately 95% with 80% of patients preserving reproductive function.[49]

Testicular tumors are removed via a high inguinal incision with high inguinal orchiectomy performed for malignant lesions and a more conservative tumor enucleation for teratoma.

Adjuvant therapy for extracranial GCTs is based on the stage, degree of resection, and histologic subtype (Table 75-4). Observation is recommended following resection of mature and immature teratomas with reported survivals of 82% to 100%.[47]

Resection of sacrococcygeal tumors with negative margins provides cure rates in excess of 90%, though this falls to 75% to 85% in the setting of microscopically involved margins, and 40% for macroscopic residual tumor.[50] There is minimal guidance for the use of RT in the adjuvant setting. A dose of ≥45 Gy

TABLE 75-4 General Treatment Guidelines for Extracranial Germ Cell Tumors

LOW-RISK DISEASE	
All teratomas Stage I gonadal Stage I extragonadal	Surgery and observation
INTERMEDIATE-RISK DISK	
Stages II-IV gonadal Stage II extragonadal	Surgery with adjuvant chemotherapy
HIGH-RISK DISEASE	
Stages III-IV extragonadal	Surgery with adjuvant chemotherapy

appears reasonable based on a report by Schneider et al.[51] Platinum-based chemotherapy has been advocated for patients with recurrent immature teratomas based on the POG 9048/CCG 8891 trial. Four of five patients with recurrence were rendered disease-free using this salvage approach.[52]

Locally Advanced Disease and Palliation

With a primary goal of resection, bulky and locally invasive disease is treated with neoadjuvant chemotherapy followed by surgery or second-look surgery as appropriate.

The POG 9049/CCG 8882 trial[53] randomized patients with stages III and IV gonadal and stages I to IV extragonadal GCTs to high-dose PEB versus standard-dose PEB with a 6-year EFS of 89.6% versus 80.5% but no benefit in OS. Progressive and metastatic GCTs often respond to cisplatin, paclitaxel, and ifosfamide regimens.[53] The COG AGCT0521 study used the regimen with carboplatin substituted for cisplatin with the goal to improve the toxicity profile. The addition of hyperthermia to resection for relapsed disease is being explored.[54]

Irradiation Techniques

The role of RT for GCTs has diminished significantly owing to the effectiveness of current chemotherapy regimens. RT is now used only in the setting of unresectable disease that is unresponsive to chemotherapy or in the setting of relapse. Radiation doses of ≥40 Gy are typically used.[51]

Treatment Algorithms, Controversies, Challenges, and Future Possibilities

Surgical resection is the first line of treatment with chemotherapy given neoadjuvantly to achieve this goal when possible and in cases of recurrent or metastatic disease. PEB chemotherapy is the currently recommended regimen for patients presenting as locally advanced or metastatic tumor with OS approaching 75%. Because of the high curability of these tumors, current protocols are seeking to decrease toxicity of therapy using algorithms based on histology, site, stage, and genetic aberrations to provide risk-adapted therapy.

JUVENILE NASOPHARYNGEAL ANGIOFIBROMA

Etiology and Epidemiology

Juvenile nasopharyngeal angiofibroma (JNA) is a highly vascular tumor that is histologically benign but locally invasive.

JNA occurs almost exclusively in adolescent boys and young adult men, suggesting a prominent hormonal role in the tumor's etiology; the average age at diagnosis is 17 years.[55,56] The incidence of this tumor is approximately 3.7 per million in the population at risk.[57] There is an increased incidence of JNA in patients with familial adenomatous polyposis, suggesting a connection to the β-catenin pathway.[58]

Biologic Characteristics and Molecular Biology

Both androgen and estrogen receptors have been demonstrated in JNAs.[59,60] Recently, estrogen beta-adrenergic receptors have been found in a high percentage of JNAs. Schlauder et al[60] have postulated that the presence of aromatase in tumor cells converts endogenous androgens to estrogens, causing tumor growth via an autocrine-like mechanism.[61] Most tumors stain for vascular endothelial growth factor, and approximately 40% have a GSTM1 mutation.[62]

Pathology and Pathways of Spread

JNA is a benign tumor, although its exact nature is controversial. Some have suggested that it is a vascular hamartoma and similar to a hemangioma,[63] but others believe it is neoplastic.[64] Histologically, tumors are composed of fibrous connective tissue with abundant endothelium-lined vascular spaces.[63] Localization of β-catenin to tumor stromal cells suggests these may be the neoplastic component rather than the endothelial cells.[65] Tumors typically arise from the superior margin of the sphenopalatine foramen and invade laterally through the pterygomaxillary fissure toward the infratemporal fossa.[55] Intracranial extension is seen in up to a third of cases, although actual dural invasion is uncommon.[66,67] Tumors can be locally invasive of bone and extend into the parapharyngeal spaces, paranasal sinuses, orbit, and base of skull. This pattern of spread predicts for a high risk of local recurrence.[67] Blood supply is primarily from the internal maxillary arteries of the external carotid system.

Clinical Manifestations, Patient Evaluation, and Staging

Presenting symptoms include recurrent painless spontaneous epistaxis, nasal obstruction, nasal discharge, a reduced sense of smell, snoring, headache, cranial nerve palsies, and facial swelling.[56] Angiography is essential to define the tumor's blood supply for planning surgery and, typically, for preoperative embolization to decrease surgical blood loss. There are usually multiple tortuous feeding vessels with a dense, homogeneous blush in the capillary phase.[68] CT and MRI help define the anatomic extent of the enhancing tumor. Distant metastases do not occur, so systemic evaluation is not required. Biopsy can be hazardous owing to the tumor's vascularity; not all authors require biopsy confirmation before treatment if clinical and radiographic data are consistent with the diagnosis.[69]

Several staging systems have been proposed (Table 75-5). Most are designed to guide decisions regarding the resectability and optimal surgical approach to the tumor rather than to predict prognosis.[69-73]

TABLE 75-5 Staging Systems for Juvenile Nasopharyngeal Angiofibroma

ANDREWS STAGING SYSTEM[36]	
Stage I	Tumor limited to the nasal cavity and nasopharynx
Stage II	Tumor extension into the pterygopalatine fossa, or maxillary, sphenoidal, or ethmoidal sinuses
Stage IIIa	Extension into the orbit or infratemporal fossa without intracranial extension
Stage IIIb	Stage IIIa with minimal extradural intracranial extension
Stage IVa	Extensive extradural intracranial or intradural extension
Stage IVb	Extension into cavernous sinus, pituitary, or optic chiasm
CARRILLO STAGING SYSTEM[34]	
Stage I	Tumor limited to nasopharynx, nasal fossae, maxillary antrum, anterior ethmoid cells, and sphenoidal sinus
Stage IIa	Invasion to pterygomaxillary fossae or infratemporal fossae anterior to pterygoid plates, with major diameter <6 cm
Stage IIb	Invasion to pterygomaxillary fossae or infratemporal fossae anterior to pterygoid plates, with major diameter ≥6 cm
Stage III	Invasion to infratemporal fossae posterior to pterygoid plates or posterior ethmoid cells
Stage IV	Extensive skull base invasion >2 cm or intracranial invasion
CHANDLER STAGING SYSTEM[37]	
Stage I	Tumor confined to the nasopharynx
Stage II	Tumor extending into the nasal cavity or sphenoidal sinus
Stage III	Tumor involvement of one or more of the maxillary or ethmoidal sinuses, pterygomaxillary and infratemporal fossae, and orbit or cheek
Stage IV	Tumor extending into the cranial cavity
FISCH STAGING SYSTEM[35]	
Type I	Tumor limited to the nasopharynx and nasal cavity with no bone destruction
Type II	Tumors invading the pterygomaxillary fossa and the maxillary, ethmoidal, and sphenoidal sinuses with bone destruction
Type III	Tumors invading the infratemporal fossa, orbit, and parasellar region remaining lateral to the cavernous sinus
Type IV	Tumors with massive invasion of the cavernous sinus, optic chiasmal region, or pituitary fossa

Primary and Adjuvant Therapy and Results

Surgical removal, often preceded by tumor embolization, is the primary treatment for JNA. A craniofacial approach is used for locally advanced tumors. Endoscopic techniques have less morbidity and are effective for earlier-stage lesions.[55] Gross total removal is usually curative.[66] A number of cases prove not to be amenable to complete resection; depending on case selection, there is a rate of local recurrence after surgery that approximates 20% to 40%, with most recurrences occurring in large, incompletely resected lesions.[55,56] Moderate doses of RT may be indicated for postoperative residual tumor, although observation is more often considered because spontaneous involution of tumor is a well-recognized phenomenon.[74,75] Most recurrences present within a year of surgery. The risk of recurrence is greatest in patients with large tumors that erode the skull base, young age at presentation, and irradiated tumors that are slow to regress.[68,76] There are

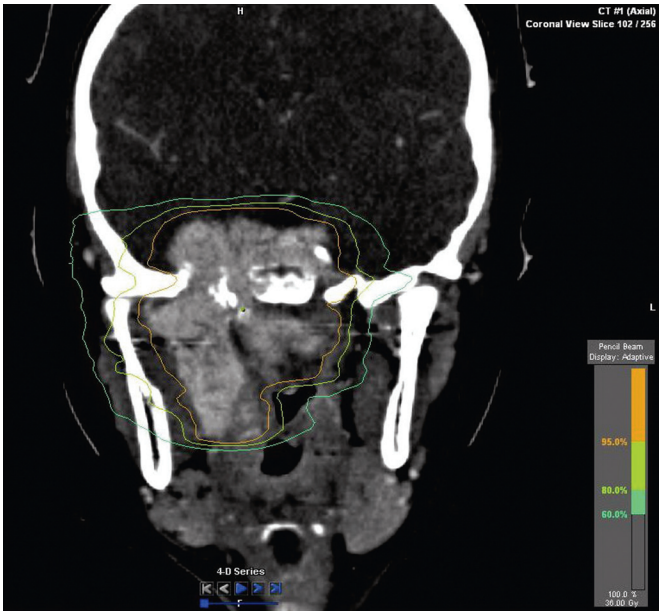

Figure 75-2 Intensity-modulated radiation therapy (IMRT) isodose plan for a patient with juvenile nasopharyngeal angiofibroma.

currently no indications for adjuvant chemotherapy after initial resection.

Locally Advanced Disease and Palliation

RT can provide effective control for recurrent or large, unresectable tumors. Objective tumor response after RT is typically slow, but ultimate control rates range from 75% to 92%[77]; 90% of responders have no residual tumor 3 years after treatment.[78] Given the strong association of JNA with hormonal receptors, there has been interest in hormonal manipulation for patients with advanced disease. Diethylstilbestrol and flutamide have been used, but results have been inconsistent.[68,79,80] A recent trial supports the use of flutamide in postpubertal patients with 13 of 15 patients showing a partial radiographic response to this agent.[81] Case reports of chemotherapy for recurrent tumor show efficacy for doxorubicin, dactinomycin, vincristine, cyclophosphamide, and cisplatin in selected patients.[82-84]

Techniques of Irradiation

No radiation dose-response curve has been reported for JNA. Local control rates greater than 80% are seen with doses ranging from 30 Gy to 50 Gy,[69,85-89] and a dose of 36 Gy is commonly used. Intensity-modulated RT (IMRT) techniques provide high conformality for sparing of normal structures (Figure 75-2). Stereotactic radiosurgery using single doses of 17 Gy to 20 Gy and hypofractionated RT using 45 Gy in three fractions have been reported effective in small series of patients.[90]

Treatment Algorithms, Controversies, Challenges, and Future Possibilities

Preoperative embolization is followed by maximal surgical resection. Postoperative residual tumor can be observed or treated with RT. Recurrent tumor can be managed with RT. Hormonal manipulation and cytotoxic chemotherapy may be tried for recurrent, refractory disease. The elevated levels of vascular endothelial growth factors in these tumors suggest a potential role for inhibitors of angiogenesis.[91]

PLEUROPULMONARY BLASTOMA

Etiology and Epidemiology

Pleuropulmonary blastoma (PPB) is a dysontogenetic neoplasm of childhood that originates in the lung or pleura.[92] Although rare, it is the most common primary lung tumor in children.[93] It is analogous to other dysontogenetic tumors such as Wilms' tumor, neuroblastoma, and hepatoblastoma.[94]

PPB is thought to progress through a distinct sequence of clinical and pathologic changes beginning as a relatively nonaggressive cystic lesion and subsequently developing into the more malignant mixed cystic/solid and purely solid morphologies.[95] Median age at presentation is 3 years.[96] Younger children typically present with predominantly cystic tumors, whereas older children are more likely to have significant solid components.[97] Boys and girls are equally affected.[97] Siblings of patients with PPB have a higher incidence of PPB than the general population, and mutations of in *DICER1* have been found in many of these families.[98] There is also an increased incidence of other types of dysplasia and neoplasia in relatives of children with PPB.[99]

Prevention and Early Detection

The incidence of PPB in apparently benign lung lesions such as congenital cystic adenomatoid malformations is approximately 4%.[100] However, cystic PPB is clinically indistinguishable from benign cysts, and some authors recommend excision of all such lesions.[101] Further supporting this approach is evidence that PPB can arise de novo from lung cysts, so that resection of these "precancerous" lesions is indicated.[102,103] Others advocate a policy of watchful waiting for purely cystic lesions, only intervening if radiographic changes suggest progression.

Biologic Characteristics and Molecular Biology

Germline mutations of *DICER1*, a gene coding for an endoribonuclease involved in regulation of mesenchymal proliferation, have been identified in families affected by PPB.[98] *TP53* mutations have been described in PPB and may portend a worse prognosis.[104] Polysomy of chromosome 8 has also been noted.[105]

Pathology and Pathways of Spread

Histologically, PPB has small, primitive blastemal cells separated by an uncommitted sarcomatous stroma.[94,97,106] Tumor cells stain with vimentin and may show myogenic differentiation.[93] Rhabdomyoblasts and cartilage nodules are reported in 40% to 50% of patients.[101]

Tumors usually arise in the lung parenchyma. Spread to contiguous structures such as the mediastinum and pleura is associated with a poorer prognosis. Invasion into the chest wall is uncommon.[107] Hematogenous metastases occur, most often to the brain. In one series,[92] the incidence of brain metastases was 11% in mixed cystic/solid tumors and 54% in purely solid tumors.

Clinical Manifestations, Patient Evaluation, and Staging

Presenting symptoms of PPB include cough, dyspnea, wheezing, symptoms of respiratory infection, and occasionally, spontaneous pneumothorax. Chest CT usually reveals a heterogeneous low-attenuation mass with pleural effusion and

mediastinal shift.[107] Differential diagnosis includes rhabdomyosarcoma, Askin tumor, and nonrhabdoid sarcomas; examination of the cystic fluid or solid tumor is required to make a diagnosis. Bone scintigraphy and MRI of the brain should be performed for staging, especially for tumors with a significant solid component.

PPB has no anatomic staging system but is classified into three morphologic types that have prognostic significance. Type I consists of purely cystic tumors, type III lesions are solid tumors, and type II have mixed cystic and solid components.[108] Both type II and type III tumors have significantly poorer prognosis than type I, with an incidence of distant metastases at diagnosis approximating 30%.[96] A fourth type, type Ir (type I, regressed), has been described for cystic lesions without a neoplastic component, hypothesized to have "regressed" from an earlier type I PPB, or alternatively, represent a genetically determined lung cyst that has not yet evolved along a dysplastic path.[109]

Primary and Adjuvant Therapy and Results

Surgery is the cornerstone of management, although most patients cannot undergo gross total resections owing to involvement of critical structures.[96,106] Neoadjuvant chemotherapy can be used in large tumors to render the tumor resectable; adjuvant chemotherapy is often given postoperatively to patients with types II and III tumors. Chemotherapy may improve survival in type I tumors,[95,109] although it is not generally recommended if the tumor is completely resected.[96] Drug regimens parallel those used for other pediatric sarcomas and include ifosfamide/carboplatin/etoposide (ICE regimen), and ifosfamide/vincristine/dactinomycin (Actinomycin-D)/doxorubicin (IVADo regimen). Other active drugs include irinotecan[110] and cisplatin.[97] RT may be indicated in unresectable tumors, although large treatment volumes and young patient age often hinder the use of this modality.[111] Five-year survival rates are approximately 80% for patients with type I tumors and 45% for patients with types II and III.[96,97,106]

Locally Advanced Disease and Palliation

In patients who experience a recurrence, local relapse is somewhat more common than distant failure.[96] When type I tumors recur, they usually recur as types II or III.[95,101] Re-resection should be performed when possible, but second-line chemotherapy is often the primary treatment owing to the extent of disease. RT may be useful for brain metastases and palliation of painful bone lesions.

Irradiation Techniques

Fractionated external beam RT using a dose of 44 Gy has been recommended for incompletely resected tumors, although its role in local control is difficult to assess.[96,106] Normal tissue tolerances may preclude this amount of irradiation; use of a lesser dose may be required in circumstances in which volume and dose exceed organ tolerance. Microscopic margins were controlled in one case report using 36 Gy,[97] but local recurrence was reported after 30 Gy in 10 fractions in a patient with gross tumor.[112] Intracavitary phosphorus-32 has also been used and may contribute to local control in selected patients.[106]

Treatment Algorithms, Controversies, Challenges, and Future Possibilities

Initial resection is performed if possible. Neoadjuvant chemotherapy is used when initially unresectable, followed by delayed surgery. Adjuvant chemotherapy is indicated for most patients. RT should be considered for microscopic or gross residual tumor after surgery. Children should be followed with chest CT at 3-month to 6-month intervals for 2 to 3 years.

HEMANGIOMAS AND LYMPHANGIOMAS

Etiology and Epidemiology

Although often considered together, hemangiomas and lymphangiomas are clinically and histologically distinct entities. Many semidescriptive terms have been applied to these lesions (especially the cutaneous hemangiomas), contributing to confusion regarding their study and management. Synonyms for cutaneous hemangioma include "neonatal stain," "stork bite," "salmon patch," "spider angioma," and "strawberry angioma."

Hemangiomas occur in about 1% of infants, most often during the first few months of life, with about a third of these presenting in the head and neck.[113] Lymphangiomas are much less common, with an incidence between 1 in 6,000 and 1 in 16,000 live births.[114] Half are congenital; 90% are evident before the age of 2 years. Three fourths of lymphangiomas occur in the neck or head areas.

Pathology and Pathways of Spread

Hemangiomas consist of thin-walled vessels lined by endothelial cells and a discontinuous layer of pericytes and reticular fibers.[115] They have been reported to occur in a wide variety of locations, including the skin, liver, bone, central nervous system (CNS), bladder, trachea, and other soft tissues.[116] Lymphangiomas are dilated endothelial-lined lymph channels with thick walls containing smooth muscle.[117] Lymphangiomas can involve the skin, skeletal tissue, spleen, liver, mediastinum, or lung.[118] Hemangiomas and lymphangiomas classically are malformations or low-grade and benign neoplasms with no capacity for metastasis.

Clinical Manifestations, Patient Evaluation, and Staging

Hemangiomas are classified as capillary, cavernous, or mixed, depending on the size of the vessels involved. When they involve the skin, capillary hemangiomas are often raised, circumscribed red lesions. They usually present early in the first year of life, and the great majority undergo spontaneous involution over the subsequent years. They are distinct from vascular malformations such as port-wine stains, which do not regress.[113] Clinical manifestations of hemangiomas are largely dependent on the location of the lesion and can include cosmetic deformity, functional impairment, airway obstruction, bleeding, infection, and high-output cardiac failure. Kasabach–Merritt syndrome describes a giant hemangioma causing thrombocytopenia due to consumption coagulopathy.

Lymphangiomas are also categorized according to the size of the abnormal lymph vessels. Lymphangioma circumscriptum contains relatively small-caliber lymph channels and is usually superficial in location. Cystic hygroma or cavernous lymphangioma consists of large, cystic areas of lymph fluid arising in deeper tissues. Unlike hemangiomas, lymphangiomas do not tend to regress spontaneously and may enlarge during adolescence.[119] Symptoms of lymphangiomas can include disfigurement, pain, infection, and complications of chronic lymph secretion. Lymphangiomas occurring in the mediastinum may cause chylothorax, which can be life threatening.

Classification schemes have been proposed for these lesions, but there is no widely accepted staging system.[115,120]

Primary and Adjuvant Therapy and Results

RT was the mainstay of therapy for both hemangiomas and lymphangiomas through the early 1950s and, in some centers, into the 1970s. Subsequently, the use of RT has been all but abandoned as the natural history of spontaneous involution of hemangiomas was recognized and the late morbidities of RT were reported.[121]

Spontaneous involution will occur in 95% of capillary hemangiomas over the course of several years; most require no treatment.[122] Cavernous hemangiomas do not usually regress spontaneously and require treatment if symptomatic.[115] For symptomatic hemangiomas, topical or intralesional corticosteroids are often the first line of treatment.[123] Systemic corticosteroids are also effective.[113] Surgical resection is an effective treatment in appropriate circumstances. Other treatments include interferon, laser ablation, cryotherapy, compression, electrocautery, and embolization. Other pharmacologic interventions include antiangiogenic and antifibrinolytic agents. Irradiation for hemangiomas with life-threatening complications can be performed and is often effective, with improvement or resolution occurring in more than 80% of patients.[116,124]

Surgical removal of lymphangiomas is curative, although can be cosmetically or functionally morbid in many anatomic sites. Sclerotherapy using agents such as OK-432 or bleomycin is a common nonsurgical treatment, with complete responses seen in about 40% of patients and partial responses in another 40% to 45%.[114] Other nonsurgical therapies include diathermy, cryotherapy, and interferon alfa-2b.[118] RT has also been used with some efficacy in selected patients.[119,125-127]

Locally Advanced Disease and Palliation

Mortality from Kasabach–Merritt syndrome can exceed 10%. Large hemangiomas causing coagulopathy or cardiac failure require aggressive treatment.[128] RT may be useful when other modalities fail.[129] Fractionated RT to doses of 10 Gy to 20 Gy has been effective in these life-threatening situations.[116,124,128,129] Tumors such as lymphangiosarcoma and malignant hemangioendothelioma are highly aggressive neoplasms and require multimodality treatment (Figure 75-3).[130,131]

Irradiation Techniques

Although the efficacy of RT for these conditions is well established, the availability of other effective treatments and the concern for late effects of irradiation in this young patient population appropriately limit RT to a seldom-used option today.[122,132] No definite dose-response relationship has been established for the treatment of hemangiomas, and fractionated radiation doses ranging from 3 Gy to 40 Gy have been recommended.[116,128] Braun-Falco et al[122] reported a large series of patients with hemangiomas; most were treated with fractionated radiation doses between 12 Gy and 25 Gy. Responses were seen in 73% of patients, with complete responses in 50%. Some have reported good results, with lower doses of 3 Gy to 11 Gy,[133] although others recommend a dose of at least 25 Gy.[134] Partial improvement after RT can often be noted within a few weeks, but maximum response can take several months to years.

Lymphangioma has been successfully treated with 10 Gy to 20 Gy of fractionated RT.[119,126,127] Responses can be seen much more quickly in lymphangiomas than in hemangiomas.

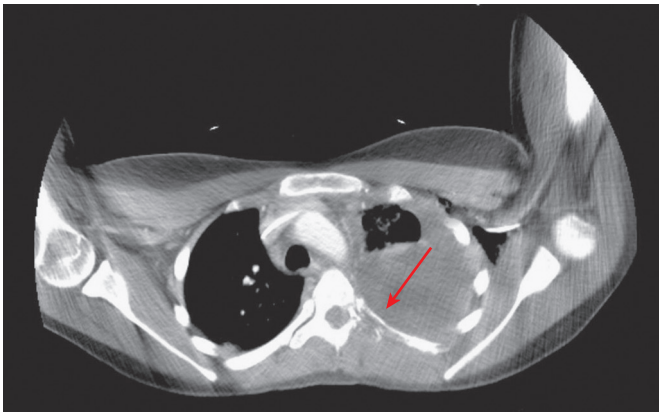

Figure 75-3 Lymphangiosarcoma in a 16-year-old girl arising from a preexisting lymphangioma. The patient's pain and chylous effusion were effectively palliated using 30-Gy radiotherapy. *Arrow* references primary site evident by bony erosion.

Treatment Algorithms, Controversies, Challenges, and Future Possibilities

Observation is usually indicated for hemangiomas. When treatment is required, corticosteroids or locally ablative treatment such as surgery or embolization can be used, as well as systemic agents. RT may be indicated for life-threatening situations. Lymphangioma is usually treated with surgical resection or sclerosing agents such as OK-432. RT, again, is reserved for life-threatening circumstances.

DESMOPLASTIC SMALL ROUND CELL TUMOR

Etiology and Epidemiology

Desmoplastic small round cell tumor (DSCRT) is a rare disease diagnosed in children and young adults at a median age of 22 years (range, 6 years to 49 years). DSCRT was first described by Gerald et al and Park et al in 1991.[135,136] There is a strong male to female predilection ranging from 5:1 to 20:1.[137] Approximately 200 cases have been reported in the literature.[135,138]

Biologic Characteristics and Molecular Biology

A t(11;22)(p13;q12) translocation is the predominant cytogenetic abnormality in DSRCT and breakpoint mapping has demonstrated that all chromosome 11 translocation breakpoints involve intron 7 of the Wilms' tumor gene *WT1*. The *EWS/WT1* fusion gene is used as a specific marker for the diagnosis of DSRCT.[139,140]

Pathology and Pathways of Spread

DSRCT arises from the serosal lining of the body cavities and visceral organs. It is histologically described as nests of small round blue cells separated by desmoplastic stroma. Tumor cells are typically small to medium-sized with round to oval hyperchromatic nuclei and scant to moderate cytoplasm with indistinct cell borders. Larger cells are less commonly present.

There is often significant heterogeneity in differentiation with immunohistochemical reactivity for epithelium (epithelial membrane antigen), mesenchyme (vimentin), myogen (desmin), and neurons (neuron-specific enolase, CD56).[141]

Clinical Manifestations, Patient Evaluation, and Staging

DSRCT usually presents with diffuse abdominal metastatic disease (Figure 75-4). Extensive peritoneal surface involvement results in poor absorption of intraperitoneal fluid and

the build-up of ascites results in symptoms of abdominal fullness and distension, with constipation, weight loss, loose stool, and jaundice. Other primary sites include bone,[142] paratestes,[143] CNS,[144] kidney,[145] and pleura.[146] Common sites of metastases are the intrathoracic cavity, mediastinum, pleura, paratesticular region, and soft tissues.[138]

Initial work-up includes CT or MRI of the chest, abdomen and pelvis with consideration for PET/CT. Extensive disease at presentation often precludes complete resection leading to open biopsy as the usual diagnostic procedure. Though a staging system has been proposed,[147] none has been widely accepted, and essentially all cases are considered "stage 4" with dissemination at the time of diagnosis.

Primary and Adjuvant Therapy and Results

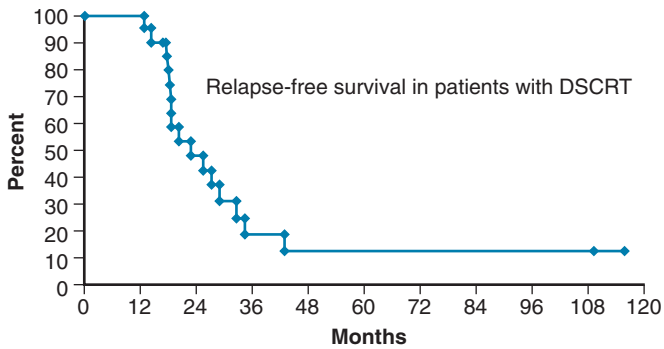
Although no universally accepted treatment recommendation exists for DSRCT, treatment usually begins with an alkylator-based chemotherapy regimen such as cyclophosphamide, doxorubicin, and vincristine alternating with ifosfamide and etoposide. This is followed by aggressive surgical debulking, whole-abdomen RT and targeted RT to high-risk sites, and autologous stem-cell transplantation. Median survival with this approach is 19 months.[148] Lal et al reported 3-year survival of 58% in patients who underwent aggressive tumor debulking versus 0% for those who did not, illustrating the importance of surgery in the management of DSRCT.[149] Hyperthermic intraperitoneal chemotherapy perfusion, typically with cisplatin, has also been used with reports suggesting a survival benefit with this approach.[138] Liver metastases have been treated using yttrium-90 with radiographic response.[150] Although radiographic and clinical response is frequent with aggressive therapy, long-term prognosis remains poor with 5-year survival of approximately 15%[149,151] (Figure 75-5).

Figure 75-4 Desmoplastic small round cell tumor in a 12-year-old boy. There is extensive caking of the omentum as well as metastases to the liver and spleen.

Irradiation Techniques

RT plays an important role in the trimodality treatment of DSRCT. In a series of patients from Memorial Sloan Kettering Cancer Center, 3-year survival was 55% for those receiving chemotherapy, surgery, and RT versus 27% when fewer than three modalities were used.[149] Because of typical presentation with extensive abdominal disease and serosal spread, whole-abdomen radiotherapy is the most commonly applied approach. Whole-abdomen dose is typically 30 Gy guided primarily by normal tissue tolerance. With IMRT or conformal techniques, boost of gross disease to 45 Gy should be considered. Kidney dose of approximately 15 Gy whole organ and 20 Gy to 50% volume as well as liver dose of 24 Gy whole organ and 30 Gy to 50% volume are typical dose constraints.

Treatment Algorithms, Controversies, Challenges, and Future Possibilities



The current treatment algorithm for DSRCT consists of biopsy followed by neoadjuvant chemotherapy, second-look debulking surgery, and whole-abdominal RT with boost to bulk disease. Hyperthemic intraperitoneal chemotherapy is being investigated in Phase II trials and autologous bone marrow transplant has also been used.[147,148,152]

Targeted biologic therapies either upfront or at time of relapse are being considered for immunohistochemically positive for markers such as placental alkaline phosphatase, *ERBB2*, androgen receptor, and c-KIT.[153] Additionally, there are case reports of antitumor activity for bevacizumab[151] and trastuzumab.[153]

LANGERHANS CELL HISTIOCYTOSIS

Etiology and Epidemiology

Langerhans cell histiocytosis (LCH) refers to the spectrum of diseases arising from clonal proliferation of the CD1a and

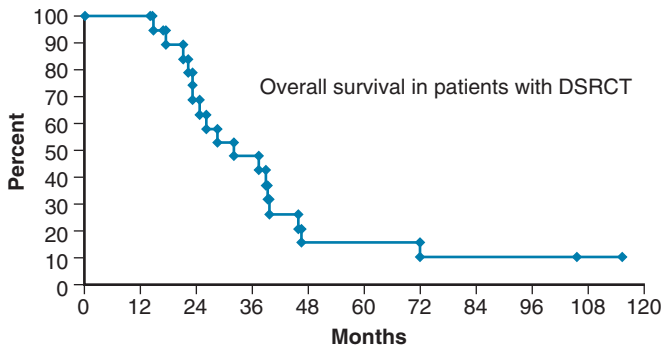


Figure 75-5 Disease-free survival and overall survival for desmoplastic small round cell tumor (DSRCT).
Data from Goodman KA, Wolden SL, La Quaglia MP, et al: Whole abdominopelvic radiotherapy for desmoplastic small round-cell tumor. Int J Radiat Oncolog Biol Phys 54:170–176, 2002.

CD207 positive reticuloendothelial Langerhans cell. The historical name "histiocytosis X" was coined in the 1950s to indicate the histiocytic origin of the disease, with the "X" reflecting the mysterious clinical spectrum of disease presentation.[154] This designation was replaced by the term LCH in 1987.[155] LCH has an incidence of between 1 and 5 cases per million in the United States with approximately 1200 cases diagnosed each year.[156] Most children are under 15 years old at the time of diagnosis with a peak incidence between 1 and 4 years of age. There is a 2:1 male predominance with a slightly higher incidence in Caucasians. The precise etiology of LCH is unknown.[156,157] Some have posited it may be caused by a viral infection, possibly human herpes virus 6 (HHV-6), although this has been disputed. Additionally, abnormalities in the intracellular communication between T cells and macrophages as well as irregularities in cytokine regulations have been proposed as etiologic mechanisms.[158-162]

Biologic Characteristics and Molecular Biology

The origin of LCH is believed to be the epidermal Langerhans cell. A clonal disorder, it is known to spontaneously regress in some patients and prove fatal in others. Most cases arise spontaneously, although there are rare genetic forms of the disease associated with specific cytokine gene variants that tend to occur early with multifocal disease.[163-165]

Pathology and Pathways of Spread

Histiocytic disorders have been classified into three groups by the Histiocyte Society: dendritic cell histiocytosis, macrophage-related disorders, and malignant histiocytosis with LCH falling into the first group.

Although the clinical manifestations of LCH can be quite varied, the pathology has more consistent characteristics. The presence of Langerhans cells is the hallmark of LCH. They are usually accompanied by macrophages, eosinophils, multinucleated giant cells, and T-cells.[166,167] The pathognomonic Langerhans cell is a large ovoid cell with a folded nucleus and a slightly eosinophilic cytoplasm. Birbeck granules can be visualized with electron microscopy. Expression of langerin (CD207) is the most specific marker. Additionally, cytoplasmic S-100 protein positivity and positivity of major histocompatibility (MHC) class II and CD1a are usually present.[168]

Clinical Manifestations, Patient Evaluation, and Staging

LCH is often grouped into three distinct entities that have different clinical presentations and prognoses. These distinctions are somewhat artificial, however, because there is a continuous spectrum of protean disease presentations. Approximately 30% of patients present with unifocal lytic lesions of bone known as eosinophilic granuloma.[169] These lesions occur in older children and commonly involve the skull. They can be painful and cause swelling and fractures, though they may also be incidentally identified.[170] This form of LCH is usually indolent and easily treated. Hand–Schüller–Christian disease is intermediate in severity. It presents as a triad of exophthalmos, skull lesions, and diabetes insipidus and occurs at a somewhat younger age.[171] Letterer–Siwe disease is the most aggressive form of LCH. It is typically seen in children younger than 3 years of age and involves multiple organ systems. Common presentations include splenomegaly, lymphadenopathy, anemia, and blood dyscrasias with diffuse skeletal involvement. These children may have fever, popular rash, and cachexia. The prognosis of this presentation is poor.

There is no uniform staging system for LCH. Children are generally grouped by burden of disease such as number of lesions involved, single or multiple organ involvement, and "non-risk sites" (skin, bone, lymph nodes) versus "risk sites" (liver, spleen, lung, bone marrow). Those with "risk sites" involved are now often considered as having "high-risk" LCH versus others considered to have "low-risk" disease.[169,172] A Turkish study of 217 patients reported 41.5% of patients with single-system disease, 34.1% with multiple-system disease, and 24.4% with multiple-system disease with organ dysfunction.[170]

Workup should include skeletal survey as lesions are typically lytic and bone scintigraphy, although recommended, may not detect some lesions. Visceral disease status is evaluated by CT or MRI of the chest and abdomen, and brain MRI to rule out CNS involvement. PET/CT can be used to assess lymphatic involvement and may be more specific for bony lesions.[173] Bone marrow biopsy is recommended in cases with cytopenias. Diabetes insipidus evaluation via urine specific gravity and osmolality should also be performed. Liver biopsy may be indicated in cases with elevated liver function tests (LFTs). Pulmonary function tests and high-resolution CT are indicated when pulmonary involvement is suspected.

Primary and Adjuvant Therapy and Results

LCH involving a solitary bone may be appropriate for observation as spontaneous regression is possible. More frequently local therapy with surgical curettage or corticosteroid injection is used. RT is effective as well, though less frequently used. These local therapy modalities have an excellent outcome for unifocal disease with a cure rate of 94% reported by Titgemeyer et al.[174] Limited skin involvement can be treated with topical steroids or photodynamic therapy.

Locally Advanced Disease and Palliation

Multifocal disease is treated with systemic therapy. Risk-adapted regimens using combinations of vinblastine, etoposide, and prednisone are usually prescribed.[175] Risk is based on age, extent of multifocal disease, and critical organ involvement. Early response to chemotherapy has been identified as a prognostic indicator with multisite patients responding to therapy at 6 weeks having a 92% OS and non-responders 11% OS.[175] In non-responders and refractory disease, stem-cell transplantation has been used.[176,177]

Irradiation Techniques

The use of radiotherapy in the treatment of LCH has steadily declined because of the effectiveness of alternative treatments and concerns for late RT effects in this young patient population. Current considerations for the use of RT include lesions where surgical intervention would have potential morbidity or in cases of lesions refractory to other treatments. Low-dose RT for bone lesions has been consistently effective with 88% to 96% local control reported for doses of 6 Gy to 15 Gy (median, 9 Gy).[178,179] RT has also been used for diabetes insipidus secondary to LCH. Doses of 15 Gy to 20 Gy to the sellar/hypothalamic area have been used, and when given within 1 to 2 weeks of onset, 25% to 35% of patients show biochemical improvement.[180-182]

Treatment Algorithms, Controversies, Challenges, and Future Possibilities

Overall, most patients enjoy a favorable prognosis. Unfortunately, there are a minority of children (up to 20% to 30%) with

extensive organ involvement who succumb to LCH within 5 years. Targeted therapy and immune modulators have been evaluated in small studies including anti-CD1a antibodies, cytokine inhibitors, alemtuzumab, low-dose oral cyclophosphamide, and all-trans retinoic acid.[183-185] Imatinib and B-raf inhibitors have also been studied.[186-188] The Histiocyte Society and its website is a frequently updated resource for ongoing clinical trials and emerging information on LCH.[189]

NASOPHARYNGEAL CARCINOMA

Etiology and Epidemiology

Pediatric nasopharyngeal carcinoma (PNC) is a rare tumor with an incidence and histologic subtype that varies significantly based on geographic location.[190]

In children, the median age at diagnosis is 13 years and there is a 2:1 male predominance.[191,192] Comparisons are often made between the adult and juvenile variants of nasopharyngeal carcinoma (NPC), and indeed much of the treatment regimens for PNC have been extrapolated from adult data owing to the rarity of the pediatric tumors. The diseases are similar in their relationship to EBV infection, to diets containing nitrites and salted fish, and to the male predominance. Additionally, certain human leukocyte antigen (HLA) subtypes are associated with an increased risk of NPC.[193,194] However, in children, the greatest incidence occurs in the Mediterranean and North America regions rather than China, Southeast Asia, and Alaska; undifferentiated histology is the most common type; and patients present with significantly more advanced disease at diagnosis. In one retrospective series, 92% of pediatric patients had stages III to IV disease versus 67% of adults. However, data show that despite higher stage disease, children have a better overall prognosis in both OS and locoregional disease control.[195-197]

Biologic Characteristics and Molecular Biology

EBV has been a long established etiologic factor for the development of NPC and is associated with 90% of PNCs, particularly the undifferentiated and nonkeratinizing types. The relationship between EBV and NPC was confirmed when EBV DNA was found in neoplastic epithelial cells but was absent in the surrounding lymphocytes.[198] The EBV genome is a double-stranded DNA virus encoding 100 genes, only 10 of which are expressed in latently infected cells in vitro. Of these, six are nuclear proteins (EBNAs), two are latent membrane proteins (LMPs), and two are nontranslated RNA molecules (EBER) that likely aid in cell growth. In NPC, latent membrane protein 1 (LMP1) acts as an oncogene, changing growth patterns and upregulating proteins that inhibit apoptosis, including BCL2.[190] Although BCL-2 is highly expressed in ~80% of adults with NPC, it is likely not associated with pediatric NPC.[199,200] LMP1 also binds to various proteins associated with tumor necrosis factor receptors and is involved in activation of transcription factors, cellular adhesion molecules, and cytokines. *LMP2* is also expressed in NPC and acts by preventing reactivation of the virus by blocking phosphorylation of tyrosine kinases.[190]

NPC development is thought to represent a multistep process initiated most frequently by EBV infection resulting in the expression of *LMP1* and overexpression of *TP53* in the epithelial tumor cells. Additionally, rearrangement of the retinoblastoma tumor suppressor genes, and polymorphism of *CYP2E1* may contribute to tumorigenesis. Genetic gains on chromosome 12 as well as losses on 11q, 13q, and 16q have been associated with invasiveness, whereas *TP53* mutation and altered expression of cadherins are associated with metastasis.[193,201-203] A small proportion of PNC exhibit t(15;19) with the BRD4-NUT oncogene, which perturbs BRD4 functions thus blocking cellular differentiation and contributing to the oncogenic progression in the highly aggressive NUT midline NPC.[204]

Pathology and Pathways of Spread

NPC is grouped into three histiotypes by the World Health Organization (WHO): type I, keratinizing squamous cell carcinoma; type II, nonkeratinizing squamous cell carcinoma; and type III, undifferentiated carcinoma, previously referred to as lymphoepithelioma. Type I shows significant keratin production, is usually seen in adults, and is not usually associated with EBV. Type II is characterized by groups of cells with oval or fusiform nuclei and scant cytoplasm. Type III is an undifferentiated tumor with prominent nonmalignant lymphocytic infiltration. The Cologne modification of the WHO classification further subdivides types II and III; type IIa has pleomorphism without lymphoid infiltration, type IIb has significant lymphoid infiltrate. Type IIIa is characterized by larger, eosinophilic nuclei, and type IIIb has smaller basophilic nuclei. Virtually all PNCs are type III undifferentiated carcinomas.[190,205]

PNC typically originates in the fossa of Rosenmüller, a pharyngeal recess posterolateral to the eustachian tube orifice. Routes of direct spread include the oropharynx or perineural spread along cranial nerves extending to the skull base. The cervical lymph nodes are typically involved early, and less commonly, the spinal accessory chain and retropharyngeal nodes. Most patients present with locoregionally advanced disease; distant metastases at presentation is infrequent. The most frequently affected metastatic sites are the bones, lungs, liver, bone marrow, and mediastinum.[206]

Clinical Manifestations, Patient Evaluation, and Staging

The most common presenting symptom of PNC, occurring in up to 90% of patients, is a painless cervical mass representing lymphadenopathy. Bilateral lymph nodes are often present because of the midline location of the nasopharynx with regional drainage to the internal jugular nodes, the spinal accessory nodes, and the retropharyngeal nodes. Local extension of tumor can cause epistaxis, nasal obstruction, hearing loss, or otitis media from obstruction of the eustachian tubes, which can also lead to ear pain and tinnitus. Base-of-skull invasion can result in headache, facial pain, neck pain, and cranial neuropathies.[190,193,194,207] Uncommonly, the syndrome of inappropriate antidiuretic hormone secretion (SIADH) has been reported and can cause severe hyponatremia.[208] The duration of symptoms before diagnosis ranges from 1 month to 24 months, with an average of 5 months.[190]

Work-up includes history and physical examination with nasopharyngoscopy. Laboratory evaluation consists of CBC, kidney and liver function tests, serum EBV titers, a baseline audiogram, and CT or MRI of the head and neck. CT of the chest and abdomen or, alternatively, PET/CT, is done to screen for distant metastases.[209] Dental and endocrine evaluations should be obtained in preparation for RT and to establish baseline function.

Staging is based on the American Joint Committee on Cancer staging system for NPC in adults (Table 75-6). The nodal staging for nasopharyngeal tumors takes into account the anatomic level of nodal involvement, an important prognostic factor. Retropharyngeal lymph nodes, regardless of their laterality, are considered N1.[210,211]

TABLE 75-6 Nasopharyngeal Carcinoma Staging: American Joint Committee on Cancer

PRIMARY TUMOR	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Primary tumor confined to nasopharynx, extending to oropharynx, or nasal cavity without parapharyngeal space extension
T2	Tumor extends to soft tissues
T2a	Tumor extends to oropharynx and/or nasal cavity (no parapharyngeal extension)
T2b	Tumor within parapharyngeal space*
T3	Invasion of bone of skull base or paranasal sinuses
T4	Tumor with intracranial extension or cranial nerve involvement, extension to hypopharynx, orbit, or infratemporal fossa/masticator space
REGIONAL LYMPH NODES	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node involvement
N1	Unilateral metastasis ≤6 cm above the supraclavicular fossa and/or unilateral or bilateral retropharyngeal lymph nodes ≤n6 cm
N2	Bilateral lymph node metastasis, ≤6 cm, above the supraclavicular fossa
N3	Metastasis in a lymph node >6 cm or extension to supraclavicular fossa
N3a	>6 cm
N3b	Extension to supraclavicular fossa
DISTANT METASTASES	
M0	No distant metastasis
M1	Distant metastasis
AJCC STAGE	
Stage 0	TisN0M0
Stage I	T1N0M0
Stage IIA	T2aN0M0
Stage IIB	T1-2aN1M0 T2bN0-1M0
Stage III	T1-2a-2bN2M0 T3N0-1-2M0
Stage IVA	T4N0-1-2M0
Stage IVB	T1-4N3M0
Stage IVC	M1

**Parapharyngeal extension denotes posterolateral spread of tumor.*

Primary and Adjuvant Therapy and Results

Surgery for PNC is limited by anatomic location and involvement of critical structures, which would usually result in a morbid and incomplete resection. Therefore, RT is the mainstay of therapy for every stage of PNC. PNC is radiosensitive. However, outcome with RT alone has been unsatisfactory, with local recurrence rates of 20% to 60% and rates of distant metastases ranging from 20% to 55%.[212-216] Therefore, combined-modality therapy is most often used.

Treatment of PNC was initially extrapolated from recommendations in the adult literature and cisplatin has been the agent most frequently used in conjunction with RT. This was based primarily on the Intergroup 0099 trial, which compared chemoradiation with RT alone in adults with NPC, delivering 70 Gy with or without cisplatin, followed by three cycles of adjuvant cisplatin and 5-fluorouracil.[217] Three-year progression-free survival was 69% with chemoradiation versus 24% with RT alone, and 3-year OS was 78% versus 47%, respectively. The use of cisplatin was further supported by a meta-analysis of adult patients that reported a 20% survival benefit for concurrent cisplatin with RT versus RT alone.[218]

Historically, PNC was treated with RT alone. OS ranged from 50% to 55% with relapse-free survival of 36% to 75%. RT doses varied significantly from 35 Gy to 86 Gy.[219-221] More recently, combined-modality regimens and advanced RT techniques such as intensity-modulated RT (IMRT) and image-guided RT (IGRT) have improved outcomes for PNC. Ayan et al[222] and Wolden et al[223] reported improved survival after chemoradiation, particularly using neoadjuvant chemotherapy, with OS as high as 76%. Data from these studies also suggested a benefit when radiation doses exceeded 60 Gy. However, the 10-year actuarial rate of severe complications using these radiation doses was 24% including a significant risk of sensorineural hearing loss when the cochlear dose exceeded 48 Gy.[224]

Ozyar et al[195] reported a large, multiinstitutional international review of PNC treated over a 25-year interval which demonstrated the benefit of cisplatin as well as higher RT dose. Overall 5-year survival was 77.4% with DFS of 68.8% after combined irradiation and chemotherapy; the only significant negative prognostic factor for OS and DFS was N3 disease. RT doses less than 66 Gy adversely affected locoregional control, and RT without chemotherapy decreased locoregional control and DFS.

Kupeli et al published their experience treating PNC using RT with concurrent cyclophosphamide versus concurrent vincristine, cyclophosphamide, epirubicin, and dactinomycin (AVAC) versus neoadjuvant cisplatin. OS with neoadjuvant cisplatin was 80% versus 63% with AVAC and 31% with cyclophosphamide.[225]

The Pediatric Oncology Group 9486 study used neoadjuvant chemotherapy (cisplatin, 5-fluorouracil, methotrexate, and leucovorin) followed by RT (50.4 Gy to the upper neck, 45 Gy to the lower neck, and a boost to the primary tumor to a total dose of 61.2 Gy).[226] Four-year EFS and OS was 77% and 75%, respectively.

A prospective German trial tested three cycles of cisplatin, 5-fluorouracil, methotrexate, and leucovorin followed by RT (59.4 Gy) for stages III IV PNC; patients were then maintained on interferon-beta for 6 months. After a median follow-up of 30 months (range, 6 months to 95 months), EFS rate was 92.4%, and OS was 97.1%. Acute toxicity was mainly leucopenia, mucositis, and nausea; late toxicity consisted of hearing loss and hypothyroidism. The excellent outcomes were hypothesized as due, in part, to the administration of interferon-beta during a period of relative immune suppression in EBV-positive NPC.[227]

Factors that correlate with DFS include age, nodal stage, TNM stage, node size, node fixation, radiation dose, and response to neoadjuvant chemotherapy.[228]

Response-adapted RT has been investigated to reduce RT toxicity. Habrand et al[229] used sequential cisplatin-based regimens and response-adapted RT doses of 50 Gy after marked response and 65 Gy to 70 Gy after poor response to chemotherapy. Five-year EFS and OS were 64% and 68%, respectively; locoregional failures were similar between the groups, but the low RT dose group actually had superior OS and EFS, with apparent reduction in late toxicities. Orbach et al[230] reported results of risk-adapted RT following one of three chemotherapy protocols (both neoadjuvant and adjuvant

chemotherapy). Objective response to preirradiation chemotherapy was seen in 78% of cases; those with complete response or good partial response received a reduced dose RT regimen (median dose 47 Gy) to the clinically negative cervical nodes and 59.4 Gy to the primary tumor. Patients not meeting response criteria were given 60 Gy median dose to all involved sites. The 5-year OS was not compromised in the reduced-dose cohort, with OS of 73% at 5 years, local failure rate of 10%, and regional failure rate of 3%.

Irradiation Techniques

Because of the high-risk of lymph node involvement at presentation, RT for PNC targets the primary tumor, clinically involved nodes, and nodal areas at risk. Prophylactic RT includes lymph nodes in the bilateral upper deep jugular, submandibular, subdigastric, midjugular, low jugular and supraclavicular, posterior cervical, and retropharyngeal chains.

The optimal doses to maximize tumor control and minimize toxicity continue to evolve with current recommendation for 60 Gy to 70 Gy to the primary tumor and gross disease and 45 Gy to 50 Gy for at-risk nodal areas. The recent COG protocol ARAR0331 specifies RT alone for stages I and IIa disease to 61.2 Gy and 66.6 Gy, respectively. For advanced disease, patients are given neoadjuvant cisplatin and 5-flourouracil, with responding patients treated to 61.2 Gy versus 70.2 Gy for non-responders.

IMRT allows for sparing of normal tissues with reduced toxicity and superior target coverage. Both acute and long-term toxicity with IMRT are likely improved as compared to other techniques. However, this comes at the expense of increased integral dose and the possibility of increased risk of radiation-induced tumors.[231] Proton therapy has been used for PNC and its use will likely grow because of the inherent decrease in normal tissue exposure with particle therapy.[232]

Simulation should be CT based, with appropriate immobilization and localization techniques. The Children's Oncology Group currently recommends delineation of the gross tumor volume (GTV) based on MRI; lymph nodes larger than 1.5 cm or of any size with a necrotic center are included in the GTV. The clinical target volume (CTV) includes the GTV plus a 1-cm margin, the entire nasopharynx, retropharyngeal nodes, skull base, pterygoid fossa, parapharyngeal space, inferior sphenoidal sinus, and posterior third of the nasal cavity, and maxillary sinuses as well as the bilateral cervical lymphatic levels I to V. The lower halves of levels IV and V can be excluded in patients with early-stage disease. A boost, or second CTV, may include the nasopharynx and residual enhancing disease that remains after neoadjuvant chemotherapy.

Critical normal structures include the spinal cord and brainstem, mandible/temporomandibular joint, temporal lobes, and optic apparatus. Other structures at risk are the parotid gland, oral cavity, larynx, eyes, lens, cochlea, and pituitary. Xerostomia, neck fibrosis, dental caries, chronic sinusitis, chronic serous otitis, trismus, hypopituitarism, hypothyroidism, hypoplasia of facial bones or clavicles, and second malignancies have been well documented[190,223,225] (Table 75-7).

TABLE 75-7 Incidence of Treatment-Related Toxicity in Nasopharyngeal Cancer

Complication	Percentage
Xerostomia	3.5-84
Soft-tissue fibrosis	23-61
Dental caries	7-33
Chronic otitis	18
Hypothyroidism	9.5-12
Trismus	7.1-9
Chronic sinusitis	7
Second malignancy	2-6
Osteoradionecrosis	3
Optic neuritis	3

Treatment Algorithms, Controversies, Challenges, and Future Possibilities

Standard treatment for most PNC is defined as three to four cycles of platinum-based neoadjuvant chemotherapy followed by RT to the primary tumor and regional lymphatics with concurrent cisplatin. This may be followed by additional chemotherapy. Early-stage disease may be considered for RT alone. Dose recommendations will likely continue to evolve with ongoing studies reviewing response-based dosing. IMRT techniques are recommended with the use of proton RT being reported on as well. Future challenges will likely be related to optimal dose definition and using improved RT techniques to minimize toxicity, integration of EBV-directed therapy, and immunomodulation.

Overview

Andrea K. Ng

BASIC ISSUES IN LYMPHOMA

Significant progress had been made in recent years in the understanding of the molecular basis of lymphomagenesis, and in the diagnosis, staging, treatment, and follow-up of patients with lymphoid malignancies. The current pathological classification incorporates molecular characteristics, in addition to morphologic and clinical features in identifying distinctive subtypes of disease entities.[1] Advances in DNA microarray techniques allow improved prognostic classification of patients and provide the opportunity to develop molecularly targeted therapy for specific disease types.[2-11] More accurate staging is now available through modern medical imaging techniques and the increasing experience with functional imaging.[12]

The treatment of lymphoid malignancies had also evolved over the years. For diseases in which a high cure rate has already been achieved, the emphasis is now on treatment reduction to reduce late effects. Meanwhile, more dose-dense and dose-intense treatment, and incorporation of targeted therapy including novel agents against molecular targets or pathways, immunotherapy, and radioimmunotherapy are being used in diseases in which the cure rate is still suboptimal.

