CHAPTER

42 Malignant Melanoma

Matthew T. Ballo and Bryan Henry Burmeister

INCIDENCE

The incidence of melanoma continues to rise faster than that of any other cancer. It is estimated in 2015 that there will be 73,870 new cases of melanoma diagnosed and 9940 deaths in the United States.

BIOLOGIC CHARACTERISTICS

Sun exposure is clearly associated with the development of cutaneous melanoma. Inherited mutations may also play a role in some cases.

The natural history of melanoma is usually characterized by early, stepwise dissemination from a primary tumor to regional lymph node lesions and then to lesions at distant sites.

The main determinants of survival are the thickness of the primary tumor (measured in millimeters), the presence or absence of primary ulceration, the status of regional lymph nodes, and the sites of distant disease.

STAGING EVALUATION

For evaluating localized disease, a thorough history and physical examination including dermoscopy can suffice. For patients with nodal spread, the staging evaluation should include serum level measurement of lactate dehydrogenase and imaging with contrast-enhanced computed tomography (CT) and positron emission tomography (PET). Magnetic resonance imaging (MRI) of the brain should be considered, and it should be routine for patients with distant metastases.

PRIMARY THERAPY

Treatment of a primary melanoma lesion that is less than 0.75 mm thick is wide local excision alone. Sentinel lymph node biopsy is generally recommended for any lesion that is 1 mm or thicker or if ulceration or Clark level IV or V invasion exists in a lesion that is ≥0.75 mm and <1 mm. If the sentinel node is not involved, the patient may be observed, but if it is involved, complete lymph node dissection should be considered because it does offer a survival benefit in patients who are node positive.

If complete lymph node dissection is not possible because of medical comorbidities, elective radiation therapy to the involved nodal basin is preferred to observation.

ADJUVANT THERAPY

For patients at risk of nodal spread in whom sentinel lymph node biopsy will not alter subsequent management because of medical comorbidities, regional irradiation (i.e., elective irradiation) is preferred compared to observation.

Indications for postdissection nodal radiation therapy are high-risk pathological features including nodal extracapsular extension, lymph nodes measuring 3 cm or more in the widest diameter, at least two involved lymph nodes, and recurrent nodal disease after previous dissection for pathologically involved lymph nodes.

Adjuvant systemic interferon alpha-2b improves relapse-free survival for patients with thick, localized melanoma lesions and those with nodal metastases. It is however associated with significant toxicity.

LOCALLY ADVANCED DISEASE AND METASTASES

Palliative radiation therapy reduces symptoms in more than 80% of patients with inoperable disease or metastatic masses. Significant improvements in overall survival are seen in patients receiving systemic CTLA-4 blockers and BRAF inhibitors.

Malignant melanoma remains a predominantly surgically treated disease, and most patients with early-stage disease are cured by simple excision of the primary lesion. By the time growth of the primary tumor reaches a few millimeters, however, the risk of nodal and distant spread increases rapidly, and the role of adjuvant radiation therapy and systemic therapy takes on increasing importance. As for many diseases, radiation therapy is often recommended as an adjuvant to surgical dissection of locally advanced disease or as a palliative treatment of distant metastases. Until recently, the acceptance of radiation therapy as part of a standard treatment algorithm for patients with melanoma has been marred by controversy.

In the early 1930s, melanoma was considered to be categorically radioresistant. This belief was perpetuated by popular textbooks of the time until laboratory data showed that the reputed radioresistance of melanoma might reflect a broad shoulder in the low-dose portion of the cell survival curve. The data suggested that melanoma cells might be more sensitive to radiation delivered as a large dose per fraction (i.e., hypofractionation regimen). Although a randomized trial performed by the Radiation Therapy Oncology Group (RTOG) did not confirm clinical superiority for hypofractionation in a heterogeneous group of patients receiving palliative radiation therapy, these types of regimens are favored by clinicians specializing in melanoma radiation therapy.[1] Retrospective reviews of clinical experiences have suggested that the hypofractionated regimens are effective and can be safely delivered in a short period of time to a group of patients for whom survival is ultimately dictated by the risk of distant metastasis.[2,3]

Although hypofractionated radiation therapy has been shown to be effective in several clinical settings, the perceived risk of distant metastatic disease and concern over the rate of long-term radiation-related toxicity often precludes its use, regardless of effectiveness. In this chapter, we present the rates

of local failure, regional failure, distant failure, and long-term treatment-related toxicity for patients with melanoma and provide data supporting the use of radiation therapy in a defined group of patients. Only by balancing the competing risks of failure and treatment-related toxicity can physicians appropriately integrate radiation therapy into the management of patients with malignant melanoma.

ETIOLOGY AND EPIDEMIOLOGY

For 2015, 73,870 new cases of cutaneous malignant melanoma are estimated to occur in the United States, or 4.5% of all newly diagnosed cancers.[4] Although the incidence of malignant melanoma more than doubled between 1975 and 2000, new cases of melanoma are being diagnosed earlier in the course of the disease because of increased public awareness, and the mortality rate has steadily decreased.[4] The reason for the rise in incidence has not been explained. The number of deaths resulting from melanoma in 2013 was estimated to be 9480.

Several lines of evidence link sun or ultraviolet (UV) radiation exposure to the development of cutaneous melanoma.[5,6] There is a higher incidence of melanoma in populations with high levels of sun exposure, among sun-sensitive people, on sun-exposed body sites, in populations with high sun exposure, among people with other sun-related skin conditions,[7,8] and in those using artificial sources of UV radiation such as sunbeds. The development of melanoma may also be reduced by protection of the skin against sun exposure.[7]

Analysis of patients with familial clustering of melanoma has identified two genes, *CDKN2A* and *CDK4*, that confer increased susceptibility to melanoma development.[9] Although only a small percentage of patients with melanoma has a mutation in *CDKN2A*, carriers of this mutation have an almost 70% chance of developing melanoma by the age of 80 years.[10,11]

The presence of an increasing number of nevi also represents a well-accepted risk factor for the development of melanoma.[12] Whether the type of nevi (i.e., common, atypical, or dysplastic) is also important or merely reflects the degree of previous sun-related damage remains controversial.

PREVENTION AND EARLY DETECTION

Advocates of early detection and screening programs generally assume that early detection and treatment will significantly affect the mortality rate and the quality of life, particularly in melanoma, for which the association between tumor thickness and survival is well documented. Unfortunately, there are no randomized clinical trials to support routine screening of the general population. In the United States, routine screening of high-risk populations is still generally recommended, and educational efforts have been directed to clinicians and the public to promote early recognition of suspicious skin lesions. Periodic separate or mass screening for high-risk individuals consists of a total cutaneous examination and a 2- to 3-minute visual inspection of the entire integument by adequately trained physicians. Risk factors include a family history of skin cancer, fair skin, multiple nevi, and a history of melanoma or other skin cancers. Recognized signs of melanoma include the ABCDs of early diagnosis: A, asymmetry; B, border irregularity; C, color variation; and D, a diameter greater than 6 mm.

The U.S. Preventive Services Task Force (USPSTF)[13] performed a thorough review of the medical literature and issued a practice policy statement regarding skin cancer prevention counseling. Recommended preventive measures include avoidance of sunlight exposure—particularly limiting time spent outdoors between 10 AM and 3 PM—and wearing protective physical barriers such as hats and clothing and sunscreens that are opaque or that block UV A and B radiation.

CLINICAL MANIFESTATIONS, PATHOBIOLOGY, AND PATHWAYS OF SPREAD

Clinical Presentation and Pathology

Primary cutaneous melanoma may develop in or adjacent to one of the precursor lesions (e.g., lentigo maligna, dysplastic nevus) or in normal skin, and it can manifest clinically in four major growth patterns.[14] The most prevalent variant is *superficial spreading melanoma,* which constitutes approximately 70% of cases.[15,16] Superficial spreading melanoma often arises in a junctional nevus, where it first appears as a deeply pigmented area, progressing gradually to a flat induration, generally over several years. As the lesion grows, the surface and perimeter may become irregular with amelanotic patches. On histologic examination, it is characterized by a prominent intraepidermal proliferation of malignant melanocytes similar to Paget's disease; hence, this pattern is called *pagetoid melanoma*.[17] The malignant cell may be confined to the lower portion of the epidermis or may spread up into the granular cell layer of the epidermis, which is frequently hyperplastic. As the lesion enlarges, clusters of malignant cells invade the dermis and subcutaneous tissues.

Nodular melanoma is the second-most common variant (15% to 25% of melanoma lesions).[15,16] Nodular melanoma develops more frequently de novo on the trunk, head, or neck of middle-aged individuals. In contrast to superficial spreading melanoma, the nodular variant affects men more than women. It manifests as a raised or dome-shaped, blue-black lesion, which is usually darker than superficial spreading melanoma. Approximately 5% of nodular variants manifest as nonpigmented, fleshy nodules, and therefore, this type of lesion is called *amelanotic melanoma*. Histologic testing shows that nodular melanoma is characterized by an expansile nodule centered at the papillary dermis, with little or no epidermal component, composed of epithelioid cells. Spindle cells, small epithelioid cells, and mixtures of cells may be present. Deeper invasion of the dermis and subcutis occurs as the lesion grows.

Lentigo maligna melanoma is seen in less than 10% of malignant melanoma lesions.[16,18] This variant occurs most frequently on the face or neck of Caucasians older than 50 years, and it arises from a precursor lesion of melanoma in situ called *lentigo maligna* (i.e., *Hutchinson's melanotic freckle*).[19] It manifests as a relatively large (>3 cm), flat, tan-colored (with different shades of brown) lesion that often has been present for more than 5 years. The border becomes irregular as the lesion enlarges. On histologic examination, an invasive tumor is usually composed of spindle-like cells. These cells may be embedded in a fibrous stroma (i.e., desmoplastic pattern) or may form fascicles displaying neural features and infiltrating endoneural and perineural structures of the cutaneous nerves.[19,20]

Acral lentiginous melanoma occurs characteristically on the palms or soles or beneath nail beds.[21-23] The relative frequency of acral lentiginous melanoma varies substantially with race. It represents about 5% of melanomas in Caucasians and 35% to 60% in dark-skinned individuals.[24,25] Most acral lentiginous melanomas occur on the foot sole in individuals older than 60 years. They generally start as tan or brown stains and evolve over a period of years to reach an average diameter of 3 cm before a diagnosis is established.[22,23] Histologic testing reveals that early-stage acral lentiginous melanoma is composed of large, highly atypical, pigmented cells along the dermoepidermal junction in an area of hyperplastic epidermis. At the

invasive stage, infiltrating cells may be epithelioid or spindle shaped.[20] Sometimes, infiltration to deeper structures occurs, predominantly through the eccrine ducts.[17]

Biology and Patterns of Spread

Superficial spreading and lentigo maligna melanomas generally grow slowly over many years (i.e., radial growth phase). Left untreated, however, these lesions gradually invade the dermis and subcutis (i.e., vertical growth phase) and acquire metastatic potential. Acral lentiginous melanomas and, particularly, nodular melanomas have a shorter natural history, with rapid progression to the vertical growth pattern.

Previously, two microstaging systems were used. The Breslow system classifies lesions by the vertical thickness between the granular layer of the epidermis and the deepest part of invasion, measured with an ocular micrometer. In ulcerated lesions, measurements are made from the surface to the deepest part.[26] The Clark method categorizes lesions into five groups by the level of dermal or subcutis invasion: level I, confined to the epidermis; level II, invasion to the papillary dermis; level III, invasion to the papillary-reticular dermal interface; level IV, invasion to the reticular dermis; and level V, invasion to the subcutaneous tissue.[15] Of the two systems, tumor thickness is more accurate in predicting outcome, although level of invasion remains prognostic for patients with lesions less than 1 mm thick.[27]

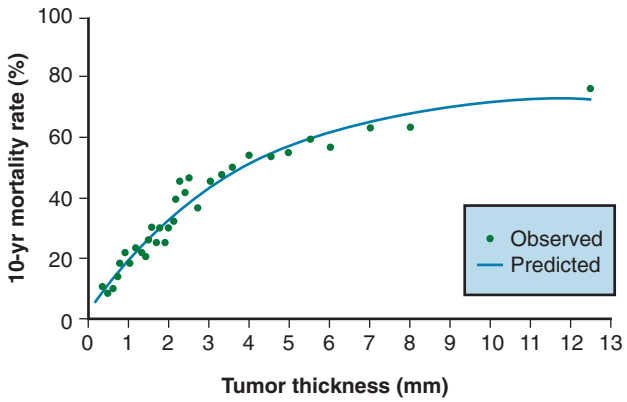
In an analysis of 17,600 patients with melanoma, several clinical and histologic variables were found to be of prognostic value, and they formed the basis for an updated American Joint Committee on Cancer (AJCC) staging system[27,28] (Table 42-1). For patients without clinical evidence of nodal spread, primary thickness and ulceration were the most important prognostic features. The 10-year melanoma-specific mortality increased proportionally as the thickness of the primary tumor increased (Figure 42-1), and the survival of patients with ulcerated primary lesions diminished to a level equivalent to that of patients with thicker primary lesions that were not ulcerated[27] (Figure 42-2). There was significantly inferior 10-year disease-specific survival (DSS) according to site of the primary lesion (i.e., worse for trunk, head, and neck lesions than extremity lesions), gender (i.e., worse for patients who were male than for those who were female), and age (i.e., worse for patients who were older than for those patients who were younger).[27]

For patients with documented nodal metastases, the most important prognostic feature was the number of involved lymph nodes, but primary tumor ulceration and burden of nodal disease (microscopic compared to macroscopic) remained of prognostic significance on multivariate analysis[27] (Table 42-2). Patients with skin, subcutaneous, and distant lymph node metastases fared better than those with visceral metastases.[27]

PATIENT EVALUATION AND STAGING

Suggested staging guidelines for patients with melanoma are shown in Table 42-3. Clinical evaluation of patients with melanoma consists of inspection and palpation of the involved area of skin and the regional lymph nodes. Patients with primary lesions 1 mm thick or larger are generally staged at the time of wide local excision with sentinel lymph node biopsy. Patients with thinner lesions may still be at risk of nodal disease and may benefit from sentinel lymph node biopsy if the primary lesion is ulcerated, is associated with satellitosis, or is Clark level IV or V. If the sentinel node is involved, CT scanning of the lungs, abdomen, and pelvis is warranted as a baseline evaluation.[29]

Chest radiography plays little or no role in the initial management of patients with localized disease. PET scans and MRI



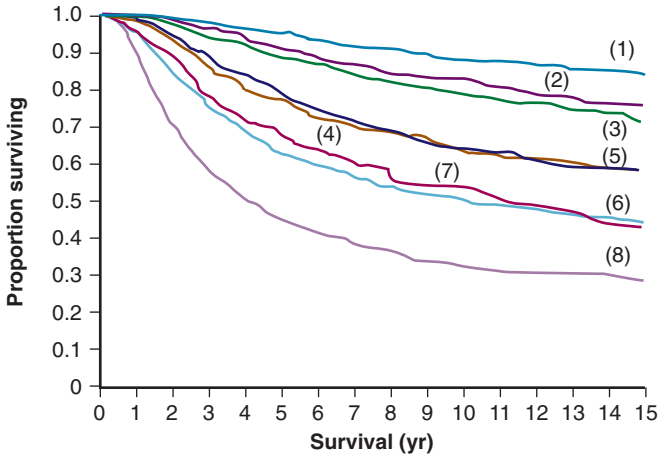


Figure 42-1 Observed and predicted 10-year mortality rate of 15,320 patients with clinically localized melanoma based on the mathematical model $f(t) = 1 - 0.998e(-211t = 0.009\ t_2)$, which is derived from the melanoma database of the American Joint Committee on Cancer (AJCC). t is the measured thickness (mm), and $f(t)$ is the 10-year melanoma-specific mortality rate ($p < 0.0001$).