PATHOLOGICAL CLASSIFICATION

The classification of lymphoid malignancies has evolved over the past century. Previous lymphoma classification relied mainly on subtleties of morphology, cell lineage and differentiation, or clinical survival data. In 1994, the International Lymphoma Study Group published the Revised European-American Lymphoma (REAL) classification of tumors of hematopoietic and lymphatic tissues, which was later modified and updated in the World Health Organization (WHO) project.[13-15] The WHO classification combined information on morphology, immunophenotype, genetic features, and clinical features to define individual disease entity. The 2008 update provided new criteria for the recognition of some previously described neoplasms and clarified the defining criteria for others. Furthermore, it added new entities that were defined by recently discovered genetic features.[16] Despite its seeming complexity, its clinical practicality is supported by the fact that the majority of cases could be classified into one of the disease categories, that an excellent interobserver reproducibility has been demonstrated, and that the disease entities in the classification were indeed clinically distinctive, both at initial presentation and in treatment outcome.

Modern pathological classification allows researchers, pathologists, and clinicians to have a common language in diagnosing and treating different disease types and in comparing treatment results. It is anticipated that with continued progress in the field of genetic analysis, continued updating and revisions of any current classification will be necessary. Advances in the field may provide additional markers for classification, and identify new categories of disease that are not currently recognized.

MOLECULAR BASIS OF LYMPHOID MALIGNANCIES

Emerging data are now available on the origin of the malignant cells of Hodgkin's disease, the Hodgkin's Reed-Sternberg cells, and the molecular events that lead to the malignant transformation.[17-19] The nuclear factor-kappa-B (NF-κB) pathway has been implicated to play an important role in the pathogenesis of Hodgkin's disease,[20,21] and continued research in this area may provide new therapeutic targets for the disease.

Researchers have used cDNA microarray techniques to identify molecular prognostic factors for lymphoma.[2-4,6] For diffuse large B-cell lymphoma (DLBCL), using transcriptional profiling, subtypes of disease with distinct clinical outcome have been identified.[2-4,7] Genes that have been implicated in predicting treatment outcome, independent of that of the international prognostic index (IPI), include ones that regulate molecular signaling pathways and apoptotic response to treatment.[3,4] Using similar techniques, it has also been shown that the tumor microenvironment and host inflammatory response may play a key role in identifying subgroups of patients with differing prognoses in both follicular lymphoma and DLBCL.[6,22-24] Molecular prognostic factors promise to further improve risk stratification, and more importantly, provide insights into molecular pathogenesis of different subtypes of lymphoma and guide the development of novel, targeted therapy.[25]

STAGING

Improvement in imaging techniques had led to the modification of the original Ann Arbor staging classification for lymphoma, allowing incorporation of computed tomography (CT) scan results in assessing disease extent.[26] Currently, functional imaging is routinely included as part of initial lymphoma staging. The superior accuracy of fludeoxyglucose

(18F)-positron emission tomography (FDG-PET) has been shown to result in a change in the stage of 18% to 45%, and a change in management in 18% to 31% of the patients.[12] Furthermore, it has been demonstrated that incorporation of FDG-PET in radiotherapy planning resulted in modification of target volume and fields in a considerable proportion of patients.[27-30]

TREATMENT

The following is a summary of the overall treatment approaches, with a focus on the role of radiation therapy, for the three types of hematological malignancies: Hodgkin's lymphoma, non-Hodgkin's lymphoma, and plasma cell neoplasms.

Hodgkin's Lymphoma

Stages I to II Hodgkin's Lymphoma

Combined modality therapy for early-stage Hodgkin's lymphoma is associated with a cure rate of more than 90%. Currently, one of the main challenges in the management of patients with early-stage Hodgkin's lymphoma is to minimize treatment-related late complications while preserving excellent disease control. Strategies to reduce treatment, from the radiation therapy standpoint, include the use of smaller treatment fields, lower radiation doses, or elimination of radiation therapy.

Over the last several decades, radiation treatment fields for Hodgkin's lymphoma have evolved from extended-field to involved-field,[31-33] and mostly recently to involved-site/involved node radiotherapy (ISRT/INRT).[34,35] Retrospective studies have shown that ISRT/INRT as part of combined-modality therapy for early-stage Hodgkin's lymphoma did not result in any marginal misses, and yielded progression-free survival rates of more than 90%.[36,37] In the EORTC/Lymphoma Study Association (LYSA)/the Italian Lymphoma Foundation (FIL) H10 and H11 trials, INRT was adopted in both the standard and experimental arms, the results of which are pending at this time. In the ongoing German Hodgkin's Study Group (GHSG) HD17 trial for patients with early-stage disease with risk factors, the standard arm consisted of chemotherapy and involved-field radiotherapy, and the experimental arm used INRT for patients with PET-positive disease after chemotherapy.

Radiation dose deescalation from 30 Gy to 20 Gy was explored in the GHSG HD10 and HD11 trials for patients with early-stage, low-risk disease (no bulky mediastinal mass or extranodal disease, less than three nodal sites, low sedimentation rate) and high-risk disease, respectively.[38,39] In the HD10 trial, at a median follow-up of 7.5 years, there were no differences in 8-year freedom-from-treatment-failure and overall survival between 20 Gy versus 30 Gy after two to four cycles Adriamycin, bleomycin, vinblastine, and dacarbazine (ABVD) chemotherapy.[38] This suggests that in patients with low-risk disease as per the GHSG criteria, two cycles followed by 20 Gy of radiotherapy is adequate. In the HD11 trial,[39] at a median follow-up of 82 months, there was no significant difference in 5-year freedom-from-treatment-failure rates between baseline bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone (BEACOPP) and ABVD when followed by 30 Gy of involved-field radiotherapy; however, inferiority of 20 Gy cannot be excluded after four cycles of ABVD, leading to the authors' conclusion that 30 Gy as optimal radiotherapy dose after ABVD for early-stage, unfavorable Hodgkin's lymphoma.

Randomized trials have been performed examining whether radiation therapy can be safely omitted.[40-47] The Cochrane Haematological Malignancies Group conducted a meta-analysis that included five randomized controlled trials comparing chemotherapy alone with identical chemotherapy combined with radiotherapy for patients with stages I to II Hodgkin's lymphoma.[48] The results showed that, in addition to a significant disease-control benefit favoring the combined-modality therapy approach, there was a highly significant overall survival benefit with the addition of radiation therapy (hazard ratio [HR], 0.4; $p < 0.00001$).

The elimination of radiotherapy based on PET-response or early PET-response to chemotherapy is being explored by a number of randomized trials. In the EORTC/LYSA/FIL H10 and H11 trials, the experimental arms consisted of omission of radiation therapy for patients with complete PET response after two cycles of ABVD, compared against the standard arms of combined-modality therapy. Interim analysis results showed that in both studies, the objective of noninferiority of chemotherapy alone as compared with combined-modality therapy has not been met, and at the recommendation of an independent data monitoring committee, the experimental arms of no radiotherapy in both groups of patients were closed.[49] The United Kingdom RAPID trial compared combined-modality therapy with chemotherapy alone in early-stage patients with complete PET-response after three cycles of ABVD.[50] At a median follow up time of 48.6 months, by intent-to-treat analysis, there was no difference between the radiotherapy versus no radiotherapy. However, by per-treatment analysis, there is a significant benefit in the radiotherapy arm (3-year progression-free survival 97% versus 90.7%, $p = 0.03$). Based on these preliminary result, there appears to be a modest, approximately 7% gain in progression-free survival with the addition of radiotherapy on patients who achieved a complete PET response after chemotherapy. This slightly lower cure rate and toxicity of salvage therapy in the small proportion of patients with relapse disease needs to be weighed against the limited toxicity of modern radiotherapy. Two ongoing trials conducted by the GHSG are exploring omission of radiotherapy by PET-response, including the HD16 trial for patients with low-risk early-stage disease, and the HD17 trial for patients with early-stage disease with adverse risk factors. Results from the ongoing trials as well as mature results of completed trials are needed to confirm the safety of elimination of radiotherapy in patients with early-stage disease with complete PET response to chemotherapy.

Stages III to IV

The role of radiation therapy in patients with advanced-stage Hodgkin disease is controversial. Most of the randomized trials do not show a significant benefit with the addition of radiation therapy to chemotherapy.[51-58] However, there are subgroups of patients who may benefit from consolidative radiation therapy, namely, patients who failed to achieve a complete response to chemotherapy and those with bulky disease at presentation.[52,56,59,60] In a study from the United Kingdom, comparing irradiated versus patients who were nonirradiated with advanced-stage disease recruited on several clinical trials,[60] at a median follow-up of 6.9 years, a significantly higher progression-free survival (71% versus 86%, $p < 0.0001$) and overall survival rates (87% versus 93%, $p = 0.014$) were found in patients who received radiation therapy, despite the fact that there were significantly more patients with bulky disease and patients with partial response in the irradiated cohort.

The GHSG HD12 trial is a four-arm study for patients with bulky stage IIB and stages III to IV disease comparing two different BEACOPP variants with or without radiation therapy.[58] At a median follow-up of 69 months, there was no significant difference in 5-year FFTF between the radiotherapy or no-radiotherapy arms (90.4% versus 87%, $p = 0.08$). However,

on subgroup analysis, among patients with residual disease of >1.5 cm, there was a significantly higher (5.8%; 95% confidence interval [CI], 1.0% to 10.7%) 5-year freedom-from-treatment failure in the radiotherapy arm. However, among patients with <1.5-cm residual disease after chemotherapy, there was no significant benefit with the addition of radiotherapy even among patients with initial disease of 5 cm or greater.

In the GHSG HD15 trial,[61] patients with advanced-stage disease with complete response or with residual disease <2.5 cm after chemotherapy received no further treatment, whereas patients with residual disease of 2.5 cm or greater underwent PET scanning. Radiotherapy was administered only in patients with residual PET-avid disease, and as such only 11% of patients on this trial received radiotherapy. The planning target volume in this trial included the PET-positive residual disease with a 1.5-cm expansion. The 4-year progression-free survival of patients who achieved a complete response to chemotherapy and did not receive radiation therapy was 92.1%. It is noteworthy, however, that this excellent outcome was based on patients treated with variants of BEACOPP regimens and may not be applicable to patients treated with ABVD. In the response-adapted trials conducted by the GITIL and FIL (HD0607 and HD0801) for patients with advanced-stage Hodgkin's lymphoma, patients with complete PET-response after ABVD chemotherapy, patients were randomized to radiotherapy versus no-radiotherapy. The results of these two trials will clarify the role of consolidative radiotherapy in patients with advanced-stage Hodgkin's lymphoma with complete PET-response after ABVD chemotherapy.

Nodular Lymphocyte Predominant Hodgkin's Disease

Nodular lymphocyte predominant Hodgkin's disease (NLPHD) is a disease entity distinct from classical Hodgkin's disease based on its morphologic, immunophenotypic, and clinical characteristics.[14,62] The majority of cases of NLPHD present with stages I to II disease. Different management options exist[63-67]; however, radiation therapy alone remains the mainstay treatment for patients with localized disease. Studies have shown that as treatment fields evolved from extended- to involved-field radiation therapy, there was no significant compromise of disease control. The current recommendation is further field reduction to ISRT to 30 Gy to 36 Gy. In the setting of radiotherapy as the only treatment modality, the clinical target volume (CTV) should encompass gross disease as well as suspected subclinical disease.[34]

Patients with additional relapses tend to remain responsive to further therapy. These patients are more likely to die from treatment-related causes than from the lymphoma, which argues for limiting treatment upfront because of the indolent nature of the disease.

Non-Hodgkin's Lymphoma

Non-Hodgkin's lymphoma is a heterogeneous disease. The two most common histologic subtypes are DLBCL and follicular lymphoma, accounting for three quarters of all cases of non-Hodgkin's lymphoma. The role of radiation therapy in both of these subtypes is mostly limited to patients with early-stage disease. Marginal zone lymphoma or mucosa-associated lymphoid tumor (MALT) is another subtype of non-Hodgkin's lymphoma, which is highly responsive to radiation therapy, and in patients who present with localized, early-stage disease, radiation therapy alone may be curative.

Diffuse Large B-Cell Lymphoma

Randomized trials have compared chemotherapy alone versus combined modality therapy in early-stage aggressive non-Hodgkin's lymphoma with mixed results, likely as a result of patient selection and differences in chemotherapy regimens used in the comparison arms in two of the trials. However, the most significant limitation of these trials was that they were conducted in the pre-Rituximab era.[68-71]

The current standard systemic therapy for DLBCL, which accounts for the majority of cases of aggressive non-Hodgkin's lymphoma, is rituximab, cyclophosphamide, vincristine and prednisone (R-CHOP).[72-75] Several studies have retrospectively compared irradiated versus nonirradiated patients after modern R-CHOP chemotherapy, all showing a significantly superior disease-free survival in patients who received radiotherapy compared to patients treated with chemotherapy alone.[76-79] In the largest study, from M. D. Anderson on 469 patients with DLBCL, not only a significantly higher progression-free (59% versus 82%, $p < 0.001$), but also overall survival (68% versus 91%, $p = 0.03$) rates were observed in irradiated patients. The significant benefit of radiation therapy in this study persisted on multivariable analysis, as well as on matched-pair analyses on patients with stages I to II disease and patients with stages III to IV disease, respectively, after a complete response to six to eight cycles of R-CHOP.

The German High-Grade Non-Hodgkin's lymphoma Study Group (DSHNHL) recently published their experience on the role of radiotherapy in selected patients with DLBCL on their clinical trials.[80,81] The first report took patients with skeletal involvement and complete response to chemo from the MabThera International Trial (MInT) and RICOVER-60 trials, and found that those who received consolidative radiotherapy had a significantly improved 3-year event-free survival rate (75% versus 36%, $p < 0.001$).[81] On multivariable analysis, the addition of radiotherapy reduced the risk of an event by 70% ($p < 0.001$). In the second report, patients with bulky disease (≥7.5 cm) from the R-CHOP-14 for six arms of the RICOVER-60 trial formed the study population. It was found that compared to patients who did not receive radiotherapy, those who received radiotherapy had significantly improved event-free survival (80% versus 54%, $p = 0.001$), progression-free survival (88% versus 62%, $p < 0.001$), as well as overall survival (90% versus 65%, $p = 0.001$).[80] However, both of these studies were retrospective subgroup analyses and may be prone to selection bias. The UNFOLDER trial, also conducted by the DSHNHL randomized patients with DLBCL to R-CHOP14 versus R-CHOP 21, Patients with initial bulky disease (>7.5 cm) or extranodal involvement and complete response to chemotherapy were further randomized to receive radiotherapy versus no radiotherapy. In the most recent interim analysis, the no-radiotherapy arm was closed because of significantly inferior event-free survival results. The formal results of this trial, however, are still pending at this time.

Radiation doses used in previous trials ranged from 30 Gy to as high as 55 Gy.[82] In a prospective trial conducted by Lowry et al,[83] 640 sites of aggressive non-Hodgkin's lymphoma (81% treated with combined-modality therapy) were randomized to 30 Gy in 15 fractions versus 40 Gy to 45 Gy in 20 to 23 fractions. At a median follow-up of 5.6 years, there was no significant difference in freedom-from-local progression and overall survival rates between the two arms, suggesting the 30 Gy may be adequate in these patients after chemotherapy. However, the study did not describe the types of chemotherapy used and data on response to chemotherapy were not available.

There have been attempts to limit radiation fields in patients receiving consolidative radiotherapy for aggressive non-Hodgkin's lymphoma. Campbell et al reported on the British Columbia experience of using INRT ≤5 cm and found no difference in patterns of failure compared with a previous cohort of patients who received involved-field radiation therapy.[84] Verhappen et al recently reported on results of 67 patients

with stages I to II aggressive non-Hodgkin's lymphoma treated with INRT (64 of 67 patients received combined-modality therapy) as per the EORTC guidelines,[85] and there was only one relapse that was outside the INRT field but in the involved-field radiation therapy volume, supporting the use of more limited fields after chemotherapy in early-stage aggressive non-Hodgkin's lymphoma.

Follicular Lymphoma

About 20% to 25% of patients with follicular lymphoma present with stages I to II disease. There have been a number of retrospective series showing that radiation therapy alone is curative in 35% to 40% of cases.[86-95] Median doses of 36 Gy to 40 Gy resulted in control rates of 90% to 95%. Relapses beyond 10 years are uncommon, accounting for less than 5% of cases. In most series the radiation fields varied over time, with larger fields employed in the earlier years, and more limited fields in patients treated in the modern era. Campbell et al reported on the British Columbia experience of 95 with localized follicular lymphoma treated with INRT <5 cm alone, and found that only 1% of patients had regional-only recurrence.[96] Because more than half the patients with stages I to II disease will eventually relapse, the use of more limited radiation fields preserves the ability to effectively treat patients with recurrent disease or those who transform to a higher grade histology.

In most of the earlier retrospective series of radiotherapy alone for stages I to II follicular lymphoma, doses of 35 Gy to 40 Gy were employed. Lowry et al from the United Kingdom conducted a randomized trial on 361 sites of indolent lymphoma comparing 24 Gy in 12 fractions versus 40 Gy to 45 Gy in 20 to 30 fractions,[83] and found no differences in rates of local progression, progression-free survival, and overall survival between the two arms, suggesting that 24 Gy may be an adequate definitive dose for indolent lymphoma.

For patients with advanced-stage follicular lymphoma, several small series, which included patients with stage III disease, have reported results on the use of "central" or "comprehensive" lymphoid irradiation, with 10-year to 15-year disease-free survival of 30% to 40%.[97-99] Molecular complete responses, assessed by polymerase chain reaction techniques, have also been demonstrated after the treatment.[100] This approach of wide-field radiation therapy, however, is not widely accepted because of concerns with long-term toxicity for the treatment for an indolent disease and the ability to deliver effective salvage therapy at the time of relapse. Emerging data are available on the effectiveness of low-dose IFRT for palliation in patients with indolent lymphoma, with response rates of 80% to more than 90%.[101-107] The advantages of this approach, in addition to the high response rate, include minimal treatment toxicity, patient convenience, potential delay in need of starting systemic therapy, and the option of reirradiation if needed. However, results of the recently published FoRT trial showed that 4 Gy in 2 fractions was significantly inferior to 24 Gy in 12 fractions in patients with either follicular or marginal zone lymphoma in terms of response rates (81% versus 74.1%, $p = 0.006$), and 2-year progression-free survival rates (93.7% versus 80.4%, $p < 0.001$) in the 4 Gy-arm.[108] These findings led to the conclusion that although 4 Gy in 2 fractions remains a useful regimen in the palliative setting, 24 Gy is the standard dose for patients treated with radical intent.

MALT Lymphoma

Marginal zone B-cell lymphoma (MALT) accounts for about 8% to 10% of non-Hodgkin's lymphoma. The majority of cases are localized at presentation and tend to remain localized for long periods of time. This subtype of lymphoma is highly responsive to radiation therapy. Doses of around 30 Gy to involved nodal regions or extranodal sites will yield local control rate of close to 100%, with a chance of long-term cure in about three quarters of the patients,[109-114] although results from the United Kingdom randomized trial suggested that 24 Gy may be adequate.[83] Relapses tend to occur at other extranodal sites in which MALT lymphomas tend to occur or in a nonirradiated contralateral paired organ.[115] The likelihood of achieving a second remission in patients with limited relapses remains excellent with further local radiation therapy.

Multiple Myeloma and Plasma Cell Malignancies

Multiple myeloma at this time remains an incurable disease. However, novel agents including bortezomib and lenalidomide have been shown to be effective in the relapsed setting, and they are increasingly being adopted as first-line therapy.[116,117] Additional novel agents, including pomalidomide, a new immunomodulatory agent, and carfilzomib, an irreversible proteasome inhibitor, have shown promising antimyeloma activity in patients with refractory disease.[118,119] Finally, monoclonal antibodies are emerging as an important modality in the treatment of the disease.[120,121]

The current role of radiation therapy in the management of multiple myeloma is therefore largely limited to palliation, in patients with painful bony lesions, nerve root or cord compression, or lytic lesions in a weight-bearing bone at risk for pathological fractures. Kyphoplasty in conjunction with radiation therapy for patients with compression fracture of the vertebral bodies may provide more immediate and effective palliation.[122-124] Fractionation schemes of 30 Gy in 10 fractions or other biological equivalent doses are recommended because lower doses are associated with less durable palliation, and retreatment is often less effective.[125-129]

Solitary plasmacytoma accounts for 5% to 10% of all plasma cell dyscrasias. In patients with solitary plasmacytoma of the bone, local radiation therapy to doses of 45 Gy to 50 Gy can provide effective local control of more than 80%.[130-136] However, about half of the patients will progress to multiple myeloma at 10 years, and by 15 years, most will develop multiple myeloma. Unlike solitary plasmacytoma of the bone, extraosseous solitary plasmacytoma is associated with a lower risk of progression to multiple myeloma and has a more favorable disease-free survival.[133,135,137-139] Most series employed doses of 45 Gy to 50 Gy, which yielded local control rates of 85% to 90%.

CHAPTER

76 Hodgkin's Lymphoma

Andrea K. Ng, Lawrence M. Weiss, and Ann S. LaCasce

INCIDENCE

There are approximately 8,500 new cases in the United States each year.

BIOLOGIC CHARACTERISTICS

Hodgkin's/Reed-Sternberg (HRS) cells are the malignant cells in Hodgkin's lymphoma.

Increasing epidemiologic and molecular evidence support that a combination of genetic susceptibility, immune response impairment, and exposure to specific infectious agents may play a central role in the pathogenesis of the disease.

PATHOLOGY

Classical Hodgkin's lymphoma (HL; CD15+, CD30+, CD45–), four subtypes: nodular sclerosis, lymphocyte rich, mixed cellularity and lymphocyte depleted.

Nodular lymphocyte predominant HL (CD45+, CD20+, CD 15–, CD 30–).

STAGING EVALUATION

History and physical examination, focusing on constitutional symptoms, nodal involvement, and organomegaly.

Complete blood count, erythrocyte sedimentation rate (ESR), and serum albumin.

Computed tomography (CT) of chest, abdomen, and pelvis; positron emission tomography (PET).

Bone marrow biopsy if constitutional symptoms present or advanced-stage disease is.

THERAPY IN EARLY-STAGE DISEASE

Standard therapy is combined-modality therapy with two to four cycles of Adriamycin, bleomycin, vinblastine, and dacarbazine (ABVD) followed by involved-site radiation therapy in favorable patients and four to six cycles of ABVD followed by involved-site radiation therapy in patients with unfavorable disease, with 5-year disease-free survival (DFS) of about 90%.

Abbreviated regimens in patients with unfavorable prognostic features (bulky disease, four or more sites of disease, presence of constitutional symptoms) should be avoided.

Clinical trials are evaluating the role of PET response to chemotherapy in guiding the use of adjuvant radiotherapy.

THERAPY IN ADVANCED-STAGE DISEASE

Standard therapy is chemotherapy alone with ABVD, with 5-year DFS of 70% to 80%.

Dose-escalated bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone (BEACOPP) and its variants may yield superior freedom-from-treatment failure but is associated with increased toxicity.

There is no difference between Stanford V and ABVD as shown in the ECOG 2496 randomized trial on advanced HL.

There may be a role for consolidative radiation therapy in selected cases, including initial bulky disease or lack of complete response to chemotherapy.

SALVAGE THERAPY

High-dose therapy with autologous bone marrow or stem-cell transplantation is the salvage therapy of choice in patients who are refractory to, or relapsed after, a short initial remission to chemotherapy.

Selected patients may be candidates for conventional dose salvage therapy, namely, patients with limited nodal relapse, absence of constitutional symptoms, and long remission duration.

INTRODUCTION

HL was first described by the British physician Thomas Hodgkin in 1832, when he reported six patients with pathologic enlargement of lymph nodes and spleen at Guy's Hospital.[1] Attempts to treat the disease using various chemical or surgical means were unsuccessful until around the turn of the century, when the effectiveness of x-ray in shrinking the disease was first demonstrated. Only crude, low energy x-ray equipment was available at the time, which merely allowed the temporary reduction of the enlarged lymph nodes. The development of kilovoltage equipment in the 1920s and the subsequent pioneering work of Gilbert, a Swiss radiotherapist, paved the way for the definitive treatment of patients with HL.[2] Vera Peters at Ontario Institute of Radiotherapy first reported the curability of early-stage HL in 1950 using high doses of fractionated radiation therapy.[3] The availability of modern, high-energy radiation therapy equipment in the late 1950s and early 1960s allowed the delivery of higher doses of radiation to deep-seated tumor with less limitations by reactions in the superficial tissues. The introduction of effective combination chemotherapy further improved the treatment outcome of HL, especially in patients with unfavorable prognostic features or advanced-stage disease.[4] Over the last three decades, continued improvements in radiation therapy techniques allowing more uniform and better targeted dose delivery, development of more effective and less toxic multiagent chemotherapy regimens, advances in radiographic imaging technology, and the refinement of prognostic factors that allow better tailoring of treatments, HL, a previously fatal illness, has now become one of the most curable forms of malignancy.

ETIOLOGY AND EPIDEMIOLOGY

HL is a relatively uncommon neoplasm, with approximately 8,500 new cases in the United States each year, representing less than 1% of all cancer diagnosis.[5] The incidence, age, and gender distribution of HL vary depending on the geographic

location. The age-incidence curve in developed countries is characterized by a bimodal distribution.[6,7] There is an initial peak in young adults at around age 25, and a second peak occurring at ages 60 to 70, in which a male predominance is observed. The majority of the cases seen in young adulthood are of nodular sclerosis (NS) histology, and many of the factors that have been associated with the development of HL in these patients appear to be a reflection of delayed exposure to infectious agents or higher socioeconomic status. These include early birth order, small sibship size, growing up in single-family houses, few playmates, and high parental education.[8-10] In contrast, in economically disadvantaged parts of the world, HL is relatively rare among young adults.[7] Mixed cellularity (MC) is the predominant histologic subtype in developing countries, with an initial peak in childhood for boys and a late peak in older patients.

The etiology of HL is an unresolved issue but is likely complex and may vary depending on the different subtypes. A combination of genetic susceptibility, immune response impairment, and environmental exposures, especially specific infectious agents, are likely to play a central role in the pathogenesis of the disease.

Several of the epidemiological and clinical features of the disease are suggestive of infectious causes, and there have been increasing evidence that Epstein Barr Virus (EBV) may be involved in the pathogenesis of HL in at least a subset of cases. Patients with history of infectious mononucleosis, in which EBV is the causative agent, are at an approximately threefold increased risk for HL, and particularly EBV-associated HL.[7,11,12] Elevated levels of the IgG and IgA immunoglobulins against the EBV capsid antigen have been demonstrated months to years before clinical HL development.[13,14] In about one third to one half of cases of classical HL occurring in Western populations, monoclonal EBV genome can be detected in the Reed-Sternberg cells.[15,16] EBV positivity is predominantly associated with the MC subtype,[17] which is more common among young children and older adults, and is less frequently associated with NS cases seen mostly in the young adults in the developed world.

The observation of familial aggregation of cases of HL suggests that genetic susceptibility as well as environmental exposure may contribute to the development of HL. A 5-fold increased risk has been demonstrated in first-degree relatives, and siblings of young adults with HL have a 7-fold increased risk.[18] The excess risk appears to be more pronounced in same-sex siblings, which may be related to more shared environmental exposure.[19] In a twin study of young adults with HL, monozygotic twins of patients had an almost 100-fold increased risk,[20] whereas no increased risk for dizygotic twins was observed, supporting the contribution of heritable factors to the development of the disease. In particular, follow-up twin studies have suggested that persons with genetically determined lower IL-6 levels may be less susceptible to young adult HL.[21] In addition, a genome screen of families at high risk for HL has provided evidence for a susceptibility gene on several chromosomes, particularly chromosome 4.[22] Finally, a number of specific human leukocyte antigen (HLA) haplotypes, as well as specific polymorphisms within chromosome 6p21.32 (an area which includes genes involved in immune function, including *HLA-DRB$_1$ and HLA-DOB$_1$*) have been identified to be associated with an increased risk of HL.[22-25] Because immune response is genetically determined by the HLA type, patients with these HLA haplotypes may have increased susceptibility to certain infections, which in turn may lead to the increased HL risk as well as increased susceptibility to autoimmune conditions. In fact, an elevated risk of HL has been found in patients with personal histories of several autoimmune conditions.

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

The malignant cells in classical HL, the HRS cells, are large, uni- or multinucleated cells, which usually comprise only 1% of the cells present in the tissue sample, with the majority of the tumor consisting of a variety of nonneoplastic inflammatory cells and fibrosis. Results of molecular single-cell studies have shown that in more than 90% of cases, HRS cells have monoclonal immunoglobulin gene rearrangements that are characteristic of mature B lymphocytes, and somatically mutated VH genes that are specific markers for germinal center B cells and their descendants, supporting a germinal center or postgerminal center B-cell origin.[26,27] However, unlike normal B cells that have undergone successful maturation through the germinal cells, HRS cells characteristically show absence of immunoglobulin gene expression. This has been attributed to mutations in the coding or regulatory regions,[28] lack of expression of transcription factors that are responsible for activation of the promoters and enhancers,[28] epigenetic silencing of the immunoglobulin heavy-chain transcription,[29] and constitutive expression of master regulators such as Notch1, ID2, activated B-cell factor 1, and STAT5.[29] Despite their inability to express immunoglobulin receptors, HRS cells are resistant to apoptosis, which normally removes immunoglobulin negative B cells that have traversed the germinal center.

There is increasing evidence connecting the prevention of apoptosis and survival of HRS cells to the activation of the nuclear factor kappa B (NF-κB) transcription factor-signaling pathway. Constitutive NF-κB is required for proliferation and survival of HL tumor cells.[30] The cause of the constitutive activation of NF-κB is probably multifactorial and may include amplification of the REL gene,[31] mutations in NF-κB inhibitors, and somatic mutations in the novel tumor suppressor gene *TNFAIP3*.[32] There is an inverse relationship between EBV infection and inactivation of A20, the protein encoded by the *TNFAIP3* gene, suggesting that they may represent alternative pathways of pathogenesis.[29]

Molecular profiling experiments using HL-derived cell lines with suppressed and unsuppressed NF-κB activity have been performed to better understand the NF-κB signaling pathway and to identify its target genes. One of the regulators of apoptosis that is expressed in dependence of NF-κB is cIAP2, a direct inhibitor of caspase 3, suggesting that HRS cells are protected from caspase 3–induced apoptosis by cIAP2.[33] Another NF-κB dependent regulator of apoptosis is CD95, which has been shown to be upregulated in HRS cells. However, unlike the other NF-κB-dependent regulators, CD95 is known to trigger apoptosis rather than prevent it. The resistance of HRS cells to CD95-mediated apoptotic cell death may be because of functional inhibition of death receptor pathways by cellular FADD-like IL1B-converting enzyme inhibitory proteins (c-FLIP), which is one of the most strongly NF-κB-regulated genes.[34] The contribution of NF-κB signaling to the development of HL is further supported by epidemiological data showing that regular aspirin use is associated with a reduced risk of developing HL, presumably through inhibition of NF-κB transcription.[35] Continued efforts in the elucidation of the NF-κB pathway in the pathogenesis of HL may have important therapeutic implications through pharmacological downregulation of NF-κB activity and its target genes, and increasing the susceptibility of HRS to apoptosis. However, bortezomib, a proteasome inhibitor that inhibits NF-κB activity, does not appear to be clinically active against HL.

The JAK/STAT pathway may also be important in the pathogenesis of HL with chromosomal gains in JAK2 found in about 20% of cases and, in rare cases, a translocation

involving JAK2 may be found.[36] JAK2 may be an activator of STAT signaling. Other signaling pathways possibly deregulated in HL include the PI3K/AKT, MAPK/ERK, and various receptor tyrosine kinase pathways.

Finally, translocations involving the MHC class II transactivator gene CIITA have been found in a subset of classical HL cases, and may contribute to the pathogenesis of HL by inhibiting MHC class II expression.[37]

PATHOLOGY

Since the 1930s, a number of pathological classification systems for HL have been developed. The Rye classification system, introduced at a conference in Rye, New York, in 1966, divided cases of HL into lymphocyte predominance (LP), nodular sclerosis (NS), mixed cellularity (MC), and lymphocyte depletion (LD).[38] This system was widely adopted in the next 25 years and was subsequently modified in the revised European-American classification of malignant lymphomas (REAL) and later in the World Health Organization (WHO) classification (Table 76-1).[39,40] In the current classification system, HL is specifically recognized as a lymphoma. Based on morphological, immunophenotypic, and clinical characteristics, it is divided into two distinct entities: classical HL and nodular lymphocyte predominant Hodgkin's lymphoma (NLPHD). Table 76-2 compares the morphological and immunophenotypic features of the malignant cells of these two entities. The diagnosis of HL is based on morphological assessment with identification of HRS cells or their variants, along with immunohistochemical studies.

Classical Hodgkin Lymphoma

In the majority of cases of the HRS of classical HL, most markers for B cells or T cells, as well as leukocyte common antigen (CD45) are absent, whereas a number of antigens including CD30 and CD15, which are not usually expressed by normal B cells or T cells, can be detected. The immunophenotypic and genetic features of the malignant cells of the four histological subtypes of classical HL are similar. However, the four subtypes vary in the morphology of the HRS cells, nature of the surrounding reactive cells, association with EBV, and clinical characteristics.

TABLE 76-1 The WHO Histological Classification of Hodgkin Lymphoma[40]

Nodular lymphocyte predominant Hodgkin's lymphoma (NLPHL)
Classical Hodgkin's lymphoma (CHL):
Nodular sclerosis classical Hodgkin's lymphoma (NSHL)
Mixed cellularity classical Hodgkin's lymphoma (MCHL)
Lymphocyte rich classical Hodgkin's lymphoma (LRCHL)
Lymphocyte-depleted classical Hodgkin's lymphoma (LDHL)

CD15	+ in majority of cases	—
CD45	—	+
CD20	— in majority of cases	+
CD79a	— in majority of cases	+

HD, *Hodgkin's disease;* HRS, *Hodgkin and Reed/Sternberg;* L&H, *lymphocytic and histiocytic;* NLPHD, *nodular lymphocyte predominant Hodgkin's disease.*

The NS subtype accounts for approximately 70% of classical HL, affecting predominantly young adults. Morphologically, it is characterized by the presence of one or more sclerotic bands radiating from a thickened lymph node capsule. The British National Lymphomas Investigation subclassified NS HL into two grades based on the percentage of nodules showing lymphocyte depletion or increased number of anaplastic-appearing HRS cells.[41,42] However, the prognostic value of this grading system with modern therapy is unclear.

The MC subtype is more frequently seen in developing countries, accounting for more than half of the cases, whereas in the more developed parts of the world, it comprises approximately 25% of classical HL. Morphologically, HRS cells are seen scattered in a diffuse inflammatory background with the absence of nodular sclerosing fibrosis. In contrast to the NS and lymphocyte rich classical Hodgkin's lymphoma (LRCHD), EBV positivity is much more frequent in the MC subtype.[43]

LRCHD accounts for approximately 5% of classical HL, has a male predominance and older median age at presentation.[44] It is characterized by a background infiltrate of small, mature, predominantly B-lymphocytes with rare HRS and variants. It can resemble NLPHD morphologically, and immunohistochemical studies of the malignant cells are essential to make the distinction. The prognosis may be slightly better than other subtypes of classical HD.[44]

The LD subtype has increased number of HRS and is depleted in lymphocytes. Many cases that were previously classified as LD HL are now determined to be anaplastic or large-cell non-Hodgkin's lymphoma based on immunohistochemical studies.[45] Reliable clinical data on this subtype is limited given its rarity and uncertainty concerning its diagnosis.

Adverse pathologic prognostic factors include macrophage gene expression signature and higher numbers of CD163+ or CD68+ macrophages; expression of BCL2, the T-cell antigens CD2 and CD4, galectin-1, ABCC1 by HRS cells; a characteristic mRNA signature; and a characteristic miRNA signature.[46]

Nodular Lymphocyte Predominant Hodgkin's Lymphoma

NLPHD comprises 5% of HL. The malignant cells of NLPHD are the LP cells, which are also known as popcorn cells because of their characteristic appearance. The pathogenesis of LP cells is probably distinct from that of HRS but probably shares constitutive NF-κB activity; recurrent translocations involving BCL6 are present in about one half of cases. Unlike classical HL, the neoplastic cells of NLPHD typically lack the expression of CD15 and CD30 markers but are consistently CD20 and CD45 positive.[47] A nodular pattern is seen usually completely or partially replacing the lymph node. The nodules tend to be large and closely packed, and the LP cells are typically seen within or around the nodules. There are usually large numbers of CD57 positive small lymphocytes in the nodules, often with ringing around the lymphocytic and histiocytic (L&H) cells. In about 3% to 5% of cases, transformation to diffuse large B-cell lymphoma may occur.

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Clinical Presentation

The most common clinical presentation of HL is nontender lymphadenopathy, mostly in the cervical nodal chain,

occurring in about 70% of cases. Axillary or inguinal adenopathy are less frequently reported, found in about 15% and 10% of patients, respectively. Another common presentation is mediastinal adenopathy detected on radiographic imaging. In cases of large mediastinal adenopathy, patients may occasionally present with local symptoms including shortness of breath, chest pain, cough, or superior vena cava syndrome. Rarely, patients may present with an enlarging anterior chest wall mass because of local extension.

Patients may also present exclusively with constitutional symptoms in the absence of any physical findings. These symptoms, also known as B symptoms, include fever, unexplained weight loss, and drenching night sweats. Severe, generalized pruritus, not classified as a B symptom, is noted in about 10% to 15% of patients, and has been associated with a poorer prognosis.[48] Alcohol-induced pain, typically at the site of lymphadenopathy or bony involvement, can be a presenting symptom in some patients.[49]

Staging System

The Ann Arbor staging classification (Table 76-3), developed in 1971, is a four-stage system formulated to provide prognostic information and to guide therapeutic decisions. However, it does not reflect other important prognostic factors such as bulky disease or multiple sites of involvement.[50] The availability of improved imaging techniques has also changed its applicability. In 1988, revisions to the Ann Arbor staging system were made based on a meeting in Coltswolds, England (Table 76-4).[51] Main changes include the following: (1) Allowed the use of CT scanning to assess disease involvement below the diaphragm. (2) For stage II disease, the number of anatomic nodal sites were indicated by a subscript (e.g., stage II_3). (3) For stage III disease, upper and lower abdominal involvement were subdivided as III_1 and III_2, respectively. (4) Bulky disease was denoted by *X*, defined as more than one third widening of the mediastinum at T5-6 level or >10 cm maximum dimension of the nodal mass. (5) Unconfirmed/uncertain complete remission (CRu) was introduced to denote presence of residual imaging abnormality but absence of pathologically confirmed residual disease.

TABLE 76-3 Ann Arbor Staging Classification

Stage	Definitions
Stage I	Involvement of single lymph node region (I) or of single extralymphatic organ or site (I_E)
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm alone (II) or with involvement of limited, contiguous extralymphatic organ or tissue (II_E)
Stage III	Involvement of lymph node regions on both sides of the diaphragm (III), which may include the spleen (III_S), or limited, contiguous extralymphatic organ or site (III_E) or both (III_{SE})
Stage IV	Diffuse or disseminated foci of involvement of one or more extralymphatic organs or tissues, with or without associated lymphatic involvement

The absence or presence of fever, night sweats or unexplained weight loss of 10% or more of body weight in the 6 months preceding admission are to be denoted in all cases by the suffix letters A or B, respectively. The clinical stage (CS) denotes the stage as determined by all diagnostic examinations and a single biopsy only. If a second biopsy of any kind has been obtained, whether negative or positive, the term pathologic stage (PS) is used.

Patient Evaluation and Staging Workup

An adequate surgical biopsy for pathological assessment by an experienced hematopathologist is essential in the initial diagnosis of HL. All patients need to undergo a careful history and physical examination. Particular attention should be placed on the presence and duration of constitutional symptoms, as well as other symptoms that may be indicative of extent and bulkiness of local disease. On physical examination, all nodal groups should be thoroughly palpated with clear documentation of the extent of disease involvement. Baseline blood work, some of which have been shown to be of prognostic value in patients with HL, should be obtained. These include complete blood count with differential, sedimentation rate, and serum albumin.[52] Fluorine-18-fluorodeoxyglucose positron emission tomographic (FDG-PET) scan, which has been shown to be more sensitive then CT scanning, and results in upstaging of 15% to 25% of patients, is now considered part of standard staging work-up for HL.[53-59] A separate diagnostic CT is not necessary if it was done as part of an integrated PET-CT scan. The performance of bone

TABLE 76-4 The Coltswolds Staging Classification for Hodgkin's Lymphoma

Stage	Definitions
Stage I	Involvement of a single lymph node region or lymphoid structure (e.g., spleen, thymus, Waldeyer's ring) or involvement of a single extralymphatic site (IE)
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm (hilar nodes, when involved on both sides, constitute stage II disease); localized contiguous involvement of only one extranodal organ or site and lymph node region(s) on the same side of the diaphragm (IIE). The number of anatomic regions involved should be indicated by a suffix (e.g., II_3)
Stage III	Involvement of lymph node regions on both sides of the diaphragm (III), which may also be accompanied by involvement of the spleen (III_S) or by localized contiguous involvement of only one extranodal organ site (IIIE) or both III SE) III_1: With or without involvement of splenic, hilar, celiac or portal nodes III_2: With involvement of paraaortic, iliac, and mesenteric nodes
Stage IV	Diffuse or disseminated involvement of one or more extranodal organs or tissues, with or without associated lymph node involvement
DESIGNATIONS APPLICABLE TO ANY DISEASE STAGE	
A	No symptoms
B	Fever (temperature >38°C), drenching night sweats, unexplained weight loss >10% of body weight within the prior 6 months
X	Bulky disease (a widening of the mediastinum by more than one third of the presence of a nodal mass with a maximal dimension greater than 10 cm)
E	Involvement of a single extranodal site that is contiguous or proximal to the known nodal site
CS	Clinical stage
PS	Pathological stage (as determined by staging laparotomy)

marrow biopsy should be limited to patients with advanced-stage disease or in those with constitutional symptoms given the low yield in patients with early-stage, favorable-prognosis disease of less than 1%.[60,61] The recommended patient evaluation and staging studies for newly diagnosed HL are listed in Table 76-5.

Prognostic Factors

For patients with early-stage HL, several prognostic factors, largely based on patients treated with radiation therapy alone, have been identified. These include B symptoms, sedimentation rates, disease bulk, number of sites of disease, age, and histology. Cooperative groups have used varying combination of these factors to stratify patients into favorable versus unfavorable disease in clinical trials. Examples of various prognostic classification systems used by cooperative groups are shown in Table 76-6.

For patients with advanced-stage disease, Hasenclever et al developed the International Prognostic Score (IPS), using data from more than 5000 patients with advanced-stage HL, mostly treated with doxorubicin-based combination chemotherapy.[52] Seven factors were found to have similar independent prognostic value in predicting freedom-from progression (FFP) and overall survival (OS). These included hypoalbuminemia (<4 g per deciliter), anemia (<10.5 g per deciliter), male sex, age 45 years or older, stage IV disease, leukocytosis (>15,000 per cubic millimeter), and lymphocytopenia (<600 per cubic millimeter, <8 percent of the white-cell count, or both). The 5-year FFP ranged from 42% in patients with an IPS score of ≥5% to 84% in patients with a score of 0 (Table 76-7). However, patients with five or more of the adverse factors account for only 7% of the study population. The IPS has been used in trials for patient selection and patient stratification, and it may also have a role in guiding tailored therapy based on relapse risk in advanced-stage patients.

An early response to PET has been identified as a powerful prognostic tool in HL.[62] In a joint Italian-Danish study,[53] PET response after two cycles of chemotherapy overshadowed the prognostic value of IPS and emerged as the single most important prognostic factor in advanced-stage HL. Several PET-adaptive clinical trials are testing the hypothesis that interim PET results can guide decisions regarding treatment escalation or deescalation.

TABLE 76-7 The International Prognostic Scoring System for Advanced-Stage Hodgkin's Lymphoma

Prognostic Score	5-Year Freedom-From-Progression (%)	5-Year Overall Survival (%)
0	84	89
1	77	90
2	67	81
3	60	78
4	51	61
>5	42	56

Note: Each of the following factors carries a score of one: hypoalbuminemia, anemia, male sex, age ≥45, stage IV disease, leukocytosis, and lymphocytopenia.

PRIMARY THERAPY FOR EARLY-STAGE HODGKIN'S LYMPHOMA

Early-stage HL comprises about 60% of all cases of HL. Historically, the primary therapy for early-stage HL had been

extended-field radiation therapy alone, with addition of chemotherapy in the presence of unfavorable prognostic factors. Since the introduction of Adriamycin, bleomycin, vinblastine, dacarbazine (ABVD), a more effective and less toxic combination chemotherapy regimen than mechlorethamine, vincristine, procarbazine, prednisone (MOPP), there has been a shift to the use of combined-modality therapy in patients with early-stage disease, which yields long-term cure rates of approximately 90% or higher. Randomized studies have shown a significantly higher FFTF with combined-modality therapy than with radiation therapy alone.[63-65]

Because of the excellent survival in this relatively young group of patients, late effects of therapy have been increasingly recognized.[66-73] Most of the current trials on early-stage HL focus on treatment reduction and modification. The key questions addressed by the trials on the use of combined-modality therapy for early-stage HL include the following: (1) What is the optimal combination chemotherapy regimen? (2) How many cycles of chemotherapy are needed? (3) What are the appropriate radiation field size and dose? (4) Can radiation therapy be eliminated?

Optimal Combination Chemotherapy Regimen

Investigators have explored alternatives or modification of the ABVD regimen to limit toxicity in favorable patients or to improve efficacy in unfavorable patients. Examples include vinblastine, bleomycin, and methotrexate (VBM)[74-77]; methotrexate, vinblastine, and prednisone (MVP)[75]; doxorubicin, cyclophosphamide, etoposide, vincristine, bleomycin, prednisolone (VAPEC-B)[78]; doxorubicin, vinblastine (AV)[63]; mitoxantrone, vincristine, vinblastine, and prednisone (NOVP)[79]; and epirubicin, bleomycin, vinblastine, and prednisone (EBVP II, administered monthly).[80] Most of these regimens showed promising results at least in patients with favorable-prognosis disease, with relapse-free survival (RFS) rates of about 90%. The Stanford V regimen (nitrogen mustard, Adriamycin, vincristine, vinblastine, etoposide, bleomycin, and prednisone, followed by radiation therapy to initial nodal involvement in selected cases), a short but intensive 12-week regimen, was originally developed for patients with advanced-stage disease or bulky, early-stage disease.[81,82] The Stanford group reported the results on 87 patients with nonbulky, stages I to IIA disease treated with an abbreviated, 8-week course of Stanford V followed by involved-field radiotherapy (IFRT) to 30 Gy.[83] At a median follow-up of 10 years, the FFP, DFS, and OS were 94%, 99%, and 94%, respectively. The German Hodgkin's Study Group (GHSG) HD13 trial compared two cycles of ABVD, AVD, ABV, and AV, all followed by 30 Gy of involved-field irradiation in clinical stage (CS) I to CS II patients without risk factors. The two arms without dacarbazine (AV and ABV) were closed early because of higher than expected relapse rates. In the most recent update, the AVD arm was significantly inferior to the ABVD arm mainly as a result of late relapses.

Attempts to deescalate chemotherapy in patients with unfavorable-prognosis disease have been disappointing.[84] To improve the treatment outcome in patients with unfavorable features, trials had been conducted to determine whether these patients may benefit from the regimen BEACOPP, originally developed for patients with advanced-stage disease. Both the European Organization for Research and Treatment of Cancer (EORTC) H9U and the GHSG HD11 studies compared four to six cycles of ABVD with four cycles of BEACOPP-baseline, followed by involved-field irradiation to 20 Gy to 30 Gy. No significant differences in 4-year EFS or OS were observed between BEACOPP and ABVD in the EORTC H9U trial. In the GHSG HD11, at a median follow-up of 82 months, a significantly higher 5-year freedom-from-treatment failure (FFTF) in the four cycles of baseline BEACOPP arm over the four cycles ABVD arm, if followed by 20 Gy of involved-field radiation therapy (86.8% versus 81.1%; 95% confidence interval [CI] of difference, 0.1% to 11.3%). However, there was no significant difference between BEACOPP and ABVD if followed by 30 Gy of involved-field radiation therapy.[85] Patients treated with baseline BEACOPP had a higher rate of severe toxicity than patients treated with ABVD (73.8% versus 51.5%, $p < 0.001$). The GHSG HD 14 trial tested increasing dose intensity using dose-escalated BEACOPP in patients with unfavorable CSs I-II disease, randomizing patients to four cycles of ABVD versus two cycles of dose-escalated BEACOPP and two cycles of ABVD (two-plus-two regimen), followed by involved field irradiation to 30 Gy. At a median follow up of 43 months, the two-plus-two regimen had a significantly improved 5-year FFTF by 7.2% (hazard ratio [HR], 0.44, $p < 0.001$), though it was associated with more acute toxicity. There was no difference in overall survival between the two arms.[86]

Optimal Duration of Chemotherapy

Whether the number of cycles of chemotherapy can be shortened in patients with favorable-prognosis disease was by addressed by the GHSG HD10 trial, in which CSs I-II patients without risk factors were randomized to four cycles or two cycles of ABVD, followed by 30 Gy or 20 Gy involved-field irradiation. At a median follow-up of 7.5 years, there were no significant differences between four versus two cycles of chemotherapy in 8-year FFTF (88.4% versus 85.7%), 8-year OS (94.6% versus 94.4%).[87] In patients with unfavorable-prognosis disease, the optimal number of cycles of chemotherapy was one of the study questions in two successive EORTC trials using different chemotherapy regimens. In the EORTC-H8U trial, patients were randomized to six cycles of MOPP/ABV followed by involved-field irradiation, four cycles of MOPP/ABV followed by involved-field irradiation or four cycles of MOPP/ABV followed by extended-field irradiation.[88] At a median follow-up of 92 months, there was no significant difference in 5-year EFS rates among the three treatment groups (84%, 88%, and 87%). The OS rates at 10 years were also not significantly different (88%, 85%, and 84%).[64] In the previously described EORTC-H9U trial, randomizing patients to six cycles of ABVD, four cycles of ABVD, or four cycles of BEACOPP, all followed by involved-field irradiation, at a median follow up of 57 months, there was no difference in 4-year EFS among the three arms (91%, 87%, and 90%, $p = 0.38$).[89]

Optimal Radiation Field Size

Historical Radiation Fields

Historically, extended field radiation therapy (EFRT) alone was standard treatment for early-stage HL, and later administered as part of combined-modality therapy. However, mature results from several randomized trials have since become available, showing no difference in FFTF and OS between EFRT versus IFRT after chemotherapy for early-stage HL.[64,90,91] As expected, more second malignancy cases were seen in the EFRT arm than the IFRT arm.

In most clinical trials conducted in the past decade, IFRT was employed. An involved field encompasses not only the involved nodes but also the other lymph nodes within the same lymph node region, as denoted by the Rye classification for staging. It was developed in the two-dimensional treatment planning era, in which the field design is largely based on bony landmark, with inclusion of a considerable volume of normal tissue in the irradiated field.[92] However, there are data suggesting that relapse sites in HL after chemotherapy

alone are largely limited to the initially involved node.[93] This has led to the concept of involved-node radiotherapy (INRT), first described by the European Organization for Research and Treatment of Cancer/Groupe d'Etudes des Lymphomes de l'Adulte (EORTC/GELA) and later the GHSG.[94,95]

Modern Radiation Fields: ISRT and INRT

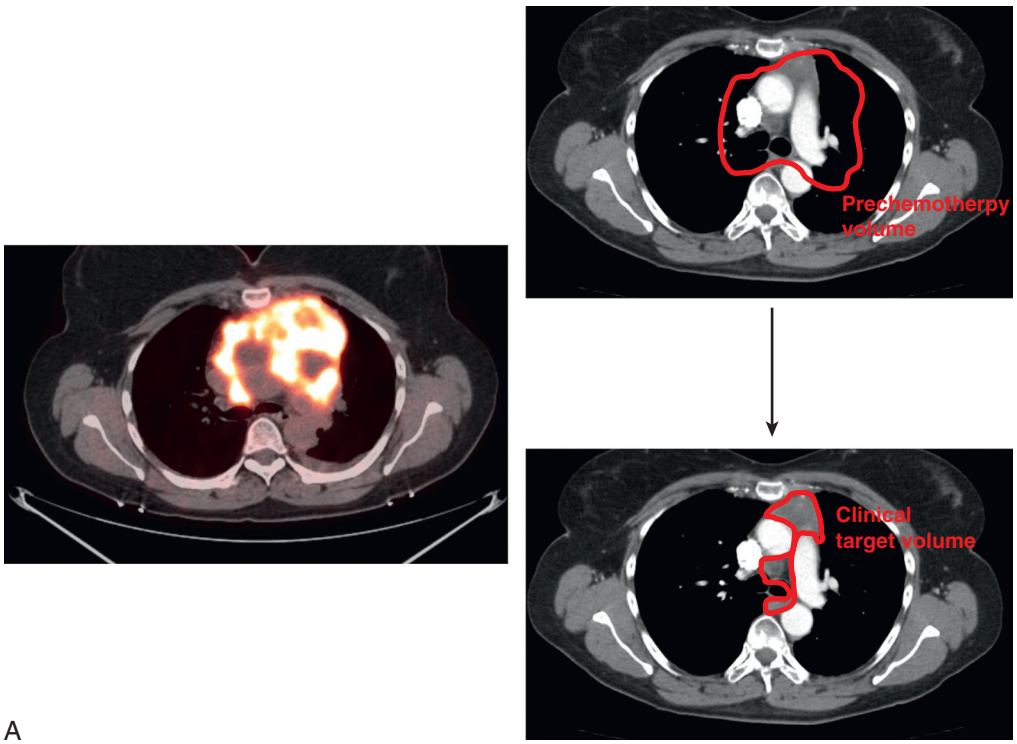
Availability of cross-sectional imaging for radiation planning, accurate dosimetry using modern algorithms that adjust for tissue inhomogeneities, complex beam shaping with multileaf collimation, and intensity-modulated beam delivery in selected cases have made it possible to better define and further decrease radiation fields. Guidelines for INRT and involved-site radiation therapy (ISRT), based on best available evidence and consensus of expert opinion, were recently published by the International Lymphoma Radiation Oncology Group (ILROG).[96] The key difference between INRT and ISRT is whether an optimal prechemotherapy PET-CT scan is available to guide the treatment planning. For INRT, ideally, the prechemotherapy PET/CT is acquired in the treatment position, using the same breathing instructions and immobilization device. However, prechemotherapy PET/CT scan with patient in an approximate position suitable for later radiation treatment is also considered sufficient. ISRT accommodates cases in which optimal prechemotherapy imaging is not available. In such cases, allowance should be made in the clinical target volume (CTV) for uncertainties resulting from differences in positioning of the prechemotherapy scan and planning CT.

For volume definitions, the guidelines recommend that the CTV be determined by fusion of planning CT with with prechemotherapy PET-CT. The original disease volume is first contoured, and then uninvolved normal structures (e.g., lungs, muscles, major vessels) are excluded. Figure 76-1 illustrates case examples of CTV determination based on prechemotherapy PET-CT results. The determination of the CTV is the most important and challenging step because it heavily relies on the availability of optimal prechemotherapy imaging.

In selected sites, there may also be a need to determine an internal target volume (ITV), with expansion of the CTV to account for uncertainties in size, shape, and position of the CTV because of motion. Margins for extension from CTV to ITV may be obtained from four-dimensional CT or fluoroscopy. This may be most relevant where target motion is expected, including chest and upper abdominal sites, and where breath-hold techniques are not available. The EORTC/GELA group defines the planning target volume (PTV) as 1-cm isotropic expansion of the CTV to allow for organ motion and set-up variations.[94] The GHSG defines the PTV as 2-cm axial and 3-cm cranial caudal expansion of the CTV (if necessary, can be reduced to 1 cm to 1.5 cm if close proximity to critical structures) and for mediastinal disease, 1-cm axial and 2-cm cranial caudal expansion.[95] Unlike the European guidelines, the ILROG guidelines do not specify the extent of the PTV expansion. Instead, the recommendation is to use standard margins per institution, depending on immobilization device, body site, and patient cooperation.

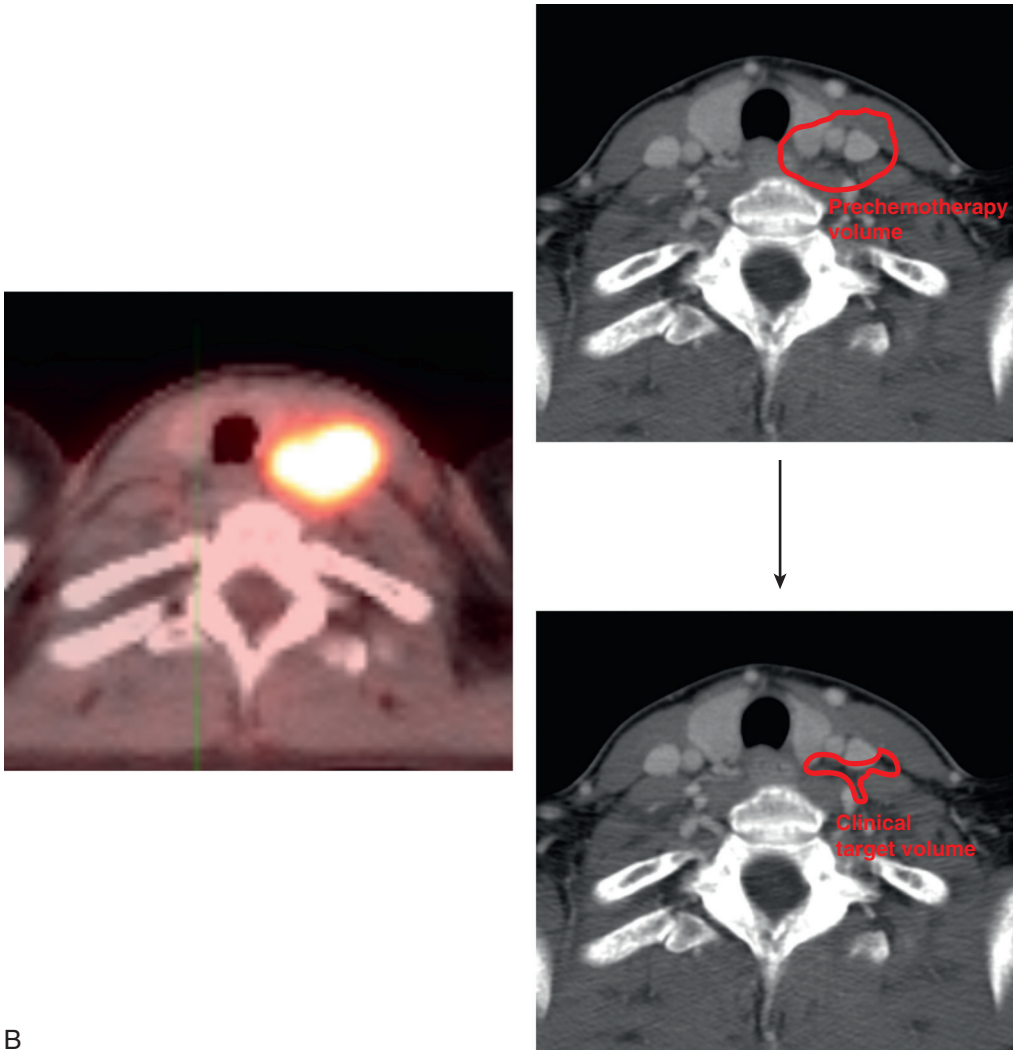
Several studies have addressed the safety of radiation field reduction from IFRT. Investigators from the British Columbia reported results of their experience on INRT for patients with early-stage HL. At a median follow up of 50 months, no local recurrences were observed. However, the INRT employed in this study encompassed the initially involved lymph nodes with a margin ranging from 1.5 cm to 5 cm to the field edge and therefore included a larger volume than that of the INRT as defined by the European groups.[97] In addition, two-dimensional planning was performed in some of the patients. In a study from the Institut Gustave Roussy, results of 50 patients with early-stage HL treated with ABVD followed by INRT as per the EORTC/GELA definition was reported. With a median follow-up time of 53 months, the 5-year progression-free survival (PFS) rate was 92%. A total of four relapses were observed, including two distant and two infield relapses. Maraldo et al reported on treatment outcome of 97 patients with early-stage HL treated with ABVD followed by INRT according to the EORTC/GELA guidelines. A 4-year FFP rate of 96% was reported at a median follow up of 50 months. There were three relapses, two of which were infield and one was in the contralateral neck. Results thus far therefore suggest that the use of a much more limited field than the traditional IFRT does not appear to be associated with marginal misses and may indeed be safe in the presence of effective chemotherapy.

In the EORTC/Lymphoma Study Association (LYSA)/the Italian Lymphoma Foundation (FIL) H10 trial (which will be discussed later) for early-stage favorable and unfavorable HL, INRT was adopted in both the standard and experimental arms. In the ongoing GHSG HD17 trial for early-stage HL with risk factors (which will be discussed later), addressing the use of PET response to guide radiotherapy use, INRT is used in the experimental arm in patients with PET-positive disease after chemotherapy.



Optimal Radiation Dose

The appropriate radiation dose after chemotherapy in early-stage HL has been explored by three trials.[80,85,87,98,99] The EORTC H9F trial is a three-arm trial in which all patients receive six cycles of EBVP II.[80] After a complete response, patients were randomized to receive no further treatment, 36 Gy, or 20 Gy of IFRT. Patients with a partial response all received 36 Gy of IFRT with or without a 4-Gy boost. A complete response or complete response unconfirmed was achieved in 619 patients. At a median follow-up of 33 months, the 4-year EFS in the three arms of 36 Gy, 20 Gy, and no radiotherapy were 87%, 84%, and 70%, respectively. The difference in treatment results between the two doses of radiotherapy was not significant. However, the no-radiotherapy arm was closed early because stopping rules were met (>20% of events, which will be discussed).



The GHSG HD10 trial is a four-arm trial for low risk (no bulky mediastinal mass or extranodal disease, 3 or less nodal sites, low sedimentation rate) patients at CSs I to II, in which involved-field radiotherapy to 30 Gy versus 20 Gy after four or two cycles of ABVD were compared.[87] At a median follow-up of 7.5 years, there were no significant differences between 30 Gy versus 20 Gy of involved-field radiotherapy in 8-year OS (94.9% versus 95.6%), 8-year FFTF (87.8% versus 88.6%) and 8-year PFS (88.1% versus 88.9%). The question of optimal radiation dose in unfavorable patients was addressed by the GHSG HD11 trial,[85] a four-arm trial comparing 20 Gy versus 30 Gy after four cycles of ABVD or baseline BEACOPP. At a median follow-up of 82 months, the 5-year FFTF rates were 81.1%, 85.3%, 86.8%, and 87.0%, respectively. Baseline BEACOPP was more effective than ABVD when followed by 20 Gy of IFRT, but the two regimens yielded similar outcome when followed by 30 Gy of IFRT. There was no significant difference in 5-year FFTF rate between baseline BEACOPP and ABVD when followed by 30 Gy of IFRT; however, inferiority of 20 Gy cannot be excluded after four cycles of ABVD, leading to the authors' conclusion of four cycles of ABVD followed by 30 Gy of IFRT as optimal therapy for early-stage, unfavorable HL.

Chemotherapy Alone

There are well-documented late effects of radiotherapy for HL, based largely on patients treated with radiation therapy

A

B

alone with larger treatment fields and higher doses of radiation than currently employed. These include risks of second malignancies,[100-103] in particular, the risk of breast cancer in women irradiated at a young age,[104,105] and lung cancer among smokers,[106-108] and risks of cardiovascular disease.[109] Because of these concerns, investigators have explored the option of eliminating radiation therapy and treating patients with early-stage disease with chemotherapy alone. Table 76-8 summarizes randomized trials that had compared combined modality therapy with chemotherapy alone.[110-117] These trials varied in the study design, patient population, types of chemotherapy, and radiation fields employed. All but one trial showed a significant DFS, EFS, or freedom-from-progression benefit with the addition of radiation therapy.[110-114] This included the recently reported National Cancer Institute Canadian (NCIC) HD6 trial,[117] which showed that the radiotherapy-containing arms were associated with an improved 10-year failure-free survival rate (92% versus 87%, $p = 0.05$). This is despite the fact that extended-field radiation therapy alone, an approach that has been shown to significantly inferior to combined-modality therapy, was used in patients with low-risk disease. In the same trial, however, despite the improved failure-free survival, the radiotherapy-containing arm was associated with a significantly reduced 10-year OS (87% versus 92%, $p = 0.04$). Ten of the 24 deaths on the radiotherapy-containing arm were from second malignancy, which is likely related to the use of extended-field radiation therapy in patients with both low- and high-risk disease in this trial.

The Cochrane Haematological Malignancies Group recently conducted a meta-analysis,[118] in which five randomized controlled trials that compared chemotherapy alone with identical chemotherapy combined with radiotherapy for patients with stages I to II HL were included. The results showed that, in addition to a significant disease-control benefit favoring the combined-modality therapy approach, there was a highly significant overall survival benefit with the addition of radiation therapy (HR, 0.4; $p < 0.00001$). However, one main criticism of this analysis was the inclusion of trials that used inadequate chemotherapy. It therefore appears that less effective or abbreviated chemotherapy, or alternatives to ABVD designed to limit chemotherapy-related toxicity, is not acceptable when radiation therapy is omitted, and the addition of radiation therapy may allow the use of lower cumulative doses of doxorubicin or less toxic regimens. Toxicities associated with full course ABVD can be nontrivial, and these include myelosuppression, peripheral neuropathy, bleomycin lung toxicity, and cardiac toxicity.[119-121] A significantly increased excess cardiac

mortality has been demonstrated after ABVD without mediastinal irradiation.[120,121]

Elimination of Radiation Therapy Based on PET-Response

Convincing data on the high prognostic value of response to chemotherapy based on PET findings, especially for patients with advanced-stage disease,[53,122] has led to an increasing interest in the use of PET response (either early in the course of chemotherapy or at the end of chemotherapy) to identify patients in whom radiation therapy can be eliminated. Picardi et al conducted a randomized trial designed to evaluate whether radiation therapy can be safely eliminated if a complete response by PET scan is achieved after chemotherapy.[123] A total of 260 patients with stages I to IV HL with tumor mass greater than 5 cm were included in the study. One hundred and sixty patients became PET negative and had a more than 75% reduction in the tumor mass at the completion of six cycles of etoposide, epirubicin, bleomycin, cyclophosphamide, and prednisolone (VEBEP). These patients were randomized to 32 Gy of IFRT versus no further treatment. At a median follow-up of 40 months, there was a significant DFS benefit with the addition of consolidative radiation therapy (96% versus 86%, $p = 0.03$), suggesting that even in carefully selected patients based on optimal functional imaging response to chemotherapy, the omission of radiation therapy is associated with a higher relapse rate. However, this study is limited by the use of suboptimal chemotherapy.

In recent years, several randomized trials were designed to specifically address the elimination of radiation therapy in patients with early-stage HL based on PET response to modern chemotherapy.[87,124] In the EORTC/LYSA/FIL H10 trial, patients with favorable early-stage disease were randomized to the standard arm of three cycles of ABVD followed by INRT, versus the experimental arm of two cycles of ABVD followed by PET scan. If the scan was negative, patients received two additional cycles of ABVD and then no further treatment. If the PET scan was positive, patients received two cycles of dose-escalated BEACOPP, followed by INRT. For patients with unfavorable early-stage disease, the standard arm consisted of four cycles of ABVD followed by INRT, whereas patients on the experimental arm received two cycles of ABVD followed by PET scan. If the scan was negative, patients received four additional cycles of ABVD and then no further treatment. If the PET scan was positive, patients received two cycles of dose-escalated BEACOPP, followed by INRT. In the most recent interim analysis, for patients with PET-negative disease after ABVD, there were 9 events in the no radiotherapy arm versus 1 event in the radiotherapy arm (HR, 9.36) in the favorable group, and 16 events in the no radiotherapy arm versus 7 events in the radiotherapy arm (HR, 2.42) in the unfavorable groups. This led to the conclusion that the objective of non-inferiority of chemotherapy alone as compared with combined-modality therapy has not been met, and at the recommendation of an independent data monitoring committee, the experimental arms of no radiotherapy in both groups of patients were closed.

In United Kingdom RAPID trial,[125] patients with CS IA and IIA non-bulky HL underwent PET scan after three cycles of ABVD. If the scan was negative, patients were randomized to IFRT versus no further treatment. In the most recent update of this trial,[124] 571 patients had a PET scan following three cycles of ABVD. The Deauville Criteria was used to determine PET response: A score of 1 or 2 was considered negative (uptake less than or equal to mediastinal blood pool). A total of 426 patients (74%) were scored as PET-negative, and the remaining were scored as PET-positive and went on to receive IFRT. Among the 420 patients who were PET-negative randomized, 209 were randomized to the radiotherapy arm, though 26 of the patients did not receive radiotherapy. At a median follow-up time of 48.6 months, by intent-to-treat analysis, there was no difference between the radiotherapy versus no radiotherapy arm (3-year PFS 94.5% versus 90.8%, $p = 0.23$). By per-treatment analysis, however, there is a significant benefit in the radiotherapy arm (3-year PFS 97% versus 90.7%, $p = 0.03$). There was a nonsignificant trend toward lower survival in the radiotherapy arm (97.1% versus 99.5%, $p = 0.07$). However, among the seven deaths in patients randomized to the radiotherapy arm, five occurred prior to initiation of the radiotherapy.

Two ongoing trials conducted by the GHSG are exploring omission of radiotherapy by PET-response. The HD16 trial randomizes patients with low-risk early-stage disease to two cycles ABVD followed by 30 Gy IFRT irrespective of PET results after chemotherapy, versus two cycles ABVD followed by 30 Gy IFRT for only patients with positive PET after chemotherapy and no further therapy if PET is negative after chemotherapy. The HD17 trial randomizes patients with high-risk early-stage disease to two cycles of dose-escalated BEACOPP followed by two cycles ABVD (two-by-two regimen), followed by 30 Gy IFRT irrespective of PET results after chemotherapy, versus the same two-by-two regimen, followed by 30 Gy INRT only for patients with positive PET after chemotherapy and no further therapy if PET is negative.

Recommendation on Treatment for Early-Stage Hodgkin's Lymphoma

The optimal treatment for early-stage HL is in evolution. At this time, in patients with early-stage disease with favorable prognosis based on GHSH criteria (no bulky mediastinal mass or extranodal disease, 3 or fewer nodal sites, low sedimentation rate), two cycles of ABVD chemotherapy followed by ISRT to 20 Gy may be adequate.[87] In patients with unfavorable early-stage disease, four cycles of ABVD may be adequate, but 30 Gy of ISRT is needed after ABVD.[85]

Based on early results, there appears to be an approximately 7% gain in PFS with the addition of radiotherapy in patients who achieved PET-negative disease (less than or equal to mediastinal blood pool uptake) after chemotherapy. Preliminarily, the lower cure rate and toxicity of salvage therapy in the small proportion of patients with relapse disease needs to be weighed against the toxicity of INRT (which will be discussed later). However, longer follow-up of these recently completed or ongoing trials will be needed to account for late relapses in both arms.

PRIMARY TREATMENT FOR ADVANCED-STAGE HODGKIN'S LYMPHOMA

The introduction of the combination chemotherapy regimen, MOPP, in the mid-1960s substantially improved the curability of patients with advanced-stage HL.[4] The ABVD regimen was initially introduced as a second-line therapy in patients who had a poor response to, or relapse after MOPP chemotherapy.[126] Its role as primary treatment in newly diagnosed patients was subsequently substantiated by several randomized trials in patients with advanced-stage disease, showing that ABVD-containing regimens are associated with a higher failure-free survival than MOPP.[127-130] Results of an intergroup randomized trial comparing MOPP/ABV hybrid versus ABVD in advanced-stage HL showed that the addition of MOPP to ABVD did not confer any therapeutic benefit but did add to treatment-related toxicity.[131] ABVD is significantly less myelosuppressive, and it also does not carry the risk of

gonadal dysfunction and leukemogenesis. Currently, in the United States, ABVD is accepted by most as the standard systemic therapy for advanced-stage HL, which yields long-term failure-free survival of 60% to 65% and OS of 70% to 75%. To further improve treatment results, dose-escalated or dose-dense regimens for advanced-stage HL have been developed. The two major regimens, BEACOPP and its variants, and Stanford V, are discussed here.

Alternatives to ABVD

BEACOPP

The dose-escalated BEACOPP regimen (eTable 76-1), developed by the GHSG, yielded significantly higher survival outcome compared with conventional-dose regimens in the GHSG HD9 study.[132] In this three-armed trial, patients with stages IIB, IIIA, IIIB, and IV were randomized to eight cycles of COPP-ABVD, baseline-dose BEACOPP, or dose-escalated BEACOPP. In the most recent update of the study on 1196 evaluable patients, at a median follow-up of 111 months, the 10-year freedom-from-relapse rate was significantly higher in the dose-escalated BEACOPP arm than the baseline BEACOPP and COPP-ABVD arms (82%, 70%, and 64%, respectively, $p < 0.0001$).[133] The corresponding 10-year OS rates were 86%, 80%, and 75%, respectively ($p = 0.0005$). However, in the standard arm of this trial, COPP-ABVD, rather than modern ABVD, was used. Also, it was noted that patients on the dose-escalated BEACOPP arm had significantly higher 10-year cumulative incidence of acute myelogenous leukemia and myelodysplasia (3.2%, 2.2%, and 0.4%, respectively, $p = 0.03$).

In an attempt to reduce treatment-related toxicity, the GHSG explored the efficacy of modified versions of the BEACOPP regimen. The GHSG HD12 trial is a four-arm study for patients with bulky stage IIB and stages III to IV disease comparing eight cycles of dose-escalated BEACOPP with or without radiation therapy, versus four cycles of escalated and four cycles of baseline BEACOPP with or without radiation therapy. In the most recent update that included 1571 eligible patients, at a median follow-up of 69 months,[134] the 5-year FFTF, PFS, and OS of the entire cohort were 85.5%, 86.2%, and 91%, respectively. There were no significant differences in outcome between the two chemotherapy regimens, but less hematologic toxicities were observed in the arm that contained baseline BEACOPP.

The GHSG HD 15 trial compared right cycles of dose-escalated BEACOPP ($8B_{esc}$), six cycles of dose-escalated BEACOPP ($6B_{esc}$), or eight cycles of $BEACOPP_{14}$ ($8B_{14}$) a time-intensified variant of baseline BEACOPP baseline.[135] This study also evaluated the use of PET to select patients for chemotherapy alone (which will be discussed). At a median follow up of 48 months, the 5-year FFTF rates were 84.4%, 89.3%, and 85.4% in the $8B_{esc}$ $6B_{esc}$ $8B_{14}$ arms, respectively, and the 5-year OS rates were 91.9%, 95.3%, and 94.5%, respectively. There were more deaths from acute toxicity and more second malignancies in the $8B_{esc}$ arm. This led to the authors' conclusion that six cycles of dose-escalated BEACOPP is more effective and less toxic than eight cycles of the chemotherapy.

Variations of the BEACOPP regimen have also been investigated by other groups. The Gruppo Italiano per lo Studio dei Linfomi conducted a randomized trial comparing four cycles of dose-escalated BEACOPP followed by two cycles of baseline BEACOPP, ABVD, and the CEC hybrid regimen (cyclophosphamide, lomustine, vindesine, melphalan, prednisone, epidoxorubicin, vincristine, procarbazine, vinblastine, and bleomycin) for patients with stages IIB to IV HL.[136] Radiotherapy was administered to sites of bulky disease to 25.2 Gy, or to slowly or partially responding sites to 30.6 Gy. Among 295 evaluated patients, at a median follow-up of 41 months, those assigned to the BEACOPP arm had a significantly higher 5-year FFS and PFS compared with patients on the ABVD arm (65% versus 78%, $p = 0.036$ and 68% versus 81%, $p = 0.038$). Unlike the GHSG HD9 trial, however, a significant difference in OS was not observed, and this may be related to the relatively small size of the study, the limited follow-up time, and the different chemotherapy used in the standard arms of the two trials. It was noted, however, that the 5-year FFS of 65% in patients treated with ABVD on this trial was inferior to the outcome of a previous trial that included similar patients receiving ABVD, where a 5-year FFS of 78% was observed.[136] The Michelangelo, Gruppo Italiano Terapie Innovative nei Linfomi (GITIL) and Intergruppo Italiano Linfomi (IIL) cooperative groups conducted a randomized trial comparing six to eight cycles of ABVD versus four cycles of dose-escalated followed by four cycles of baseline BEACOPP as first-line therapy, with preplanned high-dose therapy as salvage.[137] At a median follow up of 61 months, BEACOPP was associated with a significantly higher 7-year FFP (85 versus 73%, $p = 0.004$) than ABVD, though differences in EFS (78% versus 71%, $p = 0.15$) and OS (89% versus 84%, $p = 0.39$) were not observed. Finally, the EORTC 20012 trial, an international multicenter study, compares four cycles of dose-escalated followed by four cycles of baseline-dose BEACOPP versus right cycles of ABVD in patients with stages III to IV disease. At a median follow up of 3.8 years, there was a significantly higher PFS rate in the BEACOPP versus the ABVD arms (83.4% versus 72.8%, $p = .005$). However, there were no EFS (69.3% versus63.7%, $p = 0.03$) or OS (90.3% versus 86.7%, $p = 0.2$) differences between the two arms.[138]

A number of ongoing or recently completed trials are addressing treatment deescalation in patients who achieved negative interim PET results.[139] For patients with early PET complete response, the GHSG HD18 is comparing six cycles versus four cycles escalated BEACOPP, the RATHL study compares ABVD with AVD, and the GELA AHL trials compares BEACOPP with standard ABVD. The HD0607 and HD0801 trials conducted by the GITIL and FIL are investigating radiation therapy versus no radiation therapy after six cycles of ABVD in patients with interim and final PET-negative results.

Stanford V

The Stanford V regimen is a 12-week, seven-drug regimen that is administered on a weekly basis (eTable 76-2).[140] It contains lower cumulative doses of mechlorethamine, Adriamycin, and bleomycin than MOPP and ABVD, respectively, to limit leukemogenesis, sterility, cardiac, and pulmonary toxicity. Patients with initial disease of 5 cm or larger or macroscopic splenic disease, which account for about 90% of the patients, receive 36 Gy of involved-field radiation therapy 2 weeks after the chemotherapy. In a report on 142 patients with stage III or IV or locally extensive mediastinal stage I or II HL, a 5-year FFP and overall survival of 89% and 96%, respectively, were achieved.[140] No secondary leukemia was observed at a median follow-up of 5.4 years, although one case of acute leukemia was reported in an earlier Eastern Cooperative Oncology Group (ECOG) pilot study using the same regimen on 45 patients.[82]

The importance of radiation therapy as part of Stanford V was highlighted by a multiinstitutional randomized trial from Italy.[141] In this study, 355 patients with bulky stage II or advanced-stage HL were randomized to receive ABVD, MEC hybrid, and Stanford V. In this study, radiation therapy was limited to patients with initially bulky disease (>6 cm) or with partial response to chemotherapy, and those with only two or more sites of disease. In the most recent update, at a median follow up time of 86 months, the 10-year failure-free survival

in the ABVD, MEC hybrid, and Stanford V arms were 75%, 74%, and 49%, respectively ($p < 0.001$). Among patients randomized to receive Stanford V, the 10-year DFS rates were significantly higher in patients who received radiation therapy versus those who did not (76% versus 33%, $p = 0.004$).

Another multicenter trial, conducted by the United Kingdom National Cancer Research Institute, randomized 520 patients with poor risk early-stage and advanced-stage HL to six to eight cycles of ABVD versus Stanford V.[142] In this trial, specified indications for radiotherapy in the Stanford V arm was the same as the original regimen, although the decision on whether to irradiate was left up to teams in the individual centers. Overall, 73% of patients in the Stanford V arm received radiotherapy, which is lower than that in the original Stanford study (91%). The proportion of patients not receiving radiotherapy as specified was not reported. At a median follow-up of 52 months, there were no significant differences in 5-year PFS (76% versus 74%) and OS (90% versus 92%) between ABVD versus Stanford V.

Results of the ECOG 2496 comparing ABVD and Stanford V in patients with locally extensive and advanced-stage HL were recently reported by Gordon et al.[143] At a median follow up of 6.2 years, there was no difference in 5-year FFS between the ABVD versus Stanford V arms (74% versus 71%, $p = 0.32$) and no OS differences (88% versus 88%, $p = 0.86$). In this study, 75% of patients received radiotherapy in the Stanford V arm for disease >5 cm, whereas in the ABVD arm, 41% received radiation therapy for bulky mediastinal disease.

The Role of Radiation Therapy in Advanced-Stage Hodgkin's Lymphoma

The rationale for the addition of radiation therapy to combination chemotherapy in advanced-stage HL is based on the patterns of failure after chemotherapy, in which the majority of relapses are at the site of initial disease.[144,145] A number of randomized trials have been performed addressing the role of consolidative radiation therapy after chemotherapy in advanced-stage HL.[88,146-150] Summarized in Table 76-9 are some of the more recent randomized studies comparing combined-modality therapy versus chemotherapy alone, using the same chemotherapy regimens in both arms, for advanced-stage HL.[134,146,149-151] The results of these trials were largely negative for significant benefit with the addition of radiation therapy. The previously described study from Tata Memorial Hospital, which included patients of all stages, is the only study that showed a significant survival benefit of combined-modality therapy over chemotherapy alone.[110] On subgroup analysis, the survival benefit was limited to patients with advanced-stage disease. The 8-year overall survival for patients with stages III to IV disease was 80% in the chemotherapy alone arm versus 100% in the combined modality arm ($p = 0.006$). Other subgroups that appeared to especially benefit from radiation therapy in this trial included patients with B symptoms and younger age patients.

In the EORTC trial, patients with stages III to IV disease with a complete response to MOPP-ABV were randomized to receive either radiation therapy or no further treatment.[150] At a median follow-up of 79 months, there were no differences in 5-year EFS or OS. The 5-year cumulative risk of second malignancy was significantly higher in the 172 patients randomized to radiation therapy than the 161 patients randomized to no radiation therapy (7.8% and 4.0%, $p = 0.05$). However, among the patients with a partial response who received radiation therapy to a higher dose, the 5-year cumulative risk of second malignancy was only 3.2%, but the reason for the discrepancy is not entirely clear. The authors also separately reported results of the 227 patients with a partial response who went on to receive 30 Gy of consolidative radiation therapy with or without additional boost.[152] The 8-year EFS and OS rates were 76% and 84%, respectively, which were comparable to the treatment results of patients who had a complete response, leading to the conclusion that patients with a partial response after chemotherapy may benefit from radiation therapy.

One study analyzed the outcomes of nonrandomized consolidative involved-field radiotherapy given after an objective response to chemotherapy in 702 patients with advanced-stage or early-stage unfavorable HL.[153] Consolidative radiation therapy of at least 30 Gy was recommended for patients with incomplete response to chemotherapy or bulky disease at presentation, and was received by 300 of the 702 patients. With a median follow-up of 6.9 years, a significantly higher PFS (71% versus 86%, $p < 0.0001$) and OS rates (87% versus 93%, $p = 0.014$) were found in patients who received radiation therapy, despite the fact that there were significantly more

bulky patients and patients with partial response in the radiation therapy cohort.

As previously described, one of the study questions of the GHSG HD12 study is the role of radiation therapy in advanced-stage HL.[134] At a median follow-up of 69 months, there was no significant difference in 5-year FFTF between the radiotherapy or no-radiotherapy arms (90.4% versus 87%, $p = 0.08$) after either eight cycles of dose-escalated BEACOPP or four cycles escalated and four cycles of baseline BEACOPP. On subgroup analysis, among patients with residual CT abnormality of >1.5 cm, there was a significant 5.8% (95% CI 1.0% to 10.7%) higher 5-FFTF in the radiotherapy arm. However, among patients with <1.5-cm residual disease after chemotherapy, there was no significant benefit with the addition of radiotherapy even among patients with initial disease of 5 cm or greater.

In the GHSH HD15 trial comparing eight cycles of dose-escalated BEACOPP, six cycles of dose-escalated BEACOPP, versus eight cycles of BEACOPP-14, radiation therapy was limited to patients with residual disease of 2.5 cm and with residual PET avidity. Kobe et al reported results of 311 patients from this trial who had residual disease of 2.5 cm and underwent postchemotherapy PET scanning.[154] Sixty-six patients (21%) were found to have residual PET avidity, 63 of whom received 30-Gy radiation therapy to the residual mass as per protocol. Among patients with at least 12 months of follow-up, the 1-year PFS for PET-negative patients and PET-positive patients were 96% and 85%, respectively ($p = 0.011$). Although the treatment outcome of patients with residual PET avidity who received radiation therapy was inferior to those with negative PET in this study, the results are far superior to those reported in other series for patients with PET residual disease after chemotherapy, with PFS rates ranging from 0% to 33%.[122,155] In the most recent update, the 4-year PFS in patients with complete response or those with PET-negative disease and partial response after chemotherapy and did not receive radiation therapy were 92.6% and 92.1%, respectively.[135] As previously described, the HD0607 and HD0801 trials conducted by the Gruppo Italiano Terapie Innovative nei Linfomi (GITIL) Fondazione Italiana Linfomi (FIL) randomized patients with interim and final PET-negative results to radiation therapy versus no radiation therapy, although final results are not yet available.

Optimal Radiation Dose and Field Size

There are limited data on the optimal dose and appropriate radiation treatment field after chemotherapy in advanced-stage HL. Randomized data are not available comparing radiation doses or fields as part of combined-modality therapy in advanced-stage HL. An earlier GHSG study combined data from two of the randomized trials on patients with stages I to III disease, with or without bulk, and found no differences in FFTF and OS between 20 Gy, 30 Gy, and 40 Gy of consolidative radiation therapy.[148] The radiation dose employed in several more recent trials on advanced-stage HL varied. In general, initially nonbulky sites, if treated, received to 20 Gy to 30 Gy, initially bulky sites received 30 Gy to 36 Gy and sites with partial response were treated to 30 Gy to 40 Gy.[132,136,142,150,153-155]

The treatment fields that have been used in trials are also variable. For instance, in the EORTC trial, the protocol mandated irradiating all initially involved areas (except for bone marrow) and that both the spleen and the paraaortic nodes be included in the treatment field even if only one of the sites were involved.[150] Patients also received low-dose whole lung or whole-liver irradiation if disease was initially present at these sites. Although referred to as "involved-field," patients can be treated to a large volume because of their disease extent. Other groups have restricted the radiation treatment field to initially bulky sites. In both the Stanford V and the original BEACOPP regimens in the GHSG HD9 trial, only sites that were initially 5 cm or greater were included in the radiation field.[132,140] With more effective systemic therapy, availability of functional imaging to assess response to systemic therapy, and concerns with toxicity associated with large field radiation therapy, there are further efforts to limit the field size if radiation therapy is to be given. In the HD15 trial, for patients receiving radiation therapy, the treatment field was limited to postchemotherapy residual masses. Patterns of failure were recently reported by Eich et al. Among the 175 patients who received radiotherapy to 30 Gy to the PET-positive site(s), 28 patients relapsed. Twelve (42%) patients had an "infield" relapse, 8 (29%) patients had a relapse outside of the irradiated site, and a further 8 (29%) patients had "in- and outfield" relapse.[156]

Recommendation on Treatment of Advanced-Stage Hodgkin's Lymphoma

In the United States, six to eight cycles of ABVD is still considered by most as the standard systemic therapy for advanced-stage HL. Dose-escalated BEACOPP has been shown to result in a significant survival advantage over conventional-dose regimens (although standard ABVD was not used in the GHSG HD9), but it is also associated with substantial toxicity. Dose-reduced variants of BEACOPP have been developed and tested against ABVD, showing an improved freedom-from-progression, but at the expense of increased toxicity and no difference in OS. Results of ECOG 2496 showed no difference between Stanford V and ABVD.[143] The use of early PET response in identifying patients for treatment escalation or deescalation in patients with advanced-stage disease is addressed by a number of ongoing trials.

Routine addition of radiation therapy after chemotherapy in patients with advanced-stage disease is not supported by available data. However, in selected cases, including initially bulky disease or lack of complete response to chemotherapy, there may be a role for consolidative radiation therapy. In the context of more effective, modern systemic therapy and the availability of functional imaging to assess response, if the decision is to proceed with radiation therapy, it is reasonable to limit the radiation treatment field to initially bulky sites and postchemotherapy residual disease. With the more restricted fields to high-risk areas, doses of 30 Gy to 36 Gy should be considered.

PRIMARY TREATMENT FOR NLPHD

In the REAL and WHO classification systems, NLPHD is classified as a distinct entity based on morphologic and immunophenotypic features.[39,40] Clinically, it is characterized by a male predominance, older age at diagnosis of 30 years to 50 years, peripheral nodal presentation with seldom mediastinal, liver, spleen, or bone marrow involvement, predominantly early-stage disease, an indolent clinical course, and late, multiple relapses.[47,157-161] Because of its rarity, comprising only about 5% of all cases of HL, there is a lack of randomized data in guiding its management, which range from watch and wait,[158] surgery alone,[162] radiation therapy with or without chemotherapy,[157-160,163-165] or immunotherapy.[166-168] Observations have been made that ABVD may not be as effective in patients with NLPHD, and alkylating-agent containing regimens may be a better choice when chemotherapy is indicated,[157,169] although data from British Columbia suggested that ABVD may be associated with a better outcome. Because NLPHD is rarely fatal, and the main cause of death in these patients is

treatment-related rather than disease-related,[157,158,161,168] it is sensible to choose a modality with well-established effectiveness while limiting the treatment exposure of these patients. Several series have reported on results of radiation therapy for early-stage NHLPD, with relapses occurring in 20% to 25% of patients, typically at sites outside of the irradiated field.[157,160,164,165,170] However, patients tend to remain responsive to further therapy despite multiple relapses.[158] The use of more limited treatment fields such as involved-field or regional-field radiation therapy to 30 Gy to 36 Gy did not appear to compromise treatment outcome compared with the use of more extensive fields.[160,165] In patients with neck or axillary involvement, the mediastinum, which is rarely involved, can be blocked, thereby avoiding exposure of the lungs and heart to radiation. For limited-stage NLPHD where radiation therapy is often the sole modality, the GTV should be readily visualized during simulation. The ILROG ISRT guidelines recommend that in this situation, the CTV should be more generous because microscopic or subclinical disease is more likely to be present without chemotherapy.[96]

REFRACTORY AND RECURRENT DISEASE

The standard salvage therapy for patients who are refractory, or relapsed, after a short initial remission to chemotherapy is high-dose therapy with autologous bone marrow or stem-cell transplantation. Two randomized trials compared high-dose therapy with bone marrow or hematopoietic stem cell rescue versus conventional-dose chemotherapy as salvage for patients with refractory to or relapsed HL after chemotherapy.[171,172] The British National Lymphoma Investigation group prospectively randomized 40 patients to either high-dose carmustine (BCNU), etoposide, cytarabine, melphalan (BEAM) followed by autologous bone marrow transplantation or mini-BEAM.[172] The inclusion criteria were lack of complete response after MOPP or similar regimen, or relapsed disease either within 1 year, or disease failure after two or more chemotherapy regimens. At a median follow-up of 34 months, 3-year actuarial eventful survival of the two arms were 53% and 10%, respectively ($p = 0.025$) and PFS were 88% and 35%, respectively ($p = 0.005$), favoring the high-dose therapy arm. The GHSG conducted a similar study comparing high-dose BEAM followed by autologous stem-cell transplantation and dexamethasone with conventional dose BEAM.[171] Only patients with chemosensitive disease were included in the trial. At a median follow-up of 39 months, the FFTF of the two arms were 55% and 34%, respectively ($p = 0.019$). Significant survival differences were not detected in either of the two trials, however.

One of key factors that influences outcome is chemosensitivity to second-line cytoreductive chemotherapy prior to the high-dose therapy and transplantation. Other factors that have been shown to be of prognostic significance include duration of complete response to initial treatment,[173] extranodal disease,[173,174] constitutional symptoms[74,173,175] or bulky disease[176] at the time of relapse, and Hasenclever index.[177]

In recent years, CD30, a cell surface protein expressed on the RS Hodgkin cells, has emerged as a therapeutic target for patients with relapsed or refractory HL. Brentuximab vedotin, an antibody-drug conjugate (ADC) that selectively delivers monomethyl auristatin E, an antimicrotubule agent, into CD30-expressing cells, was shown in a Phase I study to induce durable objective responses and result in tumor regression for most patients with relapsed or refractory CD30-positive lymphomas.[178] In a subsequent Phase II study,[179] the efficacy and safety of brentuximab vedotin were evaluated in patients with relapsed or refractory HL after autologous stem-cell transplantation. A total of 102 patients were treated with brentuximab vedotin 1.8 mg/kg by intravenous infusion every 3 weeks to a maximum of 16 cycles. The overall response rate was 75% with a complete remission rate of 34%. Based on these results, brentuximab vedotin was approved by the Food and Drug Administration for patients who have relapsed after autologous stem cell transplantation (ASCT) or experiencing refractory or relapse disease after at least two prior multiagent chemotherapy regimens in patients who are deemed not to be ASCT candidates. Trials are also currently ongoing exploring brentuximab vedotin combined with second-line chemotherapeutic agents for salvage, as part of consolidation post-ASCT, and as part of frontline therapy in newly diagnosed patients.

Role of Radiation Therapy Before or After High-Dose Therapy

Further relapses after high-dose therapy tend to occur at sites of initial relapsed disease.[180] The role of involved-field radiation therapy given either before or after high-dose therapy have not been addressed prospectively by randomized trials, but retrospective studies have indicated that the addition of radiation therapy may contribute to improved outcome. In one study from Stanford, subgroups of patients who significantly benefited from involved-field radiation therapy given either before or after the transplantation included patients with relapsed stages I to III disease and patients who did not receive prior radiation therapy.[81] In a study from University of Chicago, the use of involved-field radiation therapy in conjunction with high-dose therapy significantly improved local control of all sites of disease.[181] Patients with persistent disease following high-dose therapy had significantly improved PFS (40% versus 12.1%, $p = 0.04$). Wendland et al reviewed 65 patients with refractory or relapsed HL who underwent high-dose therapy and transplant.[182] Twenty-one patients received IFRT, whereas 44 patients did not receive radiation therapy. Half of the patients in the no IFRT group (22 of 44) died compared with 23.8% (5 of 21) of patients in the IFRT group, which was of borderline significance ($p = 0.06$). Kahn et al, in a study examining the role of IFRT in patients with HL and non-HL receiving transplant, found that patients who did not receive IFRT had a 2.09 relative risk of death, which was of borderline statistical significance on multivariable analysis ($p = 0.066$).[182] A study from the University of Rochester on 62 patients who underwent ASCT for relapsed or refractory HL found improved 3-year OS (69.6% versus 40%, $p = 0.05$), disease-specific survival (82.1% versus 57.6%, $p = 0.08$), and local control (94% versus 69%, $p = 0.03$) among patients who received IFRT posttransplant.[183] Results of these retrospective series, however, need to be interpreted with caution because of differences in characteristics of patients who did and did not receive radiation therapy. For example, patients who were offered radiation therapy tend to have bulkier disease or chemotherapy refractory disease, whereas patients who did not receive radiation therapy may have more disseminated disease.

The optimal temporal relationship between radiation therapy and high-dose therapy is unclear. In patients with persistent disease after cytoreductive chemotherapy, radiation therapy given before transplantation can allow further disease debulking. Furthermore, irradiation pretransplantation avoids exposure of newly engrafted stem cell to radiation, which may increase the risk of myelodysplasia and leukemia. This is especially relevant in patients with pelvic disease requiring radiation therapy to a large volume of bone marrow. In these patients, stem-cell mobilization or bone marrow harvest should be performed before initiation of pelvic irradiation. Delivery of radiation therapy before transplantation, however, can increase peritransplant morbidity such as pneumonitis and veno-occlusive disease. Also, there is a risk of systemic

disease progression during the time of the radiation therapy with the delay of the high-dose therapy.

Limited Relapse After Chemotherapy

A small proportion of patients who relapsed after chemotherapy can be successfully salvaged with conventional-dose salvage chemotherapy or radiation therapy. A number of series showed that in selected patients with favorable features, salvage rates as high as 80% can be achieved without exposing patients to high-dose therapy.[97,184-188] Potential candidates for conventional dose-salvage therapy include patients with initial remission duration of 1 year or longer, limited nodal relapse without extranodal disease, and absence of constitutional symptoms at relapse. In one series of 28 patients with limited nodal relapse after chemotherapy, the combination of salvage chemotherapy and radiation therapy yielded significantly superior outcome than radiation therapy alone.[186] In patients who received combined modality salvage therapy, the 7-year freedom from further relapse was 93% and the OS was 85%, whereas the corresponding actuarial estimates in patients treated with radiation therapy alone were significantly lower at 36% ($p = 0.002$) and 36% ($p = 0.03$), respectively. These data suggest that in carefully selected patients with favorable criteria at relapse, salvage with conventional-dose therapy can be considered, thereby sparing patients the toxicity of high-dose therapy.

TECHNIQUES OF RADIATION THERAPY

Radiation therapy is one of the most effective modality for the treatment of HL. Radiation therapy for HL has evolved from two-dimensional treatment planning, with field set-up mostly based on bony landmark to extensive treatment fields, to conformal therapy with improved image guidance to restricted treatment volumes.

Modern Conformal Therapy

Although three-dimensional conformal therapy is currently the most widely adopted radiation technique, there are emerging data on the use of newer, more sophisticated techniques, including IMRT and proton beam therapy for HL.

IMRT uses multiple beams over the targeted volume to provide a highly conformal radiation dose distribution. Dosimetric studies have shown IMRT plans to produce the most conformal high-dose distribution, significantly better PTV coverage and greater protection of the heart, coronary arteries, esophagus, and spinal cord, though at the expense of a greater volume of normal tissue receiving low radiation doses.[189-192] In a dosimetric study reported by Fiandra et al,[191] five different treatment techniques in a cohort of young women with HL were compared: three-dimensional conformal radiation therapy (3D-CRT), and four different IMRT solutions, including single-arc volumetric-modulated arc therapy (VMAT, single-arc), B-VMAT ("butterfly", multiple arcs), helical tomotherapy (HT) and Tomodirect (TD), a rapid, low-modulation solution of the tomotherapy. The B-VMAT technique, developed to reduce low doses radiation exposure to lungs and breasts, and consists of two coplanar arcs of 60 degrees (gantry starting angles 150 degrees and 330 degrees) and one non-coplanar arc of 60 degrees, was found to be associated with the lowest mean doses to the lungs and breasts. When INRT rather than IFRT was employed, there was no difference in cardiac structures sparing between three-dimensional conformal therapy and IMRT approaches. Paumier et al reported on outcome of 32 patients with early-stage HL treated with INRT with IMRT technique to a median dose of 40 Gy. Despite the high prescribed dose, the median heart V30 and lung V20 were 15.5% and 28.6%, respectively, and the median mean heart and lung doses were 4.8 Gy and 15.1 Gy, respectively. There was one in-field relapse and two out-of-field relapses at a median follow up of 60 months. One patient developed grade-3 radiation pneumonitis and there were no cardiac events at the time of last follow-up.

IMRT can play an especially important role in selected cases, including extensive chest wall involvement where conventional techniques would result in exposing large volumes of lungs in the irradiated field, or in the retreatment setting where there is significant dose limitation to vital structures such as the spinal cord. Goodman et al reported on their experience using IMRT for extremely large mediastinal masses or in patients with prior radiation therapy to the mediastinum.[193] In these special case scenarios, the use of IMRT resulted in not only improved PTV coverage, but also lower mean doses to the lungs.

Another modern conformal technique is proton therapy, in which charged particles deposit most of their energy at a proportional depth, resulting in a characteristic dose distribution known as the Bragg peak. With the addition of multiple energies, a spread-out Bragg peak can be created such that the target can be covered by a limited number of fields. Investigators from the University of Florida reported on dosimetric outcome of 10 patients with stages I to IIIB HL treated with INRT with proton beam technique.[194] Compared with 3D-CRT, proton therapy led to a median reduction of body V4 (total body exposed to 4 Gy or higher) by 51% ($p = 0.0098$), and compared with IMRT, a median reduction by 59% ($p = 0.002$). Proton therapy also provided the lowest mean doses to the heart, lungs, and breasts. Early results of 16 patients treated with involved-node proton therapy from the same institution were recently reported. At a median follow-up of 32 months, one patient with initial stage IIB disease relapsed both in and out-of-field, and one patient developed primary mediastinal large B-cell lymphoma. Proton beam therapy therefore appears to be associated with favorable dosimetric outcome and preliminary clinical outcome data are promising. However, major limitations of proton therapy at this time include the complexity and uncertainty of the treatment planning, costs, and access to photon facilities.

The Role of PET in Guiding Radiation Planning

Data from PET-CT are increasingly incorporated into radiation therapy decision making and in the radiation planning process. A number of studies have investigated the impact of PET-CT data in target volume definition for HL radiation therapy planning. Hutchings et al identified 30 patients with HL treated with involved field.[195] All patients had prechemotherapy PET-CT scan, although only the CT component was used for planning purposes. When the PET data was incorporated retrospectively in the planning, the involved field was increased in 7 patients (23%) and decreased in 2 patients (7%). Girinsky et al fused the prechemotherapy PET scan with the post-chemotherapy CT planning scan in 30 patients with HL treated with INRT.[196] In 11 of the 30 patients (36%), the PET scan identified involved nodal disease that was missed by the CT, resulting in changes of the radiation treatment field. It was also noted that on average only 25% of the lymphoma volume on CT showed FDG avidity on PET, leading to the conclusion that the target must include both CT-positive and PET-positive disease. Similarly, Terazakis et al found that the incorporation of PET data in the treatment planning of 29 patients with hematologic malignancies to 32 sites resulted in increase in PTV in 47% and reduced PTV in 40% of the planned sites.[197] These data suggest that PET/CT is the most accurate imaging

TABLE 76-10 Treatment Algorithm for Patients with Early-Stage Hodgkin's Lymphoma

CLASSICAL HODGKIN'S LYMPHOMA, FAVORABLE-PROGNOSIS
Two to four cycles of ABVD (restaging PET/CT scan after two to three cycles and at the end of chemotherapy)*
Involved-node or involved-site radiation therapy 3 to 4 weeks postchemotherapy to 20 Gy to 30 Gy*
CLASSICAL HODGKIN'S LYMPHOMA, UNFAVORABLE-PROGNOSIS
Four to six cycles of ABVD (restaging PET/CT after two to three cycles and at the end of chemotherapy)
Involved-node or involved-site radiation therapy 3 to 4 weeks postchemotherapy to 20 Gy to 30 Gy
NODULAR LYMPHOCYTE PREDOMINANT HODGKIN'S LYMPHOMA
Involved-node or involved-site radiation therapy alone to 30 Gy to 36 Gy

**The use of two cycles of ABVD and 20-Gy IFRT limited to patients with early-stage disease without risk factors as per GHSG criteria.*

TABLE 76-11 Treatment Algorithm for Patients with Advanced-Stage Hodgkin's Lymphoma

CLASSICAL HODGKIN'S LYMPHOMA
Six to eight cycles of ABVD (restaging PET/CT after two to three cycles and at the end of chemotherapy)
Other regimens, depending on institutional experience, include Stanford V and dose-escalated BEACOPP and its variants
Consolidative radiation therapy to 30 Gy to 36 Gy to sites of initial bulky disease (>5 cm) or without complete response to chemotherapy
NODULAR LYMPHOCYTE PREDOMINENT HODGKIN'S LYMPHOMA
Alkylating-agent based chemotherapy regimen (e.g., chlorambucil, vinblastine, procarbazine and prednisolone [ChlVPP] or rituximab, cyclophosphamide, vincristine, prednisone [R-CVP])

method for determining disease extent in HL, Thus, up-front PET/CT is considered mandatory for INRT design.[96]

Respiratory Motion Adaptation Techniques

As radiation treatment fields become more conformal, it is important to take into account respiratory motion, especially when treating sites that are subject to the effect of diaphragmatic motion, such as the mediastinum, lungs, pericardial nodes, or spleen. Breathing adaptation techniques, in the simplest form, involves covering the entire span of respiratory motion of the target on a four-dimensional CT scan. With respiratory gating, the radiation beam is turned on only during a prespecified period of the respiratory cycle, such that organ motion within the radiation field is limited to the motion taking place during the prespecified beam on time. Results of deep inspiration breath-hold (DIBH) techniques have been reported in patients with HL,[198-200] all demonstrating reduced doses to the heart and lungs. The ILROG ISRT/INRT guidelines encourage the use of four-dimensional imaging or DIBH technique for disease sites that are significantly affected by respiratory motion. In addition, when highly conformal techniques such as IMRT are used, adoption of strategies that account for respiratory motion is deemed especially important.

TREATMENT ALGORITHM, CHALLENGES, AND FUTURE DIRECTIONS

The treatment algorithm for patients with early-stage and advanced-stage HL are outlined in Tables 76-10 and 76-11, respectively. In patients with favorable, early-stage disease, cure rates of more than 90% have been achieved. The key challenge in the management of these patients is to identify ways to limit late effects of HL therapy because multiple studies have demonstrated that over time, there is a significantly increased risk of mortality from causes other than HL, with second malignancies and cardiac disease being the two leading problems.[73]

There are increasing data available showing that these late effects are significantly related to radiation dose and volume.[103,105,107,201-204] A significant radiation dose-response relationship has been shown for the development of breast cancer,[104,105,202] lung cancer,[106,107] and gastric cancer[203] in HL survivors. Data are also available showing a significantly reduced risk of breast cancer with more restricted treatment fields.[103,204] These data justify current efforts of reducing radiation dose and field sizes in the treatment of early-stage HL. For patients with unfavorable prognosis disease or advanced-stage disease, the challenge remains further improving the cure of HL. More effective multiagent chemotherapy regimens are being developed and tested in clinical trials. In addition to traditional chemotherapy, new drugs and targeted immunotherapy, including brentuximab vedotin may benefit not only patients with chemotherapy refractory disease but also may serve as adjuncts to chemotherapy with curative intent.[205]

CHAPTER

77 Non-Hodgkin's Lymphoma

Karen M. Winkfield, Richard W. Tsang, and Mary K. Gospodarowicz

EPIDEMIOLOGY AND INCIDENCE

There were an estimated 70,800 new cases and 18,990 deaths in the United States in 2014. The incidence is increasing in many countries, including the United States. Most common types are diffuse large B-cell (~30%) and follicular lymphoma (~25%). The etiology is uncertain, but immunosuppression and infectious agents, including Epstein-Barr virus (EBV), human T-lymphotrophic virus-1 (HTLV-1), and *Helicobacter pylori* contribute.

BIOLOGIC CHARACTERISTICS

Lymphomas are a diverse group of diseases clinically, pathologically and genetically.

Prognosis relates to histologic subtype, age, extent of disease, and treatment.

STAGING EVALUATION

Pathologic diagnosis is performed by experienced hematopathologist. History and physical examination; blood count; lactate dehydrogenase (LDH); bone marrow biopsy; computed tomography (CT) of neck, thorax, abdomen and pelvis; and fludeoxyglucose-positron emission tomography (FDG-PET) scan are taken.