PRIMARY THERAPY AND RESULTS

Primary Tumor

Standard treatment for localized melanoma (stages I and II) is wide local excision. Wide local excision is a therapeutic intervention, but it also establishes tissue diagnosis and provides accurate microstaging. Six randomized trials have examined the appropriate width of excision for primary melanoma.[30-34] The recommended skin margins vary from 1 cm to 2 cm depending on lesion thickness and location.[34,35]

Sentinel lymph node biopsy is recommended according to the aforementioned criteria (see "Patient Evaluation and Staging" section). This diagnostic procedure involves injection of the primary site with a dye and radiotracer-tagged colloid that localizes to the first draining lymph node or nodes after a short period of time. These nodes are then removed, serially sectioned, and examined with immunohistochemical staining techniques. Patients without involved lymph nodes are spared a comprehensive lymph node dissection. The procedure provides accurate nodal staging, but it should be followed by complete lymph node dissection or nodal radiation therapy if the sentinel node is involved. The rate of nodal spread according to primary thickness is shown in Table 42-4; it is less than 5% for lesions 0.75 mm or smaller, 10% for lesions 0.76 mm to 1.5 mm, 20% for lesions 1.51 mm to 4 mm, and 30% to 50% for lesions larger than 4 mm.[36-47]

Radiation therapy is not indicated as definitive management of primary malignant melanoma. An exception to this rule is large facial lentigo maligna melanomas for which wide surgical resection may require extensive reconstruction. In a series of 25 patients treated at the Princess Margaret Hospital with primary radiation therapy using orthovoltage x-rays (100 KeV to 250 KeV) and followed for a period of 6 months to 8 years (median, 2 years), local control was achieved in 23 patients (92%).[48] Regimens used were 35 Gy in 5 fractions over 1 week for lesions smaller than 3 cm, 45 Gy in 10 fractions over 2 weeks for primary tumors of 3 cm to 4.9 cm, and 50 Gy in 15 to 20 fractions over 3 to 4 weeks for tumors 5 cm or larger.

Radiation therapy is rarely recommended as an adjuvant to wide local excision as local recurrence rates are generally low (<10%). High-risk features such as primary thickness greater than 4 mm, head or neck primary site, and primary ulceration or satellitosis have been reported to significantly increase the risk of local recurrence, but few series report recurrence rates much higher than 15%[32,49-60] (Table 42-5).

One variant of melanoma, the desmoplastic subtype with neurotropism, has historically been associated with recurrence rates as high as 50% after wide local excision alone.[61-68] In a nonrandomized series specifically examining the role of radiation therapy in 150 patients with desmoplastic melanoma, a

recurrence rate of 24% (14 of 59 patients) was reported without irradiation and 7% (5 of 71 patients) with irradiation.[67]

Regional Nodes

Elective Nodal Treatment

The role of elective nodal therapy at the time of wide local excision of the primary tumor has been disputed extensively. Advocates of elective lymph node dissection argued that melanoma progresses in a stepwise fashion from the primary lesion to regional nodes and then to distant sites, whereas opponents suggested that positive regional lymph nodes are only indicators of systemic spread. Results of an early nonrandomized study by the Sydney Melanoma Unit[69] involving 1319 patients suggested that elective lymph node dissection improved the survival rates of patients with intermediately thick melanomas (0.76 mm to 4 mm), however, four prospective Phase III trials did not confirm these results.[70-73]

The surgical community has embraced sentinel lymph node biopsy with selective lymph node dissection as a replacement to elective lymph node dissection, despite no reported therapeutic benefits in terms of overall survival (OS). This choice depends on several lines of reasoning.[74,75] The status of the sentinel lymph node is a powerful determinant of subsequent survival and provides prognostic information to the patient; it identifies patients with early regional lymph node metastases that might benefit from nodal dissection as a way of avoiding advanced regional recurrence; and it identifies patients who may be candidates for investigational systemic therapy trials.

Morton et al[76] randomly assigned 1269 patients with intermediate-thickness primary melanoma to wide excision and postoperative observation of regional lymph nodes with lymphadenectomy if nodal relapse occurred, or to wide excision and sentinel lymph node biopsy with immediate lymphadenectomy if nodal micrometastases were detected on biopsy. This trial, known as the Multicenter Selective Lymphadenectomy Trial (MSLT-I), reported improved 5-year disease-free survival (DFS) when patients undergoing sentinel lymph node biopsy with selective lymph node dissection were compared with patients who were observed. There were no differences in melanoma-specific survival. In a subgroup analysis confined to patients with nodal metastases, there was improved melanoma-specific survival in patients undergoing immediate lymphadenectomy compared with those in whom delayed lymphadenectomy was required for recurrent disease. Although the validity of this postrandomization analysis has been questioned by many,[77] the prognostic information provided by sentinel lymph node biopsy was confirmed. A second Multicenter Selective Lymphadenectomy Trial (MSLT-II) is currently examining the role of ultrasound in the staging of patients who are clinically node negative and randomizing patients with involved sentinel lymph nodes to completion lymph node dissection or observation with periodic ultrasonography.

Although sentinel lymph node biopsy remains the standard approach to patients with early-stage melanoma, there are some patients with significant medical comorbidities for whom detailed prognostic information is of little relevance and enrollment in a clinical trial is unlikely. For these patients, elective nodal irradiation is superior to observation, which places the patients at unnecessary risk of regional recurrence.[78] In a retrospective analysis from the M. D. Anderson Cancer Center, Bonnen e al[79] reviewed 157 patients with stage I or II cutaneous melanoma of the head and neck who received elective regional irradiation instead of lymph node dissection after wide local excision of the primary site. Indications for regional irradiation included primary thickness of 1.5 mm or greater or Clark level IV or V disease. There were 15 regional failures (89% regional control at 10 years) despite estimation that 33 to 40 patients had microscopically involved regional nodes (based on data from Table 42-4). Six percent of patients required medical care for a clinically significant complication, with moderate hearing loss being the most common complaint (5 patients). Although elective nodal irradiation has the same limitations as elective lymph node dissection, it can effectively provide regional control for patients at risk for regional recurrence while avoiding surgical dissection.

Therapeutic Nodal Approaches

For most patients, nodal dissection results in more than an 80% likelihood of regional control. For patients with certain clinicopathologic features, however, the surgical literature suggests regional recurrence rates as high as 80% and, therefore, a need for additional regional therapy. Although nodal extracapsular extension remains the strongest predictor of subsequent regional recurrence after surgery alone, several series have reported elevated recurrence rates if at least four lymph nodes are involved, the lymph nodes measure at least 3 cm in diameter, they are located in the cervical basin, or they are detected during a therapeutic dissection (as opposed to elective dissection or at the time of sentinel lymph node biopsy).[80-85] Although less well described in the literature, nodal recurrence after previous dissection for involved regional nodes also places the patient at increased risk of subsequent relapse. Patients with one of these six clinicopathologic features have a 30% to 50% rate of subsequent regional recurrence after nodal dissection alone (Table 42-6).

There are substantial retrospective data supporting the effectiveness of regional radiation therapy for patients with one of the aforementioned high-risk features. Relapse rates after adjuvant radiation therapy range from 5% to 20%, compared with the much higher range seen without adjuvant irradiation.[83,86-96] The Trans-Tasman Radiation Oncology Group and the Australia and New Zealand Melanoma Trials (TROG/ANZMTG) group completed a randomized trial comparing nodal observation with radiation therapy after lymphadenectomy in patients with palpable nodal disease and high-risk features.[97] High risk features included one or more involved parotid nodes, two or more involved cervical or axillary nodes, or three or more involved inguinal nodes; presence of extranodal tumor spread; or the maximum diameter of the largest metastatic lymph node was 3 cm or more (for a cervical node) or 4 cm or more (for an axillary or inguinal node). Patients received 48 Gy in 20 fractions over 4 weeks to standard conventional fields. Although there was no improvement in overall survival, this trial reports acceptable acute toxicity and 5-year regional control of 77% with radiation therapy compared with 60% without it ($p = 0.023$).

Tolerance to adjuvant radiation therapy is generally excellent and early toxic effects are infrequent and minor. Most patients receiving comprehensive neck irradiation experience transient parotid swelling after the first radiation fraction that

typically lasts 1 day. For most sites, brisk erythema with patches of moist skin desquamation, particularly within the axilla and the groin, are common. In the TROG/ANZMTG randomized trial, late radiation-related complications were distinctly uncommon, except for an increase in subcutaneous fibrosis in the adjuvant radiation therapy arm. Clinically significant extremity lymphedema (requiring some form of medical management such as a compressive sleeve or physical therapy) occurs in a minority of patients. It is more common after groin dissection than after cervical or axillary dissection, and it appears to moderately increase further in the setting of adjuvant irradiation, particularly for patients with locally advanced groin metastases[85,93-102] (Table 42-7). In one series examining the timing of lymphedema, however, half of the patients had developed lymphedema before starting adjuvant groin irradiation.[95] This suggested that the higher rate of lymphedema was to some extent a consequence of locally advanced disease and its surgical treatment and not solely the result of the radiation therapy. In this same series, there was a correlation between body mass index and the development of chronic lymphedema, suggesting that patient factors need to be incorporated into rational treatment guidelines.[95] In the randomized trial there were no differences in quality of life, although regional symptoms were worse in those patients receiving radiation therapy.

Significant on multivariate analysis.

Distant Disease and Adjuvant Systemic Therapy

A great amount of resources has been directed toward developing effective systemic therapy for patients with melanoma. Although surgical resection with selective use of adjuvant radiation therapy results in satisfactory local and regional control for most patients, even thin melanomas have significant metastatic potential. Most research initiatives have focused on interferon alpha-2b (IFN) or vaccines, or combinations of both. European investigators have examined the role of low-dose IFN therapy, and U.S. investigators have focused primarily on high-dose regimens. Three randomized Eastern Cooperative Oncology Group (ECOG) trials are used to support the use of adjuvant IFN for patients with a high risk of recurrence.[103-105]

The first trial (ECOG 1684) enrolled 287 patients with primary melanomas thicker than 4 mm without palpable nodes, lymph node metastasis detected at elective lymph node dissection, a clinically palpable regional lymph node with primary melanoma of any stage, or regional lymph node recurrence at any interval after appropriate surgery for primary melanoma of any depth.[103] This prospective study revealed a significant prolongation of relapse-free survival (RFS) (5-year actuarial, 37% versus 26%; $p = 0.002$) and OS (5-year, 46% versus 37%; $p = 0.02$) associated with high-dose IFN therapy (i.e., intravenous administration five times per week for 4 weeks, then subcutaneous administration three times per week for 48 weeks). The overall benefit of treatment in this trial was correlated with the tumor burden and the presence of microscopic nonpalpable and palpable regional lymph node metastases. The benefit of therapy with IFN was greatest among recipients with palpable regional nodal metastases or nodal recurrences.

The second trial (ECOG 1690) compared high-dose IFN for 1 year or low-dose IFN for 2 years versus observation.[104] Intent-to-treat analysis revealed 5-year RFS of 44% and 40% for the high-dose and low-dose IFN arms, respectively, compared with 35% in the observation arm ($p = 0.05$ for high-dose IFN versus observation, and $p = 0.17$ for low-dose IFN versus observation). Most of the benefit was observed for patients with two to three involved lymph nodes. For OS, there was no difference demonstrated for the three treatment arms (52%, 53%, and 55% for high-dose IFN, low-dose IFN, and observation, respectively).

TABLE 42-7 Clinically Significant Lymphedema According to Site of Regional Disease and Treatment

	Wrightson et al[99]	2003	32			

Clinically significant lymphedema required some form of medical management (e.g., compressive device or physical therapy).

The third trial (ECOG 1694) compared high-dose IFN with a ganglioside GM2 melanoma vaccine.[105] After 880 patients were randomized to one of the treatment arms, an interim analysis indicated inferiority of the ganglioside vaccine with respect to RFS and OS. In a subgroup analysis, however, the beneficial effects of IFN were seen only in the patients with stage T4N0 disease and not those with nodal disease.

Debate over the merits of routine IFN therapy has focused on the inconsistent subgroup analysis findings and concerns about the toxicity of IFN, but it is not unreasonable to recommend one year of IFN for patients with thick tumors (>4 mm thick), ulceration, a high mitotic rate (≥1 per mm^2), or nodal metastases.[106]

Frequently observed regression of primary melanoma and even occasionally metastatic disease has suggested an important role for the immune system. This has fueled a long-standing search for active immunotherapies against melanoma. Interleukin-2 has shown durable response rates in 15% of patients and is considered a reasonable first option for patients with metastatic disease with sufficient performance status to tolerate its significant toxicity.

Until recently, none of the immunologic approaches had demonstrated clinical efficacy in terms of OS. However, the U.S. Food and Drug Administration recently approved new drugs as treatment for metastatic melanoma based on Phase III trial data reporting improvement in OS.

The BRAF kinase inhibitor vemurafenib blocks the mitogen-activated protein kinase (MAPK) signaling pathway that normally promotes cell proliferation and contains BRAF kinase as one of its components. Oncogenic (i.e., abnormal) BRAF kinase has been reported in almost 50% of cutaneous melanomas resulting in uncontrolled activation of the MAPK pathway. In 675 patients randomized to either vemurafenib or dacarbazine there was an improvement in the 6 month OS (84% versus 64%, $p < 0.001$) with vemurafenib and a response rate of 48%.[107] Vemurafenib should be considered in patients with untreated metastatic disease, but genetic mutation analysis is essential to verify the appropriate BRAF mutation (V600E) is present. A second BRAF inhibitor, dabrafenib, was also tested against dacarbazine in 250 patients with the V600E mutation and resulted in improved progression-free survival.[108]

The human monoclonal antibody Ipilimumab blocks cytotoxic T-lymphocyte–associated antigen 4 (CTLA-4) and stimulates an antitumor T-cell response. In 676 patients with stage III or IV disease ipilimumab was given either alone or with gp100 vaccine and compared to a third group receiving gp100 vaccine alone. The median survival was improved in both groups receiving the ipilimumab when compared to the gp100 group (10 months versus 6.4 months, $p < 0.001$).[109] In a second trial of 502 patients with untreated metastatic melanoma ipilimumab was given with dacabazine and compared to dacarbazine plus placebo and resulted in significantly improved OS at 3 years (20.7% versus 12.2%, $p < 0.001$).[110] Ipilimumab should be considered in patients with untreated receptor negative (e.g. BRAF, cKit) metastatic disease. When temporally combined with radiation ipilimumab has been reported to result in regression of disease distant from the irradiated site suggesting the possibility of an immunologically mediated abscopal effect.[111] Trials involving combinations of targeted therapy and radiation therapy are under way to determine if responses can be improved.

LOCALLY ADVANCED DISEASE AND PALLIATION

Radiation therapy can reduce symptoms for more than 80% of patients with advanced inoperable or metastatic disease. The recommended dose-fractionation schedule for external beam therapy depends on the tumor's location and the patient's life expectancy. The most frequently used regimens are 30 Gy given in 10 fractions over 2 weeks for skeletal or multiple cerebral metastasis, 36 Gy in 12 fractions for pathologic fracture of extremity bones (after internal fixation), 50 Gy in 25 fractions for solitary metastases after resection or radiosurgery (brain), and 36 Gy in 6 fractions over 3 weeks (twice each week) for dermal or subcutaneous melanoma masses or for neck node metastasis. Conventional fractionation schedules may always be considered if tumor lies near critical structures. The use of stereotactic ablative radiation therapy has gained considerable attention recently for the management of oligometastases from melanoma in the brain, lung, bones, spine, and liver. Dose schedules vary according to the tumor volume and site of disease but are generally well tolerated.

RADIATION THERAPY TECHNIQUES

Target Volume

Adjuvant radiation therapy for primary melanoma should encompass the primary site scar with a 3-cm to 4-cm margin, depending on the anatomic site and surrounding critical structures.