PRIMARY THERAPY

Stages I and II follicular and marginal zone lymphomas are treated with involved-site radiation therapy (RT), expecting a >95% local control rate and 50% long-term disease free survival. Stages III and IV follicular and marginal zone lymphomas are not cured with currently available therapy; however, chemotherapy and RT are effective in controlling the disease.

Stages I and II diffuse large B-cell lymphoma and other aggressive histology are treated with combined-modality therapy, expecting a cure in 70% to 90% of patients depending on age and tumor burden. Stages III and IV diffuse large B-cell lymphoma and other aggressive histology are treated primarily with doxorubicin-based chemotherapy with the addition of adjuvant RT in selected cases.

SALVAGE THERAPY

Diffuse large B-cell lymphoma and other aggressive histology lymphomas refractory to chemotherapy or relapsing after previous complete response is treated with high-dose chemotherapy and autologous stem-cell transplantation (ASCT) when possible. Patients with bulky disease or incomplete response to salvage chemotherapy receive local RT to sites of disease as planned-combined salvage treatment. RT may be delivered before or after ASCT. Patients so treated have a cure rate of 30% to 50%.

PALLIATION

Palliative low dose RT (4 Gy in two fractions) for small cell lymphomas (follicular, mantle cell, and marginal zone lymphomas) provides local control in two thirds of patients and relief of symptoms in almost all. Diffuse large cell lymphomas are also responsive to RT, but results are not as good as in small cell lymphomas particularly if the disease is refractory to chemotherapy and bulky. Doses of >35 Gy may be required to achieve local control but symptom relief is common.

INTRODUCTION

Non-Hodgkin's lymphoma (NHL) encompasses a heterogeneous group of neoplasms of the lymphoid system. The common factor is the malignant cell, a lymphocyte. Beyond that, malignant lymphomas differ in their etiology, pathogenesis, genetics, clinical manifestations, patterns of spread, response to treatment, and survival. Both incidence and mortality of NHL are increasing worldwide. The increase in incidence has been related to environmental factors including occupational exposures and HIV infection. The most prevalent lymphomas in North America are of B-cell origin with follicular lymphomas and diffuse large B-cell lymphomas. Lymphomas presenting in extranodal sites account for 20% to 45% of all cases. Primary extranodal lymphomas with their propensity to present with localized disease are of special interest to radiation oncologists.

The management of NHL is primarily influenced by histology and stage. RT achieves local tumor control and is curative for those with truly localized disease. Chemotherapy is used in generalized disease. Although RT has traditionally been the treatment of choice for localized disease and remains the principal treatment modality for localized indolent lymphomas (follicular lymphoma and mucosa-associated lymphoid tissue [MALT] lymphoma), combined-modality therapy is the current standard approach for patients with localized large cell lymphomas. Chemotherapy has the potential to cure patients with large cell lymphomas and high-grade lymphomas, but currently available agents are not curative for indolent lymphomas. The management of patients with indolent lymphomas presents a challenge, given that many patients present with generalized disease, currently no curative systemic therapy is available, and prolonged survival necessitates careful application of treatment.

ETIOLOGY AND EPIDEMIOLOGY

The American Cancer Society estimates that in 2014, 70,800 new cases of NHL were diagnosed and 18,990 people died of this cancer in the United States.[1] The incidence of NHL has

been increasing in the United States and worldwide.[2-4] In many developed countries, there was a 2% to 4% per year rise in the incidence of NHL from the 1970s to 1990s, but this rate stabilized over the last two decade. In the United States, the annual rise in incidence rate had slowed to 1% to 2% in the 1990s[3,4] and was more notable in older persons. The cause of the increase in NHLs may be the result of an aging population, increase in immunosuppression (HIV infection and iatrogenic), spread of infectious agents such as HTLV-1 and EBV, increased use of chemicals, or improved pathologic diagnosis leading to more defined cases.

The epidemiology of certain histologic subtypes of lymphomas follows distinct patterns related to the epidemiology of the putative causative agent and any environmental cofactors. The classical example is Burkitt lymphoma in Africa, with the endemic role of EBV and the contribution of immunosuppression resulting from malaria infection.[5] Similarly, EBV-related T/natural killer (NK) cell lymphoma of the nasal region is more frequent in oriental populations of south Asia.[6,7] Adult T-cell leukemia/lymphoma caused by HTLV-1 is endemic in the Caribbean and southern Japan.[8] The frequency of HIV-related lymphomas is proportional to the HIV infection rate in the population, explaining the observation of high incidence rates in large urban cities, and a role of Kaposi's sarcoma-associated herpes virus.[9] MALT lymphomas of the stomach are seen more frequently in regions where *H. pylori* infection is endemic.

Despite an increasing body of knowledge on the genetic and phenotypic events underlying the development and progression of NHL, the causative agent has not been identified in the majority of cases. The putative causative agents and associated conditions with a predisposition for the development of NHL are listed in Table 77-1. There are some genetic predispositions to the development of NHL, including specific human leukocyte antigen (HLA) allele associations.[10,11] Changes in the immune state, either immunosuppression or autoimmune disease with immune stimulation can predispose to NHL. The immunosuppression can be primary, that is, inherited (severe combined immunodeficiency syndrome), secondary to retrovirus infection (HIV), or iatrogenic (following solid organ or bone marrow transplantation). The incidence of NHL in individuals who are HIV positive has declined since the late 1990s as a result of highly effective antiretroviral therapy.[12,13] Autoimmune diseases such as Sjögren's syndrome, rheumatoid arthritis, and celiac disease are also associated with an increased risk of NHL.[14]

Infectious agents have been shown to be etiologic factors in NHL (e.g., *H. pylori* in gastric MALT lymphomas and *Chlamydia psittaci* in ocular adnexal lymphomas).[15] There is a large variation in Chlamydia positivity rate in orbital lymphomas depending on geographic location.[16,17] Viruses have been implicated, including EBV,[5] HTLV-1, human herpes virus 8 (HHV-8), and hepatitis C virus (HCV). HTLV-1 carriers have a 2% cumulative risk of developing adult T-cell leukemia/lymphoma, and it is a major public health problem in some parts of the world where the seropositivity rate is high.[8] HHV-8 virus sequences have been implicated in primary effusion lymphomas and multicentric Castleman's disease. Hepatitis C infection is also a predisposing factor for some B-cell lymphomas, often in association with essential mixed cryoglobinemia.[18]

Epidemiologic studies suggest an association with environmental factors including industrial chemicals, rural residence possibly linking to use of pesticides or other agricultural chemicals, hair dyes,[19] diet,[20] and obesity.[21] Small excess risk was also found in atomic bomb survivors for males but not for females,[22] whereas minimal or no risk was found for low dose x-ray exposures (see Table 77-1).

TABLE 77-1 Causative Agents and Associated Conditions with a Predisposition to NHL

IMMUNODEFICIENCY
Congenital: Severe combined immunodeficiencies, ataxia-telangiectasia
Acquired: Organ or hematopoietic stem-cell transplantation, HIV infection
GENETIC PREDISPOSITION
Variants within 6q21 (HLA)
TNF G308A polymorphisms
AUTOIMMUNE DISEASES
Sjögren's syndrome
Hashimoto's thyroiditis
Celiac disease
Rheumatoid arthritis
Systemic lupus erythematosus
VIRAL AGENTS
Epstein-Barr virus
HTLV-1
Human herpes virus type 8
Hepatitis B and C
BACTERIAL
Helicobacter pylori (gastric lymphoma)
Chlamydia psittaci (orbital lymphoma)
Borrelia burgdorferi (cutaneous lymphoma)
Campylobacter jejuni (alpha heavy chain disease)
DRUGS
Alkylating agents
Other immunosuppressive drugs
PESTICIDES
Phenoxy herbicides
Organophosphate insecticides
Fungicides
SOLVENTS AND OTHER CHEMICALS
Benzene
Trichloroethylene
Hair dyes
DIET
N-nitroso compounds
Fat
Overweight/obesity

PREVENTION AND EARLY DETECTION

With a better definition of environmental causative factors for NHL and ongoing studies to delineate risk factor profiles,[23] it is expected that preventive strategies will be developed. For adult T-cell leukemia/lymphoma, initiatives are being implemented to reduce the disease burden in susceptible populations, the most important being the control of breast feeding to prevent maternal-fetal transmission of the HTLV-1 virus. Other promising areas of prevention currently include heightened awareness of potentially toxic agents and the development of improved products (chemicals and hair dyes). Genetic tests that aim to identify persons at higher risk of developing lymphoma are under investigation.[11,24] For viral agents, the development of vaccines is under active study.[25] For organ transplantation, avoidance of transplanting an EBV-positive donor organ into an EBV-negative recipient should reduce the risk of posttransplant NHL. For persons infected with HIV, effective combination antiviral treatments have contributed to a decreased incidence of lymphoma detection and eradication

of *H. pylori* infection in the stomach is an important strategy with potential to control or prevent MALT lymphoma[26,27] and its transformation. As additional microorganisms and viruses other than the ones mentioned here are being discovered to play critical roles in the pathogenesis of some lymphomas,[9,28] prevention and early treatment strategies will become increasingly important in the future.

BIOLOGIC CHARACTERISTICS AND PATHOLOGY

The present classification of NHL emphasizes lineage, function, and distinct clinical-pathologic disease entities, with a liberal use of phenotypic and molecular techniques. The World Health Organization (WHO) classification, fourth edition,[29] is shown in Boxes 77-1 and 77-2. The WHO classification recognized three major categories of lymphoid malignancies: B-cell, T-cell, and Hodgkin lymphoma.

BOX 77-1 WHO Classification (4th Edition, 2008)

MATURE B-CELL NEOPLASMS

CLL/small lymphocytic lymphoma
- B-cell prolymphocytic leukemia
- Lymphoplasmacytic lymphoma
  - Waldenström macroglobinemia
- Splenic B-cell marginal zone lymphoma
- Extranodal marginal zone B-cell lymphoma of MALT (MALT lymphoma)
- Nodal marginal zone lymphoma
  - *Pediatric nodal marginal zone lymphoma*
- Follicular lymphoma
  - *Pediatric follicular lymphoma*
- Primary cutaneous follicular center lymphoma
- Mantle cell lymphoma
- Diffuse large B-cell lymphoma (DLBCL), not otherwise specified
  - T-cell/histiocyte rich large B-cell lymphoma
  - Primary DLBCL of the central nervous system
  - Primary cutaneous DLBCL, leg type
  - *EBV positive DLBCL of the elderly*
- DLBCL associated with chronic inflammation

Lymphomatoid granulomatosis

Primary mediastinal (thymic) large B-cell lymphoma
- Intravascular large B-cell lymphoma
- ALK positive large B-cell lymphoma
- Plasmablastic lymphoma

Large B-cell lymphoma arising in HHV-8-associated multicentric Castleman disease
- Primary effusion lymphoma
- Burkitt lymphoma

B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and Burkitt lymphoma

B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and classical Hodgkin's lymphoma
- Heavy chain diseases
- Alpha heavy chain disease
- Gamma heavy chain disease
- Mu heavy chain disease

Hairy cell leukemia
- Plasma cell myeloma
- Solitary plasmacytoma of bone
- Extraosseous plasmacytoma

Note: The italicized histologic types are provisional entities.

The diagnosis of the individual pathologic and clinical entities continues to be based on morphology but is assisted by immunophenotyping and genotyping. The InterLymph Non-Hodgkin Lymphoma Subtypes Project pooled data from 20 case-controlled studies from North America, Europe, and Australia.[23] The most common lymphoma entities were diffuse large cell lymphoma (DLCL, 26%) and follicular lymphoma (20%). MALT/marginal zone lymphoma constituted 6% of cases, small B-lymphocytic, 13.9%, T-cell lymphomas, 5%, mantle cell. 3%, and Burkitt, <3% of cases. Slight regional variances were noted for incidence of specific disease entities. Because these were the most common entities on three continents, the discussion herein is limited to these diseases. For the rarer entities the reader is referred to the fourth edition of the WHO Classification.[29]

The lineage of B-cell lymphomas is confirmed by pan B-cell markers (CD22, CD19, CD20). T-cell lineage is evident from the presence of T-cell markers (CD3, CD2, CD7), and T-cell subset from CD4 and CD8 analysis. Among indolent lymphomas, the CD5+, CD10–, CD23+ phenotype is characteristic of small lymphocytic lymphoma (chronic lymphocytic leukemia), the CD5–, CD10+, CD23–/+ phenotype of follicular lymphoma and the CD5–, CD10–, CD23– phenotype of MALT lymphoma (Table 77-2). The CD5+, CD10–, CD23– phenotype, in addition to cyclin D1+, is characteristic of mantle cell lymphoma. Among T-cell lymphomas the CD30+ phenotype is characteristic of anaplastic large cell lymphoma (Figure 77-1), whereas CD56+ and EBV+ is associated with extranodal T/NK lymphoma of nasal type. Although surface marker analysis enhances the accuracy of the diagnosis, few surface marker characteristics are totally lineage specific. Ancillary cytologic and histologic techniques used to establish proliferative activity include labeling index, S-phase fraction, and Ki-67 antigen staining[30,31] which has been documented as a strong prognostic factor.

BOX 77-2 WHO Classification

MATURE T-CELL AND NK-CELL NEOPLASMS

T-cell prolymphocytic leukemia

T-cell large granular lymphocytic leukemia

Chronic lymphoproliferative disorder of NK cells

Aggressive NK cell leukemia

Systemic Ebstein-Barr virus positive T-cell lymphoproliferative disease of childhood

Hydroa vacciniforme-like lymphoma

Adult T-cell leukemia/lymphoma

Extranodal NK/T cell lymphoma, nasal type

Enteropathy-associated T-cell lymphoma

Hepatosplenic T-cell lymphoma

Subcutaneous panniculitis-like T-cell lymphoma

Mycosis fungoides

Sézary syndrome

Primary cutaneous CD30 positive T-cell lymphoproliferative disorders
- Lymphomatoid papulosis
- Primary anaplastic large cell lymphoma

Primary cutaneous gamma-delta T-cell lymphoma

Primary cutaneous CD8 positive aggressive epidermotropic cytotoxic T-cell lymphoma

Primary cutaneous CD4 positive small/medium T-cell lymphoma

Peripheral T-cell lymphoma, not otherwise specified

Angioimmunoblastic T-cell lymphoma

Anaplastic large cell lymphoma, ALK positive

Anaplastic large cell lymphoma, ALK negative

Note: The italicized histologic types are provisional entities.

The WHO classification, although aimed to classify distinct disease entities and acknowledges the uniqueness of certain presentations (e.g., the T-cell lymphomas cited previously), does not always consider the presenting site of the lymphoma. Recent evidence strongly suggests that the presenting site is an important factor for primary extranodal lymphomas. Examples include different etiology for MALT lymphoma arising in different sites, which is associated with differences in relapse rate.[32] Similar histology lymphomas may have distinct outcomes—DLBCL involving the brain (poor prognosis)—now clearly identified in the fourth edition of WHO, versus stomach or Waldeyer's ring structures (good prognosis).[33] With further understanding of etiology and pathogenesis of lymphomas, future modifications to classification of these diseases are expected.

The most common types of NHL seen in North America are: DLBCL and the follicular lymphoma and the management of many types of rarer lymphomas is based largely on experience with these two disease entities.

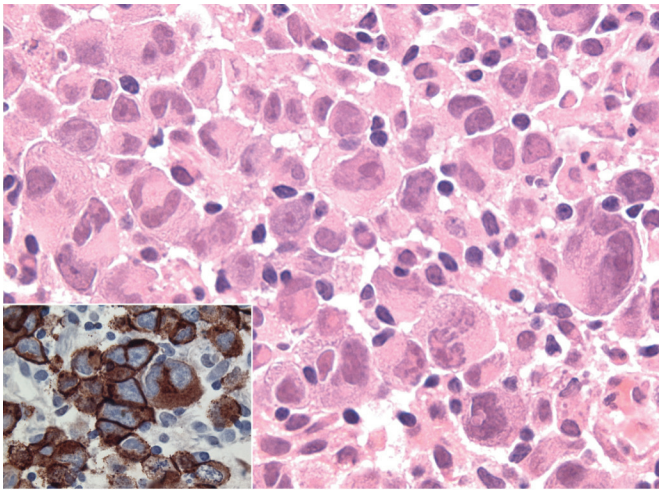

Figure 77-1 Anaplastic large cell lymphoma of lymph node (H & E stained section). The lymphoma cells are intensely CD30 immunoreactive *(inset)*.
Courtesy of Dr. Bruce Patterson, Canada.

TABLE 77-2 Phenotypic Characteristics of NHL

Lymphoma Type	Characteristic CD Antigen Profile
B cell markers	CD19, CD20, CD22
T cell markers	CD2, CD3, CD4, CD7, CD8
Anaplastic large cell lymphoma	CD30+ (Ki-1 antigen)
Small lymphocytic lymphoma (B-CLL)	CD5+, CD10–, CD23+, B-cell markers
Follicular lymphoma	CD5–, CD10+, CD23–/+, CD43–, B-cell markers
Marginal-zone (MALT) lymphoma	CD5–, CD10–, CD23–, B-cell markers
Mantle cell lymphoma	CD5+, CD10–/+, CD23–, CD43+, B-cell markers

Follicular Lymphoma and BCL-2

Follicular lymphoma (FL) is characterized commonly by lymph node involvement in a follicular pattern by follicle center cells (centrocytes) and is graded by the number of centroblasts (large cell) in 10 neoplastic follicles, per 40× high-power field (hpf) under the microscope. Grade 1 has 0 to 5 centroblasts/hpf, grade 2 has 6 to 15 centroblasts/hpf, and grade 3 follicular lymphoma has >15 centroblasts/hpf. Ten high-power fields are counted to get a good representation of the neoplastic follicles. Grade 3 is further divided into grade 3a (centrocytes are present), whereas grade 3b denotes solid sheets of centroblasts. It is generally believed that a higher proportion of centroblasts imply a more aggressive clinical course with worse prognosis, and therefore grade 3b cases are treated as DLBCL. The immunophenotype is distinctive and useful to distinguish FL from other indolent B-cell lymphomas (Table 77-2). The t(14;18)(q32;q21) translocation involving BCL-2 is the most common chromosome translocation found in 80% to 90% of FL (Table 77-3). BCL-2 encodes a 26-kDa membrane protein that controls and prevents cellular apoptosis. The gene is translocated to a J segment of the *IgH* gene on chromosome 14, giving rise to deregulation of BCL-2 with the result being the inhibition of apoptosis of B-cells. FL has a low proliferative potential, but when transformation occurs additional genetic lesions are acquired (*p53* mutation, deletion of chromosome 6q27, c-myc), in parallel with more rapid growth and an aggressive clinical course. Dual translocation (BCL-2 and c-MYC) are of a particularly worse prognosis.

Diffuse Large B-Cell Lymphoma

DLBCL is the most common aggressive lymphoma. Large transformed lymphoid cells replace the normal lymph node

TABLE 77-3 Common Genetic Alterations in Non-Hodgkin's Lymphoma

Oncogene	Translocation	Gene Product	Cellular Activity	Disease
BCL-1	t(11;14)(q13;q32)	Cyclin D1	G1/S progression	Mantle cell (>90%)
BCL-2	t(14;18)(q32;q11)	BCL-2	Suppression of apoptosis	Follicular (~90%) DLBCL (~25%)
BCL-6	3q27	BCL-6	Zinc finger transcription factor	Diffuse large cell (~30%) Follicular (~10%)
c-MYC	8q24	c-MYC	Transcription activation, cell cycle control	Burkitt Transformed DLBCL
p53	17p	p53	Tumor suppressor	Transformed NHL
ALK	t(2;5)(p23;q35) and others	Anaplastic lymphoma kinase	tyrosine kinase	T-anaplastic large cell
LYT-10	10q24	NFκB2	Transcription factor	Cutaneous T-cell lymphoma (~15%)
MALT1	t(11;18)(q21;q21) t(14;18)(q32;q21)	API2-MALT1 fusion transcript	Activates NFκB Deregulation MALT1	MALT (30%, site dependent) MALT (~10%)

DLBCL, *Diffuse large B-cell lymphoma;* NHL, *non-Hodgkin's lymphoma.*

or extranodal organ and tissue, in a diffuse pattern. It typically has a high proliferative fraction, typically Ki-67 staining is seen in 60% to 90% of neoplastic cells. Morphologic variants include the centroblastic (most common), immunoblastic, anaplastic, and T-cell/histiocyte rich subtype, although the treatment approach is similar. The immunophenotype is that of pan-B cell markers positive (CD19, CD20, CD22, CD79a). BCL2 is positive in 30% to 40% of cases. BCL-6 gene (located on 3q27) is translocated in 40% of DLBCL (Table 77-3).[34,35] BCL-6 is thought to mediate the DNA-binding activity of a number of zinc-finger transcription factors, and its presence carries a favorable prognosis, in comparison with those carrying BCL-2 who have a worse outcome, whereas those with neither translocation have an intermediate prognosis.[34,36]

The putative cell of origin can be germinal B cells, or post-germinal center origin. Microarray analysis of cDNA (the "lymphochip", NCI, Bethesda) using hierarchical clustering techniques initially classified DLBCL into two groups.[37] One expressed "germinal center B-cell-like" genes (GCB signature), such as A-myb, LMO2, Jnk3, CD10, BCL-6, c-rel, and bcl-2, whereas the other expressed "activated B-cell-like" genes (ABC signature), such as CyclinD2, IRF-4, Flip, NF-κB, and CD44. For patients treated with anthracycline-based chemotherapy in the prerituximab era, the 5-year survival for GCB group was 60%, compared with the ABC group of 35%, and a type-3 group was 39%.[38] Based on a selection of the most prognostic genes, either a larger series of 17 genes,[38] or condensing further to three immunostains for CD10, BCL-6, and MUM-1,[39] studies have shown that gene expression profiling provide additional prognostic information in addition to the clinical IPI scores.[38,39] Additional studies using oligonucleotide microarrays and a different analysis technique have also successfully identified two categories of patients with different survival rates (70% versus 12%) in DLBCL.[40] Gene profiling of the nonmalignant infiltrating cells in the tumor has also been found to be prognostic in DLBCL, whether treatment included rituximab or not.[41] The "stromal-1" group reflected extracellular matrix deposition and histiocytic infiltration had a better prognosis than the "stromal-2" group that reflected tumor angiogenesis activity.[41] At present, it is still uncertain how microarray assay results can be used to decide the treatment approach, although for cases with morphologic difficulty (e.g., gray zone lymphomas), it may assist in clarifying the diagnosis and hence the treatment required.

B-Cell Lymphoma with c-MYC and BCL-2

The presence of c-myc and bcl-2 translocations in a B-cell lymphoma is recognized as an aggressive subtype of either DLBCL, or B-cell lymphoma, unclassifiable, and carries a poor prognosis. This is also known as "double-hit" lymphoma and conventional treatment with R-CHOP may not induce remission or if a remission is obtained it is commonly not durable.[42,43] Fortunately it is found in less than 10% of patients with DLBCL. Median survival is often less than a year[44] and it is still uncertain if intensified treatment approaches are of any value.

Mantle Cell Lymphoma and BCL-1

Mantle cell lymphoma (MCL) occurs in older adults and commonly presents with generalized disease with spleen, bone marrow, and gastrointestinal (GI) tract involvement. Circulating lymphoma cells are frequently found in the blood. It is associated with a characteristic immunophenotype (CD5+, CD10–/+, and CD23–).[29] The t(11;14)(q13;q32) translocation is found in the majority of MCLs (Table 77-3). BCL-1, also known as PRAD-1, encodes for cyclin D1 that regulates cell cycle progression. This lesion appears to be highly specific for mantle cell lymphoma, with the translocation of BCL-1 on chromosome 11 to *IgH* gene on chromosome 14, making it an extremely useful adjunct to immunophenotyping in distinguishing MCL from other types of lymphomas.

Primary Mediastinal B-Cell Lymphoma

Primary mediastinal B-cell lymphoma (PMBL) is a subtype of DLBCL arising in the mediastinum and the presumed cellular origin is from the thymic B-cells. It presents as localized disease in the mediastinum, often bulky, with invasion into surrounding structures such as lung, pleura, chest wall, and pericardium. Superior vena cava obstruction is common. Females are affected more often than males and usually young adults ages 20 to 45 years. Immunophenotypic finding are similar to DLBCL, but genetic features are distinctive, with gains in chromosome 9p, and amplification of REL gene, and overexpression of *MAL* gene. Deregulated genetic pathways involved are NF-κB and JAK-STAT activation.[45] In general lacking in BLC2, BCL6, and c-MYC rearrangements. Microarray studies indicated genetic similarity of PMBL with Hodgkin's lymphoma, rather than DLBCL, characterized by overactivation of PDL2, a regulator of T cells.[46]

Extranodal Marginal Zone Lymphoma, MALT Type

MALT lymphoma is an indolent lymphoma, with the neoplastic cells being small centrocytes of marginal zone characteristics affecting diverse extranodal organs of MALT type. Most common sites are the GI tract, frequently the stomach, orbital adnexa, salivary gland, other upper aerodigestive tract mucosa sites, lung, skin, thyroid, and breast tissue. Rarely can occur in urinary bladder, liver, and dura. In glandular tissue lymphoepithelial lesions (where lymphoid cell aggregates invade and destroy the epithelium) are characteristic, and sometimes plasmacytic differentiation is also prominent and when present this needs to be distinguished from extramedullary plasmacytoma. The majority of cases (80% to 90%) are localized (stages I and II). Nodal involvement is usually associated with the extranodal site but relatively uncommon. In many cases there is a history of infection or inflammatory condition affecting the extranodal organ in question: for example, *H. pylori* infection in stomach MALT, *C. psittaci* infection in orbital MALT, and Sjögren's syndrome in salivary gland MALT. The immunophenotype is characteristic (Table 77-2). Genetically extranodal MALT lymphoma is found to have a number of mutually exclusive molecular markers: t(11;18)(q21;q21), t(14;18)(q32;q21), t(3;14)(p14.1;q32), t(1;14)(p22;q32), +3, and +18 (Table 77-3). The most important is t(11;18) as its presence in gastric MALT lymphoma is associated with *H. pylori* negative status and hence predicts a lack of response to antibiotic therapy.

Burkitt Lymphoma and c-MYC

Burkitt lymphoma (BL) is an aggressive lymphoma, with a short tumor doubling time and rapid proliferation rate. Several clinical subtypes are recognized: endemic, sporadic, and immunodeficiency-associated. The endemic BL occur in equatorial Africa and is the most common childhood cancer in that area. It affects children typically ages 4 to 7 years, with male predominance, and frequently presents as a jaw tumor. Sporadic BL is seen throughout the world, and accounts for about 1% of NHL in western countries and North America. It usually presents in extranodal organs (e.g., the gastrointestinal tract, gonadal tissue, and breast). Males in the mid-30s predominate. Immunodeficiency-associated BL are usually the result of HIV infection. Morphologically the malignant cells are medium

sized, with diffuse monotonous growth pattern. Mitotic figures are numerous, with high rate of apoptosis as well. Normal macrophages seen to have ingested apoptotic tumor cells give the characteristic "starry sky" pattern. The immunophenotype is CD19/20/22+, CD10+, BCL6+, and surface IgM+. Ki-67 proliferation is seen in 99% to 100% of tumor cells. The majority of BL present as stage IV disease. A staging system proposed by Murphy (or a modification of it) is in common use, largely based on tumor burden.[47,48] The c-MYC oncogene, located on chromosome 8q24, regulates cellular proliferation and differentiation. Its translocation is seen in 100% of BLs typically to chromosome 14q32 (IgH), less commonly to 2p11 (Ig*k*) and 22q11 (Igλ). EBV infection is responsible for and can be documented in almost all cases of endemic BL and about 30% of the sporadic cases.[49,50]

Peripheral T-Cell Lymphoma, Not Otherwise Specified

Peripheral T-cell lymphomas (PTCLs) are a heterogeneous group of T-cell neoplasms, are more common in Asia,[51,52] usually affecting adults, and are commonly generalized at presentation. It is the most-common aggressive T-cell lymphoma in Western countries. An aggressive clinical course is typical, and although potentially curable, many T-cell lymphomas are resistant to current chemotherapy regimens. T-cell immunophenotype is expressed, more frequently CD4+ than CD8+, and CD10–. BCL6—, CD30, and CD56 can be variably expressed. CD20 is negative hence rituximab has no role in therapy. TCR gene is clonally rearranged in the majority but is not mandatory for diagnosis. Males are affected more frequently, and the majority (70%) has stages III and IV disease, with involvement of lymph nodes, bone marrow, spleen, skin, and other extranodal organs. Prognosis is worse than comparably matched DLBCL.[53,54]

Mycosis Fungoides and Sézary Syndrome

Mycosis fungoides (MF) is the most common primary cutaneous T-cell lymphoma. It has indolent behavior, characterized by an evolution of skin patches and plagues, and later progressing to tumorous lesions over a course of many years. Atypical lymphocytes with indented (cerebriform) nuclei infiltrate the epidermis. Collections of these atypical cells form the characteristic "Pautrier microabscesses." The immunophenotype is typically CD2+, CD3+, CD4+, CD5+, CD8–, and TCRβ+. A unique staging system has been used clinically based on the degree of skin involvement and lymph node involvement.[55] Sézary syndrome is characterized by the presence of Sézary cells with cerebriform nuclei in the skin, lymph nodes, and the peripheral blood and is the leukemic manifestation of MF progression. Prognosis is dependent on the burden of disease and is worse for those with diffuse erythroderma, tumorous lesions, Sézary syndrome, and histologic transformation to an aggressive T-cell lymphoma.

Anaplastic Large Cell Lymphoma

Anaplastic large cell lymphoma (ALCL) is an aggressive T-cell lymphoma, separated into anaplastic lymphoma kinase (ALK)-positive, or ALK negative cases. The latter usually presents in older adults and has a worse prognosis. Patients with ALK+ ALCL are younger, and the disease can present in childhood and has a good prognosis.[54] Typically lymph nodes are involved, and where extranodal organs are affected, most common sites are skin, lung, and soft tissues. There is a broad morphologic spectrum, with typically large cells with eccentric nuclei. Variants exist where there maybe histiocytic cell infiltration, or a "Hodgkin-like" pattern. The characteristic immunophenotype of the tumor cell is strongly positivity for CD30, ALK+ for the ALK+ subtype. TCR is clonally rearranged in the majority. For the ALK+ cases, the t(2;5)(p23;q35) translocation is most commonly found (Table 77-3). This translocation involves the fusion of the NPM (nucleophosmin) gene on 5q35 and the ALK (anaplastic lymphoma kinase) gene on 2p23.[29] Others involving ALK-2p23 includes t(1;2)(q25;p23), Inv(2)(p23q35) and many others.[29]

Primary Cutaneous CD30-Positive T-Cell Lymphoproliferative Disorders

This diagnosis encompasses a spectrum of CD30+ diseases ranging from primary cutaneous anaplastic large cell lymphoma (C-ALCL) to lymphomatoid papulosis (LyP), which is a benign skin condition. Histologically the two entities may not be clearly distinguished from the skin biopsy, but the different clinical appearance and course over time is distinctive. There is diffuse infiltration of the skin by sheets of large anaplastic cells that are CD30+. The immunophenotype shows strong CD30 expression, and usually CD4+, with variable loss of CD2, CD5, and CD3. LyP has more variable morphology and some cells can be Reed-Sternberg-like (LyP type A), MF like with cerebriform cells (LyP type B), or monotonous CD30+ cells as in C-ALCL (LyP type C). C-ALCL usually presents as a solitary skin nodule but can be multifocal in 20% of cases. When localized, local RT is the treatment of choice. LyP manifest as papular skin lesions affecting extremities or trunk, with evolving appearance over several weeks, some ulcerating and then self-healing. A small proportion of cases (~5%) may develop into other T-cell lymphoma (e.g., C-ALCL, or MF). Overall the prognosis is excellent.[56]

Extranodal NK/T Cell Lymphoma, Nasal Type

There are many other specific subtypes of T-cell lymphoma but the main one to consider here with special interest to the radiation oncologist is the extranodal NK/T cell lymphoma of nasal type. The entity of NK/T cell lymphoma of nasal type includes disorders previously known as lethal midline granuloma and nasal T-cell lymphoma. It is characterized by an angiocentric and angioinvasive infiltrate[29,57] (Figure 77-2), with CD56+ (T/NK cell) immunophenotype, and are characteristically EBV-positive. Apart from presenting in nasal cavity or surrounding tissues such as the Waldeyer's ring, it may rarely present in skin, lung, testis, and central nervous system (CNS). It is more commonly seen in southeast Asia, in south America, and rarely in Europe. This disease responds poorly to conventional CHOP chemotherapy and usually follows an aggressive course.[58-60] Upfront RT (with or without chemotherapy) is important, with doses of 50 Gy or greater, and is required for disease control.[61]

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING CLASSIFICATION

Clinical Manifestations

NHL may present in any part of the body. Therefore, the presenting signs and symptoms of NHL are highly variable. The most common presentation is with an asymptomatic lymph node enlargement. Peripheral lymph node involvement (cervical, inguinal, etc.) is most common in indolent lymphomas and in generalized presentations. Lack of progressive enlargement of lymph nodes may lead to a delay in diagnosis. The

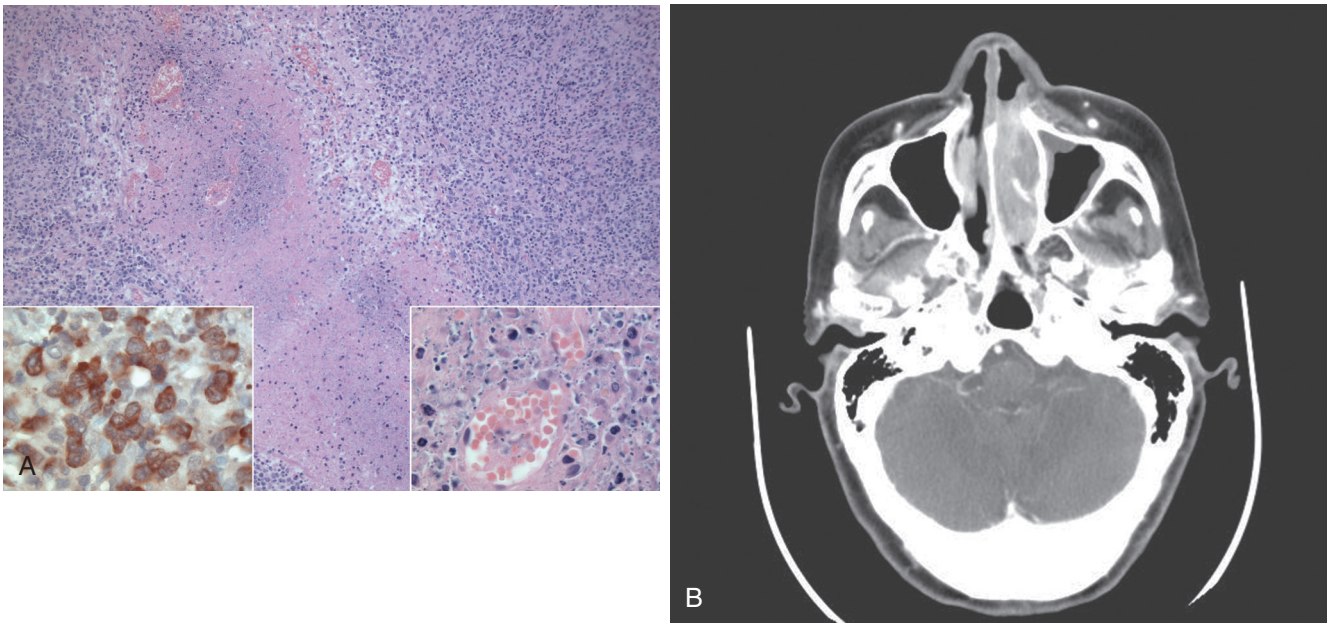

Figure 77-2 **A,** Photomicrograph of an extranodal NK/T-cell lymphoma, nasal type (H & E stained section). There is abundant necrosis, and the lymphoma cells have an angiocentric and angioinvasive growth pattern *(inset right lower corner)*. The lymphoma cells are immunoreactive for Ebstein-Barr virus (EBV) latent membrane protein *(inset left lower corner)*. **B,** Extranodal NK/T-cell lymphoma, nasal type. most common presenting sites of nodal lymphomas are cervical, inguinal, and retroperitoneal lymph nodes. Mediastinal lymph node involvement is much less common than in Hodgkin's lymphoma, except for the primary mediastinal large B-cell lymphoma. Patients may also present with systemic symptoms of fever, weight loss, and night sweats, usually heralding the presence of more advanced disease.

As in nodal lymphomas, the presenting symptoms in primary extranodal lymphomas depend on the site of origin and do not differ significantly from symptoms of other malignancies affecting a specific organ. Occasionally the clinical appearance of a lymphomatous lesion may not be characteristic of a malignancy and may mimic benign inflammatory lesions. Careful histopathologic examination, therefore, is extremely important in arriving at an early diagnosis. Characteristically gastric lymphomas present with symptoms of peptic ulcer, bowel lymphomas with intestinal obstruction or diarrhea, whereas primary bone lymphoma presents with pain. Primary lymphomas with diffuse involvement of an organ (e.g., liver, spleen, bone marrow) rather than a distinct tumor is particularly difficult to diagnose and are often a component of advanced disease. Tumor bulk at presentation is also related to primary site. Usually primary lymphomas of skin or orbital structures are visible and therefore diagnosed early; extradural lymphomas develop symptoms early and present with small bulk disease. In contrast, intestinal lymphomas present with nonspecific symptoms, and thyroid lymphomas (especially if associated with preexisting goiter) often present with bulky disease. In the absence of nodal involvement, lymphoma is often not suspected or distinguished clinically from carcinoma; therefore, immunophenotypic and histochemical analysis is particularly important.

Patient Evaluation

After a histopathologic diagnosis has been confirmed, the goal of evaluation is to determine disease extent and bulk, its anatomic distribution, and to ascertain normal organ and immune function relevant to the choice of therapy (Figure 77-3). With the diverse presentation of lymphomas, the investigations may vary, and there may be investigations that vary by institution.[62] Recommendations for initial evaluation and staging were recently updated in the Lugano Classification.[63] The minimum recommended investigations are listed in Box 77-3. Additional tests may be necessary based on the

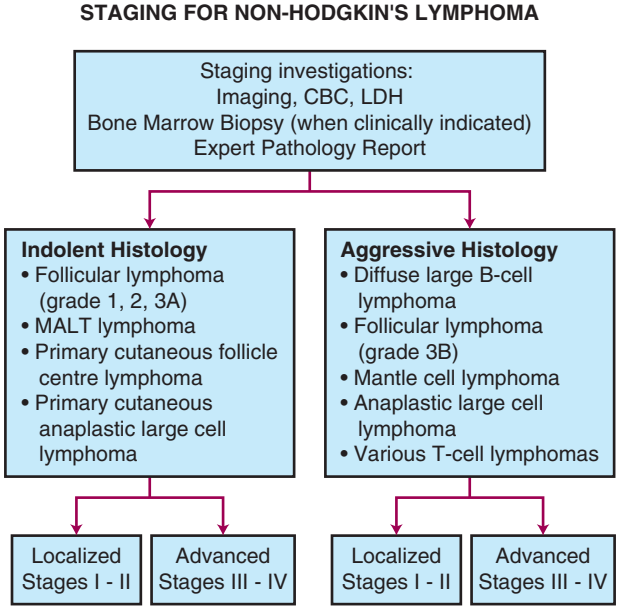

Figure 77-3 Algorithm for staging non-Hodgkin's lymphoma.
CBC, Complete blood count; LDH, lactate dehydrogenase.

BOX 77-3 Diagnostic Workup for Non-Hodgkin's Lymphoma

GENERAL

History, including systemic symptoms (unexplained fever, night sweats, weight loss >10% of body weight), risk factors for HIV infection
Physical examination: special attention to lymphatic sites, organomegaly
For palpable lymph nodes: note and record number, size, location, shape, texture, and mobility
Mirror examination of larynx and pharynx if clinically indicated

IMAGING STUDIES

Standard

Computed tomography scans of neck, thorax, abdomen, and pelvis
Fludeoxyglucose-positron emission tomography (FDG-PET)

SPECIAL TESTS

Standard

Bone marrow biopsy (only if PET negative and clinically relevant)
Review of slides by expert hematopathologist
Cytologic evaluation, if any effusion present
Lumbar puncture to examine cerebrospinal fluid for perimeningeal sites, testes, extradural presentations, or when clinically indicated

Complementary

Upper gastrointestinal or small bowel series when clinically indicated
Computed tomography scan of brain when clinically indicated
Magnetic resonance imaging if clinically indicated

LABORATORY STUDIES

Standard

Complete blood count (including platelet count, reticulocyte count), blood chemistries (including blood urea nitrogen, creatinine, uric acid levels)
Lactate dehydrogenase, bilirubin, transaminases, alkaline phosphatase

Complementary

Erythrocyte sedimentation rate
Serum electrophoresis
HIV serology when clinically indicated
Hepatitis B and C serology

presenting complaint, the subtype of lymphoma, predilection for CNS involvement, and so on.

History and Physical Examination

A complete history with attention to duration of symptoms and rate of lymph node enlargement should be obtained. Constitutional symptoms such as fever, night sweats, and unexplained weight loss as well as performance status should be documented, although presence of B symptoms have not been shown to be prognostic in available prognostic indices, and in the most recently modified Ann Arbor staging for NHL, the recommendation is to eliminate the designation of "B" from the staging.[63] Risk factors for lymphoma particularly immunosuppressive conditions including risk factors for HIV infection, immunosuppressive therapy, and the presence of autoimmune diseases should also be documented. Physical examination should include the lymphoid system, including, where relevant, Waldeyer's ring structures. If not demonstrated on imaging, the location and size of lymph node masses should be documented. This is especially important for the subsequent determination of RT target volume because following chemotherapy, no gross disease may be present at the time of RT treatment planning.

Pathologic Diagnosis

Histologic confirmation of the diagnosis by an experienced hematopathologist is mandatory. Inadequate specimens should prompt the consideration of repeat biopsy with attention to obtaining fresh tissue for immunophenotypic and cytogenetic studies.

Laboratory Tests

Minimum laboratory tests include a complete blood count, LDH, bilirubin, transaminases, and creatinine level. An HIV serology test should be performed when risk factors of HIV infection are present, or in high-grade lymphomas even if there are no obvious risk factors. Screening for hepatitis serology should be done for patients receiving chemotherapy. Because of the high sensitivity of bone marrow involvement by PET-CT, in the most recent recommendation from the Lugano meeting,[63] a PET-CT indicating bone or bone marrow involvement is deemed sufficient to designate advanced disease, and a bone marrow biopsy is not necessary. If the PET-CT is negative, a bone marrow biopsy is indicated in the setting of discordant histology, if relevant for a clinical trial, or patient management. Cerebrospinal fluid (CSF) cytology is performed in patients with risk factors for leptomeningeal spread (i.e., bone marrow, or peripheral blood involvement, Burkitt and lymphoblastic lymphomas, HIV infection, and lymphoma presenting in brain, testes, epidural space, eye, or paranasal sinuses).

Imaging Studies

PET-CT is now a standard staging procedure for all FDG-avid nodal lymphoma, including DLBCL, FL, MCL, Burkitt's lymphoma, nodal marginal zone lymphoma, ALTCL, NK/T-cell lymphoma, and peripheral T-cell lymphoma.[63] The most recent Consensus of the International Conference on Malignant Lymphomas Imaging Working Group[64] recommends staging of FDG-avid lymphomas using visual assessment, with PET-CT images scaled to a fixed SUV display and color table. In addition, the PET-CT can be used to select the best site for a biopsy. Variably FDG-avid histologies should be staged with a CT scan, and intravenous contrast should be included to allow more accurate nodal size measurement as well as to facilitate radiation planning. Other radiographs should be obtained based on the actual or suspected organ involved. Magnetic resonance (MR) imaging is indicated in delineating areas of suspected involvement of bone or CNS (e.g., spinal cord and epidural space, brain stem, base of skull and cavernous sinuses, and leptomeninges). The role of routine MR scans for the thorax, abdomen, and pelvis has not been established.

Staging Classification

The AJCC and UICC have endorsed the use of the Ann Arbor classification for staging of NHL. The Ann Arbor staging classification has been used for more than 40 years.[65,66] In the Ann Arbor system, Waldeyer's ring, thymus, spleen, appendix, and Peyer's patches of the small intestine are considered as lymphatic tissues and involvement of these areas does not constitute an "E" lesion, originally defined as extralymphatic involvement. However, because of the unique pathologic and clinical characteristics of primary lymphoma affecting these

organs, most clinicians consider them as separate clinical entities and report their involvement as extranodal presentation. The Ann Arbor classification differentiates locoregional from widespread lymphoma and documents anatomic extent of disease and B-symptoms, but it is not optimal for describing the extent of local disease, invasion of adjacent organs, tumor bulk, or multiple sites of involvement within one organ (e.g., skin, GI tract). Several modifications to the Ann Arbor classification have been proposed in the past. In gastric lymphoma, substaging of stage I to reflect the depth of the stomach wall penetration has been suggested. In stage II disease, distinction of involvement of the immediate nodal region (II_1) compared to more extensive regional lymph node involvement (II_2) has been found to be of prognostic significance in primary GI lymphomas.[67,68] In the recently published Lugano classification,[63] the designation of "B" symptoms was eliminated from the staging system for NHL because available prognostic scores for various NHL did not find presence of constitutional symptoms to be prognostic.

PROGNOSTIC FACTORS

Although the anatomic extent of disease reflected by Ann Arbor stage is an important prognostic factor, many other factors are known to influence the outcome in patients with NHL. They include histologic type, phenotype (B-cell versus T-cell),[51,52] tumor bulk,[69,70] number of involved nodal regions and extranodal sites, proliferation indices (S-phase fraction, Ki-67 antigen) as well as age, gender, and performance status[71] (Table 77-4). The International Prognostic Index (IPI) was derived from patients with aggressive lymphomas treated with doxorubicin-based chemotherapy in Phase II and Phase III trials. Based on factors identified in multivariate analysis the IPI is based on patient's age, serum LDH, performance status, and number of involved extranodal sites (Table 77-5).[71] Patients are grouped according to the number of adverse factors (i.e., age >60 years, stage III or IV, abnormal LDH level, performance status >1, and more than one involved extranodal site). Patients in the low-risk group (zero to one adverse factors) treated with doxorubicin-based chemotherapy with or without RT had a 73% 5-year survival; in low-intermediate group (two adverse factors), 51%; high-intermediate group (three adverse factors), 46%; and those in high-risk group (four or five adverse factors), 26% 5-year survival.[71] A similar pattern of decreasing survival with an increasing number of adverse factors was observed in younger patients. The validity of the IPI has been confirmed in a population of patients with T-cell lymphomas.[72] The IPI was less useful in indolent lymphomas,[73] and a different index has been proposed, the FLIPI (follicular lymphoma IPI).[74] The FLIPI is based on the following adverse prognostic factors: age >60 years, stage III or IV, abnormal LDH level, 5 or more involved nodal areas, and hemoglobin <120 g/L.[74] A subsequent study (the F2 study) proposed a modification of FLIPI (FLIPI-2) using the following adverse prognostic factors: age >60 years, bone marrow involvement, abnormal beta-2-microglobulin level, maximum tumor diameter >6 cm, and hemoglobin <120 g/L.[75] For MCL in advanced stages, there is a yet another proposed prognostic index known as the mantle IPI (MIPI), based on the following adverse prognostic factors: older age, ECOG performance status, LDH level, and the leukocyte count.[76] Other prognostic factors include the presence of BCL-6 rearrangement, high levels of BCL-2 protein secretion,[77] survivin expression,[78] and *p53* mutation.[79] The prognostic significance of gene profiling with microarray studies has been discussed previously. In addition to the genetic and phenotypic factors, the presenting site of lymphoma has prognostic implications; for example, lymphoma presenting in testis, ovary, eye, CNS, and liver has a particularly adverse prognosis, whereas orbital and skin lymphomas generally have a good prognosis.

PRINCIPLES OF MANAGEMENT

Most cases of localized NHL are treated with curative intent (Figure 77-4). A palliative approach is used when, because of the condition of the patient or the extent or location of the disease, a radical course of treatment carries no potential of cure or would cause significant toxicity. Knowledge of histology, extent, and pattern of disease is essential to select the appropriate therapeutic strategy. Local radiation is routinely used, both for cure and local control. However, the recognition

TABLE 77-4 Prognostic Factors in Non-Hodgkin's Lymphoma

	Favorable	Adverse
Histologic type	Low-grade MALT	Diffuse large-cell Mantle cell
Immunophenotype	B-cell	T-cell, NK-cell
Tumor bulk	<5 cm	>10 cm
Ann Arbor stage	I, II	III, IV
Symptoms	Asymptomatic	B-symptoms

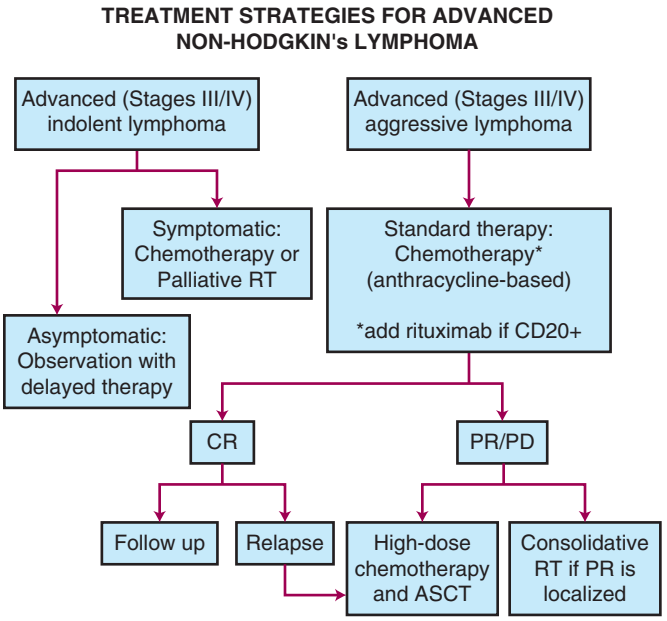

Figure 77-5 Treatment strategies for advanced non-Hodgkin's lymphoma.

of the high risk for occult distant disease mandates the use of chemotherapy in most cases. The primary treatment modalities include chemotherapy and RT, although surgery is used to diagnose and manage selected cases. For localized disease, the curative approach involves combined modality with chemotherapy and RT, chemotherapy alone, or local treatment with definitive RT. The choice is predicated on the inherent risk of occult distant disease, availability of curative chemotherapy, and the potential need for local control. Patients with advance disease (stages III and IV) are usually treated with chemotherapy alone (Figure 77-5).

Radiation Therapy

The aim of RT is to deliver an adequate dose of radiation to the target volume to ensure a high rate of local control. The design for a proper course of RT must take into account the extent of disease, the appropriate margins, routes of lymphatic and possible extranodal spread, and the radiation tolerance of normal tissues and organs. Dose fractionation parameters must assure local control with acceptable acute and long-term toxicity. The technique should guarantee reproducibility of treatment on a daily basis. Custom-designed fields should be used to conform to the target volume while keeping the volume of irradiated normal tissues to a minimum. The use of CT simulation with delineation of target volumes (gross target volume [GTV], clinical target volume [CTV], and planning target volume [PTV]) as well as dosimetric evaluation in three dimensions is standard for most indications.

RT techniques and prescriptions are discussed in detail later in the chapter. It is important to note that when RT follows chemotherapy in combined-modality therapy (CMT) protocols, RT is usually started 4 weeks to 6 weeks following the last course of chemotherapy to allow recovery of blood counts and to minimize the drug-radiation sensitization effect. Concurrent therapy is not indicated because of an increased risk of treatment interruption as a result of both thrombocytopenia and neutropenia with concurrent RT and chemotherapy.[80]

Chemotherapy

Frequently used chemotherapy regimens for NHL are listed in Table 77-6. These include single agents used for indolent lymphoma and anthracycline-containing regimens potentially curative for DLCBL (e.g., CHOP-rituximab) or T-cell lymphomas, and regimens used for patients with recurrent disease. For high-grade lymphoblastic and Burkitt lymphomas, dose-intensive protocols are used with concurrent intrathecal chemotherapy for CNS prophylaxis.[81,82] In a combined-modality approach for localized disease, chemotherapy is given first to promptly address any potential systemic microscopic disease and to reduce the bulk of the known local disease. When a combined course of therapy is planned, the goal of chemotherapy is to facilitate a response but not necessarily obtain a complete response at the local site. Quite often, residual thickening or a minimal mass of tissue remains by palpation or imaging, which should not deter from proceeding with the original radiation therapy plan.

The common acute but reversible toxicity of chemotherapy includes nausea and vomiting, alopecia, mucositis, fatigue, pancytopenia with risk of infection and bleeding, and any organ specific toxicity such as neuropathy for vinca alkaloids, diabetes for glucocorticoids, and pneumonitis for bleomycin. Rituximab may cause infusion related side effects such as fever, chills, and rigors, which can be avoided with a slower infusion rate. Advances in supportive care (e.g., antiemetic drug, and growth factor support) have alleviated many of these acute side effects. Severe long-term toxicity is infrequent, but may include gonadal damage particularly in males, cardiomyopathy (with doxorubicin), pulmonary fibrosis (with bleomycin or methotrexate), neurotoxicity (with vinca alkaloids, cisplatin, or bortezomib), and impairment of hematopoietic reserve (with alkylating drugs).

Surgery

The principal role for surgery is to establish the diagnosis of lymphoma and to obtain sufficient tissue to allow characterization of different disease subtypes. This requires optimal

pathologic interpretation, which includes immunophenotypic and molecular studies. Special fixatives and fresh tissue is commonly required, so when possible, it is important to alert the surgeon if a diagnosis of lymphoma is in the differential. The therapeutic role of surgery is not well defined. Case series reports have identified small proportion of patients with stage I nodal or extranodal lymphomas that have been cured with surgery alone. Although surgery can provide excellent local control in select extranodal sites, cure is infrequent because of a high likelihood of microscopic residual disease. Because surgical excision of lymphoma does not diminish the need for chemotherapy or radiation, aggressive surgical procedures that compromise function or cosmesis should be avoided. For example, radical neck dissection is not required for lymphoma presenting in the neck, total parotidectomy with possible risk to the facial nerve is not indicated for parotid lymphoma, mastectomy is not indicated for a breast lymphoma, and cystectomy is not required to cure bladder lymphoma. Situations where surgery is a potentially good treatment option for local control include splenectomy for splenic lymphoma and orchiectomy for testis lymphoma.

MANAGEMENT OF DISTINCT DISEASE ENTITIES

Small Lymphocytic Lymphoma

Small lymphocytic lymphoma (SLL) is a manifestation of chronic lymphocytic leukemia (CLL) and is rarely, if ever, localized. In a situation where the presenting disease appears to be localized, and peripheral lymphocytosis is not obvious, additional investigations with a bone marrow biopsy or flow cytometry of the peripheral blood should be performed and this would likely identify a CD5+ population of abnormal lymphocytes that indicate that the disease is systemic. The management of SLL is the same as for CLL and not further considered here.

Follicular Lymphoma

Localized (Stages I and II) Follicular Lymphoma

Stages I and II presentations of FL account for approximately 30% in the pre-PET era.[75] With the availability of sensitive techniques to detect subclinical disease (e.g., FDG-PET, and BCL-2 by PCR), more patients are diagnosed with stages III and IV disease.[83,84] RT produces excellent local disease control (>95%), and a freedom from relapse rate of 50% at 10 years. Data from multiple institutions[85-92] documented comparable results with more than 90% local control and 10-year relapse-free rates of approximately 50% with the OS rates of 70%. A number of representative single-institution results published in the last two decades are summarized in Table 77-7. At Stanford, the use of extended field, subtotal, or total lymphoid irradiation gave a higher relapse-free rate of 67% at 10 years, compared to 36% for patients treated to only one side of the diaphragm. However, because the OS rate was similar,[85] extended field RT has been abandoned. Prognostic factors predictive of a high risk of relapse included age, extent of disease as reflected by stage, systemic symptoms, and tumor bulk. The addition of chemotherapy (e.g., CVP) tested in several randomized trials in the 1970s did not confer an OS advantage.[93-96] Phase II trials of patients with poor prognostic factors (constitutional symptoms, high LDH, follicular large cell histology) treated with CMT (e.g., CHOP-bleomycin) documented 10-year failure-free rate and OS rates of 73% and 82%, respectively, suggesting benefit for CMT.[97]

With no definitive data showing a survival advantage with CMT, involved-site RT is currently the preferred treatment for

most patients with FLs (see Figure 77-6). Patients with grade 3B FL behave similarly to DLBCL and should be treated with CMT. Given the benefits of adding rituximab to either CVP or CHOP in patients with stages III and IV disease, it is logical to incorporate rituximab into these regimens for early-stage disease. A study of selected patients with stages I and II disease who were observed with no initial treatment showed that 38% required therapy after a median of 86 months.[98] Additional studies also showed that selected patients when observed can have similar survival to those subjected to initial RT or chemotherapy.[99,100] However, analysis of SEER database in more than 6500 patients showed that although RT was initially used in only one third of patients, patients treated with RT had consistently higher DFS and OS survival rates compared with other approaches and the benefit was maintained over a follow up period of 20 years.[101] Therefore, a policy of observation is not appropriate for all patients because a plateau in the DFS curve for the radiation-treated patients beyond 15 years has been observed suggesting that a proportion of patients are cured.[85,91,92] There is marked variation in RT practice for localized indolent lymphoma.[62,85,91,102-104] Involved site radiation is currently considered as the standard approach. The International Lymphoma Radiation Oncology Group (ILROG) recently published guidelines for involved-node/involved-site radiation therapy for nodal NHL (discussed in "Technical Aspects of Radiation Therapy"). Involved site RT is defined by three-dimensional CT planning methods with identification of the GTV, CTV, and PTV and with an RT alone approach the CTV should include suspected subclinical disease based on the pretreatment imaging. The CTV should include the GTV and as a minimum nodes adjacent to the GTV.[105] Lymph nodes outside of the involved nodal region do not need to be intentionally treated. Investigators from British Columbia reported on their experience of "involved-node radiation therapy ≤5 cm" for limited-stage FL and found that only 1% of the study cohort had a regional only recurrence.[91]

With moderate doses of radiation (24 Gy to 30 Gy, over a 2-week to 4-week period), the local control rate is more than 95%. A Phase 3 trial examining the optimal dose for indolent lymphomas from the United Kingdom demonstrated no advantage for a higher dose of 40 Gy to 45 Gy in comparison with 24 Gy (in 12 fractions) although this trial did not restrict patients in initial presentation of stages I and II disease, and that the local control rate for either arm was lower than expected—5-year freedom from local progression was slightly lower than 80% for both arms.[106] In patients receiving >30 Gy, relapse occurs almost exclusively in distant unirradiated sites. Treatment at the time of recurrence requires chemotherapy, although RT is also useful in selected cases. High response rates are observed even with a low total dose of 4 Gy (2 × 2 Gy).[107-110] Because of the indolent nature of these lymphomas, long-term follow up is required to test the effects of any new treatment approaches on survival. The variation in the approach to localized disease, the long follow-up required, and competing mortality from unrelated causes form significant barriers to the conduct of clinical trials in this disease.

Advanced (Stages III and IV) Follicular Lymphoma

The advanced stage FLs are not cured with current approaches.[111,112] For asymptomatic patients with slow disease progression, observation is appropriate. Symptomatic patients require chemotherapy and RT is reserved for control of local symptoms. In the classic Stanford report initially observed patients required treatment after a median interval of 3 years. Their OS was 73% at 10 years.[113] Spontaneous regression of disease lasting a median of 13 months was observed in 23% of cases. Patients selected to undergo intensive therapy

(n = 37) in a Phase II study had 10-year survival of 86%.[111] Histologic transformation to a more aggressive histology (usually DLBCL) occurred in 60% at 6 years in one series,[114] and 31% at in 10 years in another.[115] Deferred therapy tested in a randomized study showed no adverse effect on survival (78% versus 70% for early treatment, p = 0.24).[116] Extensive nodal irradiation has been attempted in the past and the available data indicate a high probability of disease control within radiation fields.[84,103,104] However, with the long natural history of this disease and the selection of patients submitted to protocol treatment, it is difficult to ascertain whether extensive lymphatic irradiation improves survival, or results in cure. Other strategies for the treatment of indolent lymphoma include total body irradiation,[117-119] purine analogs,[120,121] rituximab-chemotherapy combinations,[31,122-124] radioimmunotherapy,[125-128] and high-dose chemotherapy with RT and hematopoietic stem-cell transplantation,[111,129,130] autologous or allogeneic. In a Phase III trial comparing 24 Gy in 2 Gy fractions versus 2 Gy × 2 in patients with follicular or MALT lymphoma, 24 Gy was shown to produce higher response rates (91% versus 81%, p = 0.0095), as well as more durable responses (hazard ratio [HR] for time-to-local progression, 3.42, p < 0.0001).[131] Low-dose approach of 2 Gy × 2 should therefore mostly be reserved for patients treated with palliative intent, but not for those treated with curative intent.

The most common chemotherapy regimens are R-CVP, R-CHOP, R-bendamustine, or fludarabine-based regimens. Postchemotherapy maintenance with rituximab has also been shown to improve outcomes.[132,133] Favorable responses have been documented for each of these approaches, but no firm evidence for cure has been evident. A meta-analysis of trials using α-interferon concluded that when used at a dose of ≥5 mU (or ≥36 mU/month) in combination with relatively intensive chemotherapy, improvement in survival and remission duration was seen.[134]

Palliative RT with a low dose regimen of 2 × 2 Gy is useful for symptom relief, with response rates of approximately 80% and usually lasts 12 months to 18 months.[107-109] However, if the goal is to achieve durable local control, for example in a critical site such as spinal cord compression, a higher dose regimen of 20 Gy to 24 Gy is more appropriate given its superior response rates and local control.[131]

Marginal Zone Lymphoma, MALT Type

MALT lymphomas are usually indolent B-cell tumors that present with stages I and II disease in 70% to 90% of cases. They are characterized by infiltration of mucosa, lymphoepithelial lesions, and clonal proliferation of centrocyte-like B cells.[29,135] MALT lymphomas arise most commonly in the stomach, orbit, thyroid, salivary glands, breast, lung, skin, and bladder.[135] The etiology of gastric MALT lymphoma is linked to infection with *H. pylori*. Association of *C. psittaci* with orbital adnexal MALT lymphoma has been documented, with marked geographical variation in different parts of the world.[15,17,28] Cutaneous MALT lymphoma has been associated with *Borrelia burgdorferi* infection in Europe,[136] but not in the United States.[137,138]

Gastric MALT Lymphoma

Patients with gastric MALT lymphoma usually present with gastric symptoms (dyspepsia, pain) typical of gastric ulcer. Some present with significant bleeding. Most cases are associated with *H. pylori* infection, and its eradication improves symptoms and induces remission of the lymphoma. Recommended anti-*Helicobacter* triple-drug therapy includes a proton pump inhibitor (or ranitidine bismuth citrate), clarithromycin, and amoxicillin (or metronidazole).[139,140] The expected rates of eradication of *Helicobacter* are more than 90%.[27,141] Adjuvant use of chlorambucil does not improve the results.[142] However, a response can take many months, and follow-up endoscopies and histologic examination is required to assess response. Residual abnormalities can remain for some time (12 months to 18 months), including persistence of a monoclonal B-cell population by sensitive molecular techniques such as polymerase chain reaction (PCR), and provided that the patient's symptoms are improved, no additional cytotoxic treatment is required. Although the majority of patients with gastric MALT lymphoma respond to antibiotics therapy, the t(11;18)(q21;q21) translocation has been reported to be associated with resistance to *H. pylori* therapy.[143,144] The presence of this marker, or lack of response to antibiotic therapy are two main indications to treat with definitive RT. Patients with asymptomatic minimal residual disease can have an indolent course and not require further treatment,[26,145] particularly if elderly or infirm. Involved site RT with doses of 30 Gy to 35 Gy results in >95% local control and a significant proportion of patients will be cured.[146-150] Relapses are rarely seen.

Orbital MALT Lymphoma

The most common involved site in the orbit is the conjunctiva. This produces redness, swelling, and symptoms of irritation. Clinically it appears as salmon pink infiltration of the conjunctiva, often filling and obliterating the conjunctival sac. Sometimes the disease affects the lacrimal gland, appearing as a soft-tissue swelling, orbital issues, eye lid, or retro-orbital tissue in which case it will give rise to proptosis. Bilateral orbital involvement is seen in 10% of patients but should not be regarded as stage IV disease. Reported association with *C. psittaci* led to the use of antibiotics (specifically doxycycline or clarithromycin) to treat orbital MALT lymphoma, with a variable success rate. The high rate of response reported from the Milan series[28,151] has not been reproduced elsewhere.[17,152] A course of antibiotics therefore can be attempted in patients who tested positive for *C. psittaci* serology. The standard approach in cases not related to infection is orbital radiation therapy with a dose of 25 Gy to 30 Gy. It results in a local control rate of >95% and cure in the majority of patients.[153,154] The relapse rate is 15% to 20%, with patients presenting with lacrimal gland disease[155] at higher risk of relapse than those with conjunctival involvement. The relapse is usually manifest in other systemic nonorbital MALT sites, although some patients may have subsequent involvement of the contralateral orbit, which may either be a new lesion or a true contralateral relapse. Fasola et al recently reported on results of 20 patients with indolent lymphoma of the orbit treated with 2 Gy × 2 to 26 sites, and at a median follow up time of 26 months.[156] The 2-year freedom from regional relapse rate was 96%, with one case of relapse within the ipsilateral orbit (outside of the treatment field). In this study 35% of patients had stage IE disease at diagnosis, and whether 2 Gy × 2 can be used as initial definitive treatment in patients with orbital MALT lymphoma needs to be further investigated.

Other MALT Sites

Less common sites of involvement include the salivary glands, most commonly the parotid gland. This is usually preceded by the presence of Sjögren's syndrome. Patients invariably gave a history of dryness of the mouth and possibly dryness of the eyes. Appropriate serology abnormalities are usually present. Multidisciplinary management with participation of rheumatologist and otolaryngologist is important. Other sites of involvement include the thyroid gland, lung, breast, skin, urinary bladder, liver, the dura, and other organ or structures lined with mucosa. The general approach is to treat with localized therapy—for sites where surgery is possible and a

complete gross disease excision has been achieved (e.g., skin lesion, or a thyroid nodule, or a small lung lesion), no further therapy may be necessary. The more common approach, however is to treat with RT as a standard dose of 30 Gy in 15 fractions to 20 fractions is associated with a high probability of local control for virtually all sites of localized MALT lymphoma. In situations where the morbidity of a full course of therapy is significant, (e.g., lung tissue), the use of a low dose regimen with 4 Gy (2 × 2 Gy) may produce good local control for some time.[157]

Although MALT lymphomas are usually indolent, transformation into aggressive large B-cell lymphomas may occur. The risk factors for future transformation have not been confirmed. Current experience with MALT lymphomas shows a tendency to localized disease and cure with local therapy.[32,158] The nodal counterpart of MALT, also known as monocytoid B-cell lymphoma, occurs in the older age group and is similar morphologically and immunologically to MALT lymphoma,[159] with similar clinical outcomes.[160]

Advanced Stage MALT Lymphoma

Stages III and IV MALT lymphomas have an indolent clinical behavior, similar to FLs. It has a tendency to involve MALT sites and asymptomatic disease may not require cytotoxic treatment. There are case reports that antibiotic therapy can produce responses.[161] Chemotherapy is reserved for symptomatic progression of the disease, with regimens which are active in FL cited previously. Mild therapy with single agent (e.g., rituximab or chlorambucil) may often be useful and cost-effective. The prognostic factors usually relate to burden of disease, a high beta 2 microglobulin, and presence of symptoms.[160,162,163] As in FL, palliative radiation therapy with 4 Gy in two fractions can often be useful for symptom relief.

Mantle Cell Lymphoma

Localized (Stages I and II) Mantle Cell Lymphoma

MCL accounts for 3% to 10% of all newly diagnosed cases of NHL. The disease has a predilection for men and is more common in the elderly (median age 60 to 65). There appear to be two different phenotypes of MCL, the blastic variant which is associated with rapid growth and aggressive behavior, and a more indolent subtype for which a watch and wait policy can be adopted for asymptomatic patients.[164] Because the majority of cases (>90%) present at advanced stage, the evidence for management of localized disease is scarce. However, MCL is radiosensitive, and therefore involved site RT may be appropriate for local disease.

Definitive RT without systemic therapy has been shown to result in long-term remissions in patients with localized MCL[165,166] and may be curative in a subset of cases.[167] In the absence of clinical comorbidities that would preclude the use of chemotherapy, most would favor a course of CMT. Despite the excellent response to systemic agents, several small retrospective studies confirm the important role RT plays an important role in localized disease with improvements in local control and progression-free survival (PFS).[168-170]

Advanced (Stages III and IV) Mantle Cell Lymphoma

The vast majority of MCL will present as advanced disease (stages III and IV) and may involve extranodal sites, including visceral organs, skin, breast, and bone marrow.[171] Expression of a microarray gene profile characterized by high proliferation,[172] or a high Ki-67 growth fraction,[76] confers a worse prognosis. The blastic variant of MCL is also associated with rapid growth and aggressive behavior. Although advance disease is not curable (median survival of 4 years to 6 years), it is responsive to several lines of systemic and local therapies. However, because this is a disease that impacts older adults (median age mid-60s)[168] and treatment is not always with curative intent, care must be taken in deciding when to treat and what agents to use. Observation may be indicated in patients who are asymptomatic and with disease that is behaving more indolently.[164] Once a decision is made to proceed with treatment, there is evidence to support using almost any of the chemotherapy regimens listed in Table 77-6 in MCL.[173] R-CHOP and R-bendamustine are both well-tolerated and effective, with overall response rates of 91% and 97%, respectively.[174] Unfortunately, a complete response is only achieved in a proportion of patients (~30%) leading to the poorer outcomes in patients with MCL than other subtypes of NHL.

Intensive chemotherapy followed by consolidation with high-dose chemotherapy and ASCT is being evaluated as a first-line strategy in younger patients with good performance status.[30,175,176] One study comparing RCHOP compared with R-hyperCVAD followed by ASCT or observation showed no difference in 2-year survival with consolidation, but R-hyperCVAD followed by ASCT was associated with improved PFS.[177] In another study, R-DHAP induced a complete response in 57% of patients versus 12% of patients treated with RCHOP before ASCT.[178] The outcomes were still excellent, with an ORR of 95% and 93%, respectively, and a 5-year OS of 75%, suggesting ASCT may provide improved outcomes for selected patients.

Relapsed and Refractory Mantle Cell Lymphoma

There is no standard approach to relapsed and refractory MCL. ASCT is considered in the setting of relapsed MCL but with the same caveats regarding safety of high-dose therapy in older patients. With improved understanding of the molecular pathogenesis of MCH, several targeted agents have been successfully investigated and are now approved for use in patients with relapsed and refractory MCL.[175] Molecular agents can be used alone or in combination with each other or conventional chemotherapy. These targeted drugs include several classes of agents including proteasome inhibitors (bortezomib), immune modulatory drugs (thalidomide, lenalidomide), the mammalian target of rapamycin (mTOR) inhibitor temsirolimus, and inhibitors of the B-cell receptor pathway (ibrutinib). Based on encouraging results from a Phase I study in patients with relapsed and refractory NHL of a variety of subtypes, the CTLA-4 inhibitor, ipilimumab, is being investigated in several ongoing MCL clinical trials. RT is an effective modality for palliation given the radiosensitivity of MCL. Existing data suggest that doses of 30 Gy or lower provides excellent local control and palliation.[165,179]

Diffuse Large B-Cell Lymphomas

Localized (Stages I and II) Diffuse Large B-Cell Lymphoma

Approximately 30% to 40% of DLBCL presents with stages I and II disease, but factors such as IPI score, the presence of B symptoms, and the size (bulk) of the disease influence the prognosis and therefore affect treatment choices. Immunophenotype, such as the presence or absence of c-myc and BCL-2 or BCL-6, may also influence choice of therapy. RCHOP is a standard chemotherapy regimen, but dose-adjusted EPOCH, CHOEP, and ACVBP used with rituximab also have excellent outcomes, albeit with increased toxicity.[180-183] The number of cycles of chemotherapy is variable; CMT with three to four cycles of chemotherapy followed involved site radiation therapy is standard treatment for limited stage, non-bulky DLBCL (Figure 77-7) An alternative approach is six cycles of

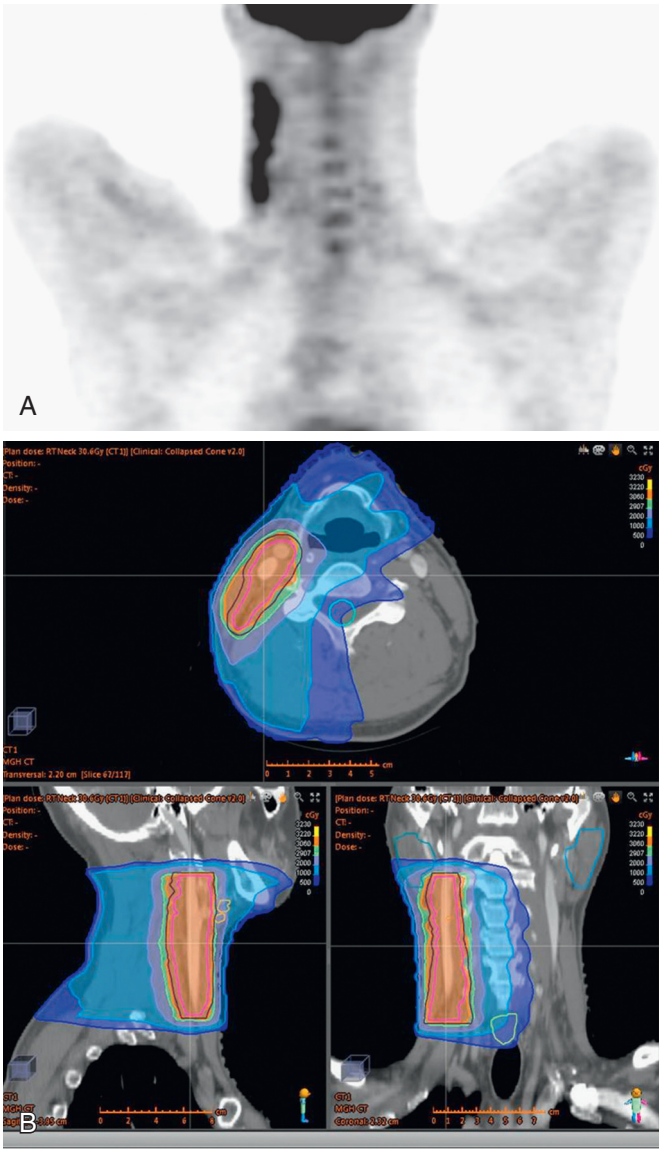

Figure 77-7 Involved site radiation therapy of cervical lymph node region. **A,** Positron emission tomography imaging showing localized disease. **B,** Isodose distribution of intensity-modulated radiation therapy plan to the involved site. Note sparing of parotid glands.

RCHOP with or without consolidative RT. Chemotherapy alone may be selected based on disease extent or location. OS at 5-years for CMT is approximately 90%. Several randomized trials from the prerituximab era showed that CMT is not inferior to longer regimens of chemotherapy alone and the addition of RT improves local control and, in several studies, PFS.[184-187]

In the rituximab-era, several retrospective studies showed an improved DFS and OS rates in patients who received RT compared to those who were treated with chemotherapy alone.[188-191] These studies included both early- and advanced-stage patients. Though the findings were limited by the retrospective study design, the use of RT was associated with improved outcome on multivariable analyses in each of these studies. Improved outcome with the addition of RT is supported by the early closure of the no-RT arms in the German UNFOLDER trial, a Phase III trial that randomized patients with stages I-IV DLBCL with initial bulky disease (defined as ≥7.5 cm) or extranodal involvement to RT versus no-RT after R-CHOP chemotherapy.

A Phase III trial comparing 30 Gy versus 40 Gy to 45 Gy in patients with aggressive NHL (67% with stages I and II) showed no difference in 5-year freedom for local progression between the two arms.[106,192] This trial, however, is limited by the fact that only 73% of patients received RT as consolidation after chemotherapy, and there was no information on response to chemotherapy before the RT. Based on retrospective data and nonrandomized data from clinical trials, radiation doses of 30 Gy to 36 Gy appears to be sufficient in patients who have achieved a complete response to systemic therapy.[185,189,190,193,194] Whether the RT dose can be deescalated to 20 Gy in these patients is currently being addressed by an ongoing Phase II study conducted at Duke University. Higher doses of radiation should be considered when a complete response is not achieved.[195]

The current standard treatment field for aggressive NHL after systemic therapy is involved-node or involved-site RT,[105] depending on the availability of optimal prechemotherapy imaging, detailed in "Technical Aspects of Radiation Therapy." After effective chemotherapy, the CTV should encompass the original lymphoma volume modified for normal tissue boundaries and expanded to accommodate uncertainties in determining the prechemotherapy volume, especially when optimal pretreatment imaging in RT planning position is not available. In a retrospective study comparing patients with early-stage aggressive NHL treated with IFRT versus involved-node RT, there was no difference in 5-year PFS rates between the two groups of patients, and patients treated with involved-node RT had better physical functioning and global quality of life compared to the IFRT group.[196]

Advanced (Stages III and IV) DLBCL

RCHOP is currently considered the standard chemotherapy for advanced (stages III and IV) disease.[191,197-199] Previous studies showed that "adjuvant" RT following a complete response to chemotherapy did not improve the OS in advanced stage NHL.[200,201] As discussed in the previous section, several more recent retrospective studies from the rituximab era that included patients with both early- and advanced-stage disease showed significantly improved outcome in patients who received adjuvant RT.

Early high-dose therapy with stem-cell transplantation had been an attractive approach when tested in patients with adverse prognostic factors, but showed no definite advantage over standard chemotherapy alone.[202-204] A French trial (GELA LNH 93-3) in high-risk and high-intermediate risk patients actually showed a worse outcome for the ASCT arm.[205] The GELA trials did not use RT, despite the inclusion of patients with stages I and II disease (some with bulky disease) that accounted for 30% to 40% of the patients studied.[204,206] In a randomized trial of 253 patients with high-intermediate-risk or high-risk disease comparing early ASCT versus further chemotherapy after CHOP or R-CHOP, an improved 2-year PFS was found in patients in the transplantation arm (69% versus 55%, $p = 0.005$), but no OS difference was detected, likely because of the effectiveness of salvage transplantation.[207] At this time, early stem-cell transplantation as part of initial therapy cannot be considered standard[208-211] but is reserved for patients with refractory or relapsed disease.

Relapsed and Refractory DLBCL

For patients with relapsed or chemotherapy-refractory large cell lymphoma, RT alone is rarely curative. However, in highly selected cases, durable long-term control of disease can be achieved with salvage RT.[212] Conventional salvage chemotherapy also has a low curative potential. Common salvage

regimens include DHAP,[213] mini-BEAM,[214] ESHAP,[215] ICE with or without rituximab,[216,217] and GDP[218] (Table 77-6). For patients with chemotherapy-sensitive disease, high-dose therapy followed by autologous hematopoietic stem-cell transplant is of benefit. A Phase III trial (PARMA) tested the role of high dose therapy in 109 patients. Those demonstrating a response to two cycles of DHAP chemotherapy were randomized to four further courses of DHAP, versus a conditioning regimen of BEAC (carmustine, etoposide, cytarabine, cyclophosphamide) followed by ABMT. The 5-year event-free and OS for the transplant arm were 46% and 53%, versus 12% ($p = 0.001$) and 32% ($p = 0.038$) for the conventional DHAP arm, respectively.[219] RT to a dose of 26 Gy in 20 fractions was given twice daily as a protocol treatment for patients with tumor bulk greater than 5 cm at the time of relapse in the transplant arm and to 35 Gy in 20 fractions in the conventional chemotherapy arm. There was a trend favoring the patients undergoing RT with a lower relapse rate in the transplant group (8 of 22 relapsed versus 18 of 33 relapsed who underwent RT, $p = 0.19$), and no obvious difference in the conventional chemotherapy group (10 of 12 patients who underwent RT relapsed, versus 35 of 42 patients who did not undergo RT relapsed). Although this trial was not designed to examine the role of RT in the salvage setting, it lends support to the use of RT for bulky disease when incorporated into a salvage treatment plan that includes high-dose therapy. The role of RT in bulky disease following partial response to salvage chemotherapy deserves further study in a randomized trial in patients undergoing hematopoietic stem-cell transplant. Until such evidence is available, we recommend routine RT to sites of bulky disease, in sequence with salvage chemotherapy and also RT to sites of incomplete response to chemotherapy.[220-224] Moderate doses of 30 Gy to 35 Gy should be the goal with individualization of the treatment plan in regard to the exact target volume (involved-site RT is preferred), and the timing of RT in relation to chemotherapy and transplant to facilitate the collection and harvesting of stem cells and minimize treatment-related toxicity. For example, if large RT fields are required, RT should be given after stem-cell harvesting and preferably pretransplant. Thoracic RT that will include significant volumes of lung tissue is less risky if given after transplantation.[225,226] In general, the principles of RT should be to treat the most likely site of relapse, or progressive disease. The decision to treat with RT is influenced by the distribution and location of the disease. The spinal cord may be more radiation-sensitive in the posttransplant setting because there are two case reports of radiation myelopathy with conventional fractionated doses of 40 Gy to 45 Gy.[227-229]

Although most cases of DLBCL are treated the same regardless of where they arise in the body, there are a few special presentations that warrant additional consideration.

Primary Mediastinal Large B-Cell Lymphoma

Several clinicopathological features have distinguished PMBL (thymic) from nodal DLBCL lymphoma. The disease typically present in females (female-to-male ratio of 3:1) in fourth or fifth decade of life, as a rapidly growing invasive tumor with contiguous spread into mediastinal tissues. Pleural and pericardial invasion with effusion and B-symptoms are common and 30% to 40% of patients have superior vena caval obstruction at diagnosis. The lesions are frequently bulky (65% being greater than 10 cm diameter), and involve the thymus. Tumors often have moderate to marked sclerosis. The outcome for patients treated with R-CHOP–based chemotherapy or CMT is equivalent to other DLBCL of equivalent stage (i.e., CR rates of 70% to 80% and 5-year survival of 60% to 80%).[230-232] Chemotherapy regimens more intensive than CHOP (e.g., MACOP-B,- or high-dose therapy with stem-cell transplantation) have been reported in retrospective studies to give improved results with 10-year OS ranging from 70% to 77%.[232-236] CMT is the standard approach.[235,236] Occasionally these tumors have demonstrated marked chemo- and radioresistance.[237] Factors determining outcome included bulk (>10 cm), the use of CMT,[233-235] and stage. The use of consolidative RT is being challenged in patients with PMBL; a Phase II trial using six cycles of dose-adjusted EPOCH-R showed that patient achieving a complete response had a 93% event-free survival and an OS of 97%, suggesting this aggressive regimen may obviate the need for RT in this disease entity, even in patients with bulky disease.[238]

Primary Central Nervous System Lymphoma

The most common site of primary central nervous system lymphoma (PCNSL) is the brain.[239] Primary leptomeningeal lymphoma, without parenchymal brain disease, accounts for only 7% of PCNSL. Primary spinal cord lymphoma is even less common.[240] The eye, a direct extension of the CNS, is another site of PCNSL. Aggressive histology B-cell lymphomas are most common; T-cell lymphomas have been reported but are exceedingly rare, with a prognosis similar to the B-cell lymphoma.[241]

Most patients with PCNSL present with symptoms of headache and raised intracranial pressure. Lesions are often multifocal or diffuse and are periventricular with easy access to the cerebrospinal fluid. The incidence of meningeal seeding varies from 7.6% to 69% when a vigorous search is conducted.[242,243] Systemic lymphoma is apparent in only 7% to 8% of autopsied patients. The diagnosis has to be confirmed histologically, but is suspected based on characteristic CT/MRI appearances of the tumor. A diffuse contrast enhancement of tumor on both CT and MRI is typical, but a small proportion of patients have nonenhancing lesions. Historical treatment consisted of whole brain irradiation to 40 Gy to 50 Gy in 1.8-Gy to 2-Gy fractions and corticosteroids producing a rapid symptomatic response. Performance status, age, and solitary tumor are the most important prognostic factors. The median survival has been reported to be 12 months to 18 months with 2-year and 5-year survival rates of 28% and 3% to 4%, respectively.[244-246] In the Princess Margaret Hospital (PMH) experience with RT alone, patients with Karnofsky performance status (KPS) older than 60 had an actuarial 5-year survival of 56% compared with 10% for those with KPS 60 or younger, whereas survival was 42% for those age 60 or younger compared with 9% for those 60 years or older, and for solitary lesions the survival was 30% compared to 15% for multiple lesions.[246] The International Extranodal Lymphoma Study Group (IELSG) study of 378 patients identified five independent poor prognostic factors for OS: age over 60 years, a ECOG performance status 2 or higher, elevated LDH level, elevated cerebrospinal fluid protein level, and involvement of deep brain structures.[247] Patient with none to one of these factors had a 2-year survival of 80%, with two to three factors, 48%, dropping to 15% for those with four to five factors.[247] These factors remain prognostic when the analysis was restricted to patients treated with intravenous methotrexate.

Because of poor results with RT alone and concerns regarding radiation neurotoxicity,[248,249] chemotherapy has become the initial standard treatment.[250-252] In the 1990s several reports have suggested improved median survivals for patients receiving chemotherapy followed by planned RT or RT at progression.[253-258] A policy change from an RT approach to initial chemotherapy consisting of methotrexate did not result in an improvement in survival for an unselected population of 122 patients in the province of British Columbia in Canada, in which up to one third of patients did not receive potentially curative therapy.[259] Despite this, protocols using strategies with high-dose methotrexate, in various combinations with

carmustine, procarbazine, vincristine, and dexamethasone have produced impressive results with or without RT, and with mild to moderate late neurologic toxicity.[250,251,253,255,256,260]

Other chemotherapy approaches included very high-dose of methotrexate (7 g/m^2) alone and deferred RT, and such treatment in 23 patients achieved an overall response rate of 74%, although only 52% had complete response.[257] Adding high-dose cytarabine to methotrexate resulted in a higher response rate in a Phase II study.[261]

In a Phase III trial of methotrexate-based chemotherapy alone versus CMT, the median PFS were 11.9 months and 18.3 months (p = 0.14), respectively, in patients who did not and did receive whole-brain RT.[252] The median OS were 32.4 months and 37.1 months (p = 0.71), respectively, yielding a HR of 1·06 (95% confidence interval [CI] 0.80 to 1.40). In this noninferiority trial, the noninferiority margin was set at 0.9. The results therefore did not support the primary hypothesis that the omission of whole-brain RT is noninferior to CMT. Long-term treatment related neurologic toxicity is a major problem after whole-brain RT for PCNSL, especially in patients older than the age of 60 years.[248,262,263] Investigators from Memorial Sloan Kettering Cancer Center reported their long-term results of a Phase II trial using reduced-dose whole-brain RT of 23.4 Gy in 1.8 Gy fractions in patients in complete response after rituximab, methotrexate, procarbazine, and vincristine.[264] The median age of the study population was 60. Among the 31 patients who achieved a complete response to chemotherapy and received reduced-dose radiation therapy, the 2-year PFS was 77% and 3-year OS was 87%. Prospective neuropsychological evaluation showed no evidence of significant cognitive decline, except for motor speed, and self-reported quality of life remained stable during the follow up period.

For patients with relapsed disease after or refractory disease to high-dose methotrexate-based therapy, salvage whole-brain RT results in response rates of 67% to 79%[265-267]. These reports show that PCNSL that are resistant to chemotherapy remain radiosensitive, but the optimal salvage approach has not yet been clearly defined.

Testicular DLBCL

In contrast to germ cell tumors, primary testis lymphoma affects mostly older men, older than the age of 50. Initial therapy usually involves orchiectomy. Almost all testicular lymphomas are DLBCL. Older series reported 5-year OS rates ranging from 16% to 65% with median survivals of 12 months to 24 months.[162,268-270] Distant failures were commonly observed. In the IELSG study of 373 patients 57% had stage I, and 21% had stage II disease.[162] Median PFS was 4 years. High risk of CNS relapse was observed with an actuarial risk of 34% at 10 years.[162] CNS relapse has been documented despite the use of chemotherapy.[271,272] Other sites of relapse involve extranodal organs including skin, pleura, Waldeyer's ring, lung, liver, spleen, bone, and bone marrow. Failure in the contralateral testis is well documented and occurs in 15% of patients at 3 years, rising to an actuarial risk of 42% at 15 years.[162] Scrotal irradiation with moderate doses (25 Gy to 30 Gy in 10 to 15 daily fractions) reduces this risk to less than 10%.[162] Doxorubicin-based chemotherapy improves survival of patients with localized testicular lymphoma.[162] A clear pattern of failure in the CNS warrants a recommendation for routine CNS prophylaxis with intrathecal chemotherapy,[270] and the IELSG data suggests that a combination of the systemic and intrathecal therapy, with scrotal RT was associated with an improved outcome.[162] In the most recent Phase II study conducted by the IELSG, 53 patients with stage I or II testicular lymphoma were treated with six to eight cycles of R-CHOP and four doses of intrathecal methotrexate (IT-MTX), followed by RT to the contralateral testis to 30 Gy for all patients and to regional lymph nodes for patients with stage II disease. At a median follow-up of 65 months, 5-year PFS and OS rates were 74% and 85%, respectively. With CNS prophylaxis and prophylactic contralateral testicular irradiation, the 5-year cumulative incidence of CNS relapse was 6%, and no contralateral testis relapses were observed.[270]

Breast Lymphoma

Breast lymphoma affecting young women tends to be associated with pregnancy and lactation and is an aggressive histology lymphoma commonly presenting with bilateral disease diffusely involving both breasts. In contrast, the disease affecting older women tends to present with discrete masses, commonly unilateral. Reports in the literature suggest synchronous bilateral involvement in up to 13% of cases and metachronous contralateral involvement in 7% of cases. The most common histologic type is DLBCL.[273] Indolent histology lymphomas are less common and if observed usually consist of secondary involvement from systemic disease.[274,275] MALT lymphoma affecting the breast is rare but has been reported.[274,276] Mastectomy is not recommended and the breast is preserved in the majority of cases. RT results in excellent local control, especially in patients presenting without bulky disease or those with indolent histology. The OS of patients treated with local treatment methods ranges from 40% to 66% at 5 years to 10 years.[273,274,277] The local control rates in patients treated with RT alone range from 75% to 84%.[273,274,278,279] Isolated CNS relapses have been reported.[273] Similarly, late failure in the contralateral breast may occur following therapy of unilateral primary breast lymphoma.[273] CMT is recommended for aggressive lymphomas,[273,280] whereas patients with indolent lymphoma can be successfully treated with RT alone.[274] CNS prophylaxis with intrathecal chemotherapy should be given to all patients with aggressive histology, such as Burkitt lymphoma.

Bone Lymphoma

With RT alone, 5-year and 10-year OS rates of 58% and 53% have been reported for solitary bone lesions. Key issues relating to local control are the intramedullary and soft-tissue extent of disease in relation to RT volume. MRI is particularly important in revealing extension of disease in the bone and soft tissues. Treatment approaches using RT have given high levels of local control (85%), but unacceptable rates of local or marginal failure (20%) probably related to underestimation of tumor extent and bulk, and systemic failure rates approaching 50% were reported. Therefore, patients with localized lymphoma of bone should be treated with CMT comprising initial anthracyline-based chemotherapy and RT.[281] The importance of consolidative RT in patients with bone involvement was highlighted in the retrospective analysis of 161 patients with skeletal involvement and complete response to chemotherapy from the MInT and RICOVER-60 trials. The 3-year event-free survival rates were significantly higher in patients who received RT, compared to those who did not (75% versus 36%, $p < 0.001$). On multivariable analysis adjusting for age, stage, LDH, performance status, E-lesions, IPI, the addition of RT reduced risk of an event by 70% ($p < 0.001$).[282]

T-Cell Lymphomas

Treatment for T-cell lymphoma is just as varied as the distinct clinicopathologic B-cell lymphomas, entities such as peripheral T cell lymphoma (PTCL), anaplastic large cell lymphoma (ALCL), and are currently treated similarly as DLBCL. ALCL has a better prognosis than PTCL. Because standard chemotherapy results in a lower cure rate for PTCL and MCL, new approaches have been advocated, including the incorporation of new drugs,[283-285] and consolidative ASCT.[30,286]

NK/T Cell Lymphoma

In Asia, a destructive, erosive lesion is a characteristic presentation and T/NK-cell tumors predominate and show the characteristic features of angioinvasion, necrosis, and epitheliotropism. Indolent lymphomas are less common. The nasal type of CD56 positive T/NK cell lymphoma is a distinct clinical-pathological entity associated with the EBV.[29,57] T/NK cell tumors with an identical phenotype and genotype can occur rarely in other extranodal sites, usually in the skin, subcutis, GI tract, and testis.[29,287] For DLBCL, the current practice of CMT yields 5-year OS rates of 60% to 75%.[61,288,289] In T/NK-cell disease, the Asian experience with stages I and II presentations are disappointing, with a response rate to doxorubicin-containing chemotherapy of less than 50%, and 5-year survival of 30% to 70%.[287,290-293] Recent Phase I and Phase II studies evaluating the efficacy of SMILE, a multidrug regimen containing dexamethasone, methotrexate, ifosfamide, etoposide, and L-asparaginase, has had more promising results. This regimen includes L-asparaginase, which has been studied in relapsed NK/T cell lymphomas as a single agent.[294,295] In patients with relapsed or refractory NK cell lymphoma, the SMILE regimen resulted in an overall response rate of 74% and complete response of 35% to 50%.[296,297]

The early use of RT to a higher dose of 45 Gy to 50 Gy appears to be important for optimal local control,[287,293,298,299] either by itself or combined with ifosfomide-based chemotherapy.[61,300] IMRT is typically recommended to allow appropriate coverage of the target while sparing normal tissues. In cases where there is skin involvement, bolus is to be applied to ensure adequate dose is delivered to the skin surface (Figure 77-8). Because of the success of single-agent L-asparaginase and the promising results in the relapsed setting, some institutions have adopted the SMILE regimen as part of an upfront combined-modality approach to NK/T cell lymphomas.[301] For patients who responded favorably to initial treatment, the use of consolidation therapy with high-dose chemotherapy and ASCT appears to result in prolonged remissions.[58]

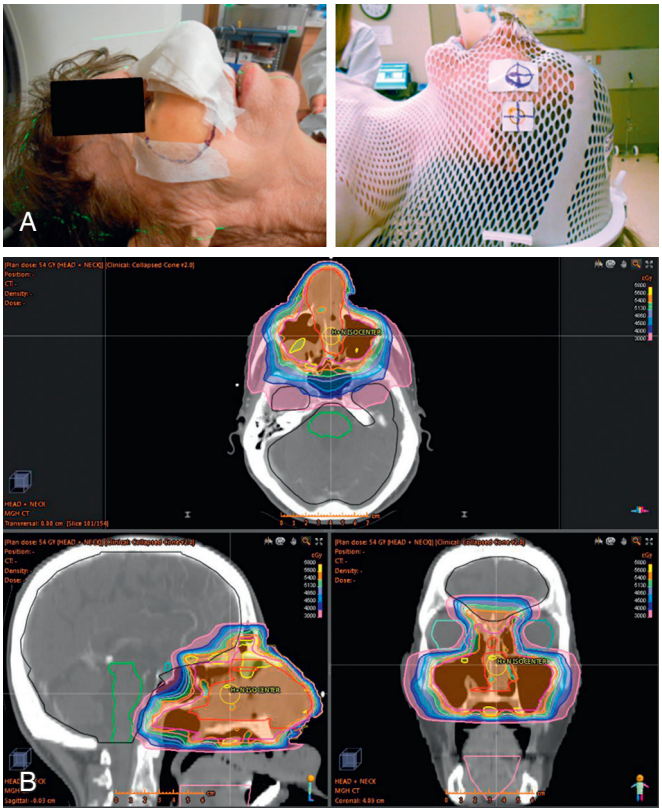

Figure 77-8 Treatment of stage I NK/T cell lymphoma using intensity-modulated radiation therapy (IMRT). **A,** Placement of bolus on areas of skin involvement under immobilizing mask. **B,** Isodose distribution of IMRT plan to the involved site. Neck nodes are not included for this patient with stage I disease.

Assessment of Response and Follow-Up

Cure requires the ability to eradicate disease; therefore, the key is to attain complete remission with the initial treatment plan. In patients treated with RT alone, response is usually assessed 4 weeks to 6 weeks following the completion of therapy. Because the RT dose fractionation schedule is determined before treatment and is usually based on information regarding dose-response relationship and tolerance of tissues within the treatment volume, the presence of residual disease at the end of the treatment course is not an indication for additional RT. The assessment of response includes examination of the organ of presentation and a general examination to rule out disease progression. In the most recent ICML recommendation,[64] PET-CT is considered standard-of-care for remission assessment for patients with FDG-avid lymphoma. However, because of therapy-related inflammation, the recommendation is to wait a minimum of 3 months after RT before obtaining a PET-CT for response assessment.

In patients with FDG-avid lymphoma treated with chemotherapy or CMT, the current recommendation is to use the 5-point scale (Deauville criteria)[302] for both interim and end-of-treatment response assessment, with a score of 1 being no uptake; 2, ≤mediastinal uptake; 3, >mediastinal uptake but <liver uptake; 4, uptake moderately higher than liver; 5, uptake markedly higher than liver or presence of new lesions; X, new areas of uptake unlikely related to lymphoma. Recent data, however, suggest that interim PET-CT may be less predictive of treatment outcome in patients who received immunochemotherapy.[303] Because of the lack of definitive evidence that modifying treatment based on interim PET-CT improves outcome in patients with lymphoma, the ICML recommends against changing treatment solely based on interim PET-CT, except for cases of clear disease progression.[64] However, end-of-treatment PET-CT to assess for remission is standard for FDG-avid lymphoma, and the recommendation is to perform the scan at a minimum of 3 weeks, but preferably 6 weeks to 8 weeks after the last cycle of chemotherapy because of posttreatment inflammatory changes.

Cutaneous Lymphomas

Histopathologic classification for cutaneous lymphomas has been proposed by a joint WHO–European Organization of Research and Treatment of Cancer (EORTC) effort, describing clinical-pathological disease entities unique to the skin.[304] Primary lymphomas of the skin can be divided into three broad categories:

1. Cutaneous B-cell lymphomas (CBCL, 25%), including indolent histologies with follicular center lymphoma and marginal-zone (MALT), and the clinically aggressive: DLBCL, leg type, or other location.
2. Cutaneous T-cell lymphomas of indolent clinical behavior (70%): Mycosis fungoides and its variants, primary cutaneous anaplastic large cell lymphoma (c-ALCL), lymphomatoid papulosis, and other rare types (e.g., subcutaneous panniculitis-like T-cell lymphoma)
3. Cutaneous T-cell lymphoma of aggressive clinical behavior (<10%): Sézary syndrome, peripheral T-cell lymphoma, and

Catheters are positioned along the surface of the mold. The areas to be treated are outlined in black.

several rare entities such as natural killer (NK) cell lymphoma of nasal type.

Cutaneous diffuse large B-cell lymphomas commonly occur in legs of elderly patients, is clinically aggressive, and has an estimated 5-year disease-specific survival of 55%.[304-309] CMT is the standard as in DLBCL of other sites. In contrast, primary cutaneous follicular center lymphomas are usually confined to the head and neck region or the trunk, with 5-year survival of higher than 95%.[304,305] Unlike nodal follicular lymphoma, BCL-2 protein expression and t(14;18) translocation are infrequent.[304,310] MALT lymphomas are indolent, respond well to local therapy, and have excellent prognosis.[304,311] Infection with *B. burgdorferi* has been implicated in the pathogensis of CBCL[136,312] although a study of 38 cases conducted in United States did not demonstrate such an association,[137] and another study showed no geographic correlation between the incidence of Lyme disease with CBCL.[138] RT is a preferred treatment modality with high local control rates (85% to 100%) and favorable survival.[313,314] Cutaneous lymphomas can be adequately treated with superficial RT techniques, including orthovoltage, electrons, and brachytherapy (Figure 77-9). Following local therapy, the relapse rate is high, frequently with skin lesions in an untreated area, but death from indolent CBCL is uncommon.[304]

Mycosis fungoides is the most common type of cutaneous T-cell lymphoma (CTCL) of indolent clinical behavior and is discussed elsewhere (Chapter 79). The other indolent CTCL is primary c-ALCL, characterized by CD30 positivity but is distinct from the nodal type of ALCL.[57,304] In contrast to nodal ALCL, the vast majority of c-ALCL does not stain for the ALK protein and is also negative for the t(2;5) translocation.[304] In patients with a solitary nodule or localized skin disease, RT is the treatment of choice. These lymphomas can relapse in the skin, but generally have a favorable prognosis,[56] with 5-year survival of 95%.[304] In a Dutch study of 79 patients, only 16% of patients have a systemic relapse of lymphoma 10 years after initial treatment.[56] Lymphomatoid papulosis is a related condition, also CD30+, and has an indolent course with spontaneously remitting disease.[56] Cytotoxic treatment is usually not necessary and life expectancy is not adversely affected, although infrequently the disease can progress to other types of T-cell lymphomas.

Other aggressive types of CTCL represent an extremely heterogeneous group and most are characterized as peripheral T-cell lymphomas—unspecified further in the WHO classification.[57] Some have morphologic and phenotypic characteristics of NK/T-cell lymphoma of nasal type,[315] and other rare entities include the aggressive CD8+ T-cell lymphoma, and gamma-delta T-cell lymphoma. Most are negative for CD30 and have a poor prognosis, with an estimated 5-year survival of 15% to 20%.[304,305]

Radiation Therapy for Palliation

In the context of recurrent lymphomas, patients are encountered where no curative therapy is available. RT is an extremely effective modality in providing symptom relief and local control. Palliative RT has been underused in lymphoma because of a variety of other systemic treatment options. The following are situations where palliative RT should be considered: (1) stages III and IV indolent histology lymphoma, with localized bulky disease; (2) relapsed or primary refractory NHL, any stage, with predominant localized disease, not eligible for intensive therapy because of old age, poor tolerance to chemotherapy or chemotherapy-resistance; (3) relapse of lymphoma postautologous and allogeneic bone marrow transplant; (4) localized lymphoma in patients with comorbidity and poor performance status not suitable for chemotherapy. When palliative RT is considered, it is important to establish the goal of therapy. Distinction should be made between attempts to achieve a prolonged local control of disease, that is, radical RT given for local control in a noncurative situation, or RT given purely for the relief of symptoms. This decision is usually based on the clinical condition of the patient, the location, size, and distribution of disease, and the life expectancy of the patient.

Radical RT for local control is not infrequently required for selected patients with chemotherapy-refractory aggressive histology lymphomas where the disease is predominately localized. In these situations, if normal tissue tolerance allows, it is desirable to deliver full dose RT with 30 Gy to 40 Gy in 10 fractions to 20 fractions over 2 weeks to 4 weeks. For rapidly progressive disease, accelerated fractionation should be considered, to 35 Gy to 40 Gy in 20 fractions to 30 fractions over 2 weeks to 3 weeks, depending on volume and normal tissue tolerance. Accelerated hyperfractionation was reported to be more effective than conventional fractionation in Burkitt's lymphomas,[316] but there are few reports of the use of altered fractionation regimens.[316,317] Concomitant chemotherapy and RT to 40 Gy for chemo-refractory bulky lymphoma was administered in a Phase II study of 21 patients and yielded a response rate of 70%, majority were partial responses.[318] When RT is given for relief of disease-related symptoms, a short course of higher dose-per-fraction therapy can be used as dictated by individual circumstance. Acceptable regimens include 20 Gy in 5 fractions over 1 week, 25 Gy to 30 Gy in 10 fractions

to 12 fractions over 2 weeks, or 12 Gy to 16 Gy in 2 fractions over 1 week.

For indolent lymphomas, excellent palliative responses to low doses of radiation, such as 4 Gy given in two fractions have been observed.[107,108,110,319] This was explained by the predominant mode of tumor cell death largely mediated by apoptosis.[320] Response rates of 90% have been obtained in selected patients with this approach.[107,108,110,319] These results are similar with the historical response rates of 71% to 83% for total body irradiation (TBI) doses of 150 cGy to 220 cGy (10 cGy to 15 cGy per fraction, two to three fractions per week) given over several weeks.[117,119]

Technical Aspects of Radiation Therapy

Because of the wide distribution of lymphoid tissues in the body, the technical aspects for RT planning for lymphomas are highly dependent on the location and extent of the target volume. Guidelines for modern RT on target definition and dose for nodal NHL were recently published by the ILROG. The concept of involved-site RT assumes that systemic therapy eradicates regional microscopic disease, and involved-site RT targets the identifiable prechemotherapy disease extent. Unlike involved-node RT where optimal, high-quality prechemotherapy imaging performed in the RT treatment planning position, ISRT accommodates cases in which optimal prechemotherapy imaging are unavailable. In such cases, the CTV determination relies on clinical judgment in conjunction with the best available imaging, accommodating for the uncertainties in defining the prechemotherapy GTV. In the setting of RT alone, for example for localized FL or marginal zone lymphoma treated with curative intent, the CTV should incorporate GTV and include as a minimum adjacent lymph nodes to encompass suspected subclinical disease.

In general, proper planning involves the appropriate use of immobilization devices, CT assistance and use of prechemotherapy PET-CT for target localization, localization of adjacent normal tissues, custom-designed beam modifying devices, and computerized calculation of isodose distributions. The goals of these steps are to define a GTV and CTV, which is expanded to create the internal target volume (ITV) and PTV. The PTV is then used to define dose coverage to achieve dose uniformity to within ±5% of the prescribed dose as specified by ICRU #83,[321] based on defining while minimizing RT dose to normal tissues. IMRT has gained increasing importance to reduce any morbidity because of the exposure of organs at risk located adjacent to the target volume, particularly in instances of repeat course of RT for relapsed disease.[322] The support of allied healthcare disciplines including dental, nutritional, physiotherapy, and social and psychology services is essential to good patient care.