The target volume for patients receiving *elective nodal irradiation* for *head and neck primary sites* includes the primary lesion, the preauricular and postauricular lymph nodes (for high facial and scalp primary tumors), and the ipsilateral lymph nodes from levels I through V, including the ipsilateral supraclavicular fossa (Figure 42-3). For patients receiving therapeutic nodal irradiation for one of the aforementioned high-risk nodal features, the target volume is essentially the same, including the dissection scar, except that the primary tumor bed is irradiated only if regional relapse occurred less than 1 year after excision of the primary disease.

For *axillary nodal metastases,* radiation fields include the axillary lymph nodes from levels I through III (Figure 42-4). The supraclavicular fossa and low cervical lymph nodes may be included if there is bulky high axillary disease but otherwise do not need to be treated.

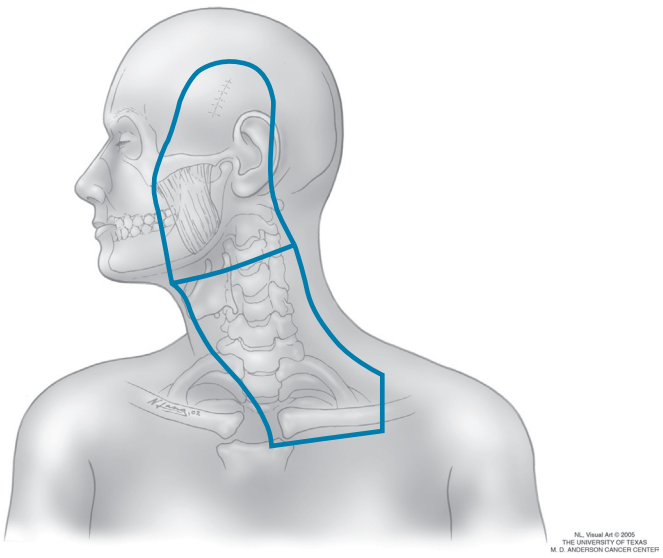

Figure 42-3 Typical external beam radiation treatment field for a patient with cervical lymph node metastases. A similar field is used for a patient requiring elective irradiation.
Courtesy NL Visual Art © 2005, The University of Texas M. D. Anderson Cancer Center, Houston, Texas.

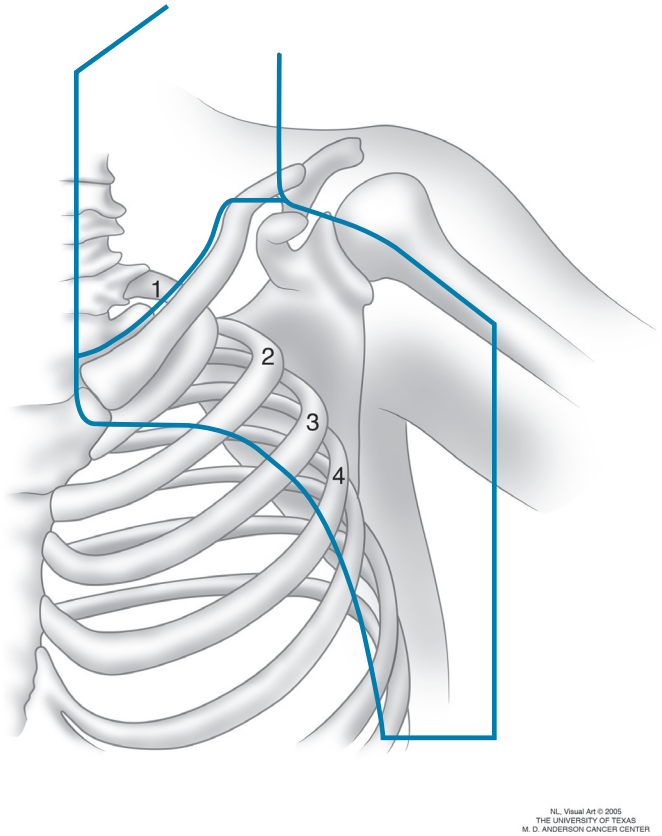

Figure 42-4 Typical external beam radiation treatment field for a patient with axillary lymph node metastases. Numbers correspond to the ribs. The upper border of the field typically ends at the superior aspect of the clavicle, but the supraclavicular and cervical lymph nodes may be irradiated if clinically involved.

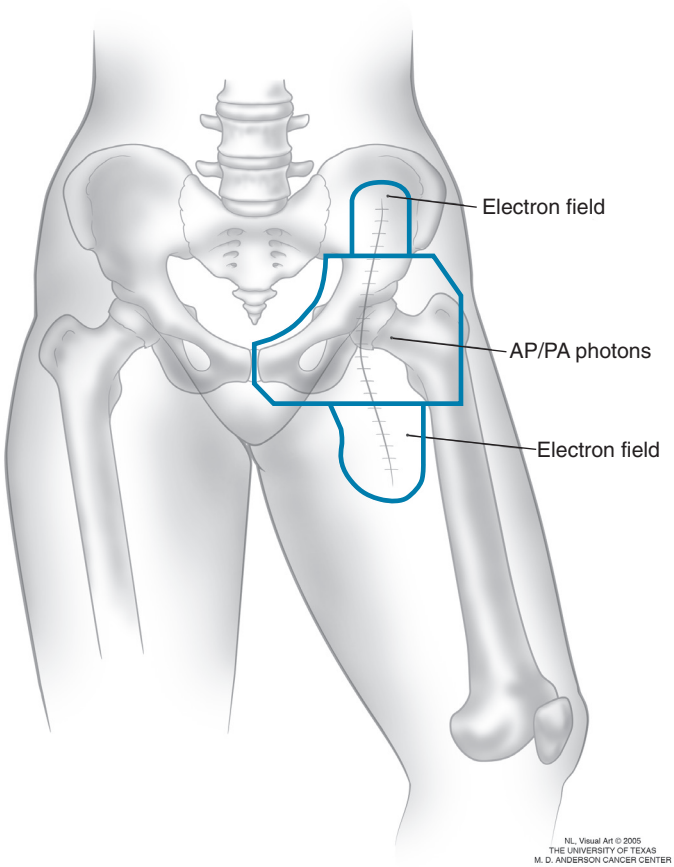

Figure 42-5 Typical external beam radiation field for a patient with groin lymph node metastases.
Courtesy NL Visual Art © 2005, University of Texas M. D. Anderson Cancer Center, Houston, Texas.

At a minimum, a field for groin lymph node metastases covers the nodal regions that have pathologically confirmed nodal disease and usually includes the entire surgical scar (Figure 42-5). Judgment must be used regarding elective irradiation of adjacent nodal regions (i.e., external iliac coverage in the setting of confirmed inguinal disease) because of concern about the increased toxicity associated with groin irradiation, particularly for patients who are obese. Unlike the cervical or axillary regions, where electrons and flashing photon fields, respectively, generally deliver a full dose to the skin, special attention must be paid to delivering a full dose to the groin scar.

Setup, Field Arrangement, and Dose-Fractionation Schedule

For patients with cervical disease, an open neck position provides access to the primary site and parotid and cervical lymphatics, and it allows treatment delivery with electrons of appropriate energy. Lesions of frontal, temporal, and preauricular areas; the auricle; and the cheek are usually treated with two or three fields, depending on the distance between the primary tumor and the parotid nodes. Matching electron fields are used to treat the primary site, the parotid and lower neck nodes. The junctions between the fields are moved (0.5 cm to 1 cm) after the second and fourth treatments to improve dose homogeneity. A tissue-equivalent bolus is placed over a line connecting the lateral canthus and the mastoid tip to spare the temporal lobe, and an additional piece of bolus may be placed over the larynx. The thickness of this bolus depends on the electron energy used. Elective or adjuvant radiation treatment is administered to a total dose of 48 Gy in 20 daily fractions (Monday through Friday) or 30 Gy at 6 Gy per fraction, twice each week (Monday and Thursday or Tuesday and Friday) over 2.5 weeks. Electron doses are specified at D_{max} (maximal depth dose) and care is always taken to ensure that the dose to the spinal cord does not exceed 40 Gy at 2.4 Gy per fraction or 24 Gy at 6 Gy per fraction.

For axillary treatment, the patient is immobilized in a supine position with the treatment arm akimbo. Laser lines that include the upper and lower torso ensure a reproducible treatment setup. Typically, anterior and posterior photon fields are used to deliver the dose to the levels I, II, and III axillary lymph nodes. Dose homogeneity is ensured using a field-within-a-field technique (using multileaf collimators). The radiation dose is 48 Gy in 20 daily fractions or 30 Gy at 6 Gy per fraction, twice each week over 2.5 weeks. If necessary the dose may be prescribed to a volume such that the isocenter dose is 3% to 6% lower than the prescribed dose as dose heterogeneity can result in unacceptable toxicity at these doses per fraction.

To irradiate the groin, patients are immobilized in a unilateral frog-leg position, eliminating any inguinal skin folds.

Photons or electrons can be used depending on the patient's contour, extent of surgical bed and whether the pelvic nodes are included as part of the target volume. Lower-energy electron fields can be used superiorly and inferiorly to cover the full extension of the scar. If a photon technique is selected, a tissue-equivalent bolus is used over the scar, and the dose is weighted anteriorly. Doses are either 48 Gy in 20 daily fractions or 30 Gy at 6 Gy per fraction, twice each week over 2.5 weeks. Appropriate reductions are made to limit the small bowel dose to 40 Gy at 2.4 Gy per fraction or 24 Gy at 6 Gy per fraction.

For all sites of regional disease, intensity-modulated radiotherapy (IMRT) may also be used to cover the aforementioned regions. IMRT is currently under investigation as an alternative technique aimed at reducing toxicity.

Radiation Therapy for Bulky or Inoperable Nodal Disease

Radiation therapy can be considered for bulky or inoperable nodal disease in which surgery is likely to be incomplete or the extent of the nodal disease would predict a poor OS. Similar techniques used in the postoperative setting can be used with surgery to follow 10 to 12 weeks later if the patient continues to have localized disease.

Patient Care during and after Radiation Therapy

Patients are informed of the specific acute side effects of treatment, such as mucositis and parotiditis after irradiation of the cervical basin and moist desquamation after irradiation of the axilla or groin. After moist desquamation occurs, cleaning the area with mild soap and water to prevent secondary infection is recommended.

Regular follow-up examinations include evaluation of the treated area for late complications and a search for potential relapse. The most common late side effects include hypopigmentation, hyperpigmentation, telangiectasia, and skin and subcutaneous tissue atrophy. After cervical irradiation, monitoring for subclinical hypothyroidism and the signs and symptoms of hearing loss, although relatively uncommon, is essential. Acute lymphedema is managed early and aggressively with physical therapy and compressive devices to avoid chronic lymphedema.

TREATMENT ALGORITHMS AND CLINICAL TRIALS

Elective Nodal Treatment

Sentinel lymph node biopsy has obviated routine elective treatment of the draining lymphatics of patients with thick primary melanomas. Although retrospective studies of elective irradiation have verified the effectiveness of this approach, sentinel lymph node biopsy with complete lymph node dissection has become accepted as the standard of care. For patients whose medical comorbidities preclude sentinel lymph node biopsy (and the required comprehensive dissection if the sentinel node is involved), elective nodal irradiation is favored over observation, which reduces the risk of regional recurrence with its associated morbidity. Although this approach is still investigational, it is suggested that patients with a positive sentinel lymph node biopsy result who refuse subsequent dissection be referred for regional irradiation. Observation in the setting of an involved sentinel lymph node is not appropriate, and systemic therapy is not a substitute for completing regional therapy.

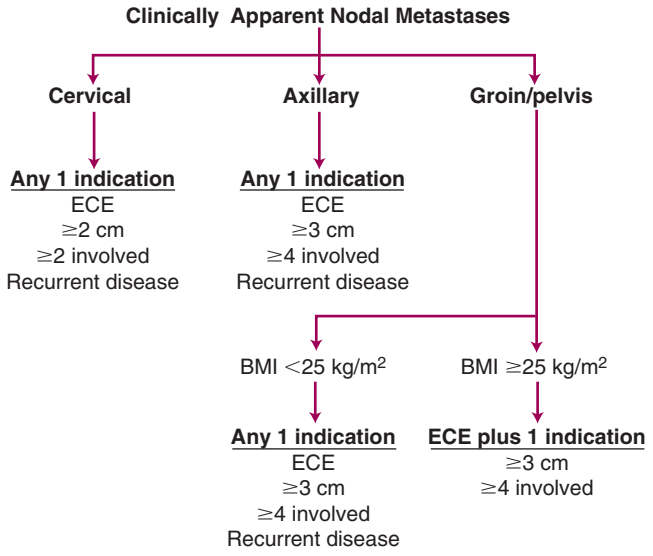

Figure 42-6 Treatment algorithm for patients with nodal metastases from melanoma. Typically, the threshold for irradiating patients with cervical lymph node metastases is lower than for those with inguinal lymph node metastases, for which the risk of long-term lymphedema is higher. *BMI*, Body mass index; *ECE*, extracapsular extension.

Therapeutic Nodal Approaches

Therapeutic nodal dissection is the standard treatment for patients with lymph node metastases, and available data support the use of systemic, high-dose adjuvant IFN. Adjuvant postoperative irradiation is also indicated to reduce the regional recurrence rate in patients with high-risk clinicopathologic features. Although some of the same features that predict regional failure, such as extracapsular extension and number of involved lymph nodes, also predict distant failure, the importance of regional control should not be underestimated, and radiation therapy should not be systematically avoided because the risk of distant metastasis is perceived to be too high.

We have developed radiation treatment guidelines that account for the complex clinical interaction between the risk of regional recurrence, the risk of regional toxicity, and the risk of distant metastatic disease (Figure 42-6). For patients with cervical disease, the threshold for irradiation may be lowered to include those with at least two involved lymph nodes or those with tumors measuring at least 2 cm in diameter. For patients with groin metastases, the threshold may be raised so that combinations (two or more) of the high-risk features must be present before adjuvant irradiation is given.

ACKNOWLEDGMENTS

To K. Kian Ang for demanding excellence.

Overview

Jeffrey A. Bogart

Primary thoracic neoplasms are reviewed in detail in the chapters of this section. In this overview, we consider developments and controversies in the diagnosis and treatment of non–small cell lung cancer (NSCLC), small cell lung cancer (SCLC), esophageal cancer, thymic tumors, pulmonary carcinoid, and mesothelioma.

EPIDEMIOLOGY

Lung Cancer

Lung cancer is the most common and deadliest thoracic malignancy, accounting for approximately 3000 deaths each week in the United States.[1] Exposure to tobacco smoke is the most common cause of lung cancer, with 85% to 90% of cases directly linked to active or passive tobacco exposure.[2] Lung cancer mortality rates have been trending downward in men because of reductions in smoking prevalence dating back to the mid-1960s, whereas mortality rates in women started to stabilize only in 2003. There is substantial geographic variation in the United States, with California the only state with decreasing lung cancer incidence and death rates in women.[3] Exposures to several occupational respiratory carcinogens have been controlled in developed nations, but environmental exposure to radon, the second-leading cause of lung cancer death, remains problematic.[4] Lung cancer in never-smokers is increasingly recognized as a distinct entity, described in greater detail in Chapter 44, and is the seventh-most common cause of cancer worldwide. Most of these cancers occur in women, and geographic, cultural, and genetic differences and hormonal factors have been implicated.[5]

The median age of patients who present with lung cancer is 70 years.[6] Lung cancer is broadly separated into SCLC and NSCLC types, and NSCLC accounts for approximately 80% to 85% of cases. Less than 50% of patients with NSCLC have resectable disease on initial presentation, and 25% of patients present with locally advanced (regional lymph node involvement without distant metastases) disease. Approximately 30% of patients with SCLC have limited-stage disease on presentation.[7]

Esophageal Cancer

In 2013, an estimated 17,990 patients Americans were diagnosed with esophageal cancer, and the incidence of esophageal cancer has increased approximately 15% during the past two decades.[8] Patients with esophageal cancers often present with advanced-stage disease, and most eventually die of their disease. Approximately 50% of patients present with locally advanced disease, and another 30% to 40% present with systemic metastases.[9]

Esophageal carcinomas are divided into squamous cell carcinoma and adenocarcinoma, each of which has a distinct epidemiology. Adenocarcinoma is associated with gastroesophageal reflux disease, Barrett's esophagus, obesity, and male gender. Squamous cell carcinoma is associated with alcohol and tobacco exposure, nutritional deficits, and lower socioeconomic status.[10] Although the incidence of squamous cell carcinoma has remained stable in the United States, the incidence of esophageal adenocarcinoma has increased dramatically over the past several decades, surpassing squamous cell carcinoma as the most common esophageal cancer in the United States.