In the CMT setting where chemotherapy is given before RT, there may be no abnormality or minimal residual disease at the time of RT planning. The CTV should encompass the pretreatment disease, but exclude normal structures such as lungs, kidneys, and muscles that were clearly uninvolved, though previously displaced by the GTV. An example is a bulky mediastinal mass that did not infiltrate lung tissue and has reduced in size following chemotherapy, where the RT plan need only cover the postchemotherapy abnormality. If, however, the disease was infiltrative initially into adjacent normal tissue, regression of the tumor mass still leaves microscopic residual disease in the infiltrated tissue and consideration must be given to adequately cover initial disease extent. An example would be bone lymphoma where the RT volume following a good response to chemotherapy should include the prechemotherapy extent of disease. Other specific examples of additional extranodal sites are outlined in the next section. The expansion from CTV to ITV is most relevant for targets affected by respiratory movement such as mediastinal or upper abdominal disease, where a 1.5-cm to 2-cm superior-inferior expansion may be needed. The determination of PTV depends on the type of immobilization device, body site, internal organ motion, and patient cooperation and may vary from case to case. However, if ISRT alone is used for definitive initial management (e.g., in localized FL or MALT lymphoma) any adjacent lymph nodes or tissues deemed to be at risk of microscopic involvement should be encompassed into the CTV.[105]

The dose of RT required to achieve local control varies depending on histologic type and tumor bulk. FL and MALT lymphoma are more responsive to RT, and a dose of 24 Gy to 30 Gy delivered in 15 fractions to 20 fractions over 3 weeks to 4 weeks results in local control rates in excess of 95%. For small cutaneous or orbital lesions RT doses of 25 Gy are sufficient to achieve 90% to 95% local control. Large cell lymphomas are less sensitive and require doses in the range of 35 Gy to 45 Gy. For low bulk disease treated with full courses of chemotherapy, excellent local control rates are obtained with 30 Gy,[185] whereas for bulky lymphomas treated with CMT, a dose of 35 Gy may be required.

Orbital Lymphomas

Primary orbital lymphomas are highly curable with RT. Doses of 20 G to 25 Gy results in excellent local control rates of >95%.[32,323,324] For anterior orbital lesions in the conjunctiva (Figure 77-10), a direct anterior beam with orthovoltage (250 kv), telecobalt, or 4-MV to 6-MVphotons can be used. A small lead shield suspended in front of the lens can reduce the lens dose to under 5% to 10%.[325] For unilateral retrobulbar lesions, a two-field technique with an anterior and an oblique wedged-field using 4-MV to 6-MV photons usually produce a satisfactory result. Alternatively, an anterior electron beam can be used if the lesion is superficial and there is a desire to spare the posterior orbital structures (Figure 77-11). Again, shielding for the lens can be placed to spare the lens. Lens dose of 2 Gy to 3 Gy (single fraction) or >12 Gy fractionated (fraction size 1.5 Gy to 2 Gy) may lead to cataract formation.[326] Alternately IMRT can be used.[327] Damage to the bony orbit, retina, optic nerve, and soft tissues should not be seen with doses of <40 Gy.[326] However, some dryness of the eye because of lacrimal gland effects can be observed since the tolerance dose of the lacrimal gland is 40 Gy in 20 fractions.[328]

Figure 77-12 A modified mantle field with encompassing superior mediastinal lymph nodes. Proton plan showing transverse, sagittal, and coronal views as well as dose volume histogram showing low radiation dose to organs at risk.

Thyroid Lymphoma

The RT target volume includes the thyroid bed and any involved nodes. Previously, adjacent nodal groups were targeted, often resulting in treatment of thyroid lymphoma with a modified mantle field. With improved imaging and standard use of PET-CT for staging, treatment of adjacent uninvolved nodes is no longer necessary. For an euthyroid patient, thyroid doses of 35 Gy to 40 Gy for Hodgkin's lymphoma results in a 47% risk of overt or subclinical hypothyroidism at 27 years after treatment.[329] Other abnormalities such as nodular thyroid disease, goiter, and thyroid cancer are also lifetime risks.[330,331]

Waldeyer's Ring and Salivary Gland

Where possible, an IMRT technique should be used for stages I to II Waldeyer's ring lymphomas with specific objectives to spare the parotid glands and the oral cavity. Acute morbidity of irradiation to doses of 30 Gy to 36 Gy includes xerostomia, loss of taste, and mucositis, which are usually mild to moderate in degree. Depending on the age of the patient, a degree of permanent xerostomia can be seen, as manifested in decreased saliva flow rates upon stimulation.[332] The severity of xerostomia is dependent on the total dose and the volume of salivary gland irradiated.[333] Emami et al estimated that the TD 5/5 for salivary gland function is 32 Gy and the TD 50/5 is 46 Gy.[334] Therefore, careful planning with IMRT should minimize this complication. Similarly for the treatment of unilateral salivary gland lymphomas, IMRT can be used to maximally spare the contralateral parotid gland. Maximum radiation doses of 35 Gy to 40 Gy given in 1.8-Gy to 2-Gy fractions are within the tolerance of all the other critical head and neck tissues such as the spinal cord, neurovascular structures, larynx, trachea, esophagus, oral cavity, lips, and soft tissues. However, proper attention in defining (contouring) these organs at risk to receive lesser doses is part of good IMRT treatment planning practice (Figure 77-7).

Radiation to Thoracic Structures

Because of the irregular field arrangement and contour variation, care is required to ensure dose uniformity with the use of attenuators. Customized shielding blocks are mandatory for the protection of lung and cardiac tissues. The TD5/5 for 20 fractions of whole lung radiation was 26.5 Gy (TD50 30.5 Gy) from pediatric series of patients irradiated for Wilm's tumor.[335] Partial lung irradiation with fractionated doses has been studied by Mah et al using radiographic changes as the endpoint.[336] A steep dose-response relationship was found, where the TD5 was 24.7 Gy, increasing to 33.9 Gy for TD50, and to 43.5 Gy for TD95%, normalized to 15 fractions. Many chemotherapy drugs potentiate the effects of RT on lung tissue (e.g., bleomycin, cyclophosphamide, and doxorubicin).[337] Symptomatic pneumonitis occurs in 5% to 10% of patients treated for lymphoma.[335] Use of optimal dose-fractionation parameters, careful treatment planning with evaluation of dose-volume histogram and mean doses to the lungs,[338-341] and allowing a 3-week and 4-week interval between chemotherapy and RT should minimize the incidence of symptomatic radiation pneumonitis. IMRT offers improved sparing of organs at risk in selected patients and is particularly important for retreatment of relapsed disease.[322] IMRT in combination with deep-inspiration breath-hold (DIBH) reduces radiation exposure of the coronary arteries, heart, and lungs in patients with mediastinal lymphoma.[342] A Phase II study showed that DIBH reduced the mean estimated lung dose by 2.0 Gy (median: 8.5 Gy versus 7.2 Gy) ($p < 0.01$) and the mean heart dose by 1.4 Gy.[343] Proton therapy is another treatment modality that allows for improved sparing of thoracic structures for patients with mediastinal lymphomas[344] (Figure 77-12).

Information on the cardiac tolerance to irradiation has been largely based on patients treated for Hodgkin's lymphoma. The TD 5/5 for 50% to 60% inclusion of the heart is 40 Gy in 16 fractions.[345] The commonest syndrome is delayed pericarditis with pancarditis occurring after much higher doses.[345,346] Late effects include coronary artery disease, cardiomyopathy, and myocardial infarction.[347-349] The dose per fraction should be kept under 2 Gy to minimize the risk of pericarditis.[350] The potential cardiotoxic effects of doxorubicin can also be additive to the long-term damaging effects of radiation on the heart.

Gastric Lymphoma and Issues Relating to Abdominal Irradiation

In planning radiation directed to intraabdominal structures, the radiation tolerance of the liver (TD 5/5: 25 Gy, whole

organ), bowel (small bowel, 20 cm × 20 cm fields, TD: 5/5 45 Gy), spinal cord (TD 5/5: 50 Gy), and kidneys (TD 5/5: 20 Gy) must be respected.[351-353] CT planning is extremely helpful and the principle and techniques similar to that used for gastric carcinoma can be adapted for use, with conformal fields or IMRT.[354] The intention here is to deliver a tumor dose of 30 Gy to 35 Gy to the entire stomach and limit the total dose to both kidneys to <20 Gy, while keeping a significant volume of liver to low doses. With fractionated doses of 30 Gy to 35 Gy, major serious complications to the bowel are uncommon.

Pelvic Radiation and Effects on the Reproductive System

In pelvic RT, the treatment planning must address effects of direct as well as scatter radiation to the genital organs. For example, direct doses of 20 Gy to 24 Gy to the ovaries will invariably produce ovarian ablation with loss of hormonal function resulting in menopause and sterility.[355] Therefore, treatment planning for pelvic lymph node RT should spare one ovary if possible, with ultrasound or CT guidance to locate the ovary. When bilateral pelvic irradiation is inevitable, the use of surgical oophoropexy with transposition of one ovary to the lateral abdomen and marking it with surgical clips to ensure exclusion from the radiation fields should be considered. However, this procedure alone can produce infertility because of interference with the vascular supply of the transposed ovary. Options of ovarian tissue cryopreservations should be discussed.

In males, direct radiation to the testes generally occurs in the CMT of primary testes lymphoma, or for testicular relapse of lymphoma where chemotherapy does not have full effect for this sanctuary site. Treatment planning is clinical and simulation of the field is not required. A direct anterior field with 4-MV to 6-MV photons with a visual check to encompass all scrotal contents is usually adequate. Because the germinal epithelium of the testes is extremely radiosensitive, where doses as low as 15 cGy can produce transient oligospermia,[356] and doses of 4 Gy to 6 Gy can result in permanent azoospermia, infertility is always a consequence of scrotal irradiation. Sperm banking should be considered before commencing therapy, preferably before chemotherapy. However, Leydig cell function with testosterone production can be preserved after doses of 30 Gy 35 Gy,[357] although dysfunction as manifested in a rise in luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels can be seen even for lower doses of 5 Gy to 6 Gy.[357] Based on a review of the literature, Izard concluded that approximately 50% of males receiving 14 Gy in fractionated doses will have an abnormal LH, whereas 33 Gy is required to see an abnormal testosterone level in 50%.[358]

Indirect (i.e., scatter) radiation to the testes is also a special consideration in the planning of fields close to the scrotum, particular if the field size is large. The scatter dose is mainly a function of distance from the field edge, where gonadal doses of <5% are usually achieved with a distance from the field edge of 10 cm or more, for a field size of 25 cm^2.[357] The scatter dose can be reduced further by shielding with a leaded box directly applied to the scrotum.[359]

Changing Practice in the RT Management of Malignant Lymphomas

The efficacy of RT in achieving local disease control has been accepted for many years. With excellent local control rates, attention has been focused on the optimization of chemotherapy. Rituximab improved the outcome of systemic therapy. Over the last decade, there has been significant change in clinical practice in applying RT for lymphomas. We witnessed continued reluctance to use RT for stages I and II indolent lymphomas, and a decreased utilization of RT in stages I and II aggressive lymphomas, favoring chemotherapy alone. In contrast, there is often desire to enhance local control and palliation in advanced stage disease, with RT given in conjunction with high dose programs incorporating stem-cell transplantation. There is always a desire to better define areas of "high risk" and FDG-PET has been used frequently to define active disease, and direct RT volume disposition. In indolent lymphomas, we now know that low-dose radiation results in excellent short-term palliation, with response rates for the irradiated disease often exceeding what can be achieved with systemic chemotherapy. In the midst of these changes in the pattern of practice, the question of optimal RT target volume in the majority of lymphomas has not been prospectively tested in randomized trials. Some of the challenges and controversies in the RT management of the NHL are:

1. The management of FLs:
   Despite the known efficacy of RT for localized FL utilization of RT remained low according to population-based data. The use of CMT and the role of addition of rituximab to RT in patients with localized disease require additional investigations.
2. Role of RT in DLBCL:
   Final results of the UNFOLDER Phase III trial may clarify the role of adjuvant RT in selected cases of DLBCL after R-CHOP chemotherapy. Whether RT offers additional benefit when a chemotherapy regimen more intensive than R-CHOP is used (e.g., the GELA protocol with ACVBP, followed by high-dose methotrexate with leucovorin, etoposide, ifosfomide, and cytarabine), is still not known.
3. Optimal RT dose and volume:
   Although randomized data exist suggesting 30 Gy may be adequate for patients with aggressive NHL after chemotherapy, the data did not take into account the response to modern chemotherapy. Limited data are available on optimal RT dose in the setting of partial response to chemotherapy and whether there is a role for radiation dose-deescalation after a metabolic complete response to R-CHOP chemotherapy. This question is currently being addressed in a Phase II study. Consensus-based guidelines are now available for volume definition for NHL, but additional data are needed to document the efficacy of these more limited fields for NHL.
4. Optimal RT in the setting of high-dose chemotherapy and stem cell support
   This relates to the indications, selection of patients for therapy, the use of FDG-PET to identify high-risk areas for RT, dose-fractionation parameters, and the timing with chemotherapy and ASCT.

Conclusion

NHL represents a heterogeneous group of diseases that may affect any part of the body. They are characterized by a tendency to present or progress to generalized disease. Therefore optimal systemic therapy is paramount. However lymphomas are also characterized by a high degree of radioresponsiveness and therefore RT is an important modality in controlling these malignancies. Recent progress in biology and histopathology, as well as cytogenetic techniques, has allowed us to study homogeneous patient populations and give opportunity for reassessing the role of RT in their management. Late effects of treatment manifesting as normal tissue toxicity and especially second cancers are continuing concerns following curative therapy. Attention to late morbidity while we devise treatments to improve the cure rate remains an important goal.

CHAPTER

78 Multiple Myeloma and Other Plasma Cell Neoplasms

Anuj Mahindra and Andrea K. Ng

INCIDENCE AND EPIDEMIOLOGY

More than 24,000 new cases of multiple myeloma (MM) are diagnosed annually in the United States. MM accounts for 1.4% of all new cancers and 1.9% of cancer-related deaths. The rate in blacks is twice that in whites. Agricultural workers, woodworkers, and paper workers have a higher risk than other occupational groups.

ETIOLOGY AND BIOLOGIC CHARACTERISTICS

The etiology remains unknown. This hematologic malignant disease with mature plasma cell morphologic characteristics evolves from a cell late in B-cell development.

STAGING EVALUATION AND PROGNOSTIC FACTORS

The diagnosis of myeloma requires the presence of end-organ damage: anemia, elevated creatinine or calcium levels, and lytic bone lesions. Prognostic factors of most importance for MM are an increased β_2-microglobulin level and a decreased serum albumin level.

PRIMARY THERAPY AND RESULTS

Treatment of patients with symptomatic disease is indicated, excluding those with monoclonal gammopathic findings of undetermined significance or smoldering MM. The past decade has witnessed a dramatic improvement in the therapeutic options in MM. Several novel biologically targeted agents are in clinical use and have resulted in improved outcomes, including the proteasome inhibitors and immunomodulatory drugs. High-dose therapy with stem-cell transplantation remains a standard of care. A survival advantage of approximately 1 year has been shown for patients receiving high-dose therapy in two prospective randomized studies.

For solitary plasmacytoma of bone and extramedullary plasmacytoma, radiotherapy is the treatment of choice, with effective local control rates but high rates of progression to MM. Magnetic resonance imaging (MRI) may help to predict which patients are at higher risk of subsequent progression to MM.

TREATMENT OF PRIMARY REFRACTORY AND RELAPSING MYELOMA

Several promising drug therapy combinations are undergoing evaluation for refractory and relapsing myeloma. Localized radiotherapy is useful in palliation of painful or life-threatening disease.

Monoclonal gammopathies, also referred to as *paraproteinemias* or *dysproteinemias*, are a group of diseases characterized by the proliferation of a clone of plasma cells. The plasma cells produce an electrophoretically and immunologically homogeneous protein usually referred to as *monoclonal protein, M protein, M component*, or *paraprotein*. The progressive proliferation of plasma cells results in marrow replacement with a resulting normochromic or slightly macrocytic anemia. Direct infiltration of the overlying bony cortex by the malignant cells causes lytic bone disease, osteoporosis, and compression fractures of the spine. In addition, the production of a monoclonal light chain in the urine can result in a severe toxic response in renal tubules, with renal failure. Differentiation of monoclonal gammopathy of undetermined significance (MGUS) from MM and solitary plasmacytoma (SPB) is important to the selection of appropriate therapy and is discussed later in this chapter.

EPIDEMIOLOGY AND ETIOLOGY

An estimated 24,050 new cases of MM will occur in the United States in 2014, representing 1.4% of all new cases of cancer. MM accounts for 10% to 15% of all hematologic malignant diseases diagnosed in the United States, 20% of all deaths resulting from hematologic malignant diseases, and 1.4% of all cancer deaths. MM is an uncommon malignant disease in Pacific Rim countries.

The male-to-female ratio for the disease is 1.3:1. MM is a disease of older adults. The median age at diagnosis is 66 years; only 10% and 2% of patients are younger than 50 years and 40 years, respectively. The risk of developing MM is approximately 3.7-fold higher for persons with a first-degree relative with MM.

The average age of patients presenting with MM is approximately 63 years. In Olmsted County, Minnesota, the overall incidence of MM is 4.3 cases per 100,000 population per year.

Radiation has been linked to the pathogenesis of MM, but radiation exposure is found in only approximately 1% of patients. In the Hiroshima and Nagasaki tumor registries, there was no sign of an excess risk of MM.[1]

Data regarding the role of antigenic stimulation are conflicting. Epidemiologic studies in the United States have demonstrated associations between MM and agricultural workers.[2] An increasing trend for the incidence of lymphohematopoietic cancers has been associated with lifetime exposure to the chemical alachlor, a commonly used pesticide. The risk for MM gave a rate ratio of 5.66 in the highest exposure category.[3] Other occupational groups associated with the development of MM include miners, workers exposed to wood dust, and sheet metal workers.[4]

The etiology of MM remains unknown. Cytogenetic studies in MM demonstrate no consistent chromosome break point that identifies the majority of patients. Cytogenetic abnormalities, however, are less frequent in patients with MGUS, and an increase in frequency is seen as this condition evolves into MM untreated and MM relapsed. MM probably originates from a germinal center B cell of the lymph node. Receptors allow these cells to migrate from the lymph node to the bone marrow (BM).

Myeloma plasma cells express several adhesion molecules, including neural cell adhesion molecule (NCAM). Adhesion molecules are involved in homing of plasma cells to BM.

Although MM is a neoplasm of end-stage plasma cells, most investigators believe that myeloma stem cells exist as a self-renewing population derived from an earlier compartment. The identity of the cells responsible for the initiation and maintenance of MM remains unclear. Circulating B cells clonally related to MM plasma cells have been reported in some patients with myeloma. Data suggest that myeloma stem cells are CD138– B cells, whereas the terminally differentiated plasma cell is consistently CD138+, though this concept needs further validation. These CD138– B cells can replicate and differentiate into the malignant CD138+ plasma cells.[5] Overexpression of BCL-2 and BCL-6 proteins has been seen in clinical myeloma and myeloma cell lines.[6] Cytokines, including tumor necrosis factor-alpha (TNF-α), interleukin-1 (IL-1), and IL-6, play an essential role in the biology of the malignancy as well as in mediating the bony manifestations of the disease. Both IL-6 and BCL-2 have been shown to prevent apoptosis, and IL-6 has been implicated as an essential growth factor in MM.[7]

PATHOLOGY AND MOLECULAR GENETICS

The morphology of the plasma cell in MM is relevant prognostically. Immature and plasmablastic plasma cells are associated with a poor prognosis. When 3% of the plasma cells in the BM are indistinguishable from lymphoblasts, this has been defined as *plasmablastic myeloma* and is associated with a higher prevalence of renal insufficiency and bone disease. Other prognostic features seen on evaluation of the BM biopsy specimen include marked dysplasia, number of mitoses per high-power field, and packing of the BM by tumor.

MM is distinct in that the BM is involved in virtually all patients (Figure 78-1), yet the peripheral blood shows large numbers of circulating cells in only a few patients. Adhesion molecules mediate both homotypical and heterotypical adhesion of tumor cells to either extracellular matrix (ECM) proteins or BM stromal cells. They play a critical role in disease progression. After class switching in the lymph node, adhesion molecules (e.g., CD44, VLA-4, VLA-5, LFA-1, CD56, syndecan-1, and MPC-1) mediate homing of MM cells to the BM stromal cells. Syndecan-1 is a multifunctional regulator of tumor cell growth and survival as well as of bone cell differentiation, and elevated serum syndecan-1 correlates with increased tumor cell mass, decreased metalloproteinase-9 activity, and poor prognosis.[8] Syndecan-1 is shed from the surface of most MM cells, induces apoptosis and can inhibit the growth of MM cells; it also mediates decreased osteoclast and increased osteoblast differentiation.[8] Novel agents, including thalidomide, and derivatives (IMiDs), including lenalidomide, as well as the proteasome inhibitor bortezomib can target both the tumor cell and its BM microenvironment, thereby overcoming cell adhesion-mediated (CAM) conventional drug resistance.[9,10] *TP53* mutations are associated with more advanced myelomas and are related to the terminal phases of the disease.[11] Mutations of *RAS* are more prevalent in MM than in other lymphoid malignant diseases. In a study using genomic DNA in 128 patients, *RAS* mutations were far more common in patients with aggressive plasma cell leukemias (30%) than in MM patients (9%). The *RAS* mutations appear to represent a late molecular lesion in the process of myeloma evolution. When levels of *RAS* were studied in 160 patients with newly diagnosed MM, the median survival rate for patients with mutations of N-*RAS* was no different from that of patients with no *RAS* mutations. However, patients with K-*RAS* mutations had significantly higher tumor burdens at diagnosis and a median survival time of 2 years versus 3.7 years for those who did not have K-*RAS* mutations. The *RAS* mutations appear to have an independent impact on the median survival rate of patients with MM.[12]

IgH rearrangements can be found in 75% of patients. Dysregulation of cyclin D_1 can be detected in 30% of MM tumors. Cell lines that overexpress cyclin D_1 have a translocation detectable into a gamma switch region that suggests an error in VDJ recombination. V_H analysis of the clonal cells in MGUS showed much lower mutation frequencies than in MM. The clonogenic cell in MM likely originates from a preswitched but somatically mutated B cell. Genetic studies have demonstrated that the progression of MM from plateau phase to relapse does not involve a new B-cell clone, and progression beyond the plateau phase is not the result of clonal succession.[13] Advances using molecular probes for fluorescence in situ hybridization (FISH) have demonstrated aneuploid chromosomes where conventional cytogenetics are normal. Chromosome 13 abnormalities on metaphase cytogenetics have been associated with an unfavorable prognosis in patients with myeloma. The translocation t(11;14) results in up-regulation of cyclin D_1 and is the most common translocation detected in patients with MM. Sixteen percent of patients carry the t(11;14) and have better survival and response to therapy rates.[14] Immunoglobulin heavy-chain translocations are seen in 60% of patients, and these translocations are more likely to be nonhyperdiploid. Patients with light-chain myeloma never display a functional immunoglobulin heavy-chain recombination. Most patients with light-chain myeloma have one immunoglobulin heavy-chain allele with a germline configuration. The second allele is usually involved in an illegitimate recombination. Light-chain myeloma may be the result of the absence of legitimate immunoglobulin heavy-chain rearrangement at the DNA level.[15]

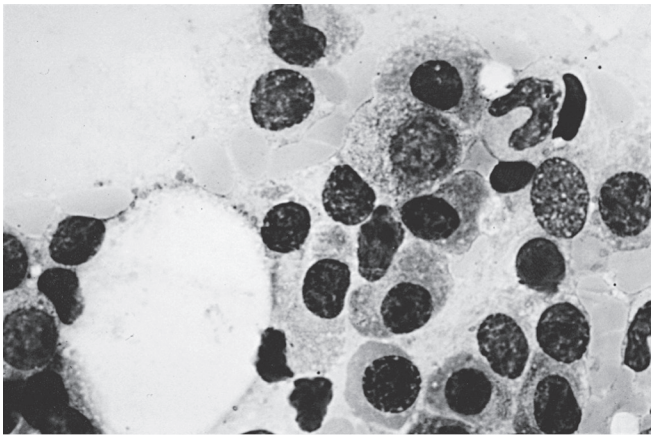

Figure 78-1 Bone marrow diagnostic for multiple myeloma. (Wright stain; original magnification ×1000.)

CLINICAL MANIFESTATIONS AND PATIENT EVALUATION

Multiple Myeloma and Monoclonal Gammopathy of Undetermined Significance

The key to early detection of MM is recognizing the associated clinical syndromes and presentations and permitting appropriate diagnostic tests to be performed. The clinician must order electrophoresis of serum and urine for all patients who present with normochromic normocytic or slightly macrocytic anemia. Electrophoresis of serum and urine can often obviate needless diagnostic investigations for gastrointestinal tract blood loss or other invasive techniques. In a patient who has

Figure 78-2 Advanced compression fractures of multiple myeloma. Note the lack of features specific for malignancy.

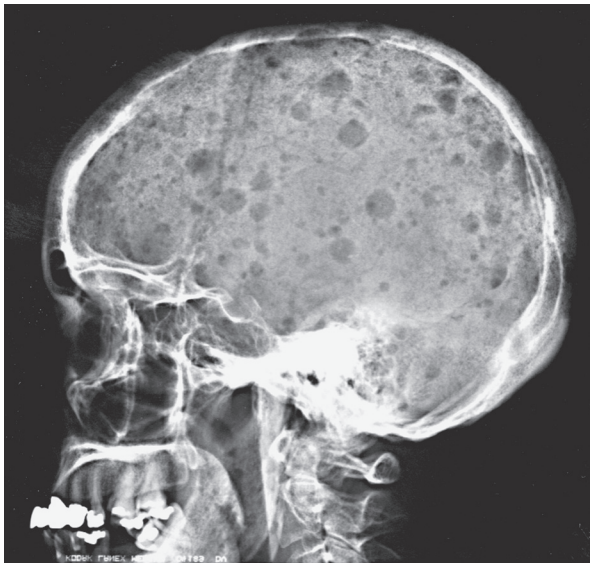

Figure 78-3 Calvarial radiograph from a patient with multiple myeloma.

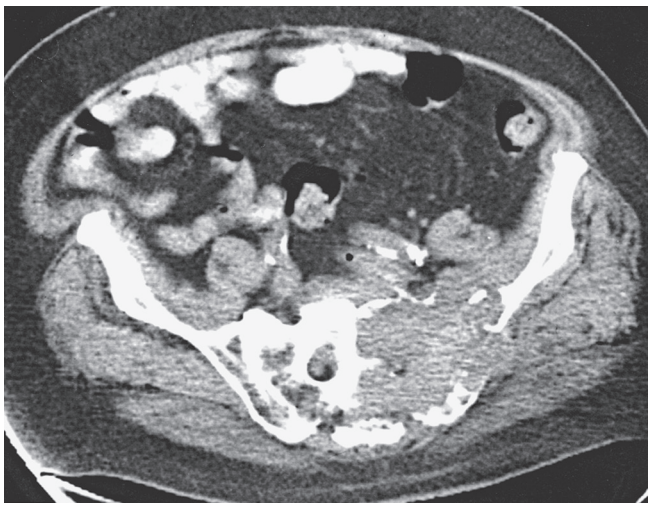

Figure 78-4 Diagnostic computed tomographic scan of pelvic plasmacytoma. Plain radiographs revealed only rarefaction and were not diagnostic.

any degree of unexplained renal insufficiency (i.e., a nonhypertensive, nondiabetic patient), urine immunoelectrophoresis often leads to recognition of myeloma cast nephropathy.

Bone involvement is frequent in patients with myeloma and bone pain is a common problem. Radiographs of the spine in patients with MM frequently show osteoporosis and compression fractures. It is virtually impossible to distinguish the compression fractures associated with MM from those seen in patients with senile osteoporosis (Figure 78-2). Spine radiographs poorly demonstrate the small lytic lesions frequently responsible for collapse of these vertebrae. All patients with back or rib pain, even with no malignant features on radiographs, should have electrophoresis of serum and urine. If a monoclonal protein is found, radiographs of the entire skeleton often demonstrate lytic lesions in the calvaria, pelvis, and long bones of the humerus and femur (Figure 78-3).

Assessment of bone disease initially requires a radiographic bone survey. Because the lesions of MM are primarily lytic, with little evidence of bony repair, radionuclide bone scans tend to be an inferior approach. In difficult cases in which osteoporosis and monoclonal gammopathy are found with no other changes, computed tomography (CT) scan or MRI of the spine and pelvis can be valuable in detecting clear-cut evidence of neoplasia (Figure 78-4). Positron emission tomography (PET) may be useful in MM because the lytic lesions are PET avid. When 66 patients were studied with PET and compared with CT and MRI, negative PET findings reliably predicted stable MGUS.[16] All patients with active myeloma had focal or diffusely positive scans, four of whom had negative full radiographic bone surveys. Extramedullary uptake was detected by PET in 23% of relapsing patients. PET also tracks response, showing a decline in lesion metabolic activity with successful intervention. It is more sensitive than other imaging techniques, and it can find additional lesions in a third of patients, which affected therapeutic decision making for a quarter of these patients.[17]

Failure to perform electrophoresis studies in patients presenting with back pain or osteoporosis can delay a diagnosis of MM. The need for screening electrophoresis cannot be overemphasized. The most common reason for a delayed diagnosis of MM is the simple finding that MM was not included in the differential diagnosis.

A second clinical problem is distinguishing MGUS from overt MM. In MGUS, the patient is expected to be asymptomatic, without evidence of anemia, hypercalcemia, bone involvement on skeletal survey, or renal insufficiency. In the absence of symptoms and with a low monoclonal protein value, regular monitoring of the level of the monoclonal protein should suffice. Patients with monoclonal gammopathies, however, should be monitored indefinitely because the risk for transformation to a malignant plasma-proliferative process is approximately 1% per year. The risk for transformation is predicted by the initial size of the M protein peak. Patients

with low monoclonal protein levels (≤0.5 g/dL) had a 6% risk for developing MM at 10 years compared with an 11% risk at 10 years for those with a 1.5-g/dL peak and a 24% risk at 10 years for those with a 2.5-g/dL peak.[18]

The frequency of monitoring patients with MGUS depends on risk factors identified at initial evaluation. Although there are no findings at diagnosis of MGUS that reliably distinguish patients who will remain stable from those who will progress to MM, the size and type of the M protein at diagnosis are predictive factors for progression of MGUS to myeloma or related malignant disease. MGUS is associated with a low risk of progression when the M protein level is less than 1.5 g/dL. Patients with IgM or IgA monoclonal protein had a significantly increased risk of progression to disease, as compared with patients having an IgG monoclonal protein. Presence of an abnormal (monoclonal) kappa/lambda free light-chain ratio in the serum is also associated with a significantly higher risk of disease progression.

Staging of Multiple Myeloma

Classification of patients with MM by stage is important. Comparison of outcomes in single-arm studies of MM depends on patient selection and case mix. Therefore, ensuring that patients have comparable severity of disease is important when comparing the outcomes of various studies. In addition, stage may be useful in selecting patients with unfavorable outcomes for more intensive therapies. Conversely, patients who are at a low stage and whose prognosis is good may be candidates for less intensive therapies and may achieve outcomes similar to those of aggressively treated patients.

The most widely accepted classification is the International Myeloma Working Group staging system, where stage III myeloma is a β_2-microglobulin level higher than 5.5 μg/mL. Stage I includes patients with a β_2-microglobulin level that is less than 3.5 μg/mL and a serum albumin level that is less than 3.5 g/dL, and stage II includes all patients who do not fit stage I or stage III (Table 78-1).

The older staging system in clinical use is that of Durie and Salmon (Table 78-2). One problem with the Durie-Salmon staging system is that the criteria for stage I MM in this scheme are also consistent with smoldering MM and indolent MM, which do not require any form of therapy. In most clinical therapy studies, no more than 10% of patients have stage I disease, and many studies exclude patients with stage I from participation. The second difficulty is the subjective nature of interpretation of advanced lytic lesions to distinguish stage II from stage III. No specific well-defined criteria exist to ensure that all institutions use the same definition of advanced MM.

Response is generally assessed by the reduction in monoclonal protein; a reduction of 25% to 50% is considered a minor response and 50% to 99% an objective response. Complete eradication of the monoclonal protein in the serum and in the urine with less than 5% plasma cells in the BM is considered a complete response. Patients who either did not have a BM test performed or whose monoclonal protein was no longer visible but detectable by immunofixation are considered to have a near-complete response. In recipients of autologous transplants, a complete response predicts improved outcome after transplantation.[19]

TABLE 78-1 International Myeloma Working Group Staging System

Stage	Criteria
I	β_2-microglobulin <3.5 μg/mL and albumin ≥3.5 g/dL
II	β_2-microglobulin <3. μg/mL and albumin <3.5 g/dL or β_2-microglobulin = 3.5-5.5 μg/mL
III	β_2-microglobulin ≥5.5 μg/mL

THERAPY FOR MULTIPLE MYELOMA

The treatment of MM is reserved for patients who are symptomatic. There are ongoing studies to assess impact of treatment in patients with high risk smoldering myeloma. Generally, outside a clinical trial, observation is currently recommended for patients with smoldering myeloma.

Most patients with MM have symptomatic disease at diagnosis and require systemic therapy. Specific indications for treatment include decreasing concentration of hemoglobin, increasing concentration of calcium and creatinine, lytic bone lesions, and extramedullary plasmacytoma.

Patients undergoing therapy for MM should have clinical and laboratory assessment to ensure both safety and efficacy of treatment (Table 78-3). Before each course of treatment, a complete blood count, including differential and platelets, should be done. Serum chemistries should be measured at

TABLE 78-2 Durie-Salmon Staging System of Multiple Myeloma

Stage	Criteria
I	All of these required: hemoglobin >10 g/dL, Ca^{2+} <10.5 mg/dL, IgG <5 g/dL or IgA <3 g/dL and light-chain loss <4 g/dL No lytic bone lesions
II	Not fitting stage I or III
III	Any one of the following: hemoglobin <8.5 g/dL, Ca^{2+} >12 mg/dL, IgG >7 g/dL, IgA >5 g/dL, or light-chain loss >12 g/dL Advanced lytic lesions
IIIA	Creatinine <2 mg/dL
IIIB	Creatinine ≥2 mg/dL

TABLE 78-3 Required Testing to Evaluate Multiple Myeloma

Category	Test
Blood	Complete blood cell count Creatinine Calcium Sodium, potassium Uric acid Albumin Alkaline phosphatase Aspartate aminotransferase Serum protein electrophoresis with immunofixation Serum free light-chain assay β_2-microglobulin Lactate dehydrogenase C-reactive protein
Urine	Urine protein electrophoresis Urine immunofixation Creatinine clearance
Radiography	Skeletal survey
Miscellaneous	Electrocardiogram Bone marrow aspirate and biopsy

least every 3 months or more often if clinically indicated. Concomitantly, monoclonal protein in the serum should be measured by immunoelectrophoresis or, preferably, using more sensitive immunofixation techniques and a serum free light-chain assay must be done in patients with light-chain disease. A skeletal survey should be done annually, with BM examination reserved for diagnosis and time of subsequent change in clinical status, in monoclonal Ig, or in hemogram. A BM examination is typically done at diagnosis and subsequently at the time of change in clinical status (i.e., for assessment of response or at time of relapse).

Treatment and Emerging Novel Therapies

In patients who are candidates for hematopoietic cell transplantation (HCT), induction chemotherapy is administered for 2 to 4 months before stem-cell collection to reduce the number of tumor cells in the BM and peripheral blood, lessen symptoms, and mitigate end-organ damage.

There has been a shift in the treatment paradigm in MM toward moving away from conventional chemotherapy and incorporating the use of novel agents. Thalidomide was used as a sedative and antiemetic in the 1950s, when it was withdrawn from the market as a result of teratogenicity. Its exact mechanism of action is unknown, but its antiangiogenic properties are thought to inhibit the growth of myeloma. Thalidomide also alters the adhesion of myeloma cells to the BM stroma. Several trials using thalidomide in the management of relapsed MM have shown response rates from 30% to 45%.[20] There is no clear relationship between dose and response. Although doses of up to 800 mg have been used, 50 mg to 200 mg is the typical dose for long-term management. The side effects of thalidomide are significant and, when combined with dexamethasone, deep vein thrombosis occurs in 16% and grade III or IV toxicities in 44% of patients.

Lenalidomide was developed as a thalidomide analog, using the structural backbone of thalidomide but with the elimination of a carbonyl group and the addition of an amine, originally to more effectively inhibit TNF-α. Several other potential mechanisms for the anti-MM effect of lenalidomide have been identified. Lenalidomide was noted to have a better side effect profile, with decreased peripheral neuropathy, somnolence, and gastrointestinal toxicity compared with thalidomide, but with greater myelosuppression. The favorable side effect profile and efficacy of lenalidomide was confirmed in two large, randomized, multicenter, double-blind, placebo-controlled studies in patients with relapsed or refractory myeloma—the MM-009 North American trial and the MM-010 European/Israeli/Australian trial.[21,22] In both studies, patients were randomized to receive 25 mg of oral lenalidomide or placebo on days 1 to 21 of a 28-day cycle. All patients received dexamethasone on days 1 to 4, 9 to 12, and 17 to 20 for the first four cycles and subsequently, after the fourth cycle, only on days 1 to 4. The median time to progression was significantly longer in the lenalidomide/dexamethasone combination (MM-009: 11.1 months; MM-010: 11.3 months) compared with placebo/dexamethasone (4.7 months in both trials). Similar superiority was seen for the lenalidomide/dexamethasone combination in terms of overall response (OR) rate (MM-009: 61%; MM-010: 60.2%) compared with placebo/dexamethasone (MM-009: 19.9%; MM-010: 24%).

In a Phase III trial conducted by the Eastern Cooperative Oncology Group (ECOG E4A03), 445 previously untreated patients with MM were randomly assigned to lenalidomide plus "standard" high-dose dexamethasone (40 mg/day by mouth on days 1 to 4, 9 to 12, and 17 to 20 of each cycle) versus lenalidomide plus lower-dose dexamethasone (40 mg by mouth on days 1, 8, 15, and 22 of each 28-day cycle).[23] The trial was stopped prematurely by the data safety monitoring committee because mortality was increased in the high-dose dexamethasone arm.

Pomalidomide, a new immunomodulatory agent, has demonstrated significant anti-MM activity in patients who have disease refractory to thalidomide, lenalidomide, or bortezomib. Pomalidomide in combination with dexamethasone has demonstrated response ~35% in patients with prior treatment with lenalidomide, thalidomide, and bortezomib.[24,25]

Prophylaxis against clotting with aspirin, Coumadin, or subcutaneous heparin is needed when patients are treated with lenalidomide or pomalidomide therapy.

Bortezomib represents a novel class of anticancer compounds, the proteasome inhibitors. These drugs induce cell death by blocking degradation of apoptotic molecules that are normally catabolized via proteasome proteolysis. They inhibit nuclear factor kappa B (NFκB) activation by stopping the cleavage of its bound suppressor. Increased NFκB activity has been described in myeloma cells, and proteasome inhibitors seem to overcome chemotherapy resistance. A Phase III study of bortezomib with dexamethasone suggested that the time to progression was prolonged in the bortezomib group. Bortezomib produces a response in approximately one third of patients with relapsed MM; its primary toxic effects are thrombocytopenia and peripheral neuropathy.[26]

The bench to bedside translation of bortezomib and approval by the U.S. Food and Drug Administration (FDA) were also rapid. NFκB was identified as a target in MM because it conferred drug resistance, modulated adhesion molecule expression on MM cells and BM stromal cells, and modulated constitutive and MM binding-induced transcription and secretion of cytokines. Phase I trials showed tolerability and early evidence of anti-MM activity. The Phase II SUMMIT trial demonstrated responses in relapsed refractory MM, including complete responses, prolongation of time to progression and survival, and associated clinical benefit.[27] The Assessment of Proteosome Inhibition for Extending Remissions (APEX) trial, which compared dexamethasone versus bortezomib therapy of relapsed MM, was unblinded because of a statistically significant prolongation in time to progression in the bortezomib-treated cohort, forming the basis for its FDA approval extending to relapsed MM.[26] With follow-up, time to progression and overall survival rates are significantly improved with bortezomib and neurologic complications manageable.

Carfilzomib is a novel irreversible proteasome inhibitor of the epoxyketone class that is selective for the chymo-trypsin-like protease, with less affinity for other proteasome proteases. In the open-label, single-arm Phase II PX-171-003-A1 study, patients received carfilzomib 20 mg/m^2 intravenously twice weekly for 3 out of 4 weeks in cycle 1, then 27 mg/m^2 for up to 12 cycles with low-dose dexamethasone as premedication. Patients had a median of five prior lines of therapy and 80% were refractory to or intolerant of both bortezomib and lenalidomide. The overall response rate was 23% with median duration of response of 7.8 months and a median overall survival of 15.6 months. Common adverse events included fatigue (49%), anemia (46%), nausea (45%), and thrombocytopenia (39%). Twelve percent of patients experienced peripheral neuropathy, primarily grades 1 to 2.[28]

In the PX-171-004 study, carfilzomib with low-dose dexamethasone premedication was given to patients with MM who were bortezomib-naïve. Patients in cohort 1 received IV carfilzomib 20 mg/m^2 for all treatment cycles, whereas those in cohort 2 received 20 mg/m^2 in cycle 1 and 27 mg/m^2 in subsequent cycles. The clinical benefit (minimal response or better) was 59% and 64% in cohorts 1 and 2, respectively. Median duration of response was 13 months and not reached in the respective cohorts, and median time to progression was

8 months and not reached, respectively. The most common treatment-related adverse events were fatigue (62%) and nausea (48%). There was a relatively low incidence of peripheral neuropathy at 17% and other nonhematologic toxicity proved manageable.[29]

The combination of bortezomib, lenalidomide, and dexamethasone has been studied in the relapsed/refractory and upfront setting. In the upfront setting, 66 patients received eight 3-week cycles of bortezomib 1 mg/m^2 to 1.3 mg/m^2 (days 1, 4, 8, and 11), lenalidomide 15 mg to 25 mg (days 1 to 14), and dexamethasone 40 mg or 20 mg (days 1, 2, 4, 5, 8, 9, 11, and 12). Responding patients proceeded to maintenance or transplant. Phase II dosing was determined to be bortezomib 1.3 mg/m^2, lenalidomide 25 mg, and dexamethasone 20 mg. The rate of partial response or better was 100% in both the Phase II population and overall, with 74% and 67% achieving a very good partial response or better. Adverse cytogenetics had no effect on the rate of response or progression-free survival (PFS).[30] The combination of lenalidomide, carfilzomib, and dexamethasone has demonstrated similar impressive results.[31]

The combination of pomalidomide, carfilzomib, and dexamethasone has been shown to have encouraging results even in patients with high-risk features in a preliminary study in patients with relapsed/refractory myeloma.[32]

Monoclonal antibodies [MoAbs] are as an important modality in the treatment of myeloma. Examples include anti-CS1 MoAb elotuzumab, anti-CD 38 MoAbs (daratumumab, SAR 650984) and anti-CD 138 antibody conjugate BT062 comprised of the anti-CD138 chimerized MAb and the cytotoxic agent DM4,[33-35] which are being evaluated in clinical trials presently.

Stem-Cell Transplantation

The use of alkylating agents (melphalan, cyclophosphamide, busulfan) in a higher-than-conventional dose followed by infusion of autologous stem cells as part of management is considered the standard of care. In one prospective randomized study, the probability of event-free survival for 5 years was 28% in the transplant group and 10% in the conventional-dose group.[36] The estimated rate of survival for 5 years was 52% in the high-dose group and 12% in the conventional-dose group (p = 0.03). The U. K. Medical Research Council, in a prospective randomized study, demonstrated a higher rate of complete response, 44%, versus 8% with conventional therapy, and an improved overall survival time of 54.1 months versus 42.3 months.[37] Patients with sensitive disease and who are less heavily pretreated have the most favorable outcomes.

In 162 patients who had allogeneic BMT for MM, the European Group for Blood and Marrow Transplantation (EBMT) reported a 32% survival rate at 4 years and a 28% rate at 7 years.[38] In the 72 patients (44%) who achieved complete remission after BMT, the overall PFS rate was 34% at 6 years. Only 9 patients, however, remained in complete remission more than 4 years after allogeneic BMT. With allogeneic BMT, some of the decreased survival time can be attributed to peritransplantation mortality, approaching 40% in some series, because of graft-versus-host disease and other complications of the procedure itself.

Because of these difficulties with allogeneic BMT, autologous peripheral blood stem-cell transplantation has become the more common procedure in the treatment of untreated, refractory, or recurrent MM. Applicability to older patients (upper age limit of 75 years in many centers) without the need for a matched donor and with less risk for transplant-related mortality (<3% in larger centers) has made this procedure accessible to more patients with MM. The disadvantages of autologous BMT in this BM malignant disease include the difficulty of removing tumor cells from the transplanted peripheral blood or marrow and the lack of a potential graft-versus-myeloma effect.

In a prospective randomized study, sequential tandem autologous transplantation demonstrated superior survival rates compared with single stem-cell transplantation. Drawbacks of this study included conditioning that does not conform to current standards and the fact that the single-transplant group achieved a median survival time of only 48 months, which is shorter than survival times in many other reported studies.[39] The second transplantation is normally completed within 6 months of the first.

The benefit of high-dose chemotherapy and autologous stem-cell transplantation in the era of novel agents is the focus of ongoing studies.

The principal characteristics that determine eligibility for HCT are performance status or the presence and severity of certain comorbid conditions. Among patients with symptomatic standard-risk MM who are not candidates for autologous HCT, we recommend a regimen consisting of lenalidomide plus low-dose dexamethasone, Velcade (bortezomib), melphalan, and prednisone (VMP) or bortezomib plus low-dose dexamethasone. In a prospective Phase III randomized trial comparing VMP with melphalan and prednisone (MP) in the treatment of 682 older adults (median age 71 years) with newly diagnosed MM at a median follow-up of 16.3 months, patients treated with VMP had a significantly longer median time to progression (24 months versus 17 months), and higher rates of overall survival (87% versus 78%) when compared with those treated with MP.[40] Combined with prior data, these results led to the approval of VMP by the FDA for the initial treatment of MM.

In a Phase III trial comparing the efficacy and safety of Revlimid and dexamethasone to that of melphalan plus prednisone and thalidomide in patients with newly diagnosed MM who were 65 years and older (median age of 73 years) or not eligible for stem-cell transplantation, patients were divided into one of three treatment groups, receiving either Revlimid plus dexamethasone (Rd) until disease progression, Rd for 72 weeks, or melphalan plus prednisone and thalidomide (MPT) for 72 weeks. The results showed that more patients responded to continuous treatment with Revlimid (75%) than 72 weeks of RD (73%) or MPT (62%). The median PFS was significantly longer for those who received continuous Rd (26 months) than for those who received Rd for 72 weeks (21 months) and those who received MPT (21 months). The differences in PFS became apparent at the 72-week mark when two of the groups discontinued treatment. The 4-year overall survival was longest for those who received continuous Rd (59%), compared to those who received Rd for 72 weeks (56%) and those who received MPT (51%). The difference was significant for continuous Rd compared to MPT.[41]

Maintenance Therapy

Novel therapies are now being evaluated to prolong PFS rates. For example, the 3-year median and overall PFS times were prolonged by the use of thalidomide following transplantation. Thalidomide with or without prednisone has been evaluated as maintenance. Because lenalidomide is an oral drug with fewer side effects, it has undergone evaluation as maintenance treatment. In a Phase III study to determine the efficacy and safety of lenalidomide in combination with melphalan and prednisone (MPR) in elderly patients with newly diagnosed MM, the PFS rate was significantly improved in patients who received MPR followed by lenalidomide maintenance

compared with those who received MP followed by placebo maintenance.[42] In a Phase III intergroup study of lenalidomide versus placebo maintenance therapy following single autologous stem-cell transplant (CALGB 100104) maintenance therapy with lenalidomide, when compared to placebo, prolonged time to disease progression. The median time to progression was 46 months in the lenalidomide group and 27 months in the placebo group ($p < 0.001$).[43]

Supportive Treatment

Newer supportive modalities are useful in the management of patients with MM. Although chemotherapy can destroy the malignant clone and may prevent progression of bony disease, it does not lead to remineralization or recalcification of previously involved bone. Monthly infusions of pamidronate or zoledronic acid for 9 consecutive months reduced the proportion of patients who had any skeletal events from 41% to 24%.[44] Patients who received pamidronate had significant decreases in bone pain and an improved quality of life. Pamidronate or zoledronic acid has a significant palliative effect in patients with bone pain secondary to metastasis. Bisphosphonates act by inhibiting bone resorption. They have a major effect on osteoclasts and reduce bone-resorbing cytokine production. Zoledronic acid is 100 times more potent than the bisphosphonate most commonly administered orally, alendronate. These agents reduce the frequency of skeletal-related events, including the need for irradiation for bone pain, pathologic fracture, and spinal cord compression. The toxic effects of bisphosphonates include an increase in the serum creatinine level, proteinuria, and osteonecrosis of the jaw. Vertebroplasty is high-pressure injection of low-viscosity material into the vertebral body, designed to stabilize painful vertebral compression fractures. It can be done on an outpatient basis by an interventional radiologist. Its risks include leak of the material and encroachment on a nerve root.

Solitary Plasmacytoma

Solitary plasmacytoma, which accounts for 5% to 10% of all plasma cell dyscrasias, is characterized by the presence of a plasmacytoma in the absence of multiple osteolytic lesions or other features of MM.[45] Approximately two thirds of the cases are solitary plasmacytomas of the bone, which most commonly involve the axial skeleton, while the remaining one third are extramedullary plasmacytomas, most frequently presenting in the upper aerodigestive tract. Progression to MM is more likely to occur in plasmacytoma of the bone than in extramedullary plasmacytoma.[46] The 5-year and 10-year rates of progression to MM in patients with solitary plasmacytoma of the bone are 30% to 50% and 70% to 90%, respectively, whereas around 10% to 35% of patients with extramedullary plasmacytoma eventually progress to MM.[47,48]

Definitive radiation therapy is considered standard therapy for patients with solitary plasmacytoma. Retrospective series using doses ranging from 35 Gy to 60 Gy showed a more than 80% local control rate. In the largest series to date reported by the European Multicenter Rare Cancer Network, which included 258 patients with solitary plasmacytoma (206 with solitary plasmacytoma of the bone and 52 with extramedullary plasmacytoma), the median dose of radiation therapy was 40 Gy (range, 20 Gy to 66 Gy).[49] At a median follow-up time of 56 months, 14% of patients developed a local recurrence (median, 20 months). The 10-year probability of progression to MM was 72% for solitary plasmacytoma of the bone and 36% for extramedullary plasmacytoma.

Several studies have evaluated optimal radiation doses for solitary plasmacytoma,[47,49-55] although most have failed to show a significant dose-response relationship. In the study by the European Multicenter Rare Cancer Network,[49] after adjusting the radiation dose to a biologically equivalent dose (BED) of 2 Gy per fraction, no dose-response relationship was observed for doses of more than 30 Gy. Of the 244 patients treated with radiation therapy, 2 (6%) of 32 patients treated with 30 Gy or less developed local failure compared with 27 (13%) of 212 patients treated with more than 30 Gy. When limiting the analysis to tumors of 4 cm or larger, there continues to be a lack of a significant dose-response relationship beyond 30 Gy. Other smaller series also failed to show significant differences in local control rates with doses of less than 30 Gy versus higher doses.[47,51,54] A meaningful evaluation of optimal radiation dose may be limited by the retrospective nature and the small patient numbers in the available studies. Suh et al reported on radiation treatment outcome of 38 patients with solitary plasmacytoma and found that radiotherapy doses of >40 Gy was associated with a significantly higher local control rate (10-year local control of 100% versus 60%, $p = 0.04$).[56] One study from France on 17 patients with extramedullary plasmacytoma of the head and neck region,[52] showed that a dose of >45 Gy to the target volume is associated with an improved local control rate (5-year local control of 100% versus 50%, $p = 0.034$). In a study from Turkey that included 80 patients with solitary plasmacytoma,[50] on multivariable analysis, doses of 50 Gy or less were associated with a significantly lower PFS rate (hazard ratio [HR], 2.3; $p = 0.04$). Although data supporting the use of higher doses are limited, most centers recommend doses of 45 Gy to 50 Gy in 1.8-Gy to 2-Gy daily fractions as definitive treatment for patients with solitary plasmacytoma.

The optimal radiation treatment volume has not been specifically addressed for solitary plasmacytoma. However, it is generally acceptable to include the gross disease plus a margin of 2 cm. Patients with extramedullary plasmacytoma, especially of the head and neck region, may benefit from treatment with intensity-modulated radiation therapy (IMRT) techniques to limit doses to normal structures and to preserve the quality of life.[47] For these patients, most series also included clinically uninvolved regional nodes in the treatment volume. In the European Multicenter Rare Cancer Network study, however, which also included 52 patients with extramedullary plasmacytoma,[49] the planning radiation treatment volume was limited to the radiographically visible gross tumor volume plus a margin; no attempt was made to cover regional lymph nodes. At a median follow-up time of 54 months, no regional nodal relapses were observed.