Thymic Neoplasms

Thymoma is the most common tumor in the anterior mediastinum. Most thymic neoplasms arise in the epithelial cells of the thymus. The incidence of thymoma in the United States is estimated to be 0.13 to 0.15 per 100,000 people.[11] The median age of patients with thymoma is older than 50 years, and thymomas are diagnosed equally in men and women.[12] Thymic carcinomas account for a minority of all thymic neoplasms,[13] and they are more aggressive than thymomas.[14] Thymic carcinoids represent less than 5% of anterior mediastinal tumors, but they have a higher rate of regional lymph node metastases on presentation compared with carcinoids found in other locations in the body.[15]

Pulmonary Carcinoid

Pulmonary or bronchial carcinoid tumors are often low-grade neoplasms that arise from bronchial mucosal cells known as enterochromaffin cells or Kulchitsky cells.[16] These specialized cells are capable of producing bioactive amines, which cause carcinoid syndrome if released into the blood stream by the tumor. The respiratory tract is the second-most common site for carcinoids (after the gastrointestinal tract). Pulmonary carcinoid tumors are often centrally located and confined to the main or lobar bronchi.[17]

The incidence of bronchopulmonary carcinoids in the United States is estimated to be 0.6 per 100,000 people.[17] Carcinoid tumors tend to occur at a younger age than other lung cancers, with a median age ranging from 50 to 56 at diagnosis. In contrast to NSCLC and SCLC, bronchial carcinoids are more common in women.

Mesothelioma

The incidence of mesothelioma in the United States is estimated to be 10 per 1 million people,[18] or approximately 3000 patients per year, and the rate is expected to increase to about 4000 cases per year by 2025. Approximately 90% of mesotheliomas can be attributed to prior occupational asbestos exposure, and a lag of 20 to 40 years between asbestos exposure and diagnosis is typical.[19] Mesothelioma occurs predominantly in men, but secondary asbestos exposure from a spouse or parent can be as significant as environmental exposure. Major histologic subtypes of mesothelioma include epithelioid, biphasic, and sarcomatoid. Although epithelioid tumors are most common and have a better prognosis than other histologic types, the prognosis for most patients with mesothelioma remains poor.[20]

BIOLOGY

Lung Cancer

Lung cancers have a propensity to disseminate early and have a high rate of relapse despite aggressive treatment with surgery, chemotherapy, radiotherapy (RT), or combinations of these modalities. Molecular characteristic of NSCLC and SCLC are described in Chapters 43 and 44. Although NSCLC has traditionally been treated as a single disease, there is increasing recognition that histologic and molecular characteristics may help direct therapy, and targeted drugs are now considered first-line therapy for advanced NSCLC with specific epidermal growth factor receptor (EGFR) mutations or anaplastic lymphoma kinase (ALK) gene rearrangements.[21,22] Efforts to take advantage of molecular abnormalities in small cell lung cancer in developing more effective treatment have been less successful.

Esophageal Cancer

Esophageal cancer is characterized by early locoregional and distant spread of disease. Although the biologic characteristics of squamous cell carcinoma and adenocarcinoma of the esophagus differ, implications for therapeutic approach are unclear at this time. Molecular targets of interest identified in carcinoma of the esophagus include EGFR, Her2-neu, vascular endothelial growth factor (VEGF), cyclin D1, and cyclooxygenase-2.[23] Alterations in p53 may be important in the development of esophageal cancer, although mutations for squamous cell carcinoma differ from adenocarcinoma, and p15 and p16 have been found to be involved in the pathogenesis of esophageal cancer.[24]

Thymus Tumors

The cause of thymic neoplasms is unclear. Environmental factors that contribute to the development of thymic neoplasms may include Epstein-Barr virus infection[25] and exposure to ionizing irradiation.[26] The translocation of chromosomes 15 and 19 has been observed in thymic carcinoma.[27] Benign thymoma has been associated with deletion of the short arm of chromosome 6. Abnormalities in TP53, epidermal growth factor, and EGFR may contribute to the development of thymoma.[28,29]

Thymic carcinoma displays features that are similar to features of carcinoma arising in other body sites. It has a higher rate of capsular invasion, involvement of the regional lymph nodes, and systemic metastases compared with invasive thymomas.[30] Features of thymic carcinomas may include expression of high levels of EGFR, VEGF, and basic fibroblast growth factor.[31,32] CD70 positivity may serve as a marker for thymic carcinoma.[33] In contrast to lung cancer, thymic carcinomas usually do not express transcription termination factor-1.[34]

Pulmonary Carcinoid

Although most pulmonary carcinoids are nonfunctional, some can secrete various substances, which can lead to paraneoplastic syndromes, including carcinoid and Cushing's syndrome.[35] Serotonin is the most common substance released by carcinoid tumors, but corticotropin, histamine, dopamine, substance P, neurotensin, prostaglandins, and kallikrein may also be involved.[36]

Typical carcinoids usually display an indolent clinical course, but atypical carcinoids have a higher rate of regional and systemic involvement on presentation.[37] Most familial pulmonary carcinoids have been reported in patients with multiple endocrine neoplasia type I.[38] In atypical carcinoids, there seems to be a higher rate of inactivation of TP53.[39] Other genetic alterations in lung carcinoids include losses of 3p, 5p, 9p, 10q, and 13q.[40]

STAGING AND WORKUP

Lung Cancer

As with other medical conditions, the workup begins with a careful history and physical examination. There should be an emphasis on the duration of symptoms and signs related to the thoracic neoplasm and the overall baseline medical condition of the patient.

Diagnosis and staging should be accomplished in an orderly and cost-effective manner. Although sputum cytology reveals a diagnosis in only a small percentage of patients, it is a simple and noninvasive evaluation that should be considered for patients with respiratory symptoms and a suspicious lung mass. Traditionally, bronchoscopy has been employed for biopsy of central lesions, whereas transthoracic needle biopsy is often the first consideration for peripheral lesions. Endobronchial ultrasound is increasingly used to obtain tissue from mediastinal lymph nodes or parenchymal lung lesions; esophageal ultrasound may be used for biopsy of paraesophageal lymph nodes.

Staging evaluation is often initiated before a definitive pathologic diagnosis has been established. Positron emission tomography with ^{18}F-fluorodeoxyglucose positron emission tomography (^{18}F-FDG-PET) combined with computed tomography (CT) imaging is indicated in most patients with localized NSCLC and SCLC and can replace the traditional workup that included CT imaging of the chest and abdomen plus a bone scan. The use of ^{18}F-FDG-PET imaging has been shown to reduce the number of futile thoracotomies for patients with NSCLC and has a substantial impact on the radiation treatment plan for NSCLC and SCLC, particularly when an approach of involved field RT is used.[41-43] Generally, biopsy of suspected distant metastatic sites should be considered in lieu of biopsy of the primary lung lesion because this would confirm both histology and stage. ^{18}F-FDG-PET imaging is typically not warranted in patients presenting with evidence of distant metastases (on other imaging studies) because treatment would not likely be altered by the PET results. Magnetic resonance imaging (MRI) of the brain should be obtained in patients with localized SCLC and patients with clinical stage III NSCLC, in addition to patients presenting with neurologic symptoms.

The TNM (primary tumor, regional nodes, metastases) staging system for bronchogenic cancer has undergone substantial revision to correlate stage better with clinical outcome

(see Tables 44-2 and 44-3). Changes in T stage include subclassifying T1 into T1a and T1b and T2 into T2a and T2b, reclassifying T2c and additional nodules in the same lobe as T3, and reclassifying nodules in the ipsilateral nonprimary lobe as T4. Malignant pleural or pericardial effusions have been reclassified from T4 to M1.[44] Although the American Joint Committee on Cancer (AJCC) system has been proposed for use in staging patients with both SCLC and NSCLC, it is more common to use the 1973 Staging System of the Veterans Administration Lung Cancer Study Group for staging SCLC. It distinguishes disease extent as limited versus extensive,[45] with limited-stage SCLC often described as one that can be treated with a "reasonable" RT portal to encompass the known disease.

Mediastinal staging is indicated for most patients with early-stage clinical node-negative NSCLC because CT and ^{18}F-FDG-PET imaging have a false-negative rate (in the mediastinum) ranging from 10% to greater than 25%.[46] Combined anatomic and functional imaging is generally sufficient to assess mediastinal lymph node involvement for the subset of patients with peripheral stage I NSCLC.[47] Whether comprehensive mediastinal lymph node sampling with endobronchial ultrasound can replace mediastinoscopy is an area of active investigation.

Esophageal Cancer

The staging of esophageal cancer underwent substantial revision in the most recent version (seventh edition) of the AJCC Staging Manual (see Box 45-1). Staging groups are now divided according to histology, acknowledging the difference in biology between squamous cell carcinoma and adenocarcinoma. The staging system has also been amended to account for the influence of tumor grade on prognosis. Regional lymph nodes have been redefined, and N has been subdivided according to the number of lymph nodes involved. In addition, the previous division between M1a and M1b has been abandoned because it was not found to be useful.

Clinical staging is typically based on findings of endoscopy with biopsy, endoscopic esophageal ultrasound, and anatomic CT imaging. Endoscopic ultrasound can assess the depth of invasion with up to 90% accuracy once the tumor has gone through the submucosa and can detect abnormal or enlarged lymph nodes.[48] Assessment with ^{18}F-FDG-PET/CT has become commonplace in the workup of esophageal carcinoma and is particularly helpful in detection of unsuspected distant or regional disease, although the sensitivity of ^{18}F-FDG-PET imaging in defining regional lymph node metastases seems to be improved with integrated ^{18}F-FDG-PET/CT imaging.[49-51] A randomized prospective trial from the American College of Surgeons Oncology Group showed that ^{18}F-FDG-PET after conventional staging evaluation identified confirmed metastatic disease in approximately 5% of patients. This study was performed before routine availability of integrated ^{18}F-FDG-PET/CT.[52] Thoracoscopic or laparoscopic assessment may be helpful in certain cases to help determine disease extent and resectability.

Thymic Tumors

Approximately 10% to 15% of patients with myasthenia gravis have thymoma, and 30% to 45% of patients with thymomas have myasthenia gravis.[53] Serum alpha-fetoprotein and beta-human chorionic gonadotropin levels should be obtained in young men to exclude nonseminomatous germ cell tumors.[54] Thymic carcinoids may also be associated with Cushing's syndrome, Eaton-Lambert syndrome, syndrome of inappropriate secretion of antidiuretic hormone, and hypercalcemia.[55]

TABLE C-1 Masaoka Staging System for Thymoma

Stage	Criteria
I	Completely encapsulated macroscopically and no microscopic capsular invasion
II-1	Macroscopic invasion into surrounding fatty tissue or mediastinal pleura
II-2	Microscopic invasion into capsule
III	Microscopic invasion into adjacent organs
IVA	Pleural or pericardial implants
IVB	Lymphatogenous or hematogenous metastasis

Symptoms of classic carcinoid syndrome are rare in patients with thymic carcinoids.

A routine chest x-ray examination can detect 30% to 40% of patients with thymic neoplasms.[56] CT is the most valuable radiologic study in the workup of thymic tumors.[57] It can establish the initial clinical staging and response to treatment. MRI has not been shown to be more accurate than CT in assessing anterior mediastinal tumors.[58] ^{18}F-FDG-PET has not been established as routine in the workup of thymic neoplasms. The risk of tumor spillage and pleural seeding during biopsy of thymoma is uncertain, although current guidelines suggest biopsy may be avoided for resectable tumors if thymoma is strongly suspected by clinical and radiographic features.

Thymomas histologically display epithelial and lymphatic cell types. They can be classified according to the degree of the epithelial and lymphatic cell combination. The neoplastic cells are the epithelial cells, but there is no consistent correlation between the histology of thymomas and their malignant potential or systemic syndromes. The degree of invasion of the capsule and adjacent tissues defines malignancy.[59] The Masaoka staging system[60] is used widely and is based on the anatomic extent of disease at the time of surgery (Table C-1). Thymic carcinoma histology is cytologically not different from carcinomas in other sites. Thymic carcinomas often involve the pleura and locoregional lymph nodes. Distant metastases to the lungs, liver, brain, and bone can also develop.[61]

Pulmonary Carcinoid

Pulmonary carcinoids are often located centrally within the tracheobronchial tree, and approximately 10% to 20% are in the peripheral lung parenchyma.[62] The AJCC lung staging system (TNM) is commonly used for lung carcinoids. Most patients with typical carcinoid present with early-stage disease, and less than 5% have evidence of distant spread. Approximately 20% of patients with atypical carcinoids have stage IV disease at presentation.

Functioning carcinoids may be diagnosed by showing an increase in urinary excretion of the serotonin metabolite, 5-hydroxyindoleacetic acid. In addition to anatomic CT imaging, targeted radioactive octreotide or pentetreotide has been used to stage carcinoids.[63] Such targeted imaging against type 2 somatostatin receptors may be useful in 80% of carcinoids. The utility of ^{18}F-FDG-PET imaging is controversial, although PET imaging using alternative tracers seems promising.[64,65]

Mesothelioma

A detailed history of asbestos exposure should be investigated for any patient with mesothelioma. Thoracentesis and percutaneous fine-needle aspiration biopsy have a low diagnostic

sensitivity because mesothelioma can be difficult to differentiate from benign pleural disease and other malignancies.[66] Video-assisted thoracoscopic biopsy seems to be the most accurate means to establish a pathologic diagnosis.[67]

Contrast-enhanced CT imaging of the chest is indicated as part of initial staging but can underestimate the extent of the disease. MRI may be more accurate in predicting the extent of chest wall and diaphragm invasion. Additional invasive studies such as laparoscopy and peritoneal lavage may be indicated to document resectability. The AJCC staging system, which is based on the International Mesothelioma Interest Group staging system, is commonly used, and the most common sites of metastatic disease are the peritoneum, contralateral pleura, and lung.[68]

NORMAL TISSUE TOXICITY CONSIDERATIONS

The spinal cord, lung, esophagus, and heart are the dose-limiting structures in RT for thoracic malignancy. Generally, functioning subunits of an organ may be arranged as an in-series or in-parallel structure. Normal tissue such as the lung is an example of an in-parallel structure in which critical numbers of functioning units must be damaged before the organ is impaired.[69] Organ failure occurs when functional subunits are damaged beyond a critical level. The gastrointestinal tract and spinal cord represent in-series structures in which a loss of a single functioning subunit may lead to organ impairment or development of clinical symptoms. Current grading systems for toxicities include Common Terminology Criteria for Adverse Events version 4.0 (CTCAEv4) from the National Cancer Institute.

Although many reports suggest limited toxic effects after stereotactic body radiotherapy (SBRT) for early-stage NSCLC, mature prospective results are just starting to appear in the literature.[70] Phase II data from Indiana University initially showed an increased risk of toxic deaths after SBRT for centrally located lesions, although a statistically significant difference in severe toxicity was not seen between central and peripheral lesions with longer follow-up.[71,72] Nevertheless, central tumors were excluded from the subsequent multiinstitutional RTOG Phase II study (RTOG 0236), and caution should be used in treating central lesions with SBRT outside of a clinical study.[73] No treatment-related deaths were reported on RTOG 0236, which was reported with 34-month median follow-up, although 14% grade 3 and 4% grade 4 *protocol-specified* toxicity was observed, and six additional patients had severe toxicity that was not classified prospectively as protocol specified. Rigorous quality assurance was mandated. In addition to tumor location, size of the gross tumor volume was a significant predictor of severe toxicity in the Indiana University trial.[74] In other experience, fatalities have been observed secondary to fistula (tracheoesophageal or bronchopulmonary), pneumonitis, pleural effusion, and hemoptysis.[75] Several more recent SBRT reports have also shown higher than expected skin, rib, soft-tissue, and brachial plexus toxicity.[76-78] Specific dose constraints for SBRT regimens have been suggested by the RTOG and National Comprehensive Cancer Network (NCCN).

The following sections are generally based on data derived with conventionally fractionated RT and may not apply when large doses per fractions are used, such as in SBRT. Routine integration of conformal RT planning has facilitated the assessment of dose-volume relationships for conventionally fractionated RT. A systematic review of the literature found that an ideal dose-volume parameter predicting for pulmonary toxicity has not been identified,[79] although the most widely used measures are the total lung volume receiving at least 20 Gy (i.e., V20) and the mean lung dose.[80-82] Other metrics, including baseline pulmonary function and perfusion abnormalities, have also been used, and it is likely that multiple physical and biologic factors are important in predicting the risk of pulmonary toxicity.[83,84] Barriers to describing accurately the relationship between treatment and its resultant toxicity include the use of imperfect metrics and the inaccurate reporting of toxic effects. The latter may be particularly relevant for patients with underlying pulmonary toxicity, where it may be difficult to determine whether a functional decline is attributable to the effects of therapy.

The dose-volume relationship may also be affected by the integration of systemic chemotherapy, and the sequencing of therapies may have a significant impact on the toxic effects of therapy.[85] Most current prospective combined modality trials have adopted V20 as a treatment planning parameter and limit V20 to a maximum 30% to 40% of the total lung volume. Current NCCN guidelines recommend limiting the V20 lung to less than 37% and the mean lung dose to less than 20 Gy. There is increasing recognition of the potential impact of exposing relatively large volumes of lung to low doses of 5 Gy or 7 Gy, which is particularly relevant when intensity-modulated radiotherapy (IMRT) techniques are employed for lung cancer, esophageal cancer, or mesothelioma.[86]

Esophageal toxicity is generally the major clinically relevant acute toxicity during thoracic RT. The implementation of conformal techniques may affect esophageal toxicity by reducing the volume of esophagus irradiated, particularly for patients without extensive mediastinal adenopathy. The risk of radiation-induced acute esophageal toxicity varies according to fractionation, and increased acute toxicity has been observed with hyperfractionated and accelerated RT regimens.[87] The integration of concurrent chemotherapy with thoracic RT results in significantly increased severe esophagitis compared with primary RT or sequential therapy. Dosimetric parameters that may correlate with esophageal toxicity include the length of esophagus treated to greater than 40 Gy to 50 Gy, the volume of esophagus receiving greater than 50 Gy, and the mean esophageal dose.[88-90] Current NCCN guidelines recommend keeping the mean esophageal dose less than 34 Gy if possible, but esophageal dose guidelines are not absolute, and acute esophagitis should be managed aggressively with measures including pain management and nutritional support.

It is crucial that the patient's treatment plan not be compromised because of a (generally) temporary toxic effect of therapy. The role of "radioprotective" agents is unclear; the RTOG conducted a randomized trial to test the ability of amifostine to reduce esophagitis in locally advanced NSCLC treated with concurrent RT and chemotherapy.[91] The rate of grade 3 esophagitis did not differ between arms (34% versus 30%), although subjective swallowing function was apparently better with the addition of amifostine. Amifostine was associated with higher rates of acute nausea, vomiting, cardiovascular toxicity, and infection or febrile neutropenia. Amifostine is not recommended in combination with thoracic RT outside of a clinical trial.

Spinal cord radiation injury, covered in detail in Chapter 30, is a serious but rare complication of thoracic RT. Most contemporary clinical trials of concurrent fractionated RT and chemotherapy for thoracic malignancies limit the maximum point dose to the spinal cord to 45 Gy to 50 Gy.

The risk of radiation-induced cardiovascular disease is difficult to define for patients treated for locally advanced lung cancer and esophageal cancer as there are relatively few long-term survivors, though a recent analysis of RTOG 0617 demonstrated a negative impact of increasing heart dose (V50) on overall survival in patients with locally advanced NSCLC

(ASCO 2013).[92] Most data relating to cardiovascular toxicity is derived from patients with Hodgkin's disease and breast cancer. Multiple studies have shown that patients with Hodgkin's disease are at higher risk for the development of cardiovascular disease after mediastinal irradiation, and fatal myocardial infarction is the leading cause of noncancer death in this population.[93] Although the total dose used to treat Hodgkin's disease has been reduced over the years, it is not yet clear whether this results in a reduced risk of myocardial infarctions.

The increased risk of cardiac mortality for patients treated with RT for breast cancer has been defined by the Early Breast Cancer Trialists' Collaborative Group meta-analyses of randomized clinical trials, which showed patients treated with RT have a 1.27 relative risk of mortality from cardiac disease compared with patients not receiving RT.[94] The treatment of left-sided breast cancer and the treatment of internal mammary lymph nodes seem to increase the risk of cardiac morbidity further.[95] There seems to be a decline in RT-induced cardiac disease with modern RT planning. The implementation of advanced treatment techniques including conformal therapy, IMRT, image guidance, and respiratory gating should reduce the risk of cardiac toxicity, through improved sparing of cardiac structures, in treating thoracic cancers. Current NCCN guidelines suggest that no more than 50% of the heart should receive 4000 cGy when combined RT and chemotherapy is given.

TREATMENT CONSIDERATIONS

Non–Small Cell Lung Cancer

The standard of care for fit patients with early-stage I NSCLC is anatomic resection (lobectomy). Patients with borderline cardiopulmonary function should be assessed for rehabilitation and smoking cessation before being deemed to be medically inoperable. In a Phase III trial conducted during the 1980s for fit patients with peripheral stage I (<3 cm) NSCLC, limited resection was associated with a substantially higher risk of local tumor relapse and increased risk of death from cancer compared with lobectomy.[96] Evidence has emerged supporting the use of limited resection for peripheral NSCLC smaller than 2 cm, although most experience comes from Asia where the biology of small peripheral lesions may differ from the biology in North America and Europe.[97] An ongoing North American Phase III trial studying limited resection for lesions less than 2 cm should soon complete accrual.[98] Alternatively, provocative results with SBRT have been reported in certain *fit* patients with early-stage NSCLC. Prospective Phase II trials of SBRT in operable patients have been completed in North America and Japan and mature outcomes are pending. Phase III trials comparing SBRT and surgery in this population have not successfully met accrual goals.[99-101]

Treatment of patients with early-stage NSCLC and cardiopulmonary dysfunction has rapidly evolved during the past decade. Fractionated RT has been the most frequent treatment, but approaches including sublobar resection, SBRT, and radiofrequency ablation are increasingly used.[102,103] Local tumor control approaching 90% has been reported in several trials of SBRT for stage I NSCLC, although some trials with aggressive SBRT regimens restrict entry to lesions in the lung periphery owing to concerns about severe toxicity.[75] Accelerated hypofractionated RT regimens, with daily fractions given over 3 to 4 weeks, also seem promising.[104,105] Although traditional dose escalation is feasible with modern treatment planning, protracted regimens do not seem to be as effective as accelerated regimens and are more burdensome for patients.[106-108] Although pilot experience suggested the addition of I-125 brachytherapy might reduce local relapse for high-risk patients treated with sublobar resection for stage I NSCLC, an initial report of a Phase III American College of Surgeons Oncology Group (ACOSOG) trial failed to show a benefit with intraoperative I-125.[109] The relative merit of SBRT and sublobar resection in high-risk early stage NSCLC remains unclear. A randomized Phase III trial comparing SBRT and sublobar resection for high-risk peripheral stage I NSCLC was closed prematurely because of poor accrual, and it is not likely that level 1 evidence will emerge in the foreseeable future. Large randomized studies show that adjuvant chemotherapy improves survival for patients with resected NSCLC, although the benefit diminishes over time.[110] The role of adjuvant chemotherapy for early-stage node-negative NSCLC is controversial. A Cancer and Leukemia Group B (CALGB) trial did not show a benefit for adjuvant chemotherapy for T2 NSCLC, although there was a suggestion of improved survival for tumors larger than 4 cm.[111] Whether chemotherapy should be given to patients treated with primary RT for node-negative NSCLC has not been well studied.

The role of surgery for patients with stage IIIA NSCLC is unclear despite the reporting of mature results of a Phase III trial comparing concurrent chemotherapy and definitive RT (61 Gy) with induction concurrent chemotherapy and RT (45 Gy) followed by surgical resection.[112] Improved relapse-free survival, but not overall survival, was observed for patients assigned to receive surgery. Nevertheless, surgical resection is currently used in certain patients with stage IIIA NSCLC, although it is recognized that induction therapy should be administered. Whether induction therapy should consist of chemotherapy or combined chemotherapy and RT is controversial, and a randomized trial assessing the question closed prematurely because of poor accrual.

The cornerstone of treatment for patients with "unresectable" locally advanced NSCLC is concurrent systemic doublet chemotherapy and thoracic RT as described in Chapter 42. There are several controversies regarding the optimal treatment of this population, as described next.

Chemotherapy Regimen and Schedule During Radiotherapy

The landmark Phase III studies supporting concurrent chemotherapy and RT over a sequential approach used cisplatin-based chemotherapy in a schedule similar to that administered when chemotherapy is given for systemic disease.[113] Nevertheless, several Phase III trials have adopted a regimen of weekly paclitaxel and carboplatin as standard of care despite a lack of level 1 evidence.[114] Whether the weekly chemotherapy schedule or the substitution of carboplatin for cisplatin affects outcomes is unknown, though the excellent results from the standard (60 Gy) arm of RTOG 0617 lend support to the considering weekly concurrent paclitaxel and carboplatin as an acceptable standard therapy.[92]

Sequencing and Timing of RT and Chemotherapy

Trials conducted in the 1980s first showed that giving cisplatin-based chemotherapy before thoracic RT improved overall survival compared with RT alone, and subsequent trials showed that concurrent administration of chemotherapy and RT was better than sequential treatment.[115] Additional chemotherapy is frequently given in clinical practice either before or after concurrent therapy, although more recent Phase III randomized trials failed to show benefit for either induction chemotherapy or consolidation chemotherapy.[116,117] Toxicity was enhanced in the cohorts receiving longer duration chemotherapy. Further research assessing consolidation chemotherapy is likely given more recent reports favoring "maintenance" chemotherapy for patients with metastatic NSCLC treated with primary chemotherapy.[118]

Radiation Dose Escalation and Fractionation

The standard RT regimen for NSCLC, 60 Gy in daily 2-Gy fractions, was defined by an RTOG trial conducted in the 1970s.[119] The emergence of conformal RT planning ushered in several dose escalation studies, and encouraging outcomes of Phases I-II studies led to development of a Phase III trial, RTOG 0617, testing 74 Gy compared with 60 Gy with weekly carboplatin and paclitaxel chemotherapy.[120,121] Unexpectedly, results of this seminal trial demonstrate that higher doses of RT result in significantly worse survival and provides strong evidence against dose-escalated RT outside of a clinical trial.[92]

Altered fractionation has been tested in several Phase III trials of locally advanced NSCLC. Regimens that accelerate the time to complete therapy by giving multiple daily treatments have shown promise, although the utility of these regimens is limited by difficulty in integrating concurrent chemotherapy and the logistic challenge for many centers to treat patients up to three times a day.[122,123] The use of hyperfractionated RT seems to have no benefit if the time to complete treatment is not shortened.[124-126] The emergence of advanced treatment technologies, which facilitate limiting radiation dose to critical normal tissue, has resulted in increased interest in studying accelerated hypofractionted regimens, and ongoing cooperative group studies are assessing hypofractionated RT concurrent with chemotherapy.

Although there is limited experience treating locally advanced NSCLC with proton therapy, the increase in proton facilities in the United States and worldwide has resulted in the development of a Phase III RTOG trial comparing photon and proton radiotherapy concurrent with chemotherapy. A planned total dose of 7000 cGy is recommended in both arms, although there is allowance for dose reduction if normal tissue constraints cannot be met.[127]

Radiation Target Volumes

The role of elective nodal irradiation (ENI) is controversial; current practice has generally evolved such that clinically uninvolved lymph node regions are not intentionally targeted.[128,129] Studying the impact of ENI and accurately documenting sites of relapse in locally advanced NSCLC is challenging, although a modest-sized Chinese study showed less toxicity without a detriment in survival with involved field treatment compared with ENI.[130]

The potential influence of ENI may be lessened in the era of routine ^{18}F-FDG-PET staging, and most ongoing prospective trials do not include ENI.

Integration of Molecular Targeted Agents

A Phase III trial conducted by SWOG from 2001 to 2005 demonstrated worse survival with maintenance EGFR inhibitor gefitinib after chemoradiotherapy in locally advanced NSCLC,[131] curbing enthusiasm for large-scale study of targeted agents in potentially curable populations. Pilot data from CALGB showed gefitinib concurrent with chemoradiotherapy results in poor outcomes, although encouraging results were observed with concurrent administration of gefitinib with RT if concurrent chemotherapy was not given.[132] A subsequent Phase II trial assessing erlotinib and RT for patients who were a poor risk with stage III NSCLC failed to reach the primary survival endpoint although the median survival of 17 months was reasonable for a poor-risk population.[133] Additionally, although Phase II studies showed that combining cetuximab (a monoclonal antibody against EGFR) with concurrent chemotherapy and RT yielded encouraging outcomes,[134,135] cetuximab did not improve survival in the recently reported Phase III RTOG 0617 trial.[92] Routine administration of targeted agents do not appear to have a role in the treatment of unselected patients, but a recently activated randomized RTOG study is assessing the role of induction targeted therapy in patients with locally advanced NSCLC harboring either an EGFR mutation or an ALK gene rearrangement.

The addition of the VEGF inhibitor bevacizumab to doublet chemotherapy improves survival for patients with advanced non–squamous cell carcinoma.[136] Although there was initial enthusiasm for studying bevacizumab in locally advanced disease, an increased risk of tracheoesophageal fistula has been shown when bevacizumab is given with chemoradiotherapy for both NSCLC and SCLC. Administration of bevacizumab months to years after completion of thoracic RT has been linked to fistula formation.[137] These agents should not be used in combination with RT outside of a clinical trial.

Prophylactic Cranial Irradiation

The role of prophylactic cranial irradiation was assessed in four early trials for locally advanced NSCLC,[138-141] with the general conclusion that prophylactic cranial irradiation reduces brain metastases but does not improve overall survival. Results of an RTOG-led an intergroup study confirm this observation, although the trial was terminated prematurely because poor accrual.[142]

Postoperative Radiotherapy

Meta-analyses of postoperative RT has been roundly criticized on many counts, including the use of outdated technology, inclusion of patients with early-stage disease, and administration of excessive RT doses.[143] Nevertheless, a survival detriment was shown for postoperative RT in early-stage node-negative NSCLC, with an unclear benefit in patients who are node positive. Current efforts have generally focused on assessing postoperative RT for resected N2 disease, and a more recent Surveillance, Epidemiology, and End Results (SEER) analysis supports the contention that postoperative RT may be beneficial in N2 disease when delivered with modern technology in appropriate doses (e.g., 50 Gy in 2-Gy fractions).[144] A Phase III European study assessing postoperative RT is ongoing.[145]

Small Cell Lung Cancer

Treatment of limited stage SCLC includes the concurrent administration of RT and chemotherapy. Standard practice includes delivery of full dose cisplatin-based systemic chemotherapy during accelerated hyperfractionated thoracic RT (1.5 Gy twice daily to 45 Gy over 3 weeks). Prophylactic cranial irradiation is indicated after completion of thoracic RT and chemotherapy in patients with a good tumor response. Several issues that remain unresolved in the standard treatment of limited SCLC are described next.