Investigators have explored factors predicting for local recurrence and progression to MM in patients with solitary plasmacytoma. Findings on the impact of tumor size on local control rates have been conflicting. Tsang et al showed that the 8-year local control rate was 100% for tumors of less than 5 cm as compared with 38% for tumors of 5 cm or more in diameter ($p < 0.01$).[54] Dagan et al reported local control rates of 100% and 79%, respectively, for tumors of 5 cm or less versus tumors larger than 5 cm, although the difference did not reach statistical significance ($p = 0.09$).[47] Others, however, have failed to show a significant relationship between tumor size and local control rates.[53,55,57,58]

The anatomic location of the tumor can also influence local control rates. Knobel et al demonstrated a trend to higher 10-year local control rates for presentation in vertebral bodies versus other sites (89% versus 78%; $p = 0.07$).[53] The previously described Turkish study showed that surgical resection before radiation therapy is associated with an improved PFS rate. Similarly, a study from Japan on 67 patients with solitary extramedullary plasmacytoma of the head and neck found radiotherapy combined with surgery to be an independent

prognostic factor for overall survival.[58] However, in a study by Ozsahin et al, complete or partial resection prior to radiation therapy had no impact on local control rates.[49] The same study showed that surgery alone for solitary plasmacytoma is clearly inadequate: 7 of 9 patients (78%) treated with surgery without radiation therapy relapsed locally, as compared with 29 of 248 patients (12%) who received radiation therapy. Other factors that have been associated with inferior prognosis include older age at diagnosis[49,50,53] and persistence of myeloma protein for more than 1 year after radiotherapy.[59,60]

Radiation Therapy as Palliation in Multiple Myeloma

Radiation therapy represents an effective form of palliation for patients with MM with symptomatic local involvement.[61,62] The main indications for palliative radiation therapy include bone pain with or without pathologic fractures, neurologic compromise including cord compression, impending cord compression, nerve root compression, or cranial nerve deficits. Patients with impending fractures of weight-bearing bones should first be evaluated by an orthopedic surgeon for consideration of surgical stabilization. Patients with compression fractures of vertebral bodies may also benefit from vertebroplasties or kyphoplasties before radiation therapy.[62-65] For cases of cord compression with associated acute neurologic symptoms, prompt neurosurgical intervention may improve the chance of neurologic recovery, as has been demonstrated in a randomized trial for patients with metastatic cancer and cord compression. Patients with hematologic malignant diseases were not included in this trial, however. An international multiinstitutional study on 172 patients with MM and cord compression found that radiation therapy without surgery resulted in improvement in motor function in 52% of patients.[66] This study showed that a more gradual development of motor deficits (>7 days) was associated with a better functional outcome than rapid development of motor dysfunction (1 day to 7 days). In a recent update from the same group, the overall survival in patients with MM receiving radiotherapy for cord compression was significantly associated with Eastern Cooperative Oncology Group (ECOG)-performance status ($p < 0.001$), preradiotherapy ambulatory status ($p < 0.001$), other osseous lesions ($p < 0.001$), and extraosseous lesions ($p < 0.001$).[66] One small series found that radiation therapy alone can be safe and effective even in the setting of spinal instability on radiographic images.[67] Patients with cord compression in whom radiation therapy is offered as first-line therapy should be placed on steroids before initiation of radiation therapy to reduce the risk of further neurologic compromise from acute radiation-related local inflammation.

Although plasma cell tumors are considered a radiosensitive entity, durable local control with adequate doses of radiation therapy may be important, especially in light of recent advances in MM therapy, resulting in longer life expectancies. In the multicenter study on patients with MM and cord compression described previously, it was found that long-course radiation therapy with higher BED (10 fractions of 3 Gy, 15 fractions of 2.5 Gy, and 20 fractions of 2 Gy) was associated with a significantly higher chance of motor function improvement than short-course radiation therapy (1 fraction of 8 Gy, 5 fractions of 4 Gy).[68] Motor function recovery at 1 year was found to be 76% versus 40% in patients who received long-course treatment versus short-course treatment ($p = 0.003$). In the updated study specifically addressing radiation dose fractionation and local control, there was a higher local control rate with long-course radiation therapy (10×3 Gy, 15×2.5 Gy, or 20×2 Gy) compared with short-course treatment (1×8 Gy or 5×4 Gy), with 2-year local control rates of 91% versus 68%, although the difference did not reach statistical significance ($p = 0.12$).[66] In a study from Germany on 138 patients with MM irradiated to 272 sites,[54] pain reduction was significantly lower in patients who received less than 30 Gy compared with those who received 40 Gy to 49 Gy (65% versus 92%; $p < 0.001$). On multivariable analysis for pain reduction, a daily fraction of 2 Gy was superior to daily doses of 4 Gy to 15 Gy (odds ratio [OR], 11; $p = 0.027$). Alcorn et al reported on 74 patients with MM irradiated to 117 sites to a median dose of 30 Gy, or a BED of 39 Gy.[69] At a median follow-up of 32 months, 26% recurred locally. On multivariable analysis, a BED of less than 39 Gy was significantly associated with increased local recurrence rates (OR, 2.8; $p = 0.03$). At our institution, commonly used radiation dose fractionation schemes for MM palliation include 37.5 Gy in 2.5-Gy fractions or 30 Gy in 10 fractions; although in patients with limited life expectancies, 20 Gy in 5 fractions or 8 Gy in 1 fraction can be considered.

FUTURE DIRECTIONS

Advances in our ability to treat MM and other monoclonal gammopathies depend ultimately on understanding the etiology and pathogenesis of these diseases. In the past decade, there has been an improvement in the understanding of the molecular and cellular biology of the myeloma clone. The cause of these diseases remains elusive, however, as does the identity of the myeloma precursor cell itself.

Advances in the clinical staging of MM, particularly with respect to prognostic factors such as clinical laboratory parameters, are allowing more rational decisions on appropriate therapy. Although progress has been made in the therapeutic management of MM in the past 30 years, particularly with the introduction of chemotherapy and promising results from transplant studies, curative therapy for all plasmacytomas and for MM remains to be defined. Radiotherapy combined with drugs continues to be an important modality in the treatment of MM. Much research remains to be done in finding the right schedules for transplantation, the best sources of hematopoietic stem cells, and optimal preparative regimens for transplantation.

The novel agents thalidomide, lenalidomide, and bortezomib are now first-line options for patients with both newly diagnosed and relapsed MM and provide a paradigm of drug development in MM. It is hoped that ongoing research efforts will provide additional insight regarding the optimal use of novel therapies as well as the role of other emerging new compounds with activity in MM, so as to maximize clinical benefit.

Until better therapies emerge based on an understanding of the biology of MM, clinical research in the next decade will continue to focus on more effective and less toxic drug and radiotherapy regimens. The need to find new therapeutic approaches to treat this disease remains one of the daunting challenges in oncology today.

CHAPTER

79 Mycosis Fungoides

Grace L. Smith, Lynn D. Wilson, and Bouthaina S. Dabaja

INCIDENCE

The age-adjusted incidence of mycosis fungoides (MF) is approximately 6.4 cases per million. Three thousand cases per year are diagnosed in the United States, representing 72% of cutaneous T-cell lymphomas (CTCLs).

BIOLOGIC CHARACTERISTICS

MF is a chronic malignant disease of the skin involving skin-homing CD4+ T cells. The classical immunophenotype is CD2+ CD3+ CD4+ CD5+ CD45RO+ CLA+ (cutaneous lymphoid antigen) CD8– CD30–. Early disease is characterized by patches and plaques affecting the skin, with or without nodal or blood involvement. Advanced disease is characterized by cutaneous tumors, erythroderma, or lost epidermotropism and visceral involvement.

STAGING EVALUATION

TNMB staging is based on the percentage of cutaneous involvement, nature of the lesions, nodal, visceral, and blood involvement. History taking and a physical examination are needed to stage the disease. Skin biopsy with immunophenotyping and polymerase chain reaction (PCR) are performed to determine the T-cell receptor gene rearrangement. A complete blood count with manual differential, serum chemistries, liver function tests, and lactate dehydrogenase (LDH) should be performed. For stages IB to IV disease, peripheral blood flow cytometry, and peripheral blood T-cell receptor gene rearrangement should be assessed. A chest radiograph should be obtained for all patients. Computed tomography (CT) scanning should be done and positron emission tomography (PET)-CT considered for stages IB to IV disease. Suspicious lymph nodes require excisional or core biopsy.

PRIMARY THERAPY

For early-stage disease, therapy is focused on sequential skin-directed therapies, to simultaneously balance the objectives of achieving an optimally durable response but minimizing toxicity. Therapeutic options include irradiation, corticosteroids, psoralen plus ultraviolet A (PUVA), narrow band ultraviolet B, mechlorethamine, carmustine, and topical bexarotene. Total skin electron beam therapy (TSEBT) monotherapy produces a 10-year relapse-free survival rate of approximately 50% for IA disease. TSEBT provides rapid and effective palliation, with complete response rates of 95% for T1, 90% for T2, 60% for T3, and 75% for T4 disease. Total dose for TSEBT varies widely, with a growing emphasis on lower doses and repeat courses of TSEBT. TSEBT is also often followed by adjuvant maintenance therapy. However, skin-directed therapies are not anticipated to be curative over long-term follow-up, with the natural history of disease expected to be chronic and relapsing. For progressive or refractory disease, systemic therapies include interferon-α, retinoids, bexarotene, extracorporeal photochemotherapy, denileukin diftitox, vorinostat, nucleoside analogs, and cytotoxic chemotherapy. Biological response modifiers are being currently evaluated.

LOCALLY ADVANCED DISEASE

TSEBT is effective therapy for achieving durable control for most cutaneous lesions. Other skin-directed therapies are also applied for patients with locally advanced disease. Traditional multiagent systemic chemotherapy does not enhance survival times but may produce palliation. Allogeneic bone marrow transplant is a promising approach for young patients with a good performance status and is considered a curative option.

PALLIATION

Most patients require long-term therapy to relieve cutaneous symptoms. All of the skin-directed therapies produce substantial palliation. Additionally, novel biologic agents such as bexarotene, denileukin diftitox, and vorinostat (or other emerging histone deacetylase inhibitors [HDACs]) have efficacy in disease refractory to standard treatments.

MF is a low-grade, non-Hodgkin's lymphoma caused by skin-homing $CD4^+$ T cells that form cutaneous patches, plaques, and tumors.[1,2] MF was initially described in 1806 when Alibert described a patient with cutaneous tumors that he attributed to yaws. Although initially termed *pian fungoides*, he later changed the name to mycosis fungoides.[3] In 1938, Sézary and Bouvrain described a leukemic variant called the Sézary Syndrome (SS),[4] and Lutzner and Jordan elucidated the ultrastructure of the Sézary cell in 1968.[5] The term *cutaneous T-cell lymphoma* was introduced by Edelson in 1975 and encompasses a variety of cutaneous lymphoproliferative disorders including MF/SS, adult T-cell leukemia/lymphoma, primary cutaneous CD30+ anaplastic lymphoma, lymphomatoid papulosis, pagetoid reticulosis, and others.[6] In clinical practice, the terms *MF* and *CTCL* are often used interchangeably; however, such usage is incorrect.[7] MF constitutes the majority of all CTCLs and the clinical history and therapy for each subtype of CTCL are different.[2]

MF is a challenging disorder from all perspectives. Despite improving molecular techniques, diagnosis early in the course of disease is often difficult because of the nonspecific nature of skin lesions and the numerous benign dermatoses that may mimic MF. Once a diagnosis of MF has been correctly established, the optimal initial treatment strategy often remains unclear, given heterogeneity of clinical presentations and limited data from controlled studies. Although radiotherapy is the most effective single agent in the treatment of MF,[8] TSEBT is not readily available at many centers. This chapter provides a summary of the clinically relevant aspects of MF and describes the role and techniques of radiotherapy in patient management.

ETIOLOGY AND EPIDEMIOLOGY

MF primarily affects adults older than the age of 40, with incidence rates peaking in the seventh decade. The incidence of CTCL has consistently increased from 1974 through 2002, reaching a current yearly incidence rate of 9.6 cases per million (with approximately 6.4 cases per million represented by MF).[9] Risk factors for development of CTCL include black race and male gender. Both characteristics are associated with higher T stage at presentation[10] and a poor prognosis.[11] Markers of high socioeconomic status, such as residence in areas with high home values, high level of educational attainment, and high physician density are associated with an increased incidence CTCL; it is unclear whether these factors are causative or simply increase the likelihood of diagnosis.[9]

Etiologic agents for the development of MF remain highly speculative.[12] Although numerous exposures including pesticides, radiation, industrial solvents, tobacco, and alcohol have been investigated, no consistent causative factors have been identified.[13] High rates of seropositivity for both cytomegalovirus[14] and human T-cell lymphotrophic virus type I[15,16] have been reported, but these studies await further corroboration before a causal relationship can be inferred.[17-19]

The observation that MF is more common in blacks and tends to present in sun-shielded areas (i.e. "bathing suit" distribution) suggests that sun exposure may protect against the development of MF. Sun exposure may mediate its protective effect by exerting a cytotoxic effect on either the malignant CD4+ T-cell of MF or the epidermal antigen-presenting dendritic cell, also known as the Langerhans cell. This cell presents antigens to the malignant CD4+ T cells of MF and may stimulate their growth. The histologic evidence for this interaction is Pautrier's microabscess, an intraepidermal collection of malignant CD4+ T cells clustered around an antigen presenting dendritic cell. This finding is considered pathognomonic for MF and suggests that MF may be an antigen-driven malignancy, though a specific antigen has yet to be identified.[20]

TABLE 79-1 Proposed Algorithm for Diagnosis of Early Mycosis Fungoides

Criteria	Score
CLINICAL	2 points for basic + two additional criteria
Basic	1 point for basic + one additional criterion
Persistent or progressive patches or thin plaques	
Additional	
1. Nonsun-exposed location	
2. Size/shape variation	
3. Poikiloderma*	
HISTOPATHOLOGIC	2 points for basic + two additional criteria
Basic	1 point for basic + one additional criterion
Superficial lymphoid infiltrate	
Additional	
1. Epidermotropism without spongiosis	
2. Lymphoid atypia†	
MOLECULAR BIOLOGIC	1 point for clonality
Basic	
Clonal T-cell receptor gene rearrangement	
IMMUNOPATHOLOGIC	1 point for one or more criteria
1. <50% CD2+, CD3+, or CD5+ T cells	
2. <10% CD7+ T cells	
3. Epidermal/dermal discordance of CD2, CD3, CD5, or CD7‡	
Four or more points satisfy criteria for a diagnosis of early MF.

**Poikiloderma is defined as the combination of skin atrophy, telangiectasia, and mottled pigmentation.*

†Lymphoid atypia is defined as cells with enlarged, hyperchromatic nuclei, and irregular or cerebriform nuclear contours.

‡T-cell antigen deficiency confined to the epidermis.

PREVENTION AND EARLY DETECTION

No agents have been identified that will prevent the development of MF. However, early diagnosis is critical because local therapy directed against uni- or oligolesional MF is highly curative.[21-23] The most typical presentation of early disease—an erythematous patch with scale arising in a sun-shielded area—may be confused with a number of benign dermatoses including atopic dermatitis, psoriasis, and tinea corporis.[24] At this early stage, most of the lymphocytes noted on histopathology represent reactive inflammatory cells rather than the malignant clone.[25] As a result, the histopathology of early MF mimics numerous benign inflammatory conditions,[25,26] and a rapid and correct histologic diagnosis is not always possible. In this setting, molecular studies such as PCR for the T-cell receptor will identify a clonal T-cell population in 50% to 80% of patients who ultimately develop overt histologic evidence of MF.[27,28] To improve diagnostic accuracy of early MF, the International Society for Cutaneous Lymphoma proposed a points-based algorithm for early diagnosis (Table 79-1).[29,30]

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

A malignant clone in patch-plaque MF bears the immunophenotype of activated, skin-homing CD4+ helper T cells.[20] When a naïve T-cell identifies its cognate antigen in a skin-draining lymph node, activation occurs, and the T cells begins to express cutaneous lymphocyte antigen (CLA) and CC chemokine receptor 4 (CCR4). As these activated T cells pass through the capillaries of inflamed skin, CLA and CCR4 bind to their respective ligands on the dermal capillaries, resulting in extravasation of the activated T cells into the dermal connective tissue. Once outside the circulation, activated T cells migrate to the epidermis and interact with antigen-presenting dendritic (Langerhans) cells (Figure 79-1).

Clinically, progression of MF is associated with loss of epidermotropism and increasing tumor burden. Molecular studies have shown that progression of MF is associated with *p53* mutation,[31] numerous chromosomal rearrangements,[32] and microsatellite instability.[33] In addition, the malignant cells in MF develop mechanisms to escape destruction by the host immune system. For example, although benign activated T cells are eliminated by fas/fas-ligand mediated apoptosis, the malignant T cells of MF evade fas-mediated apoptosis via fas downregulation, mutation, or alternative splicing.[34]

As a malignancy of the immune system, MF results in substantial alteration of host immunity with consequent increased risk of infection[35] and possibly second malignancy.[36] For example, in patients with Sézary syndrome, the absolute number of normal circulating T cells often drops dramatically, reaching levels typically only seen in acquired immunodeficiency syndrome.[37] In addition, malignant CD4+ T cells produce large amounts of interleukin-10 and transforming growth factor-β, resulting in further suppression of cell-mediated

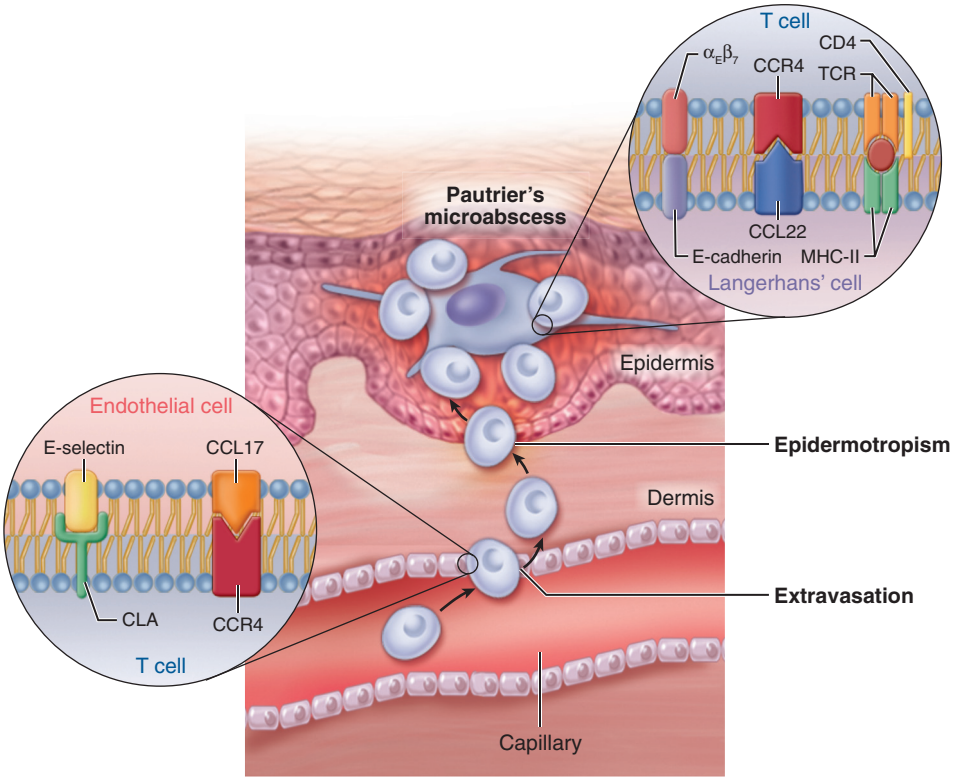

Figure 79-1 Molecular pathology of mycosis fungoides. Activated skin-homing T cells extravasate through the dermal capillaries because of interactions of cutaneous lymphocyte antigen (CLA) and chemokine receptor 4 (CCR4) with their respective ligands on the dermal capillaries, E-selectin and chemokine ligand 17 (CCL17). T cells then migrate to the epidermis and interact with antigen presenting dendritic cells.

immunity.[38,39] The malignant cells of MF also produce large amounts of soluble interleukin-2 receptor that can inactivate interleukin-2,[40] a cytokine needed to promote normal T-cell activation. Finally, the malignant cells of Sézary syndrome can elaborate large amounts of interleukin-4 and interleukin-5, producing a syndrome characterized by atopy and eosinophilia.[39]

PATHOLOGY AND PATHWAYS OF SPREAD

The diagnosis of MF remains challenging, even for the experienced clinician and dermatopathologist, as a result of both the absence of a diagnostic gold standard and the number of benign inflammatory dermatoses that may mimic MF, particularly in its early stages. Currently, diagnosis relies on integrating clinical presentation with histopathologic, immunophenotypic, and genotypic data. The current World Health Organization–European Organization for the Research and Treatment of Cancer (WHO–EORTC) pathologic classification scheme for cutaneous T-cell lymphoma is presented in Table 79-2.[41]

Histopathology

The most striking finding of early MF is profound epidermotropism, characterized by lymphocytes clustered along the basement membrane of the epidermis (Figure 79-2, *A, B*).[42] Microdissection studies have shown that virtually all of the lymphocytes in the epidermis belong to the malignant clone, whereas most dermal lymphocytes are reactive.[43,44]

Several microscopic findings help to discriminate early MF from benign inflammatory mimics. For example, an EORTC study reported that identification of epidermal lymphocytes with extremely convoluted, medium-large (7-9 μm) nuclei enabled correct diagnosis of MF with 100% sensitivity and 92% specificity (see Figure 79-2, *B*).[26] In contrast, a study from Stanford University found that intraepidermal atypical lymphocytes surrounded by a clear halo (an artifact of fixation) were the most robust indicator of MF in a multivariate model.[45] Another finding, Pautrier's microabscess, is considered pathognomonic but is seen in less than 20% of early lesions (see Figure 79-2, *D*).[45] A proposed grading system has attempted to improve diagnostic accuracy.[25,46]

As MF progresses from patch to plaque stage, the lymphoid infiltrate increases in density and begins to invade the deeper reticular dermis (see Figure 79-2, *C*). Furthermore, as a result of the increased burden of neoplastic cells, findings such as Pautrier's microabscesses (see Figure 79-2, *D*), haloed lymphocytes, and convoluted nuclei are more readily identified, resulting in improved diagnostic accuracy. Tumor formation results from vertical growth of the lymphoid infiltrate, and may be associated with complete loss of epidermotropism and sparing of the upper papillary dermis (see Figure 79-2, *E*). Erythrodermic MF often resembles patch-stage MF, although epidermotropism may be more subtle and neoplastic cells may be quite sparse.[47]

Immunophenotyping of Skin Lesions

Assessment of T-cell marker expression within the lymphoid infiltrate provides additional information that helps to establish a diagnosis of MF. The hallmark of MF is expression of CD4, the marker of mature helper T cells. A typical immunophenotype for MF is CD2+ (pan T cells), CD3+ (pan T cells),

TABLE 79-2 WHO–EORTC Classification for Cutaneous T-Cell Lymphomas

Histologic Findings	Frequency	5-year Disease-Specific Survival	Clinical Behavior
Mycosis fungoides	44%	88%	Indolent
Variants of mycosis fungoides			
Folliculotropic mycosis fungoides	4%	80%	Indolent
Pagetoid reticulosis	<1%	100%	Indolent
Granulomatous slack skin	<1%	100%	Indolent
Sézary syndrome	3%	24%	Aggressive
Adult T-cell leukemia/lymphoma	—	—	—
Primary cutaneous CD30+ Lymphoproliferative disorders			
Primary cutaneous anaplastic large cell lymphoma	8%	95%	Indolent
Lymphomatoid papulosis	12%	100%	Indolent
Subcutaneous panniculitis-like T-cell lymphoma (α/β type)	1%	82%	Indolent
Extranodal NK/T-cell lymphoma, unspecified	<1%	—	Aggressive
Primary cutaneous peripheral T-cell lymphoma, unspecified	2%	16%	Aggressive
Primary cutaneous aggressive epidermotropic CD8+ T-cell lymphoma (provisional)	<1%	18%	Aggressive
Cutaneous γ/δ T-cell lymphoma (provisional)	<1%	—	
Primary cutaneous CD4+ small/medium-sized pleomorphic T-cell lymphoma (provisional)	2%	75%	Indolent

NK, *Natural killer;* WHO–EORTC, *World Health Organization–European Organization for the Research and Treatment of Cancer.*

CD4+ (helper T cells), CD5+ (pan T cells), CD45RO+ (memory T-cell), CLA+ (cutaneous lymphoid antigen), CD8– (cytotoxic T-cell), CD30– (activated T-cell).[48] Although many benign dermatoses express a similar immunophenotype, two markers, CD7 and Leu-8, are often underexpressed in MF and may be helpful in distinguishing between MF and benign mimics. Finally, rare cases of apparently classic MF that are CD4-, but CD3+ and CD8+ have been reported.[49]

T-Cell Receptor Gene Rearrangement

Clonal T-cell receptor gene rearrangements are frequently identified in MF skin lesions and may help to differentiate between early MF patches and benign mimics. Clinical data indicate that PCR will identify a dominant clonal T-cell receptor-γ rearrangement in 63% to 90% of skin biopsies that show definite histologic evidence of MF.[50,51] Furthermore, PCR identifies a clonal T-cell population in 50% to 80% of histologically borderline biopsies obtained from patients who subsequently develop classic MF.[27,28] In contrast, T-cell clonality occurs in only 6% to 24% of benign dermatoses that contain a lymphoid infiltrate.[50,51] These observations suggest that identification of a clonal T-cell population should always be considered in light of the clinical and histologic context and may help to confirm a diagnosis of MF when already suspected on these grounds.

Transformation to Large Cell Histology

Transformation to a large cell variant occurs in up to 39% of patients initially diagnosed with MF, and the likelihood of transformation is directly correlated with higher stage.[52] Histologic diagnosis of transformation requires large cells (≥4 times the size of a small lymphocyte) comprising >25% of the lymphoid infiltrate or forming microscopic nodules.[53] Transformation is associated with expression of CD30 in 30% of cases and expression of CD20 in 45% of cases. Transformed MF is typically aggressive, with clinical behavior similar to high-grade lymphoma, and must be treated as such, particularly with the goal of allogeneic transplantation when possible.

CLINICAL MANIFESTATIONS

According to the EORTC classification of cutaneous lymphomas, the term *mycosis fungoides* should be reserved for those $CD4^+$ cutaneous lymphomas that are "characterized by the subsequent evolution of patches to more infiltrated plaques and eventually tumors."[2] Over time, MF may spread to involve lymph nodes, blood, bone marrow, and visceral organs. Symptoms may vary by degree of involvement, but weight loss, night sweats, and fever are uncommon unless infection is present.

Premycotic Phase

Early MF typically begins with mildly erythematous, slightly scaling, annular or arcuate macules that classically involve sun-shielded areas (Figure 79-3, *A*). These lesions may wax and wane for years before histologic findings show definitive evidence of MF.

Patch Phase

In this stage, patches lose their predilection for sun-shielded areas and may become eczematous, hypopigmented, or hyperpigmented. The trunk, pelvis, and proximal extremities are most commonly involved. Histologic features consistent with MF may now be discernible.

Plaque Phase

If untreated, some patches will progress to form more generalized, deeply infiltrative, scaling plaques that often have well-demarcated, palpable borders and may exhibit central clearance and arcuate morphology (see Figure 79-3, *B*). Associated findings include hyperkeratosis of the palms and soles and fissures.

Tumor Phase

More than 80% of tumors emerge in the setting of established patch-plaque MF (see Figure 79-3, *C*). The most common sites

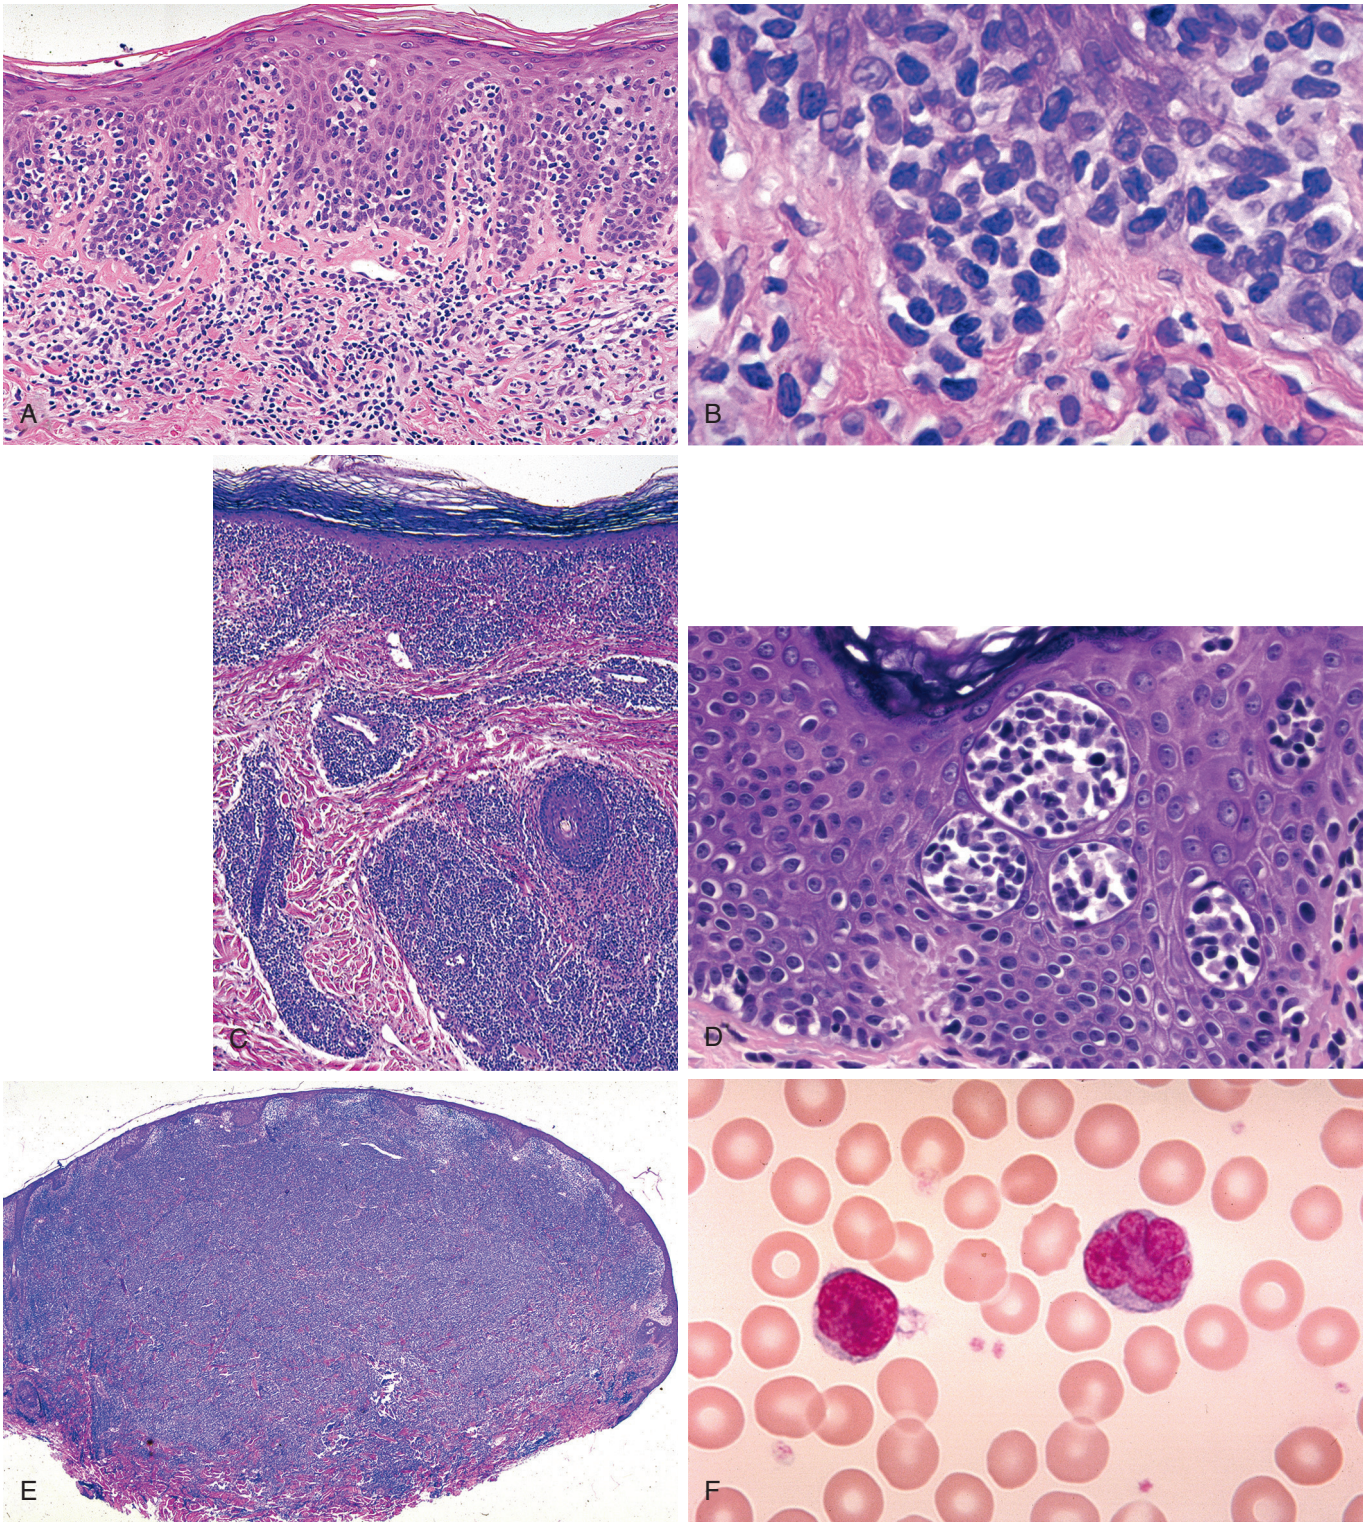

Figure 79-2 Classic histopathologic findings in mycosis fungoides (MF) and Sézary syndrome. A, Advanced patch-stage lesion of MF exhibiting abundant lymphocytes within the basal layer of the epidermis, associated with an underlying band-like lymphocytic infiltrate and papillary dermal fibrosis. **B,** Advanced patch-stage lesion of MF exhibiting enlarged, convoluted lymphocytes within the epidermis. The lymphocyte cell size approximates the width of keratinocyte nuclei. **C,** Plaque-stage MF shows, in addition, involvement of the reticular dermis. **D,** Pautrier's microabscesses are well-defined aggregates of lymphocytes within the epidermis, which are strongly indicative of MF. **E,** In tumor stage MF, the dermis is distended by the lymphocytic infiltrate. Epidermotropic capacity is often lost. **F,** Sézary cells, such as the cell at the right, are enlarged circulating lymphocytes that exhibit cerebriform nuclear convolutions.

of tumor involvement include the face, digits, and perineum. Tumors frequently ulcerate and are prone to infection.

Tumeur d'Emblée

The term *tumeur d'emblée* refers to the rare patient who presents with tumors that arise in the absence of antecedent skin lesions; some cases may be more appropriately classified as CD30– cutaneous large T-cell lymphoma rather than MF.[54] The clinical course may be more aggressive than patients with classic MF.

Erythroderma

Erythroderma is defined as greater than 80% body surface involvement with confluent patches or plaques. It is associated with intense pruritus, hyperkeratosis of the palms and soles, skin atrophy, and lichenification (see Figure 79-3, *D*). Erythroderma may arise de novo or from progression of patch and plaque MF.

Lymph Nodes

Lymph node involvement is present in 15% of newly diagnosed patients and is associated with advanced cutaneous disease.[55] Nodes are typically non-tender, mobile, and measure from 1 cm to 4 cm, though typically a size threshold of 1.5 cm is considered clinically abnormal, and biopsy is recommended to evaluate nodes that reach this threshold.[56] Bulky adenopathy is uncommon.

Internal Organs

Visceral involvement is typically seen only in patients with advanced cutaneous disease, nodal disease, and blood involvement. The most common sites include the lungs, central nervous system, oral cavity, and oropharynx,[55,57] although MF has been observed in other sites such as the breast, thyroid, and pancreas. Visceral involvement is often subclinical and does not routinely precipitate death. Bone marrow involvement at initial staging has been reported in 6% to 28% of patients and is also associated with advanced skin and nodal disease.[58,59]

TABLE 79-3 Proposed Hematologic Criteria for Diagnosis of Sézary Syndrome

Absolute Sézary cell count ≥1000 cells/μL.
CD4/CD8 ratio ≥10 due to an increase in CD3+[1] or CD4+[1] cells by flow cytometry.
Aberrant expression of pan-T-cell markers (CD2, CD3, CD4, CD5) by flow cytometry. Deficient CD7 expression on T cells (or expanded CD4+,[1] CD7– cells ≥40%) is a tentative criterion.
Increased lymphocyte count with T-cell clone in blood identified by Southern blot or polymerase chain reaction.
A chromosomally abnormal T-cell clone.

Adapted from Vonderheid EC, Bernengo MG, Burg G, et al: Update on erythrodermic cutaneous T-cell lymphoma. Report of the International Society for Cutaneous Lymphomas. J Am Acad Dermatol 46:95–106, 2002.

Sézary Syndrome

Sézary syndrome (SS) is defined as erythroderma plus evidence of malignant circulating T cells that satisfy any of the five criteria listed in Table 79-3.[60] For the purposes of these criteria, the Sézary cell is defined as "any atypical lymphocyte with [a] moderately to highly infolded or grooved nucleus"[60] (see Figure 79-2, *F*). Clinical findings may include edema and tumorous involvement of the face leading to leonine facies, severe fissures of the palms and soles, intense pruritus, and cutaneous pain. Currently, no consensus has emerged

regarding the pathologic link between MF and SS. However, some clinical observations help to elucidate the relationship between these two disorders. SS often arises de novo without antecedent MF. MF may also evolve to an erythrodermic stage with concomitant hematologic findings that satisfy a diagnosis of SS.

VARIANTS OF MYCOSIS FUNGOIDES

The progression from subtle patches to indurated plaques, cutaneous tumors, and erythroderma represents classical, so called "Alibert-Bazin" MF. According to the EORTC classification, variants such as bullous and hyper- or hypopigmented MF manifest similar clinical behavior and should not be considered separately from classical MF.[2] Several variants sharing some clinical and pathologic features with MF have been described.

Folliculotropic Mycosis Fungoides

This entity presents with follicular papules, comedolike lesions, milialike lesions, patches, and plaques, all of which may produce alopecia.[1,41] Although it typically involves the head and neck, any skin site may be affected.[2] Pathologically, atypical lymphocytes invade follicles and may deposit acid mucopolysaccharides in the pilosebaceous units. Folliculotropic MF, often presenting with thick plaques, tends to be refractory to topical treatments such as PUVA and nitrogen mustard, and risk of relapse after treatment with TSEBT appears to be higher when compared to patients with classical MF.[61] Five-year disease-specific survival is approximately 80%[41] but only 41% by 15 years.[62]

Pagetoid Reticulosis and Woringer–Kolopp Disease

Pagetoid reticulosis, also known as Woringer–Kolopp disease, typically presents as slow-growing, hyperkeratotic or psoriasiform, localized patch or plaque involving a distal extremity. Pathologically, an abundant epidermotropic infiltrate composed of atypical large lymphocytes is noted, along with pagetoid spread of individual lymphocytes interspersed among keratinocytes. Benign-appearing small lymphocytes are found in the upper dermis.[1] The prognosis for localized pagetoid reticulosis is excellent with either surgery or radiotherapy, and disease-related deaths have not been reported.[2,41] Ketron–Goodman type is a disseminated, more aggressive cutaneous lymphoproliferative disorder that histologically resembles localized pagetoid reticulosis.

Granulomatous Slack Skin

This rare variant presents with lax skin in the axillae, neck, breasts, and inguinal regions. Histological features include epithelioid or giant cell dermal granulomas and associated destruction of elastin fibers.[2] Notably, Hodgkin lymphoma has been associated with granulomatous slack skin in roughly one third of reported cases.[63] Because of its rarity, optimal treatment has not been established.

RELATED CUTANEOUS T-CELL LYMPHOPROLIFERATIVE DISORDERS

In addition to MF and its variants, several other distinct cutaneous T-cell lymphoproliferative disorders have been described. Their clinical and pathologic features and optimal therapy is briefly reviewed here.

Primary Cutaneous Anaplastic Large Cell Lymphoma/CD30+ Large Cell CTCL

This entity typically presents as a red or flesh-colored nodule or tumor that frequently ulcerates. Histopathology shows sheets of CD30+ large lymphocytes without epidermotropism. In contrast to systemic CD30+ anaplastic large cell lymphoma, overexpression of anaplastic lymphoma kinase (ALK) is not found in primary cutaneous CD30+ large cell lymphoma. Patients with localized disease are typically treated with radiotherapy alone, and prognosis is excellent with a 5-year disease-specific survival of approximately 90% to 95%.[2,64,65] Treatment using anti-CD30 monoclonal antibody may be considered, but is typically not an upfront strategy.

Lymphomatoid Papulosis

Lymphomatoid papulosis (LyP) presents with grouped erythematous or violaceous papules or nodules at different stages of development. Lesions typically resolve spontaneously within 2 to 8 weeks, but scarring is common.[66] Three different histologic subtypes have been described, with types A and C consisting of malignant CD30+ T cells, often with an extensive inflammatory infiltrate, and type B simulating classical plaque-stage MF. For type C lesions, discrimination between LyP and CD30+ large cell lymphoma may be difficult on histologic grounds, and assessment of the clinical context may be required to ensure the proper diagnosis.[2] Although cytologically malignant, it should be emphasized that LyP is clinically benign with a 5-year survival of 100%.[2,41,64] Thus, neither aggressive chemotherapy nor radiotherapy is indicated.[67] Treatment options include PUVA or low-dose methotrexate, but neither is considered curative. In the long term, at least 15% to 20% of patients with LyP will develop a second malignancy, most commonly MF, CD30+ large cell lymphoma, or Hodgkin's disease.[67,68] In patients undergoing TSEBT for MF, a history of LyP is associated with an increased risk of relapse.[61]

Adult T-Cell Lymphoma/Leukemia

Adult T-cell Lymphoma/Leukemia (ATLL) develops in 2% to 4% of individuals infected with human T-cell lymphotrophic virus type I (HTLV-I), a retrovirus endemic in southern Japan and the Caribbean.[1,66,69,70] Skin findings are present in up to 60% of patients with ATLL and strongly resemble those of MF, including plaques, tumors, and erythroderma. The characteristic immunophenotype is CD2+ CD3+ CD4+ CD5+ CD7– CD8– and the malignant cells strongly express the high affinity interleukin-2 receptor (CD25, CD122, and CD132). Clinical features vary from an acute form presenting with B symptoms, hypercalcemia, metabolic bone disease, hepatosplenomegaly, generalized adenopathy, and leukemic infiltration to a smoldering or chronic form presenting with skin infiltration and little or no systemic involvement. Although patients often respond to conventional chemotherapy, long-term survival is rare. Other agents include denileukin diftitox[71] and interferon-α in combination with zidovudine.[72] In appropriately selected candidates, allogeneic stem-cell transplantation may be considered, though evaluation of efficacy in this scenario is ongoing.[73]

Subcutaneous Panniculitis-Like T-cell Lymphoma (α/β type)

In prior years, subcutaneous panniculitis-like T-cell lymphoma was thought to run two markedly different clinical courses—an indolent course and an aggressive course. Recently, molecular studies have indicated that the indolent form of subcutaneous panniculitis-like T-cell lymphoma is

caused by CD8+ T cells that express the α/β T-cell receptor. This entity typically presents with subcutaneous nodules or plaques involving the legs or trunk and has a 5-year disease-specific survival of approximately 82%.[41] In contrast, the more aggressive form of subcutaneous panniculitis-like T-cell lymphoma is caused by CD8– T cells that express the γ/δ T-cell receptor, and is now classified as cutaneous γ/δ T-cell lymphoma in the updated WHO–EORTC system.[41] This entity is often fatal and complicated by hemophagocytic syndrome. Treatment for the α/β type is often observation while treatment for the γ/γ type includes combination chemotherapy and possibly cyclosporine.[1,2]

PROGNOSIS AND STAGING

Early (skin involvement characterized by patches and plaques, regardless of nodal or blood involvement) versus advanced (involvement with tumor, high-grade nodal, or visceral organ) stage is the primary predictor of prognosis. Treatment strategy should be planned accordingly.[56] Skin is systematically assessed and scored using the modified Severity Weighted Assessment Tool (mSWAT), which not only quantifies the percent body surface area (BSA) involved with patch, plaque, or tumor, but further weights the total score by the type of lesion (patch = 1, plaque = 2, tumor = 4).[74,75]

Various staging systems exist and have evolved over time. Previously, the American Joint Committee on Cancer (AJCC) staging system for MF identified extent and character of skin lesions, extracutaneous disease, and leukemic transformation.[76] Shortcomings of this system included difficulty in assigning T stage for patients on the border between T1 and T2; failure to discriminate between the prognosis of patients with extensive patches as compared to extensive plaques; similarity in prognosis between patients with tumors and erythroderma; the questionable prognostic relevance of enlarged, pathologically uninvolved lymph nodes; and the rarity of the N2 descriptor because biopsies of nonpalpable lymph nodes are seldom performed.[77,78]

To address these shortcomings, the EORTC, in conjunction with the International Society for Cutaneous Lymphoma (ISCL), proposed a revised TNMB staging system (Tables 79-4 and 79-5) addressing both MF and SS and incorporating greater detail on skin and nodal involvement and also considering clonal and tumor burden in the blood.[79] Detailed definitions and descriptions of the extent and character of skin as well as nodal and visceral disease are provided to provide more systematic classification. In addition to quantification of body surface involvement, pigmentation, scale, crusting, and poikiloderma are additional important features of skin classification. On histology, folliculotropism, large-cell transformation, $CD30^+$ or $CD30^-$, and ulceration are notable. T-cell clonality requires PCR or Southern blot analysis of the T-cell receptor gene.[79]

The TNMB system has been increasingly adapted into treatment algorithms and provides a systematic approach to prospectively compare longitudinal changes in tumor burden, and hence the clinical effectiveness, of various therapies.[56,75,80] Furthermore, it provides a rational stratification of patients into "early" versus "advanced" stages, an initial categorization that drives therapeutic decision making.

T stage continues to be a strong predictor of outcome. Data from a cohort of 468 patients with newly diagnosed MF evaluated at Stanford University are presented in Table 79-6.[55] More than 60% of patients presented with patches or plaques without nodal or visceral disease. Such patients rarely developed disseminated disease, even at 20 years of follow up. In contrast, 50% to 60% of patients presenting with tumors or erythroderma will develop extracutaneous disease.

TABLE 79-4 TNMB Classification for Mycosis Fungoides/Sézary Syndrome, Based on the International Society for Cutaneous Lymphomas/European Organisation for Research and Treatment of Cancer (ISCL/EORTC) Revision

SKIN	
T1	Limited patches, papules, or plaques covering <10% of the skin surface
T2	Patches, papules, or plaques covering ≥10% of the skin surface
T3	One or more tumors (≥1 cm)
T4	Confluence of erythema covering ≥80% body surface area
NODE	
N0	No clinically abnormal peripheral lymph nodes; biopsy not required
N1	Clinically abnormal peripheral lymph nodes; histopathology Dutch grade 1 or NCI LN0-2
N1a	Clone negative
N1b	Clone positive
N2	Clinically abnormal peripheral lymph nodes; histopathology Dutch grade 2 or NCI LN3
N2a	Clone negative
N2b	Clone positive
N3	Clinically abnormal peripheral lymph nodes; histopathology Dutch grades 3-4 or NCI LN4; clone positive or negative
Nx	Clinically abnormal peripheral lymph nodes; no histologic confirmation
VISCERAL	
M0	No visceral organ involvement
M1	Visceral involvement (must have pathology confirmation and organ involved should be specified)
BLOOD	
B0	Absence of atypical circulating cells: ≤5% of peripheral blood lymphocytes are atypical (Sézary) cells‖
B0a	Clone negative
B0b	Clone positive
B1	Atypical circulating cells, low blood tumor burden: >5% of peripheral blood lymphocytes are atypical (Sézary) cells but does not meet the criteria of B2
B1a	Clone negative
B1b	Clone positive
B2	Atypical circulating cells, high blood tumor burden: ≥1000/μL Sézary cells‖ with positive clone

Data from Stanford showed that patients with limited patches and plaques (stage IA, T1 N0 M0) experience 10-year survival similar to a matched control population. In contrast, median survival for patients with extensive patches and plaques (T2), tumors (T3), and erythroderma (T4), was 11, 3.2, and 4.6 years, respectively.[81] Patients with either pathologically documented lymph node involvement or visceral involvement experienced a median survival of roughly one year.[55]

Another multiinstitutional study showed that survival is also related to the pattern and extent of lymph node involvement, but the prognostic strength of nodal status is debated.[82]

- Histologic findings
  - Epidermal lymphocytes with medium to large, extremely convoluted nuclei
  - Haloed epidermal lymphocytes
  - Pautrier's microabscesses
- Immunophenotype
  - Classically: CD2+ CD3+ CD4+ CD5+ CD45RO+ CD8– CD30–
  - Rarely, CD4– CD3+ CD8+
- PCR for T-cell receptor gene rearrangement

Biopsy of Enlarged Lymph Nodes with Attention to

- Histologic findings, both number of atypical lymphocytes and disruption of nodal architecture
- In dermatopathic nodes, consider PCR for T-cell clonality and immunophenotyping to rule out occult involvement

Evaluation of Blood

- CBC with manual differential, liver function tests, and serum chemistries for all patients
- In those with suspected stages IIB to IV disease
  - LDH, soluble interleukin-2 receptor
  - Flow cytometry for CD2, CD3, CD4, CD5, CD7, CD8, CD20, CD45RO
  - PCR for T-cell receptor gene rearrangement

Imaging

- Posteroanterior and lateral chest radiograph for stage IA
- CT of (neck), chest, abdomen, and pelvis for suspected stages IB to IV
- Consider PET/CT scanning for patients with suspected stages IB to IV

CBC, *Complete blood count;* CT, *computed tomography;* LDH, *lactate dehydrogenase;* PCR, *polymerase chain reaction;* PET, *positron emission tomography.*

For example, partial or complete effacement of nodal architecture by malignant lymphocytes conferred a median survival to 2.3 years. In contrast, lymph nodes with aggregates of atypical lymphocytes but preserved nodal architecture resulted in a median survival of 6 years and lymph nodes with only dermatopathic changes or few atypical lymphocytes resulted in a median survival of 9 years.

Other factors that may herald a poor prognosis include age ≥60,[83] elevated LDH,[83] elevated soluble interleukin-2 receptor levels,[40] a low percentage of $CD8^+$ tumor infiltrating lymphocytes,[84] extent of skin involvement in those with T3 disease,[85] T-cell clonality within the cutaneous infiltrate detected by PCR,[86,87] an identical T-cell clone in the skin and peripheral blood,[88] and T-cell clonality in dermatopathic lymph nodes.[89]

For those patients with transformation to a large-cell variant of MF, median survival ranges from 19 months to 36 months.[53,90] Factors predictive of poor survival after transformation include short interval between diagnosis of MF and transformation (< 2 years), and the presence of stages IIB to IV disease.[53]

PATIENT EVALUATION

All patients should have a thorough history performed by the evaluating dermatologists, radiation oncologists, and any other consultants (Table 79-7). Careful attention should be given to the duration, change in appearance, and distribution of the eruption according to the patient. Inquiry related to a history of pruritus, pain, exfoliation, fissures, bullae, and perineal discomfort should be made. Previous diagnostic considerations, procedures, and therapies should be recorded in detail to establish temporal relationships. The clinical interview, along with the examination, are the two most important aspects of the workup because they can help exclude other diagnoses and establish whether the narrative and findings are consistent with a diagnosis of MF.

Physical Examination

All patients should undergo a complete physical examination with special attention to the skin surface, lymph nodes, and abdomen for organomegaly. Specific notations should be made of the number, location, character, and distribution of cutaneous lesions and the presence of ulceration. The percentage of cutaneous involvement should also be quantified. Body surface area (BSA) along with a weighted severity score provides a systematic approach to assessing skin involvement.[75] Other non-MF cutaneous findings such as previous excision sites, pigmented lesions, or any findings consistent with other skin malignancy should be noted. Adenopathy should be carefully documented with respect to location, size (particularly ≥1.5 cm), consistency, mobility, and discomfort on palpation. Photographs of the skin for baseline documentation should be considered.

Diagnostic Testing

Pathology

A biopsy of the most indurated area of involved skin should be performed for hematoxylin and eosin evaluation. Material for immunophenotyping (including at least CD2, CD3, CD4, CD5, CD7, CD8, and a B-cell marker such as CD20 or consideration of CD30) and T-cell receptor gene rearrangement should be obtained. Excisional biopsy of adenopathy is recommended and tissue should be submitted for the same pathologic studies. Needle aspiration of nodes is not recommended.

Routine bone marrow examination is generally not required but may be considered in patients with blood or other visceral involvement. Bone marrow involvement at initial staging has been reported in 6% to 28% of patients and is associated with advanced skin and nodal disease.[58,59] However, it is unclear that marrow involvement is an independent predictor of outcome.[59,83] Furthermore, although a clonal T-cell population within the marrow is identified in 75% of patients with identical skin and peripheral blood T-cell clones, this finding does not appear to alter prognosis.[58]

Hematology and Chemistry

A complete blood count including differential and smear in addition to serum chemistries (to include renal and hepatic function) and LDH should be obtained before initiation of therapy. For patients with stages IIB to IV disease, serum levels of soluble interleukin-2 receptor and LDH reflect overall tumor burden and could be used to assess response to therapy, although this measure is not an established standard for follow-up.

A thorough examination of the peripheral blood for evidence of malignant T cells is indicated for those with stages IIB to IV MF, and may be considered for those with stages IA to IIA. Peripheral blood flow cytometry should be performed to assess expression of CD2, CD3, CD4, CD5, CD7, CD8, CD20, and CD45RO. Findings suggestive of blood involvement include an elevated CD4/CD8 ratio (normal range 0.5 to 3.5), or an expanded population of $CD4^+CD7^-$, $CD4^+CD26^-$ or $CD45RO^+$ lymphocytes.[60] If initially abnormal, findings on peripheral blood flow cytometry should be followed to assess response to therapy. If flow cytometry is unremarkable, peripheral blood PCR for T-cell receptor gene rearrangement should be considered. PCR reveals a clonal T-cell population identical to that found in the cutaneous infiltrate in 40% of patients with erythroderma and 14% of patients with patches, plaques, or tumors.[50]

Diagnostic Imaging

A minimum of chest radiography should be completed for stage IA disease. CT of the chest, abdomen, and pelvis (and neck as clinically indicated) should be considered for patients with higher stage disease, particularly patients with tumors, erythroderma, or nodal involvement.[91] The role of fluorodeoxyglucose-positron emission tomography (FDG-PET) is being refined but may be beneficial for staging patients with advanced skin disease; for example, Stanford University investigators reported that CT alone identified pathologic adenopathy by size criteria in only 5 of 13 patients, whereas the addition of PET identified hypermetabolic adenopathy in 13 of 13 patients. The standardized uptake value (SUV) of the FDG correlated with the extent of nodal involvement, with the highest SUVs noted in patients with complete nodal effacement and large cell transformation.[92] Therefore, PET-CT may be considered for patients with ≥T2 disease, palpable adenopathy, abnormal laboratory studies, or patients with large cell transformed or folliculotropic MF.[80] To confirm nodal involvement and document the presence or absence of transformation, excisional biopsy should be strongly considered for selected abnormal lymph nodes, which are radiographically identified.

PRIMARY THERAPY

Because MF is a disease of cutaneous (i.e., skin-homing) lymphocytes, therapy is quite distinct from that of nodal lymphomas. A treatment algorithm for early versus advanced MF is presented in Table 79-8.[93] Multiple treatment options are listed, which reflects the increasing variety of available therapies, heterogeneity in institutional treatment preferences, and the paucity of randomized trials directly comparing different treatment modalities.

In general, however, the treatment approach to early disease involves selecting sequential skin-directed therapies, each based on the expectation to provide the greatest duration of response with the least toxicity, including radiation therapy as an option. Once the disease trajectory proves to be increasingly relapsing or refractory, repeat radiation therapy, systemic, or combined therapies as the second line may be considered. However, allogeneic stem-cell transplant has evolved as a promising therapy for long-term durable control or even cure. Transplant is appropriate for patients who have

TABLE 79-8 Treatment Recommendations, Early and Advanced Mycosis Fungoides/Sézary Syndrome

Stage	Initial Treatment	Treatment for Relapsed or Refractory Disease
Early (IA, IB, IIA)	Topical corticosteroids PUVA UVB Topical HN2 Local radiotherapy TSEBT	Retinoids, rexinoids Interferon-α Low-dose MTX HDACi Denileukin difitox Localized, superficial radiotherapy TSEBT Evaluate for allogeneic stem cell transplant with refractory disease
Advanced (IIB)	Interferon-α TSEBT PUVA	Retinoids, rexinoids Interferon-α alone PUVA + interferon-α HDACi Denileukin difitox Novel agents Chemotherapy Evaluate for allogeneic stem-cell transplant with refractory disease
Advanced (III to IV)	Interferon-α PUVA PUVA + Interferon-α TSEBT	Rexinoids HDACi Denileukin difitox Alemtuzamab or other monoclonal antibody Novel agents Chemotherapy TSEBT Evaluate for allogeneic stem cell transplant with refractory disease

failed multiple primary therapies and demonstrate a progressive course with decreasing durability of response, or who have undergone large cell transformation. Notably, however, this treatment strategy is being used selectively in appropriately selected candidate (in general, younger patients with good performance status).[94-96]

The available treatments for advanced disease are similar to early disease, but systemic therapy should be considered sooner in the disease trajectory given the systemic involvement of disease. At the same time, cutaneous lesions and symptoms remain problematic, and therefore maintaining a skin-directed regimen is also important, and therefore the treatment approach requires multimodality considerations. Novel agents may be considered as second-line therapy particularly for this group with a poorer prognosis compared with patients presenting with early-stage disease, and stem-cell transplant should also be explored as a possible treatment option in this group.

For patients with disease limited to the skin, topical therapy alone produces high rates of remission and even cure. Topical therapies include corticosteroids, mechlorethamine (nitrogen mustard), carmustine (BCNU), bexarotene gel (rexinoids), PUVA, ultraviolet B (UVB), and either localized or total skin electron radiotherapy. For patients with localized unilesional MF, topical therapies alone produce long-term disease-free survival rates in excess of 85%.[21-23] For those with more than one patch or plaque but with less than 10% body surface area involvement (T1 N0 and T1 N1), topical therapies alone produce long-term disease-free survival rates ranging from 30% to 50%. For patients with more extensive patches or plaques, topical therapies may produce remission, but long-term cure is unlikely. Such patients should receive intensive topical therapy to induce a complete remission followed by less intensive adjuvant topical therapy to sustain a remission.[97,98]

Those with tumors or erythroderma experience severe cutaneous symptoms and are at high risk for extracutaneous dissemination. Of all the topical therapies, TSEBT is associated with the highest rates of complete response for this patient subgroup.[98-100] Therefore, it is recommended that TSEBT be administered to induce cutaneous remission and that adjuvant systemic or topical therapy be administered to sustain remission. Systemic therapies include interferon, retinoids, oral bexarotene, denileukin diftitox, vorinostat or other histone deacetylase inhibitors, and extracorporeal photochemotherapy (photopheresis). Cytotoxic chemotherapies considered for this group include liposomal doxorubicin, gemcitabine, and low-dose methotrexate.

In the following section, we first discuss all nonradiation topical therapies and then discuss the various systemic therapies. Finally, we discuss the clinical data for radiation and qualitatively compare this to clinical data for various topical and systemic therapies.

Skin-Directed Therapy

Topical Corticosteroids

High potency topical or intralesional glucocorticoids are an important component in the treatment of MF because of their ability to alleviate cutaneous symptoms and induce lesion regression. Typically, corticosteroids are applied to active lesions only, as widespread application can induce reversible depression of serum cortisol in 10% to 15% of patients.[101] Persistent application can lead to skin atrophy.

Mechlorethamine

Topical mechlorethamine hydrochloride (HN2), also known as nitrogen mustard, is an alkylating agent with proven activity in the treatment of MF patches and plaques. Mechlorethamine is typically applied daily and continued for at least 6 months after complete response.[77] Cutaneous intolerance, manifested by erythema and pruritus, occurs in roughly 50% of patients treated with aqueous HN2[102] but is reduced to less than 10% in patients treated with HN2 dissolved in ointment such as Aquaphor.[77] Other cutaneous side effects of HN2 may include xerosis, hyperpigmentation, and rarely, bullous reactions, urticaria, and Stevens–Johnson syndrome.[102] Bone marrow suppression is not observed because of minimal systemic absorption. The carcinogenicity of HN2 remains debated, as one series reported no increased risk of secondary skin cancers in patients treated with HN2 monotherapy,[77] whereas another series reported an eightfold increase in the risk of nonmelanoma skin cancers attributable to HN2 monotherapy.[103] HN2 may also potentiate the carcinogenicity of other topical therapies such as total skin radiation or PUVA.[104]

Carmustine

Topical carmustine (BCNU) is another alkylating agent with activity in MF. Because of systemic absorption that may produce bone marrow suppression, the drug should be applied to no more than 10% of the body surface area, duration of treatment should be limited to 4 months, and complete blood counts should be monitored. Cutaneous hypersensitivity is uncommon (7% in one series) but chronic skin telangiectasis and hyperpigmentation may occur.[105]

Topical Rexinoids

Bexarotene belongs to a new class of agents called *rexinoids* that bind to the retinoid X receptor, resulting in transcription of various genes that control cellular differentiation and proliferation.[106] Topical bexarotene gel was recently approved after Phase I and II trials demonstrated a 44% to 54% response rate in refractory cutaneous MF.[107,108] Most patients will develop an irritant dermatitis and thus require close observation and dose titration. Because of its irritant effects, bexarotene gel is not indicated for patients with more than 15% body surface area involvement. As with systemic retinoids, bexarotene in both its topical and systemic forms should be avoided in pregnant women as a result of possible teratogenicity.

PUVA and Ultraviolet B

Ultraviolet light used in the treatment of MF includes UVB (wavelength 320 nm to 290 nm), narrow-band UVB (wavelength 311 nm), or psoralen plus UVA (PUVA, wavelength 400 nm to 320 nm). Because UVB has limited penetration, its efficacy is limited to thin patches. PUVA penetrates more deeply and will effectively treat some plaque lesions. PUVA requires ingestion of a photochemotherapeutic agent, 8-methoxypsoralen, before UVA exposure. UVA activates 8-methoxypsoralen, resulting in DNA cross-linking and apoptotic cell death.[109]

Both PUVA and UVB are initially administered 2 to 3 days a week as the light dose is gradually increased. Once a complete response has been achieved, treatment frequency may be gradually reduced to once every 2 to 4 weeks. Ultraviolet treatments may be continued on a maintenance basis for several years, provided the patient remains in complete response with treatment administered once every 4 to 8 weeks.

Acute side effects of PUVA and UVB include skin erythema that may be painful, hyperpigmentation, xerosis, pruritus, and blistering. Eye goggles are used to decrease the risk of cataract formation. One side effect unique to PUVA is nausea and vomiting after ingestion of 8-methoxypsoralen (8-MOP). This

may be avoided by substituting 8-MOP for either a topical "psoralen bath" or 5-methoxypsoralen, a nonemetogenic analog that is currently available in Europe.[110] Long-term toxicity includes photoaging and increased risk of melanoma and nonmelanoma skin cancers.[111,112]

Systemic Therapy

Interferon

Interferon-α-2a (IFN-α) is an effective agent, particularly for patch and plaque disease, likely as a result of a direct antitumor effect or immunomodulation.[113] IFN-α has been used alone[113,114] or in combination with retinoids, PUVA,[115-117] and extracorporeal photopheresis.[118] A recent prospective trial showed a benefit from combining IFN-α with PUVA as compared to IFN-α plus a retinoid, but it is not clear that combination therapy is clearly superior to single-agent therapy.[119] Toxicity may include flulike symptoms, psychiatric disturbances including depression and confusion, elevated transaminases, leukopenia, thrombocytopenia, proteinuria, and myelopathy.[116,117] Despite these side effects, in a recent Phase II trial of IFN-α and PUVA, only 8% of patients withdrew as a result of toxicity.[117]

Retinoids

Oral retinoids such as isotretinoin and acitretin influence cellular differentiation and may be particularly beneficial in the treatment of folliculotropic MF. Retinoids can be safely combined with other therapies such as PUVA,[120] IFN-α, and TSEBT.[121] Side effects include photosensitivity, xerosis, myalgias, arthralgias, headaches, impaired night vision, corneal opacities, teratogenicity, elevated transaminases, hyperlipidemia, and pancreatitis.[81]

Rexinoids

Oral bexarotene has been approved by the Food and Drug Administration for use in all stages of treatment refractory MF.[122,123] Preliminary data suggest that bexarotene can be combined safely with other therapies including PUVA, extracorporeal photopheresis, IFN-α, and HN2.

Hypertriglyceridemia, the most common adverse event, occurs in 80% of treated patients and may result in reversible pancreatitis if triglyceride levels exceed 800 mg/dL.[106] Therefore, atorvastatin or fenofibrate should be initiated if triglyceride levels exceed 350 mg/dL. Gemfibrozil increases serum bexarotene concentrations, resulting in a paradoxical elevation of triglycerides, and should therefore be avoided.[106] Another side effect, central hypothyroidism, affects roughly 75% of patients but responds well to levothyroxine and resolves when treatment is discontinued.[106] Patients taking bexarotene therefore require monitoring of estimated free thyroxine, as levels of thyroid-stimulating hormone (TSH) will always be low. Other side effects include self-limited headaches, mild neutropenia, mild transaminase elevations, skin peeling, and pruritus. In the Phases II to III trial of oral bexarotene for advanced, refractory cutaneous T-cell lymphoma, only 10% of patients receiving the optimal dose withdrew as a result of an adverse event.[122]

Denileukin Diftitox

Denileukin diftitox is a recombinant fusion protein that contains portions of interleukin-2 and diphtheria toxin and has proven activity in refractory MF, stages IB to IVA.[74] It selectively targets T cells that express the high affinity interleukin-2 receptor (a complex of CD25, CD122, and CD132), resulting in endocytosis of diphtheria toxin, inhibition of protein synthesis, and cell death. In the pivotal Phase III clinical trial leading to its approval, only patients with neoplastic T cells expressing the high affinity interleukin-2 receptor received denileukin diftitox, and it is currently controversial whether or not patients without significant expression of the high affinity interleukin-2 receptor benefit from denileukin diftitox.[124] Recently published results reported 44% overall response rate, including 10% complete response and 34% partial response. This compared with 16% in the placebo group. Median time to progression exceeded 2 years in the treated group. In the randomized trial, the response rate was higher in the 18 μg/kg group versus the 9 μg/kg group.[125] Denileukin diftitox is typically administered by a 30-minute venous infusion given on 5 consecutive days and repeated every 3 weeks for up to eight cycles.

Toxicities commonly encountered in the Phase III clinical trial of denileukin diftitox included acute hypersensitivity reactions including dyspnea, back pain, hypotension, and chest pain occurred in 60% of patients. Furthermore, a vascular leak syndrome characterized by hypotension, hypoalbuminemia, and edema was encountered in 25% of patients. Other toxicities may include constitutional symptoms, thrombotic events, infections, transaminase elevations, renal impairment, and lymphopenia. In total, 21% of the patients in this trial withdrew because of adverse events.[74] Subsequent investigations have suggested that pretreatment with corticosteroids substantially reduces the risk of acute toxicity.[126]

Histone Deacetylase Inhibitors

Vorinostat is a histone deacetylase inhibitor (HDAC) approved for use in patients with MF who have progressive, persistent, or recurrent disease following treatment with at least two prior systemic therapies. HDAC inhibitors increase accumulation of acetylated histones, resulting in decreased availability of nuclear DNA to bind to transcription factors. The decrease in transcription lowers intracellular protein levels, ultimately producing cell cycle arrest and apoptosis. In preclinical studies of MF cell lines, vorinostat has been shown to induce apoptosis and downregulate stat6.[127] Phase II clinical studies have reported clinical response rates of 25% to 30% in pretreated patients, with a modest median response duration of 15 weeks to 26 weeks.[128,129] Common toxicities include diarrhea, nausea, fatigue, and anorexia. Romidepsin is another approved HDAC inhibitor for relapsed/refractory CTCL. Initial single-arm studies suggest that the duration of response in treated patients is potentially even more sustained, with several patients who achieved response lasting longer than 3 years.[130,131] Other potential novel HDAC inhibitors include belinostat and panobinostat.[132]

Other Novel Agents

Studies are planned or ongoing to evaluate the role of monoclonal antibodies, purine nucleoside phosphorylase inhibitors, proteasome inhibitors, immunomodulatory drugs, synthetic oligodeoxynucleotides, fusion toxins, protein kinase C inhibitors, Toll-like receptor agonists, and antifolate agents. However, though feasibility testing for these agents is ongoing, the efficacy and role of these agents are not yet established.

Extracorporeal Photochemotherapy

Extracorporeal photochemotherapy (EP), also known as photopheresis, is a novel immune therapy that has shown activity in the treatment of erythrodermic MF.[109,133] Peripheral blood leukocytes are harvested by leukapheresis, mixed with 8-methoxypsoralen, exposed to 2 Joules/cm^2 of ultraviolet A, and then reinfused into the patient. This results in DNA cross-linking and gradual apoptotic death of the circulating MF cells that were exposed to psoralen + UVA. For unclear reasons, monocytes are resistant to the apoptotic effects of EP, but, instead are stimulated to become immature antigen presenting

dendritic cells because of the physical process of leukapheresis. Therefore, once treated leukocytes are reinfused into bloodstream, activated dendritic cells may phagocytose remnants of the apoptotic MF cells, present their antigens on major histocompatibility class I, and stimulate expansion of antitumor CD8+ T cells.[134]

EP is typically administered on 2 consecutive days every 4 weeks, although the frequency may be increased in patients with extensive disease.[135] For patients who achieve a complete response, therapy should be maintained for roughly 6 months and then gradually tapered. In general, EP is well tolerated, although hypotension, arrhythmias, and heart failure may occur because of fluid shifts. Patients with a history of cardiac disease therefore require close monitoring.[133] EP has been safely combined with IFN-α and TSEBT.[118,136,137]

Chemotherapy

Systemic chemotherapy is typically reserved for refractory cutaneous disease, visceral disease, or large-cell transformation. Chemotherapy is not typically used in the initial management of patients with MF because a randomized Phase III trial comparing concurrent TSEBT and systemic chemotherapy to sequential topical therapy failed to show an improvement in disease-free or overall survival.[138] For advanced, relapsed/refractory disease, the durability of response may be limited.

For patients who may benefit from chemotherapy, two main strategies exist. The first relies on oral agents such as methotrexate,[139] etoposide, or chlorambucil. This strategy avoids the need for central venous lines, which are associated with a high risk of infection because of frequent bacteremia caused by open skin lesions. The second strategy relies on intravenously administered chemotherapy. One exciting new prospect is pegylated liposomal doxorubicin, an agent that tends to remain intravascular but will extravasate into the inflamed lesional skin of MF. A pilot study conducted on 34 patients with CTCL reported complete response in 15 patients, partial response in 15 patients, and six severe adverse events.[140] Another notable agent is the nucleoside analog gemcitabine, which has been shown to induce complete response rates of approximately 10% and overall response rates of 70% without an increased risk of infection.[141] Attention has also focused on purine analogs such as fludarabine, 2′-deoxycoformycin, and 2-chlorodeoxyadenosine. However, clinical trials of these agents have produced response rates ranging from only 28% to 51% and have documented substantial toxicity, including myelosuppression, infection, and pulmonary dysfunction.[142-145] Other agents with activity in MF include the lipophilic antifolate trimetrexate[146]; 5-fluorouracil; cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP)[147]; etoposide, vincristine, doxorubicin, cyclophosphamide, and prednisone (EPOCH); cisplatin; etoposide; bleomycin; vinblastine[141]; and though early results are limited, temozolamide.[148]

High-Dose Chemotherapy with Autologous or Allogeneic Bone Marrow Transplant

Increasing experience has been reported using high-dose chemotherapy with either autologous or allogeneic transplant in the treatment of advanced or refractory MF. Autologous stem-cell rescue has resulted in several complete responses; however, relapses within 1 year are the rule rather than the exception.[149-151] In contrast, myeloablative or nonmyeloablative conditioning regimens with allogeneic transplant may result in prolonged disease-free survival. One series of three patients treated with cytoreductive chemotherapy and total body irradiation (TBI) found that two of the three patients remained disease-free at 4.5 years and 15 months after transplant. The third patient recurred after allogeneic transplant but developed a second complete response on withdrawal of prophylactic cyclosporine, suggesting a graft-versus-tumor effect.[152,153] In another series, six of eight patients with heavily pretreated, refractory MF who underwent allogeneic transplant with either TBI or non-TBI preparative regimens were alive without evidence of lymphoma at a median of 56 months posttransplant, but two deaths secondary to toxicity were reported.[154] Nonmyeloablative transplants have also been reported, with one series reporting clearance of clonal T cells and durable complete remissions in three out of three patients, although one died from infectious complications.[155]

More recent series report significant improvements in overall survival and progression-free survival, particularly in patients who received matched related transplantation. Another recent experience reported 68% overall response rate and 58% complete response rate using debulking with total skin electron beam and reduced conditioning regimen. Bacterial sepsis was a major complication reported in this series.[96] Overall, cumulative evidence supports the important role of graft-versus-lymphoma effect in producing durable remissions, lasting even up to several years in some cases.[94,95,156]

Collectively, these experiences strongly support the use of allogeneic transplant for younger patients with treatment-refractory, advanced MF.

Radiotherapy

Radiation is the most effective single modality in the treatment of MF[8] and plays an important role in the treatment of localized or disseminated cutaneous disease and in the palliation of skin and nodal and visceral metastases.

Dose

In general, a dose response has been reported both for radiation of single MF lesions and for TSEBT, and given that evidence, doses >30 Gy have served as the historical standard.[99] More recently, however, lower doses for TSEBT, as low as 12 Gy, have been considered. The clinical decision for an individual patient on planned dose for a single course of therapy concomitantly considers two issues: first, the minimum dose that produces a clinical response for a single patient may be somewhat idiosyncratic; and secondly, patients are expected to require repeat skin-directed therapies including repeat courses of radiation, with chronic relapses over time.

In an earlier study of 110 lesions from 14 patients with at least of 1 year follow-up, Cotter et al reported an infield recurrence rate of 42% for those treated to a total dose ≤10 Gy, 32% for 10.01 Gy to 20 Gy, 21% for 20.01 Gy to 30 Gy, and 0% for >30 Gy.[157] In a study of 30 lesions from patients with stage IA MF treated with localized radiotherapy, Wilson et al reported local failure in 20% (4 of 20 patients) treated with ≤20 Gy, compared with 0% (0 of 10 patients) treated with >20 Gy.[22] Kim et al treated different lesions from the same patient with various total doses and fraction sizes, finding that division of the total dose into two fractions separated by 1 or 7 days did not alter local control.[158] This suggests that the malignant cells of MF have minimal ability to execute sublethal damage repair and provides justification for using low daily fraction sizes to minimize normal tissue toxicity without sacrificing local control. Collectively, these experiences initially suggested that a durable response required total doses of 20 Gy to 30 Gy. To spare normal tissue toxicity and to ensure that patients can receive TSEBT in the future, fraction sizes of 1.2 Gy to 2.0 Gy are generally recommended.

Historically, the Stanford University experience with 176 patients undergoing TSEBT from 1958 to 1975 revealed that complete response rates increased with total dose: 18% for 8 Gy to 9.9 Gy, 55% for 10 Gy to 19.9 Gy, 66% for 20 Gy to 24.9 Gy, 75% for 25 Gy to 29.9 Gy, and 94% for 30 Gy to

36 Gy.[159] Similarly, patients treated with higher doses experienced improved overall survival, regardless of T stage. The experience at Hamilton Regional Cancer Center between 1977 and 1992 further supported the importance of high-dose TSEBT. From 1977 to 1980, 25 consecutive patients received 30 Gy TSEBT. From 1980 to 1992, 121 consecutive patients received 35 Gy TSEBT.[160] Treatment with high-dose TSEBT was an independent predictor of response, with a complete response rate of 64% for the 30-Gy group and 85% for the 36-Gy group. The EORTC previously recommended that TSEBT deliver a total dose of 31 Gy to 36 Gy to the skin surface to produce a dose of 26 Gy at a depth of 4 mm in truncal skin along the central axis.[161] Such doses were classically delivered over an 8-week treatment period, though a recent alternative schedule of 30 Gy in 20 fractions delivered over 5 weeks was reported with comparable response rates.[162]

Updated data continue to note an overall response rate of 100% to TSEBT with 60% complete response rate. In patients receiving a second course of TSEBT, 100% overall response rate was also seen, with a median duration of response of 6 months.

However, in a separate retrospective analysis of patients with T2 to T4 tumors, analysis stratified by TSEBT dose still noted excellent response rates in patients treated to 10 Gy to <20 Gy of 98% compared with 20 Gy to <30 Gy of 97%.[163] Given this newer evidence, the clinical potential of lower-dose TSEBT is being revisited.[164] Currently, National Comprehensive Cancer Network (NCCN) guidelines recommend treatment doses of 12 Gy to 36 Gy,[80] and our institutional experience suggests even lower doses, on the order of 8 Gy to 10 Gy can produce durable response for some patients.[90]

Clinical Results: Limited Superficial Radiotherapy

Approximately 5% of patients with stage IA disease present with a single skin lesion, or with two or three lesions in close proximity, such that all clinically apparent disease can be encompassed by either one field or several abutting fields.[22] Radiotherapy is the treatment of choice in this situation because results from three institutions have reported long-term disease-free survival in excess of 85%.[22,23,165] Wilson et al published a series of 21 patients with minimal stage IA disease managed with local, superficial radiotherapy.[22] Ten were treated with 100 Kv to 280 Kv and 11 with 4 MeV to 12 MeV electrons with appropriate bolus. The median dose was 20 Gy, and 17 of 21 received ≥20 Gy. With a median follow up of 36 months, the rate of complete clinical remission was 97% and the long-term disease-free survival was 91% among patients receiving ≥20 Gy. Similarly, Micaily et al reported an 86% 10-year disease-free survival in 18 patients with unilesional MF treated with localized radiotherapy to a median dose of 30.6 Gy.[23] In summary, radiotherapy for unilesional stage IA disease is an excellent first-line therapy given minor acute and chronic toxicities and excellent long-term results. Because few patients with two to four lesions have been reported in the literature, optimal treatment for this subgroup remains unclear. Although some advocate limited superficial radiotherapy, others advocate a strategy such as TSEBT or PUVA to treat all skin surfaces.

Clinical Results: Total Skin Electron Beam Therapy

Limited Patches or Plaques: T1 N0 M0 (IA) and T1 N1 M0 (IIA)

Initial treatment options for patients with patches or plaques involving less than 10% body surface area include topical corticosteroids, mechlorethamine, topical carmustine, phototherapy, bexarotene gel, and TSEBT. Currently, no randomized data exist to support selection of a radiation-based strategy over another topical strategy for this patient population. Although single-institution experiences suggest that patients managed with TSEBT may experience superior complete response rates and relapse-free survival, there is little strong evidence to suggest that this will translate into improved overall survival.

For example, patients with T1 disease treated with modern TSEBT experience a complete response rate of at least 90%[99,166] (Table 79-9), compared with a complete response rate of 65% to 70% for topical mechlorethamine.[77,103] Furthermore, 10-year relapse-free survival is roughly 50% for TSEBT[167] compared with 34% for mechlorethamine.[77] However, in this group of patients whose long-term survival is similar to healthy controls, initial treatment with TSEBT has not been associated with an overall survival advantage.[166] The administration of TSEBT for patients with stage IA MF as first-line therapy remains controversial, and although some reserve TSEBT for those refractory to standard therapies, others recommend TSEBT as first-line therapy for even pauci-lesional stage IA disease. For patients with limited patches, UVB therapy results in a complete response rate of roughly 80% with a median response duration of 2 years.[168,169] PUVA is appropriate for both patches and plaques, producing complete responses rates of at least 80%. Although relapse is common, most patients will respond to additional PUVA.[170,171] Similar to mechlorethamine, topical BCNU produced a complete response rate of

**This table contains data from Hamilton, Ontario, updated through 2004 and representative of the results of TSEBT as first-line therapy for stages IA and IB. Results shown for 222 patients receiving TSEBT alone document high rates of complete remission. For those who fail TSEBT, limited second-line therapies[142] may produce prolonged remissions, as indicated by the time to second progression outcome measure. Results shown for 32 patients receiving TSEBT plus adjuvant PUVA indicate that PUVA significantly improves progression-free survival rates (p = 0.03), with follow-up under 5 years as of 2004.[142]*

86%, partial response rate of 12%, and 5-year relapse-free survival of 35%.[105]

Recurrent or refractory T1 disease can still respond to TSEBT,[161] class I steroids (complete response 63%, partial response 31%),[101] interferon-α monotherapy (complete response 50%, partial response 35%),[113] topical bexarotene (complete response 21%, partial response 42%),[107] and oral bexarotene (complete response 7%, partial response 47%).[123] For example, data from Hamilton showed that 70% of patients were free of disease 15 years after first-line TSEBT and second-line salvage treatments as needed.[167]

Extensive Patches or Plaques: T2 N0 M0 (IB) and T2 N1 M0 (IIA)

TSEBT in such patients can demonstrate excellent response rates and rapid palliation. For example, complete response rates for T2 disease range from 76% to 90% (Table 79-9), compared with a complete response rate of 34% for topical mechlorethamine.[77,98,161] Adjuvant therapy following TSEBT is crucial for patients with T2 disease because 10-year relapse-free survival is only 10% in those treated with TSEBT alone.[167] Retrospective data from Yale University found that patients receiving adjuvant PUVA experienced a 5-year disease-free survival of 85% versus 50% for those not receiving adjuvant PUVA.[97] A prospective pilot study at Hamilton documented a similar benefit (Table 79-9). Retrospective data from Stanford University showed that patients treated with TSEBT and adjuvant topical mechlorethamine experienced 10-year relapse-free survival of roughly 40% compared to 10% with TSEBT alone.[98]

Patients with T2 disease who are relatively asymptomatic can receive treatment similar to that recommended for T1 disease. Topical corticosteroids may also be helpful for patients with extensive patches, with data suggesting a complete response rate of 25% and partial response rate of 57%.[101]

Again, topical mechlorethamine is a reasonable choice for these patients, resulting in a complete response rate of 34%, partial response rate of 38%, and 10-year relapse-free survival rate of 20%.[77] Similarly, BCNU produced a complete response rate of 47%, partial response rate of 37%, and 5-year relapse-free survival rate of 10%.[105]

As an alternative to topical chemotherapy, topical phototherapy may be considered for extensive patch or plaque disease. UVB should be reserved for extensive patch disease only because of its superficial penetration. In contrast, PUVA may be considered for patients with patches or thin plaques and has resulted in complete response rates of 60% to 100%.[101,170,171] Phase II trials suggest promising improvements in both complete response rate and duration of remission when adding IFN-α to PUVA for the treatment of T2 disease.[116,117,119]

Cutaneous Tumors: T3 N0-1 M0 (IIB)

Radiotherapy is an important treatment modality for cutaneous tumors because of its ability to treat the full thickness of deeply infiltrative lesions. For the rare patient with asymptomatic tumors involving less than 10% of the skin, either topical skin-directed therapy, along with local radiotherapy or TSEBT are reasonable first-line treatment options, with both producing a similar 5-year overall survival of roughly 50%.[98] However, most patients with T3 disease present with extensive, symptomatic tumors. Such patients often benefit from TSEBT as a first-line, palliative treatment because of a superior complete response rate as compared with topical HN2 plus localized radiotherapy, 44% to 54% versus 8%.[98,99]

Adjuvant therapy should be strongly considered for patients after completing a course of TSEBT, even as maintenance therapy after a complete response. Retrospective data suggest that adjuvant topical mechlorethamine may improve the duration of response, resulting in 5-year relapse-free survival of 55% compared to 30% with TSEBT alone.[98] Adjuvant photopheresis is another reasonable option, with retrospective data reporting 5-year overall survival of 100% for patients receiving this modality compared with 50% in patients who did not receive adjuvant therapy.[136] Other adjuvant therapies worthy of consideration include IFN-α, bexarotene, and denileukin diftitox.[172]

Erythroderma: T4 N0-1 M0 (III)

TSEBT is an appropriate initial therapy for erythrodermic MF because of its ability to produce a rapid and sustained response, thereby ameliorating the severe cutaneous symptoms experienced by such patients. Further, data suggest that TSEBT can result in a substantial reduction in the number of malignant cells circulating in the peripheral blood, potentially altering the natural history of the disease.[173,174] Retrospective data indicate that TSEBT monotherapy produced a 100% complete response rate and 5-year progression-free survival of 69% for patients with T4 N0 M0 B0 MF.[100] However, when including those with blood or visceral involvement, the complete response rate dropped to 74% and only 36% remained progression-free at 5 years. Patients with erythroderma and blood or visceral involvement are particular candidates who may benefit from adjuvant photopheresis because retrospective data suggest that such treatment improves 2-year cause-specific survival from 69% without EP to 100% with EP.[137]

For patients without access to TSEBT, several other topical treatment options exist. For example, a series of 10 patients treated with PUVA reported a complete response rate of 70% and median progression-free survival of 5 months.[175] Although not studied in a randomized setting, prospective phase II experiences suggested that addition of IFN-α to PUVA may improve the duration of response, in advanced disease.[115-117] Another option for T4 disease is photopheresis monotherapy because 80% of patients will experience at least some cutaneous improvement.[109] Patients with a normal peripheral blood CD4/CD8 ratio appear more likely to respond.[135]

Total Skin Electron Therapy: Toxicity

TSEBT is generally well-tolerated, and toxicity is minimized by using low daily fractions sizes[176] and a shielding regimen that reduces the dose to eyes, ears, lips, hands, and feet. Common acute toxicities from TSEBT include pruritus, dry desquamation, erythema, alopecia, xerosis, bullae of the feet, edema of the hands and feet, hypohidrosis (diminished perspiration),[177] and loss of fingernails and toenails.[167,178] Rare acute side effects include gynecomastia in men, mild epistaxis, and mild parotiditis.[167] Because of the superficial penetration of electrons, patients do not experience gastrointestinal or hematologic toxicities. In general, TSEBT does not cause serious long-term complications,[179] although permanent nail dystrophy, xerosis, telangiectasias, partial scalp alopecia, and fingertip dysesthesias have been described.[160] Second cutaneous malignancies including squamous cell carcinoma, basal cell carcinoma, and malignant melanoma have been observed in patients treated with TSEBT, particularly in those exposed to multiple therapies that are themselves known to be mutagenic, such as PUVA and mechlorethamine.[104,180]

PALLIATION

In current practice, for the majority of patients, age or performance status ultimately preclude allogeneic transplant, and therefore palliative treatment options remain a mainstay of therapy. A palliative approach usually includes novel biologic agents, cytotoxic chemotherapy, and radiation. For example, oral bexarotene has shown efficacy in patients with relapsed or refractory MF, producing an overall response rate of 57%

for stage IIB, 32% for stage III, 44% stage IVA, and 40% for stage IVB.[122] Another option, denileukin diftitox, resulted in an overall response rate of 30% for patients with treatment-refractory stages IB to IVA disease.[74] Systemic chemotherapy should also be considered and may result in complete response rates of 20% to 60%.[147]

Radiotherapy, including TSEBT, plays an important role in the palliation of both cutaneous and extracutaneous disease.[181,182] For those patients with extensive skin disease recurrent after TSEBT, a second course of TSEBT may produce substantial palliation with acceptable toxicity.[183] Typically median doses for repeat TSEBT courses after an initial course of >30 Gy tend to be lower, on the order of 18 Gy to 23 Gy. However, evidence suggests that lower doses can still achieve high rates of overall and complete response.[163,184] Toxicity of repeat TSEBT is typically characterized by xerosis, telangiectasias, pigment changes, and alopecia. Criteria for retreatment include complete response to the initial course, an extended disease-free interval after the initial course, diffuse cutaneous involvement at relapse, or failure of other modalities. Localized, symptomatic skin lesions can benefit from a local radiotherapy field, with options including higher doses on the order of 20 Gy to 30 Gy, or lower doses on the order of 8 Gy in two fractions or 7 Gy in one fraction.[185] Recent evidence suggests that the lower dose approach produces complete response rates in excess of 90%, and that retreatment with higher doses of radiation is safe and effective for those patients whose tumor recurs following low dose irradiation.[186] Finally, patients with symptomatic nodal or visceral disease often benefit from a course of palliative megavoltage radiotherapy to a total dose of 20 Gy to 30 Gy delivered in 2-Gy to 3-Gy fractions.

Follow Up

Follow up after definitive treatment for MF is best carried out by a multidisciplinary team with expertise in CTCL. Because most patients managed with TSEBT now receive adjuvant treatment, they remain in close contact with their dermatologists every 1 month to 3 months for many years. Biopsy of clinically borderline or suspicious lesions is important to document relapse and to rule out transformation to a large-cell variant. In addition, close surveillance is required to detect treatment-related skin cancers and ensure that appropriate therapy is initiated promptly. Patients with an elevated CD4/CD8 ratio, LDH, or soluble interleukin-2 receptor level at initial diagnosis should have these values followed closely to determine response to therapy.

TECHNIQUES OF IRRADIATION

Historical Development

Localized radiation was first used to treat MF in 1902, shortly after the discovery of x-rays.[187] In 1939, Summerville reported treatment of extensive cutaneous MF with an "x-ray bath" of kilovoltage photons delivered with two large fields.[188] A total air exposure of 900 roentgen delivered in daily fractions of 10 roentgen produced a complete response. In 1945, Levin and Behrman proposed that the total air exposure at the skin surface should be 600 roentgen to 800 roentgen for patches or plaques and 1000 roentgen to 1600 roentgen for tumors.[189]

The development of total skin electron beam therapy began in the early 1950s. Trump et al at the Massachusetts Institute of Technology used a Van de Graaff generator to produce a vertically oriented, stationary beam of 2.5 MeV electrons incident on a motorized couch.[190] By placing the patient in the prone, supine, and lateral decubitus positions and translating the couch through the electron beam, all skin surfaces could receive a meaningful dose. This treatment approach produced complete responses in two patients with extensive MF. In 1960, Stanford University reported the first method for linear accelerator-based TSEBT.[191] With a patient standing 10 feet from the end of the accelerator, two fields were treated, one directed above the patient's head and a second directed below the patient's feet. This approach is known as the dual-field technique. In addition, patients were treated in two positions with respect to the accelerator: anteroposterior and posteroanterior. Over time, it became clear that increasing the number of treatment positions improved dose homogeneity in the lateral dimension.[192,193] Ultimately, Stanford adopted a six-treatment position technique in which patients stand in six different orientations with respect to the accelerator: anteroposterior, posteroanterior, right and left anterior oblique, and right and left posterior oblique.[194] Although commonly called the "six-field" technique, it should be remembered that two fields are actually treated for each of the six treatment positions.

The first clinical results of TSEBT were published in 1962 by a group from St. John's Hospital for Diseases of the Skin in London.[195] Using the dual-field, four treatment position technique developed at Stanford, all five patients treated for MF experienced "very good" responses at total doses ranging from 12 Gy to 18 Gy. However, four of five patients relapsed within 8 months and disease was difficult to control in the axillae and perineum because of underdosing. In 1971, Stanford University reported 107 patients with MF who received TSEBT between 1957 and 1968.[194] Using a variety of doses, they produced a 52% complete response rate. In addition, among patients with localized patches or plaques, 30% experienced long-term disease-free survival, providing the first evidence that MF could actually be cured.

Target Volumes

The target volume for TSEBT should include the epidermis and dermis.[99] The thickness of the epidermis varies from 0.05 mm to 0.50 mm and is greatest in the distal extremities. The thickness of the dermis varies from 1 mm to 4 mm and is greatest in the hands and feet. Therefore, the thickness of the skin varies from a minimum of about 2 mm on the trunk to a maximum of about 4.5 mm at the hands and soles of the feet.[99] As a result, the EORTC TSEBT consensus statement recommends that the 80% isodose line should be ≥4 mm deep to the skin surface to ensure that the epidermis and dermis fall with the high-dose region. Because of their thickness, the deep margin of cutaneous tumors is often underdosed when treated with TSEBT alone and may require supplemental boosts with appropriately selected electrons to ensure adequate dose to areas typically underdosed such as axillae and perineum.

Limited Superficial Radiotherapy

Minimal stage IA disease should be treated with a single radiation field where possible, though abutting fields may be required at a convex surface such as the scalp, an axillary fold, breast, hand, or foot. The junction of abutting fields should be shifted during the course of treatment to improve homogeneity. Field margins can be limited by lead cut-out to only 1 cm to 2 cm beyond the visible (or palpable) clinical lesion. Electrons of 4 MeV to 16 MeV energy with appropriate bolus material are usually sufficient, and the dose should be approximately 8 Gy to 30 Gy (one to two treatments per week) with the expectation of durable response. One or several fields of 6 MeV to 16 MeV electrons can also be used to encompass the limited volumes required to palliate symptomatic skin lesions, including most tumor nodules and skin ulcers. Clinical regression can be seen at 12 Gy to 14 Gy and considered adequate for a first course of treatment, and in certain cases,

as low as 8 Gy is acceptable.[22,90,99,157] Treating with the lowest dose that induces clinical remission preserves as much radiation tolerance of the skin as possible and enables future delivery of local radiotherapy or TSEBT. Furthermore, in situations of coexisting cancer diagnoses (e.g., Hodgkin's, breast, prostate or rectal cancers), radiation treatments for those diagnoses must be carefully planned to minimize the superficial skin exposure to preserve the option of TSEBT in the future.

Node, Viscera, and Blood Radiotherapy

Nodal regions (e.g., axillary and inguinal) and some visceral organs (e.g., lungs, larynx, and brain) can be encompassed using standard beam arrangements and energies. Prescriptions are typically 20 Gy to 30 Gy in 10 to 20 fractions over 2 to 4 weeks.

Several experiences using TSEBT in combination with either low dose total body irradiation[196] or total nodal irradiation[197,198] have been reported. However, such treatment may increase the risk of secondary malignancies or myelodysplastic syndrome[198] and has not demonstrated superiority over conventional systemic agents. For patients undergoing allogeneic bone marrow transplantation, incorporation of TBI in the preparative regimen may be considered.[153]

TSEBT delivers a total dose to the blood and marrow of approximately 0.4 Gy in 30 or more fractions over 6 weeks to 14 weeks. In general, hematologic values remain normal during a course of TSEBT. However, for those with Sézary syndrome, the number of circulating Sézary cells may fall by 50% to 95% and, in rare instances, may remain in a sustained remission.

Modern TSEBT

Technical advances since the initial Stanford and St. John's publications have included dose escalation to 35 Gy to 36 Gy, improvements in shielding, and integration of boost treatments to underdosed regions, culminating in the publication of a consensus statement from the EORTC regarding appropriate techniques for TSEBT (Table 79-10).[161]

The method of TSEBT used at our institution achieves these objectives with a ≥4 MeV modern linear accelerator using the dual-field, six-treatment position technique. The patient stands 3 meters from the electron source, and the gantry is angled up and down at 113 degrees and 67 degrees to produce the dual-fields. A Lucite plate is placed in front of the patient and serves to scatter the incident electrons and attenuate x-ray contamination (Figure 79-4).

TABLE 79-10 EORTC Guidelines for Total Skin Electron Beam Therapy

- Dose inhomogeneity in air at treatment distance should be <10% within vertical and lateral dimensions.
- 80% isodose line should be ≥4 mm deep to the skin surface to ensure that the epidermis and dermis fall within the high-dose region.
- 80% isodose line should receive a minimum total dose of 26 Gy.
- 20% isodose line should be <20 mm from the skin surface to minimize dose to underlying structures.
- 30 to 36 fractions should be used to minimize acute side effects.
- Total dose to bone marrow from photon contamination should be <0.7 Gy.
- Patch treatments should be used to underdosed areas, such as the perineum, scalp, and soles of feet.
- Internal and external eye shields should be used to ensure that the dose to the globe is not more than 15% of the prescribed skin surface dose.

A total of six treatment positions are designated: anteroposterior, right and left anterior oblique, posteroanterior, and right and left posterior oblique (Figure 79-5). These positions maximize skin unfolding, thereby improving dose homogeneity in the lateral dimension. Each position is treated with two fields, an upper field and a lower field to maximize dose homogeneity in the vertical dimension. For example, on cycle one, the anteroposterior, right posterior oblique, and left posterior oblique positions are treated. On cycle two, the posteroanterior, right anterior oblique, and left anterior oblique positions are treated with the same dose. Over the course of two treatment cycles, a patient will receive 2 Gy to the entire skin surface. This pattern continues, with patients receiving one to two cycles per week for classically 6 weeks to 10 weeks (Table 79-11).

This technique places the dose maximum at 1 mm, the 80% isodose line at 6 mm, and the 20% isodose line at 12 mm,[199] thus satisfying the EORTC criteria for TSEBT[167] (Table 79-10). Photon contamination because of bremsstrahlung scattering in the machine head, intervening air, scatterers or degraders, and patient, is acceptable at 1.2%. A comparison of the depth-dose curves for a single anteroposterior treatment position and for all six treatment positions is presented graphically in Figure 79-6 and by film dosimetry in Figure 79-7.[199] Using six treatment positions shifts the isodose curve toward the skin surface because of the obliquity of the incident electrons.

As a result of the shielding inherent to these treatment positions, underdosed areas must be considered for supplemental treatment. Areas of potential underdosing include the shoulders, axillae, inframammary folds, folds under any

pannus, groin and medial thighs, perineum, and perianal area; though underdosed areas are dependent on body habitus. Obesity and idiosyncratic lateral and flatter regions or individual folds may determine other areas that are underdosed. The scalp may be underdosed, but is supplemented typically only if involved to decrease risk of alopecia. Therefore, supplemental patch fields should be guided by in vivo dosimetry along with clinical assessment and suspicion, to ensure that the surface dose is at least 50% of the prescribed TSEBT dose.[200,201]

The hands, and feet, as well as areas of the perineum receiving tangential beam may be overdosed as a result of a variety of factors including tissue heterogeneity (e.g., bone), high convexity, and overlap between more than three of the six primary fields.[99] Thus, these regions should be shielded for a certain proportion of the treatments to reduce the total dose to 32 Gy to 36 Gy or less. Upfront planning for cyclic blocking is warranted, particularly in the context of comorbidities such as diabetes (or other vasculopathy) that may further compromise skin integrity or worsen the morbidity associated with acute radiation skin toxicity. Detailed dosimetric measurements are typically required to determine the most appropriate shielding regimen using lead or other shielding material, for a particular treatment arrangement and patient geometry (Table 79-12). Eyes may be shielded with a combination of external eye shields and lead internal eye shields.[202] Although internal eye shields may cause conjunctival irritation and corneal abrasions, the risk is usually less than 1%[167] (Tables 79-10 and 79-11).

Because many tumors have a thickness greater than 6 mm, TSEBT alone may result in significant underdosing. As a result, for patients with bleeding, weeping, or painful tumors at presentation, an initial or concurrent boost of 10 Gy in five fractions with either 6 MeV to 16 MeV electrons or orthovoltage photons has been effective. In addition, asymptomatic plaques and tumors that persist at the end of treatment receive a similar boost to ensure adequate dose delivery at depth.

Other Radiation Management Issues

Cutaneous symptoms including xerosis, pruritus, and pain from fissures or ulceration are often severe and should be managed aggressively with topical corticosteroids, emollients, oral antihistamines, and aggressive wound care with nonocclusive dressings.[81] Acute skin toxicity from TSEBT usually responds to the above measures, although treatment breaks on the order of 1 week to 2 weeks may occasionally be required.[203]

Figure 79-8 Disseminated herpes simplex during the course of total skin electron beam therapy.

Large bullae that develop during TSEBT should be lanced under sterile conditions and require nonocclusive dressings until they reepithelialize.

As previously discussed, patients with advanced MF may experience a profound degree of immunosuppression. As a result, cutaneous and systemic infections are an important cause of morbidity and mortality. The most common infections include cellulitis resulting from *Staphylococcus aureus* or *β-hemolytic streptococci*, cutaneous herpes simplex or herpes zoster (both of which may disseminate cutaneously), bacteremia (most commonly with *S. aureus*), and bacterial pneumonia.[35] Signs and symptoms of such infections should be evaluated promptly and treated aggressively. Independent of MF, TSEBT also suppresses cutaneous immunity, likely as a result of destruction of normal skin-homing lymphocytes and epidermal antigen presenting dendritic cells. Thus, any new eruption that develops during the course of TSEBT should be evaluated promptly, as disseminated cutaneous bacterial, fungal, and viral infections are not uncommon[204,205] (Figure 79-8).

TREATMENT CONTROVERSIES, PROBLEMS, CHALLENGES, AND FUTURE POSSIBILITIES

A major challenge is the need for prospective randomized trials to compare radiation-based and nonradiation-based approaches to initial treatment. Adequately powered trials are problematic given the rarity of MF and difficulty in accruing patients. A recent Cochrane meta-analysis evaluated 14 trials that included 675 participants, the majority representing stages IA to IIB patients. Unfortunately, the efficacy of treatments could not be directly compared among the agents studied. Disease clearance was the primary outcome in most studies, with widely heterogeneous results, ranging from 0% to 83% response for skin-directed therapies.[206] This meta-analysis highlights ongoing challenges to prospectively evaluating treatment options for MF. In the absence of randomized data, treatment will continue to be guided by institutional expertise and patient preference.

The clinical management of patients with MF is complex and typically requires an interdisciplinary team approach that attends to the patient as a whole. Most patients require a fairly detailed understanding of the disease, its implications and risks, and all treatment options. The majority of patients are seeking a cure, which for many is unrealistic. Improvements in quality of life are possible regardless of presenting stage. The relative contributions of various factors in determining quality of life have not been systematically explored. However, clinical experience indicates that the most salient factors are controlling symptoms; achieving remission regardless of prior clinical trajectory; using treatments that are efficient and of limited duration (so as to be less disruptive to lifestyle and personal circumstances over the long term); addressing any anxiety and depression; and providing sustained and reliable support and expertise that extends into years and even decades of follow-up.

Many biologic and clinical questions pertaining to the pathophysiology and treatment of MF remain unanswered. For example, it is unclear whether the development of MF is initially driven by a specific exogenous antigen or by random mutational events occurring in activated T cells. In addition, the molecular factors that influence disease progression and response to various treatment modalities are just beginning to be elucidated. Clinically more studies with homogeneous patient populations are required to evaluate putative prognostic factors.

The future will likely bring additional novel systemic therapies for MF. For example, biologic and immunologic agents including monoclonal antibodies directed against CD4, CD52, CD25, and CD30, individualized dendritic cell-based tumor vaccines, HDACi, purine nucleoside phosphorylase inhibitors, proteasome inhibitors, immunomodulatory/immunostimulatory agents, fusion toxins, and antifolates continue to undergo investigation, with the goal of improving the

treatment of recurrent or refractory disease.[207,208] Strategies for integrating novel biologics with standard therapies such as TSEBT are needed to maximize the benefits of each. For long-term disease control and cure, allogeneic stem-cell transplant is an encouraging development, with present challenges focused on developing the optimal conditioning scheme and strategies to manage the complications.

Urethral cancer, brachytherapy for, 282, 282*f*
Urethral stenosis, penile cancer and, 1168-1169
Urinary reservoir, cutaneous, 1104.e1
Urinary tract reconstruction
  continent, 1104
  incontinent, 1104
Urothelial carcinoma, 200
Uterine cancer
  epithelial, classification of, 1205.*e1b*
  mesenchymal and mixed, 1205, 1205.*e1b*

Uterine sarcomas, treatment of, 1220
Uterine tumors, primary, 202-203
Uveal melanoma, etiology and epidemiology of, 541
Uveal metastasis, 548

V

VA Lung Cancer Study Group's Staging System, 800
Vaccines, for human papillomavirus infection, 600
Vagina, clear cell adenocarcinoma of, 1255, 1262-1263
Vaginal brachytherapy
  for endometrial cancer, 1225
    stage II, 1214
  for vaginal cancer, 1259-1260, 1260*t*
Vaginal cancer, 1230-1263
  adjuvant therapy for, 1254
  biologic characteristics of, 1254
  brachytherapy for, 1259-1260, 1260*t*
  chemoradiation for, 1259
  chemotherapy for, neoadjuvant, 1258.e1
  clinical manifestations of, 1255-1257
  complications of treatment for, 1261-1262
  diagnostic algorithm for, 1256, 1256*f*
  etiology and epidemiology of, 1254-1255
  external beam irradiation for, 1260-1261
  incidence of, 1254
  irradiation techniques and tolerance for, 1259-1262
  locally advanced disease and, 1259
  palliation of, 1254, 1259
  pathology of, 1254-1255
  pathways of spread of, 1255
  patient evaluation of, 1255-1257
  prevention and early detection of, 1255
  primary therapy for, 1254, 1257-1259
    invasive, 1257-1259
    rationale and general principles, 1257-1258, 1258*t*
    results, 1258-1259, 1258*t*
    VAIN, 1257
  salvage for, 1254
  staging of, 1254-1257, 1257*t*
  tolerance to treatment for, 1261-1262
  treatment algorithm and future possibilities for, 1262
  and vaginal intraepithelial neoplasia, 1254, 1257
Vaginal carcinoma, 1172
Vaginal cylinder brachytherapy, 279
Vaginal intraepithelial neoplasia (VAIN), 1254
Vaginal malignancies, nonsquamous, 1262-1263
Vaginal melanoma, 1262
Vaginal sarcomas, 1262
Vaginal vault brachytherapy, 279, 279*f*
Valence band, 112-113
Valvular heart disease, radiotherapy and, 267
VAMP chemotherapy, for Hodgkin's lymphoma, 1480
Vandetanib (Caprelsa), 81*t*-82*t*, 85-86
Variance, 239
Vascular brachytherapy, 292
Vascular disrupting agents, 58, 58*t*, 59*f*
Vascular endothelial growth factor (VEGF), 83*f*, 85
  antibodies against, 86
  for esophageal cancer, 845, 850
Vascular endothelial growth factor receptor-tyrosine kinase inhibitors (VEGFR-TKIs), 85-86
Vascular permeability, agents that increase, 404
Vascular response, to hyperthermia, 382, 382*f*
  and improvement in macromolecular and liposomal drug delivery, 382-384, 383*f*
Vascular supply, tumor cells and, 52, 52*f*
Vascular system, radiobiologic reactions in, 1373
Vascular targeting agents, tumor hypoxia and, 51, 58, 58*t*
  angiogenesis inhibitors as, 58
  vascular disrupting agents as, 58, 59*f*
Vasectomy, and prostate cancer, 1040.e1
Vegetative intermitotic (VM) cells, 27
Vemurafenib, 81*t*-82*t*, 177
Veno-occlusive disease (VOD), 347
Verification, for external beam treatment, 129-130, 129*f*
Verrucous carcinoma
  HPV and, 562
  of larynx and hypopharynx, 651, 661
  of vulva, 1232, 1252
Vertebral hemangioma(s), 538, 1381
Very low dose rate (vLDR) brachytherapy, 280, 281*t*
Vestibular schwannoma(s), 491
  biologic characteristics of, 491
  clinical manifestations of, 492
  combined-modality therapy for, 497
  etiology and epidemiology of, 491
  incidence of, 491
  with neurofibromatosis 2, 497-498
  pathology and pathways of spread of, 492, 492*f*
  patient evaluation in, 492, 494*t*
    for facial nerve function, 492, 494*t*
    imaging in, 492, 493*f*
    for sensorineural hearing loss, 492, 493*f*
  primary therapy for, 491, 494-498
  proton beam radiotherapy for, 363
  radiotherapy for, fractionated stereotactic, 495-499, 497*t*, 499*f*
  staging of, 491-492, 492*t*
  stereotactic radiosurgery for, 424, 424*f*, 495, 496*t*, 498, 498*f*
  surgery for, 494-495, 495*t*
  surveillance for, 497
  targeted therapy for, 497
  treatment algorithms for, 500, 500*f*
VHL gene, 1142
Vinblastine, 71, 181*t*