Thoracic Radiotherapy Dose and Fractionation

Although high clinical response rates are expected with combined-modality therapy, durable local tumor control is poor when modest dose, conventionally fractionated thoracic RT is employed. Intensifying the RT course by accelerating the time to complete treatment seems to be an effective strategy in limited stage SCLC. Intergroup trial 0096 randomly assigned patients to receive 4500 cGy in either conventional (180 cGy daily fractions) or hyperfractionated, accelerated (150 cGy twice daily fractions) regimens.[146] Thoracic RT was initiated with the first cycle of etoposide and cisplatin chemotherapy. Mature results favored accelerated RT. With accelerated RT, 5-year survival was 26% compared with 16% for patients receiving conventional RT. The major increased toxicity of the accelerated regimen was a doubling of the grades 3 to 4 acute esophagitis rate (e.g., 16% versus 32%). Despite this result, the

regimen of 45 Gy twice daily has not been well accepted in clinical practice. The Patterns of Care Study published in 2003 noted that less than 10% of patients with limited stage SCLC received this regimen, whereas more than 80% were treated with daily RT.[147] Reluctance to accept accelerated RT may be in part as a result of the increased acute toxicity and practical issues involved with treating patients twice each day. However, the results of the study have also been questioned because of the inclusion of relatively low dose (45 Gy) daily RT as the standard treatment.

The CALGB studied high dose daily thoracic RT. CALGB 8837,[148] a Phase I study, assessed the maximum tolerated dose of RT given in standard daily and accelerated twice daily schedules. The maximum tolerated dose of twice daily RT was determined to be 45 Gy in 30 fractions over 3 weeks, whereas it was judged to be at least 70 Gy in 35 fractions for daily RT. The median survival for patients receiving daily RT was 29.8 months compared with 24 months for patients receiving twice daily RT. A subsequent Phase II study suggested encouraging survival with less apparent toxicity than was observed on studies using twice-daily fractions to 45 Gy.[149] Alternatively, the RTOG studied a concomitant boost strategy in limited stage SCLC. A Phase II study, RTOG 0239, employing a 61.2-Gy concomitant boost regimen demonstrated excellent local tumor control although 2-year overall survival fell well short of expectations.[150] An ongoing Phase III trial, CALGB 30610/RTOG 0538, initially compared standard thoracic RT (1.5 Gy twice daily) with the CALGB 70-Gy once daily and the RTOG 61.2-Gy concomitant boost regimens, but the 61.2-Gy cohort was discontinued in 2013 after an interim analysis of acute toxicity.[151] A Phase III study in Europe for limited small cell lung cancer, assessing 45-Gy twice-daily RT compared with 66-Gy once-daily RT, recently completed accrual and results should be reported in the next few years.[152]

Timing of Radiotherapy

The optimal timing of thoracic RT relative to chemotherapy is controversial. CALGB 8083 randomly assigned patients to receive initial RT plus chemotherapy, delayed RT plus chemotherapy, or chemotherapy alone. Mature results showed that survival with chemotherapy alone was inferior to both thoracic RT arms. A significant difference was not observed between early and delayed RT, although there was a trend favoring delayed thoracic RT ($p = 0.14$).[153] Conversely, a Phase III trial from the National Cancer Institute of Canada showed a benefit for initiating RT, 40 Gy in 3 weeks, with the second chemotherapy cycle compared with the sixth cycle of chemotherapy.[154] In the early thoracic RT cohort, 5-year survival was 20% compared with 11% in the late thoracic RT arm; the difference was ascribed to a reduction in brain metastases because local tumor control did not differ between arms. Additional studies have attempted to address the timing of thoracic RT. Meta-analyses have been published addressing this issue.[155,156] Although definitive conclusions cannot be reached, there is general consensus that the early initiation of thoracic RT (e.g., first through third cycle) may be beneficial, particularly in the context of intensive thoracic RT.

Treatment Volume

The issue of optimal thoracic RT volume in limited stage SCLC therapy has not been well studied in comparative trials. Investigators from the Southwest Oncology Group found that targeting the postchemotherapy tumor volume instead of the tumor volume on presentation did not result in increased failure rates.[157] More recent prospective trials using delayed (e.g., third or fourth cycle) chemotherapy incorporated reduced volume thoracic RT for all patients.[158,159] Mature patterns of failure data from the North Central Cancer Treatment Group, showing that only 2 of 90 local relapses may have occurred outside the postinduction volume but inside the preinduction volume, indicate that reduced field thoracic RT may be an acceptable strategy.[159]

Data attesting to the role of ENI for limited stage SCLC are lacking. Most prospective trials have included selected bilateral mediastinal stations as part of the initial target volume, although elective inclusion of the supraclavicular regions and the contralateral hilum is not indicated. Whether implementation of ^{18}F-FDG-PET imaging can reduce the role of ENI for SCLC has not been well studied, though small trials from the Netherlands suggest that promising results can be obtained with FDG-PET–guided involved field radiotherapy.[160]

Prophylactic Cranial Irradiation

The meta-analysis by the Prophylactic Cranial Irradiation Overview Collaborative Group[161] showed a convincing survival benefit (5.4% at 3 years) for the addition of prophylactic cranial irradiation following a complete response to therapy. A Phase III trial compared standard dose (25 Gy in 10 fractions) and high dose (36 Gy in either once-daily or twice-daily fractions) in limited stage SCLC. Higher doses of prophylactic cranial irradiation did not further reduce brain metastases, but increased mortality was observed on the patients receiving high doses.[162]

Chemotherapy Regimen

SCLC is exquisitely sensitive to systemic chemotherapy. The combination of cisplatin and etoposide became standard frontline therapy in the 1980s because of its clinical activity and tolerability in combination with concurrent thoracic irradiation. Efforts to improve outcomes by adding a third chemotherapy agent have been disappointing. A Phase III trial showed increased severe toxicity without a survival benefit when paclitaxel was added to etoposide and cisplatin for first-line therapy in extensive SCLC.[163] The RTOG conducted a Phase II study of paclitaxel, etoposide, and cisplatin chemotherapy with 45-Gy twice-daily RT in limited stage SCLC. Although the regimen was active, the authors of the study concluded that the addition of paclitaxel was unlikely to improve survival in patients with limited stage SCLC.[164] Topotecan and irinotecan, topoisomerase I inhibitors, are active agents against SCLC. Topotecan has been studied in combination with paclitaxel in both extensive and limited SCLC, but Phase II results did not warrant study in a Phase III setting.[165] In contrast, chemotherapy with irinotecan and cisplatin was superior to cisplatin and etoposide in a Phase III study for extensive SCLC conducted by the Japanese Cooperative Oncology Group.[166] Nevertheless, confirmatory trials conducted in North America failed to show improved survival for irinotecan and cisplatin chemotherapy over cisplatin and etoposide chemotherapy.[167,168]

Esophageal Cancer

There is no universally agreed on standard treatment for many patients with esophageal cancer, due in large part to the difficulty conducting large-scale randomized trials. Surgical resection alone is considered curative therapy for the few patients with early stage disease, with the potential for a minimally invasive approach (endoscopic mucosal resection) in certain patients.[169]

Treatment of locally advanced disease with primary RT is inappropriate for patients able to receive combined-modality therapy. This point is best illustrated by the results of RTOG 85-01, which showed a statistically and clinically significant survival benefit for concurrent chemotherapy[170] and RT compared with primary RT. In that experience, none of the patients

assigned to receive primary RT survived at least 5 years compared with a 5-year survival of 27% of patients receiving chemoradiotherapy.

Whether induction therapy improves outcomes for surgically treated patients has been debated extensively, and recently reported studies contribute substantially to evidence supporting multimodality therapy. The Phase III Chemoradiotherapy for Oesophageal Cancer followed by Surgery Study (CROSS) included 366 patients, and overall survival was significantly improved with preoperative radiotherapy (41.4 Gy) with concurrent weekly paclitaxel and carboplatin. Median survival was 24 months for patients assigned to surgery and 49.4 months in the preoperative chemoradiotherapy group.[171] A North American Intergroup trial also demonstrated improved survival with the addition of neoadjuvant chemoradiotherapy to surgery, even though the study was closed because of poor accrual after only 56 patients were randomized.[172] The impact of induction chemotherapy (without RT) on survival for surgically treated esophageal cancer is likewise controversial, and the two largest studies addressing the question reached different conclusions.[173,174]

The role of surgical resection after concurrent RT and chemotherapy remains unclear. Two European Phase III trials, the French FFCD 9102 trial[175] and the German Esophageal Cancer Study Group trial,[176] did not find a significant difference in survival between patients who received preoperative chemoradiotherapy or chemoradiotherapy alone, although the local recurrence rate was higher without surgery. On the other hand, locoregional tumor relapse was only 14% with trimodality therapy in the recently reported CROSS study, which is far less than would be expected with either definitive chemoradiotherapy or surgery alone, suggesting trimodality therapy should be considered for fit patients with locally advanced disease.[177] Additional studies suggest reduced local relapse with the addition of surgery. The possible benefit of surgical resection needs to be weighed against the risk of perioperative morbidity and mortality.

The standard RT dose regimen for patients treated with definitive RT and concurrent chemotherapy is 5040 cGy in 180-cGy fractions, and prospective studies have demonstrated that higher doses of radiotherapy result in increased toxicity without improving outcomes.[178] When neoadjuvant chemoradiotherapy is used, radiation doses typically range between 4500 cGy and 5040 cGy, similar to nonsurgical treatment, although a slightly reduced dose of 4140 cGy was used in the CROSS trial. Whether the integration of advanced technology, including ^{18}F-FDG-PET imaging, image-guided RT, and motion management, might alter the therapeutic radio of delivering more intense doses of RT remains open to study.

The combination of cisplatin and 5-fluorouracil, which had been considered standard chemotherapy for esophageal cancer in the United States (before the CROSS trial was reported), has resulted in pathologic complete response rates of approximately 20% to 30%. Although no chemotherapy regimen has proven superior to cisplatin and 5-fluorouracil in combination with RT, the regimen of weekly paclitaxel and carboplatin resulted in encouraging outcomes in the CROSS study and is increasingly used in clinical practice and clinical trials. An active CALGB Phase II trial is assessing the role of FDG-PET response directed chemotherapy and should complete accrual in the near future.[179] Despite overexpression of EGFR in esophageal cancer, several trials assessing agents that inhibit the EGFR pathway have reported disappointing results.[180] An active RTOG Phase III trial specific to Her2-overexpressing esophageal adenocarcinoma is evaluating trastuzumab in patients treated with trimodality therapy.[181]

RT guidelines have been published for gastroesophageal junction adenocarcinoma, and these tumors are sometimes managed similarly to gastric adenocarcinoma with initial surgical resection followed by adjuvant chemotherapy and RT as pathologically indicated.[182-185]

Thymoma

The initial treatment of choice for thymic tumors is surgery. Adjuvant RT or chemotherapy should be considered for patients at high risk for recurrence. Complete en bloc surgical resection is the standard of care for resectable thymomas. The primary determinants of clinical outcome are surgical-pathologic staging, tumor size, histology, and extent of surgical resection.

Complete resection of thymoma can lead to low recurrence and excellent survival rates.[186] Although prospective, randomized data on the value of adjuvant RT after resection of invasive thymoma are lacking, certain retrospective studies have shown improvements in local tumor control and survival in patients receiving RT for invasive disease.[187-189] However, conflicting results regarding the utility of adjuvant RT have been reported from analyses of large multiinstitutional series, including the SEER database. A more recent analysis of SEER data showed postoperative RT had no advantage in patients with localized thymoma (Masaoka stage I), but a possible survival benefit was suggested in patients with regional disease (Masaoka stage II-III).[190] The strongest data supporting postoperative RT were in the population of patients with non-extirpative surgery. In contrast, Kondo and Monden[13] reported a large multiinstitutional, retrospective study of 1320 patients with stage II or III thymic epithelial tumors for whom no significant benefit of adjuvant irradiation after surgery was found.

Primary RT has been administered to certain patients with unresectable thymoma with reasonable results, including approximately 65% local control and 5-year survival rate of 40% to 50%.[191] Likewise, salvage RT for patients with recurrent thymoma may achieve a 7-year survival rate of approximately 70%.[192]

Similar to the treatment for thymomas, surgery remains the predominant treatment for patients with thymic carcinomas, which are treated similarly to carcinomas found in other body sites. Adjuvant RT is commonly administered after surgery.[193] There may be a trend toward improved survival and local control with adjuvant therapy, but it is difficult to show.[194] There are reports of promising 5-year overall survival rates of more than 50% for patients who received irradiation after surgery.[195]

Pulmonary Carcinoid

Surgery is the primary treatment for typical and atypical pulmonary carcinoids, and long-term results after complete resection are excellent.[196] Clinical symptoms such as flushing can be relieved with ondansetron, a serotonin 5-HT$_3$ antagonist. Somatostatin analogs, inhibitors of neuropeptide release, relieve the symptoms of carcinoids by binding to somatostatin receptors.[197] Long-acting analogs of somatostatin, such as octreotide and lanreotide, are used to control diarrhea and flushing, and they have an approximately 70% chance of improving symptoms.

Typical carcinoids do not require adjuvant therapy after curative resection.[198] Patients with a tumor greater than 3 cm in diameter, lymph node metastasis, atypical histology, or residual disease may benefit from RT.[199]

Tumor targeting with radioactive somatostatin analogs has been used in patients with carcinoids with inconclusive results.[200] Interferon-α, alone or in combination with octreotide, has resulted in symptomatic relief in some patients.[201]

Chemotherapy results have been inconclusive, with a possible role for cisplatin and etoposide in patients with atypical carcinoids.[202] RT may palliate symptoms in patients with locally advanced or metastatic disease.[203]

Mesothelioma

Because mesothelioma usually involves the visceral and parietal pleural surfaces of the lung and extends into the pleural-lined pulmonary fissures, it can be difficult to perform a complete resection without an extrapleural pneumonectomy (EPP). EPP includes en bloc removal of tissues in the hemithorax, including the parietal and visceral pleura, involved lung, mediastinal lymph nodes, diaphragm, and pericardium. Given the aggressive nature of the surgery, EPP is considered only for patients with localized disease who have minimal comorbid medical problems. Even with EPP, R0 resections cannot be accomplished, and the relative value of EPP compared with lesser resection has been questioned.[204]

The value of RT in patients with unresectable mesothelioma is controversial. A report from Cancer Care Ontario's Program in Evidence-based Care suggested there was little evidence in the published literature to support a role for RT in the management of mesothelioma.[205] A more recent review of the SEER database identified epithelioid histology, pneumonectomy, and RT as predictive of increased survival.[206] Median survival for patients treated with pneumonectomy with and without RT was 19 months and 13 months ($p = 0.01$). Additional studies have suggested improved local tumor control when RT is administered after EPP.

The combination of pemetrexed and cisplatin is considered standard of care for patients with advanced (unresectable) mesothelioma,[207] and the expected median survival in patients treated with the regimen approaches 12 months. Carboplatin is frequently substituted for cisplatin, often owing to medical comorbidity, without an apparent decrease in efficacy. Chemotherapy has now routinely been integrated as part of trimodality therapy for patients with resectable mesothelioma based primarily on promising results in select series.[208]

Treatment of the ipsilateral hemithorax with IMRT after EPP has been associated with a high rate of toxic deaths in several single-institution experiences.[209,210] Fatal pneumonitis has been related to radiation exposure of the contralateral lung, and NCCN guidelines suggest that the mean lung dose be limited to 8.5 Gy and the V5 lung be kept as low as possible. Recent series suggest IMRT can be used with acceptable toxicity if normal tissue dose constraints are strictly followed.

CHAPTER

43 Small Cell Lung Cancer

Steven E. Schild and Walter J. Curran, Jr.

INCIDENCE

Approximately 30,000 Americans are diagnosed with small cell lung cancer (SCLC) each year. This represents 13% to 15% of all cases of bronchogenic carcinoma.

BIOLOGIC CHARACTERISTICS

The 2004 World Health Organization (WHO) classification system describes two variants: small cell carcinoma and combined small cell carcinoma. The latter includes SCLC cells with any of the histologic types of non–small cell lung cancer (NSCLC).

STAGING EVALUATION

The International Association for the Study of Lung Cancer (IASLC) TNM Staging System is recommended for use in staging SCLC, but the 1973 Veterans Administration (VA) distinction of extensive stage (E-SCLC) compared to limited stage (L-SCLC) is commonly employed. Imaging studies including whole body 2-[18F] fluoro-2-deoxy-D-glucose positron emission tomography (FDG-PET)/computed tomography (CT) and brain magnetic resonance imaging (MRI) should be routinely obtained if possible.

PRIMARY THERAPY, ADJUVANT THERAPY, AND LOCALLY ADVANCED DISEASE AND PALLIATION

Chemotherapy is standard therapy for all patients with SCLC who are fit enough to tolerate its use and etoposide with cisplatin (EP) are the most commonly used agents in the United States. The standard management of L-SCLC disease is EP given concurrently with thoracic radiation therapy (TRT). A Phase III trial demonstrated a survival advantage for twice-daily TRT over standard once-daily TRT. Fit patients with L-SCLC should undergo combined-modality therapy including twice-daily TRT to 45 Gy with concurrent EP for four cycles. Most current clinical protocols for L-SCLC employ the involved-field technique of TRT, in which the target volume includes the known extent of the primary tumor and malignant lymphadenopathy (as defined with CT and FDG-PET imaging). Elective radiotherapy (RT) of the supraclavicular and contralateral hilum is discouraged. If a patient achieves any degree of favorable response on restaging, prophylactic cranial irradiation (PCI) should be recommended. For patients with E-SCLC, primary therapy consists of EP and irradiation for symptomatic or nonresponding sites. Carefully selected patients with E-SCLC (with complete responses outside of the chest) should receive TRT. Following chemotherapy, PCI should be offered to all patients having any degree of response. Although long-term survival with E-SCLC is quite uncommon, about one fourth of patients with L-SCLC will survive 5 years or longer.

INTRODUCTION

During 2013, lung cancer was diagnosed in an estimated 246,210 patients and caused an estimated 163,890 deaths in the United States.[1] Between 13% and 15% of patients with lung cancer have SCLC, and of these, about 30% have L-SCLC.[2] Few patients with SCLC have stage I disease. Lung cancer occurs quite frequently in the elderly with a median age of 71 years at diagnosis.[3]

The natural history of untreated SCLC included rapid tumor progression with a median survival of only 2 to 4 months.[4] Until the late 1960s, physicians did not differentiate the management of SCLC from non-SCLC (NSCLC), and clinical trials in the 1970s continued to include both major histological types. It was recognized that most patients with SCLC had poor survival following resection or TRT with little apparent survival benefit from either. A major change in management occurred in the late 1960s and was linked to the recognition that SCLC was more responsive to chemotherapy than NSCLC.[5]

ETIOLOGY AND EPIDEMIOLOGY

The most common cause of SCLC is tobacco smoking. Additionally, secondary exposures to tobacco smoke and inhalation of asbestos or radon have also been associated with the development of this disease. Radon gas is the daughter product of decay of uranium and is most commonly found in areas with uranium within the soil.

Prevention and Early Detection

Prevention of SCLC is possible by addressing the causes of this disease mentioned previously. Smoking prevention and cessation are the chief methods of prevention. Radon can be removed from homes where it is present through proper ventilation. Asbestos exposure has been dramatically decreased recently by removing it from buildings and work environments.

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

Cigarette smoke is a powerful mutagen that is strongly associated with the development of SCLC. Acquired hypermethylation of the promoter region of key genes is a common mechanism to inactivate tumor suppressor genes (TSGs) in tumor formation. The common molecular abnormalities in

TABLE 43-1 Molecular Anomalies Frequent in Small Cell Lung Cancer

Chromosomal Anomalies	Roles
Deletions or epigenetic inactivation of 3p, 5q, 13q, and 17p 3p21 (*RASSF1*, *FUS1*, *SEMA3B*, and *SEMA3* genes) 3p14.2 (*FHIT* gene) 3p24 (*RARβ* gene) 13q14 (*RB* gene) 17p13.1 (*p53* gene)	Disabled tumor suppressor genes

SCLC are shown in Table 43-1.[6-8] A large number of genetic mutations are frequently observed in SCLC tumors, especially common in TSGs. The mutations lead to dysfunction of these suppressor molecules resulting in unrestricted tumor growth. It is common to find deletions or epigenetic inactivation of 3p, 5q, 13q, and 17p that contain a number of TSGs (Table 43-1). The chromosome 3 genetic deletions, observed in almost all cases, are found in both dysplastic and preneoplastic cells and have been demonstrated as the genetic mutations associated with the transformation of precancerous lesions into carcinoma. There has been substantial progress in understanding the molecular abnormalities leading normal bronchial epithelium to become carcinoma. However, there has not yet been much progress in preventing these events or reversing them once they have taken place.

Amplification or overexpression of 1p, 2p, 3q, 5p, 8q, and 19p are common. These contain oncogenes (Bcl-genes, myc and telomerase genes) that promote survival and growth of SCLC. Telomerase is unique in that it functions in the maintenance of telomeres, which are repeated nucleotide sequences at the ends of DNA molecules. Telomeres shrink over time leading eventually to cell death. The enzyme telomerase adds more nucleotides to the DNA ends and can confer immortality to tumor cells.

Intracellular signal pathways become defective leading to increased tumor growth and survival. These have been focus of much research in an attempt to develop effective targeted therapies. None of these are used in standard practice today. Molecular chaperones are large proteins that alter the conformation of client proteins leading to both activation and deactivation of pathways that can result in disregulation of normal cellular growth and development. Receptor tyrosine kinases are overexpressed stimulating growth and survival of SCLC through many pathways. Cell surface proteins are overexpressed modulating growth, differentiation, and cell adhesion.

Another biologic feature that distinguishes SCLC from NSCLC is the more frequent expression of neuroendocrine markers in SCLC. These neuroendocrine markers include enzymes (neuron-specific enolase and L-dopa decarboxylase), peptide hormones (gastrin-releasing peptide, arginine vasopressin), and surface markers such as neural cell adhesion molecule (NCAM). There are also peptide hormones that meet the criteria of autocrine growth factors, which require the production of a growth-promoting protein for which the producing cell has functional receptors. In the case of gastrin-releasing peptide, there is clear evidence that it is produced and secreted by many SCLC cells and then attaches to its cellular membrane receptors stimulating tumor growth.[9]

PATHOLOGY AND PATHWAYS OF SPREAD

The 2004 WHO classification defined SCLC as "a malignant epithelial tumor consisting of small cells with scant cytoplasm, ill-defined cell borders, finely granular nuclear chromatin, and absent or inconspicuous nucleoli." The cells are round, oval, and spindle shaped. Nuclear molding is prominent. Necrosis is extensive, and the mitotic count is high. SCLC occurs in two variant forms: small cell carcinoma and combined small cell carcinoma. The latter type includes SCLC cells and any of the histologic types of NSCLC.[10]

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

The signs and symptoms of lung cancer depend on the location and bulk of the primary tumor, adenopathy, and metastatic disease. Because of the high frequency of extensive mediastinal and hilar nodal involvement in SCLC cases, patients frequently present with symptoms such as dyspnea, dysphagia, hoarseness, and superior vena cava (SVC) syndrome. Many patients with SCLC present with other thoracic symptoms including cough, hemoptysis, chest pain, and weight loss.

SCLC is the most common solid tumor associated with paraneoplastic syndromes. Several of these are endocrinologic or neurologic. The most common endocrinologic abnormality is the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). This condition results from the excessive secretion of ADH from tumor cells, leading to severe hyponatremia with resultant hypoosmolality. SIADH occurs in about 11% of patients with SCLC and typically resolves after response to anticancer therapy. Restriction of free water intake is critical to maintaining proper sodium concentrations before SIADH improves secondary to cancer therapy.[11] Atrial natriuretic peptides (ANP) or arginine vasopressin (AVP) syndromes also result in hyponatremia. Paraneoplastic syndromes associated with SCLC are found in Table 43-2.[12]

The neurologic syndromes associated with SCLC (Table 43-2) include Lambert-Eaton syndrome, cerebellar degeneration syndrome, encephalomyelitis, sensory neuropathy, and cancer-associated retinopathy. Each of these is observed in well under 5% of all patients with SCLC. Lambert-Eaton syndrome is an autoimmune disorder that affects calcium channels of the neuromuscular junction. Antibodies are directed against the calcium channels responsible for the presynaptic release of acetylcholine. These antibodies prevent the opening of calcium channels, which presents the release of acetylcholine. Patients with Lambert-Eaton syndrome present with myasthenia gravis–like symptoms of proximal myopathy, autonomic dysfunction, and hyporeflexia. Like many paraneoplastic syndromes, this condition is generally improved with response to anticancer therapy, although there can also be symptomatic responses to anti-myasthenia therapies.[13] The other neurologic syndromes are believed to be primarily autoimmune phenomena, which usually respond poorly to cancer therapy.[14,15]

SCLC can be diagnosed with histologic or cytologic sampling. In most cases, a diagnosis can be obtained via sputum expectoration, bronchoscopic sampling, or CT-guided transthoracic needle aspiration.

The VA Lung Cancer Study Group's Staging System, which distinguishes between limited and extensive SCLC, is most commonly used.[16] The initial definition of limited disease was an extent of intrathoracic disease encompassable within a "reasonable" radiation field. Investigators in recent years have recognized the dangers of variable interpretations and recent cooperative group trials require staging of patients with SCLC with the standard TNM system. However, the categorization of patients with SCLC into limited versus extensive stage disease has been extremely helpful for making rational treatment choices and designing trials.

Approximately two thirds of patients with SCLC have extensive-stage or stage IV disease at presentation. Staging evaluation would traditionally include a history and physical

TABLE 43-2 Paraneoplastic Syndromes Associated with Small Cell Lung Cancer

Syndrome	Manifestation(s)	Frequency (%)	Correctable with Therapy
SIADH	Hyponatremia	11	Yes
ANP or AVP syndrome	Hyponatremia	15	Yes

**Other neurologic syndromes are often related to Hu antibody and include cerebellar degeneration, encephalopathy, sensory neuropathy, or opsoclonus/myoclonus.*

examination, complete blood cell count, chemistry panel, contrast-enhanced CT scan of the thorax and upper abdomen, pulmonary function testing, and CT or MRI scan of the brain. PET scans are quite accurate for the staging of this SCLC. PET scan can aid with the choice of appropriate therapy and radiotherapy (RT) planning by better identifying tumor extent.[17] PET/CT scanning can replace the traditional radiographic staging studies for SCLC with the exception of CT or MRI of the brain. Because of the high uptake of the tracer (radioactive glucose) within the normal brain, metastases are difficult to distinguish from the brain itself.

Investigators need to be cautioned regarding the influence of ever improving staging techniques on the interpretation of survival results. Many patients previously believed to have limited disease are currently "upstaged" to the extensive-disease category because of more sensitive staging studies. It is likely that their inclusion in the extensive-disease group and their exclusion from the limited disease category will improve survival rates of both groups. This effect is known as the *Will Rogers phenomenon*, which was first used in oncology regarding patients with SCLC and is based on Rogers's quote, "When the Okies left Oklahoma and moved to California, they raised the average IQ in both states." The best method of minimizing this potential bias is to perform properly stratified randomized trials.

There have been several efforts to identify prognostic factors other than staging as a means to better select patients for specific therapies. As with many malignancies, good performance status, young age, and female gender are associated with better prognosis, and these have been verified in large multivariate analyses.[18-21] The Mayo Clinic/North Central Cancer Treatment Group (NCCTG) evaluated 1598 patients with SCLC to determine prognostic factors. Multivariate analysis revealed that performance status, age, gender, number of metastatic sites, and baseline creatinine levels were all associated with survival of patients with E-SCLC. Among patients with L-SCLC, only age and gender were associated with survival.[20] One critical reason for determining prognostic factors is for use in the proper patient stratification and selection when designing trials.

One must consider a patient's pulmonary and cardiac fitness, ability to tolerate specific chemotherapeutic agents, prior malignancies, patient age, and performance status when making decisions regarding optimal therapy for patients with SCLC.

PRIMARY THERAPY LOCALLY ADVANCED DISEASE AND PALLIATION

Thoracic Radiotherapy in LSCLC

In the 1960s it was recognized that chemotherapy was quite active against SCLC and that patients treated with surgery or radiation alone did quite poorly. Therefore, chemotherapy became the primary therapy for SCLC.[22,23] Unfortunately, recurrence inevitably followed the response to chemotherapy and these relapses were most frequently in areas of previous disease. This pattern of failure led investigators to reexamine the use of TRT for L-SCLC. Today, both RT and chemotherapy have central roles in the treatment of SCLC.[24,25] A series of randomized trials were performed comparing chemotherapy alone to chemotherapy with TRT for patients with L-SCLC.[26-29] In 1992, two meta-analyses were published regarding the role of TRT in addition to chemotherapy.[2,29] Pignon et al reported a 3-year survival rate of 14.3% with combined-modality therapy compared to 8.9% with chemotherapy alone ($p = 0.001$). This 5.4% absolute difference in 3-year survival rates was identical to the 5.4% difference in 2-year survival ($p < 0.001$) in a similar meta-analysis reported by Warde and Payne. Although this 5.4% difference appears rather small, it represented a 61% increase in the 3-year survival of 8.9% achieved with chemotherapy alone.[29] In addition, the intrathoracic tumor control was improved by 25% with TRT.[2]

Sequencing and Timing of TRT and Chemotherapy

Chemotherapy and TRT can be delivered concurrently, sequentially, or in an alternating manner. Potential advantages of concurrent delivery include a shorter overall treatment time, increase in treatment intensity, and potential anticancer synergism between the various therapies. Disadvantages include the heightened toxicity and the inability to assess the antitumor response of the chemotherapy alone. The Japanese Clinical Oncology Group performed a Phase III trial in which patients with L-SCLC were randomized to sequential or concurrent therapy. All 231 patients received four cycles of EP every 3 weeks (sequential arm) or 4 weeks (concurrent arm) and were randomized to receive TRT during the first cycle of chemotherapy in the concurrent arm or after the fourth cycle in the sequential arm. TRT included 45 Gy (1.5 Gy twice daily) over 3 weeks. The median survival time was 19.7 months in the sequential arm compared with 27.2 months in the concurrent arm ($p = 0.097$). The 5-year survival rate for patients treated sequentially was 18.3% compared to 23.7% for those treated concurrently. Hematologic toxicity was more severe in the concurrent arm as was severe esophagitis which occurred in 9% in the concurrent arm and 4% in the sequential arm. The authors concluded that the findings strongly suggested that concurrent therapy was more effective for L-SCLC.[30] Although the p value was not significant, the trend favors concurrent therapy. The interpretation of this result is confounded by the difference in timing of TRT because TRT was initiated several months earlier in patients receiving concurrent therapy.

There have been conflicting results from the randomized trials that have addressed the issue of timing of TRT during chemotherapy. However, recent meta-analyses do help make sense of the contradictory data. One study analyzed randomized trials published after 1985 addressing the timing of TRT relative to chemotherapy in L-SCLC. Early TRT was initiated before 9 weeks after starting of chemotherapy and late TRT after 9 weeks. Seven trials ($n = 1524$ patients) met the inclusion criteria and were included. The relative risk of survival for early TRT compared to late TRT for all studies was 1.17 ($p = 0.03$), indicating an increased 2-year survival for patients undergoing early TRT. This translated to a 5.2% ($p = 0.03$) improvement in the 2-year survival for early TRT. This small but significant improvement in 2-year survival for early TRT was similar in magnitude to the benefit of adding TRT or PCI to chemotherapy.[31]

A subsequent meta-analysis investigated the influence of the time interval between the start of any treatment until the end of TRT (SER) on local tumor control, survival, and esophagitis. There was a significantly higher 5-year survival rate in the shorter SER arms (relative risk [RR] = 0.62; $p = 0.0003$), which was more than 20% when the SER was less than 30 days. A low SER was also associated with a higher incidence of severe esophagitis (RR = 0.55; $p < 0.0001$). Each week of extension of the SER beyond that of the study arm with the shortest SER resulted in an overall absolute decrease in the 5-year survival rate of 1.83%. Thus, earlier, shorter, more intense TRT programs improved survival.[32] The current Phase III trial, CALGB 30610/RTOG 0538, allows TRT to start with either the first or second cycle of chemotherapy. Given the complexity of modern RT planning and the urgency to initiate therapy in patients with SCLC, the majority of patients treated in the United States and Europe appear to receive TRT starting with the second cycle of chemotherapy.

Thoracic Radiation Therapy Dose

SCLC is considered a radioresponsive malignancy because the low doses of TRT previously used produced encouraging responses. Total TRT doses for L-SCLC have ranged from 25 Gy to 30 Gy in 10 fractions in the 1970s to up to 70 Gy in 35 fractions in recent years. Doses in the lower end of this range may have been acceptable when chemotherapy was less effective and disseminated disease occurred earlier in the disease course. Improvements in systemic therapy have increased the need for aggressive TRT regimens that produce more durable responses. It was estimated by Choi and Carey that the risk of intrathoracic tumor failure at total doses of 40 Gy or less was 80%,[33] which was confirmed in a National Cancer Institute of Canada (NCIC) L-SCLC trial in which patients were randomized between 25 Gy over 10 fractions versus 37.5 Gy over 15 fractions.[34] The 2-year actuarial rates of local failure were 80% and 69%, respectively.

The most commonly administered doses of TRT range from 45 Gy to 70 Gy in 1.8 Gy to 2.0 Gy daily fractions. Most trials estimated the local control rates in this dose range between 58% and 85%.[35] Cancer and Leukemia Group B (CALGB) investigators have explored high-dose conventionally fractionated TRT in detail. A Phase I trial suggested 70 Gy was feasible given with the fourth cycle of chemotherapy with provocative 5-year survival of 36%, albeit in a select cohort of patients.[36] Subsequent Phase II trials, where TRT was given with the third cycle of (carboplatin based) chemotherapy have reported mixed results. Pooled data from these prospective studies include 200 patients assigned to receive TRT of 70 Gy (35 daily fractions of 2.0 Gy) with median follow-up of 78 months. Treatment was relatively well tolerated (grade 3 or greater esophagitis was 23%), and median survival was similar to reports with 45 Gy (1.5 Gy twice daily). The median survival for the entire cohort assigned to 70 Gy TRT was 19.9 months and 5-year survival rate was 20%. This experience may aid practitioners decide whether high-dosage daily RT with platinum-based chemotherapy is appropriate outside of a clinical trial.[37,38]

The feasibility of high-dose daily TRT coupled with the fact that the majority of patients are treated with daily TRT in clinical practice has resulted in a Phase III trial (CALGB 30610/RTOG 0538) comparing EP and concurrent TRT with either 45 Gy in 30 twice-daily fractions or 70 Gy in 35 daily fractions.[37] A Phase III trial conducted in Europe has also directly addressed the question of high-dose once-daily TRT. The CONVERT Trial randomized more than 500 patients to receive 66 Gy in 2 Gy daily fractions or 45 Gy in 1.5 Gy twice-daily fractions starting with the second cycle of chemotherapy. The trial recently completed accrual and results should be reported in the next few years.[39]

TRT and Altered Fractionation

In addition to increasing the number of daily treatments, another means of intensifying TRT is the use of altered radiation fractionation. For patients with L-SCLC, most altered fractionation strategies have employed twice-daily fractionation with fraction sizes varying from 1.1 Gy to 1.8 Gy and total doses ranging from 40 Gy to 54 Gy. Most regimens have tested the principle of accelerated hyperfractionation in which a twice-daily regimen allows the delivery of a standard total TRT dose over a shortened duration. These regimens should provide an improved therapeutic index for patients with rapidly growing tumors such as SCLC with a small shoulder and a steep slope on their in vitro cell survival curves.

Several encouraging pilot studies led to the development of Intergroup Trial 0096, a Phase III trial testing the concept that accelerated hyperfractionation would improve the outcome for patients with L-SCLC (Table 43-3). The experimental regimen was 45.0 Gy in 1.5 Gy twice-daily fractions beginning on day 1 of a four-cycle regimen of EP. The interfraction interval was 6 to 8 hours and the elapsed treatment time was 19 to 21 days. A total of 419 patients were randomized between the TRT regimens of 45.0 Gy in 1.8 Gy daily fractions compared to 45.0 Gy in 30 to 1.5 Gy twice-daily fractions. Of these, 10 treatments were often given with off cord oblique fields (afternoon session of the final 2 weeks) and dose to the spinal cord was limited to 36 Gy. In both arms the TRT began on day 1 of a four-cycle course of EP. There was a significant survival advantage for the patients with twice-daily TRT s compared to the patients with daily TRT with 5-year survival rates of 26% and 16%, respectively ($p = 0.04$). The median survival time was 19 months for the daily TRT group and 23 months for the twice-daily TRT. The intrathoracic tumor failure rate was 36% for the twice-daily TRT arm and 52% for the daily TRT arm ($p = 0.06$). The principal difference in toxicity was a higher rate of grade 3 esophagitis in the twice-daily TRT arm: 27% versus 11% ($p < 0.001$).[40] This study confirms the principle that an intensification of TRT beyond the relatively low dose daily TRT can improve both local control and survival. This trial has altered the standard of care of patients with L-SCLC because this twice-daily fractionation program is considered to be the standard by which all other programs are compared.

TABLE 43-3 Intergroup 0096 Study Comparing Once- with Twice-Daily Thoracic RT for Patients with L-SCLC Treated with Concurrent Cisplatin and Etoposide

Characteristic	Arm 1 (Once Daily)	Arm 2 (Twice Daily)	*p* Value
Number of patients	206	211	—
Median survival time (mo)	19	23	—
2-year survival rate	41%	47%	—
5-year survival rate	16%	26%	0.04
Failure-free survival rate	24%	29%	0.10
Local failure rate	52%	36%	0.06
Simultaneous local and distant failure rate	23%	6%	0.005
Grade 3 esophagitis rate	11%	27%	<0.001

L-SCLC, *Limited-stage small cell lung cancer;* RT, *radiation therapy.*

The North Central Cancer Treatment Group (NCCTG) performed a trial (89-20-52) that has been misinterpreted as contradicting the findings of the Intergroup Trial 0096. This trial included 310 patients with L-SCLC initially treated with three cycles of EP.[41] Subsequently, the 261 patients without progression were randomized to two cycles of EP plus either daily TRT (50.4 Gy in 28 fractions) or split-course twice-daily TRT (24 Gy in 16 fractions, 2.5 week break and 24 Gy in 16 fractions). Patients then received a sixth cycle of EP followed by PCI. The median and 5-year survival rates were 20.6 months and 21% with daily TRT compared with 20.6 months and 22% for twice-daily TRT($p = 0.68$). The findings of these two Phase III studies comparing daily to twice-daily TRT for L-SCLC led to the conclusion that continuous course of twice-daily TRT is better than daily TRT, but split course twice-daily RT is not.

There has also been investigation of higher doses of twice-daily RT in an attempt to further improve outcome. NCCTG

95-20-53 was a Phase II trial that included six cycles of EP.[42] PCI (25 Gy over 10 fractions) was delivered during cycle three. Cycles four and five included concurrent EP and TRT (30 Gy over 20 twice-daily fractions, a 2-week break, and 30 Gy over 20 twice-daily fractions). The 5-year survival rate of the 76 evaluable patients was 24% (median, 20 months). The 5-year survival rate of the 64 patients who received TRT was 29% (median, 22 months). The 5-year cumulative incidence of in-field failure was 34%. This high-dose twice-daily TRT regimen resulted in a favorable 5-year survival rate. Local failure remains a problem that will require further investigation. Newer technology should allow the safe administration of greater doses of TRT that should improve outcome. Schild et al evaluated data from this trial and others to demonstrate a positive correlation between biologically effective dose (BED) and 5-year survival.[42]

A hybrid approach of concomitant boost TRT has been investigated by the RTOG in both a Phase I and a Phase II setting.[43,44] A dose of 61.2 Gy was given with the first cycle of EP in the Phase II study with twice-daily TRT given during the final 9 days of therapy. Although encouraging local tumor control was reported, overall survival was less than predicted. This regimen was initially included as one of the experimental treatment arms on the CALGB 30160/RTOG 0538 trial, though the concomitant boost arm was discontinued after a planned interim analysis of toxicity between the two experimental arms. As noted previously, the CALGB 30160/RTOG 0538 trial continues as a direct comparison of 45 Gy twice-daily TRT with 70 Gy daily TRT, testing the hypothesis that the higher BED twice-daily regimen will improve survival.

Chemotherapy

The selection of chemotherapeutic agents to combine with TRT for patients with L-SCLC is largely based on trials of multiagent regimens used for E-SCLC. The currently accepted standard chemotherapy regimen for both E-SCLC and L-SCLC in the United States is the two-drug regimen of EP. SWOG was the first group to report a completed trial of concurrent TRT with EP for L-SCLC. They reported a median survival time of 17.5 months and 4-year survival rate of 30%, which appeared superior to the previously reported results with TRT combined with other non–platinum-containing regimens.[45] Additionally, promising results were subsequently reported with TRT and EP and were confirmed in the Intergroup Trial 0096.[46-48] No randomized trial has demonstrated the superiority of TRT and EP over any other regimen for L-SCLC.

New Agents

A recent Japanese Trial compared irinotecan and cisplatin compared with EP for E-SCLC. The median survival was 12.8 months with irinotecan and cisplatin compared to 9.4 months with EP ($p = 0.002$).[48] A similarly designed SWOG Trial S0124 was unable to confirm a survival advantage obtained by irinotecan and cisplatin.[49] Hanna et al reported similarly negative findings from a third similar Phase III trial.[50] Paclitaxel has also been studied extensively in SCLC. A Phase III study in extensive stage disease showed increased fatal toxicity without an improvement in survival with the addition of paclitaxel to EP.[51] A Phase II RTOG trial in LSCLC demonstrated that paclitaxel could be given together with EP during twice-daily TRT, though overall survival did not appear to be better than prior studies using only two chemotherapy drugs.[52] In this age of targeted biological therapy, many compounds have been tested, with a particular interest in antiangiogenic agents, including bevacizumab, in extensive stage disease. These agents have generally demonstrated improved progression-free survival but not overall survival, though results of a completed Phase III trial assessing bevacizumab in extensive disease[53] are pending. The integration of targeted agents in L-SCLC should be undertaken with caution and not done outside of a clinical trial, given that severe tracheoesophageal fistula has been reported in pilot studies using bevacizumab with TRT.[54]

Role of Surgery

The use of resection as primary management of SCLC was largely abandoned by the 1970s when poor survival rates were reported and few complete resections were achieved.[55] In a report by the VA Surgical Oncology Group published in 1982, 5-year survival rates for patients with resected T1N0, T1N1, and T2N0 SCLC were 60%, 31%, and 28%, respectively.[56] All of these patients received chemotherapy. A SWOG protocol enrolled 15 patients with L-SCLC who underwent resection followed by chemoradiation and found this group to have a better 2-year survival rate than a cohort of matched patients treated nonoperatively in other SWOG trials (45% versus 14%).[57] Ichinose et al reported on 112 patients with SCLC who underwent surgical resection and were then randomized between two chemotherapy regimens.[58] Although the chemotherapy regimens produced comparable outcomes, the 3-year survival rates were encouraging: 65% for N0 disease, 52% for N1 disease, and 29% for N2 disease. Chandra et al also found a favorable 5-year survival of 38% in patients with stages I and II SCLC who had resections performed.[59] Each of these three reports suggests that for patients with the rare N0 or N1 L-SCLC, resection followed by chemotherapy produced survival results that may be superior to nonoperative approaches. The role of TRT in this setting remains unclear. A pattern-of-failure study of patients with resected SCLC receiving postoperative chemotherapy alone would help clarify this issue.

A randomized trial was conducted by the Lung Cancer Study Group in which patients with L-SCLC achieving a partial response (PR) or complete response (CR) to chemotherapy received either resection or none.[60] There was no survival difference between the arms, with a 2-year survival rate of 20% in both arms ($p = 0.55$). Based on this trial and on the proven survival benefit of concurrent chemotherapy and TRT, adjuvant surgery following chemotherapy is not recommended.

There are limited data regarding the role of resection of intrathoracic recurrences. Shepherd et al reported on 28 patients with L-SCLC who underwent salvage surgery following either a PR to chemotherapy or subsequent progressive disease.[61] Ten of these 28 patients had NSCLC elements in their specimen. Their 5-year survival rate was 23%. There are only anecdotal data regarding surgical salvage of patients initially treated with both chemotherapy and TRT. Although there may be a role for resection in patients with stages I or II SCLC, it is unclear that surgical intervention would provide a benefit when compared to TRT for similar volumes or stages of disease. While it appears that some patients may be salvaged after a PR or local failure, resection has not been widely employed. This may be as a result in part of the propensity of SCLC to metastasize.

Prophylactic Cranial Irradiation for Both L-SCLC and E-SCLC

PCI was initially introduced into practice in the 1960s for patients with acute lymphoblastic leukemia who had a high risk of failure in the central nervous system (CNS).[62] It was first tested for patients with SCLC in the 1970s following the recognition that brain metastases were frequent. The blood-brain barrier prevents the penetration of most chemotherapeutic agents leaving the brain as a sanctuary site for relapse.

PCI has been shown to improve survival of patients who achieve a CR. Auperin et al published a meta-analysis that included data from seven Phase III studies that compared PCI to no PCI after a CR was achieved.[63] As in the TRT meta-analyses, the 3-year survival rate was 5.4% better for those who received PCI at 20.7% compared with 15.3% for those with no PCI ($p = 0.01$). Although 5.4% appears small, it does reflect a 35% increase in 3-year survivors.

PCI is important for the majority patients with E-SCLC. Slotman et al conducted a randomized trial (EORTC 08993-22993) of PCI in patients with E-SCLC who had had any degree of response to chemotherapy.[64] Patients received either PCI or no further therapy (control group). The PCI included 20 Gy in 5 to 8 fractions, 24 Gy over 12 fractions, 25 Gy in 10 fractions, or 30 Gy over 10 or 12 fractions. The cumulative risk of brain metastases within 1 year was 14.6% in the PCI group and 40.4% in the control group (hazard ratio, 0.27; $p < 0.001$). PCI was associated with an increase in median survival from 5.4 months to 6.7 months. The 1-year survival rate was 27.1% in the PCI group and 13.3% in the control group ($p = 0.003$). PCI had side effects but did not have a significant effect on global health status. The largest mean difference between the two arms was observed for fatigue and hair loss, which were greater with PCI.[65] PCI reduced brain metastases and prolonged survival.[64] PCI should be standard care for all patients with SCLC who have any degree of favorable response to initial chemotherapy. This trial did not evaluate which dose-fractionation regimen was best.

The optimal PCI regimen would include the following desirable characteristics: decreases brain metastases, increases survival, takes the least time from the patients' remaining life, decreases cost, and causes the least toxicity. An international consortium studied dose-fractionation in a Phase III trial. Le Pechoux reported the results of this study that compared standard to higher doses of PCI. This trial included 720 patients with L-SCLC in CR after chemotherapy and TRT. Patients were assigned to either standard ($n = 360$, 25 Gy over 10 fractions) or high-dose PCI ($n = 360$, 36 Gy). The high-dose PCI was either conventional (18 daily fractions of 2 Gy) or accelerated hyperfractionated (24 twice-daily fractions of 1.5 Gy) regimens. There was no significant difference in the 2-year incidence of brain metastases between the standard PCI group and the higher-dose group at 29% and 23%, respectively ($p = 0.18$). The 2-year overall survival was 42% in the standard-dose group and 37% in the higher-dose group ($p = 0.05$). The most common acute toxic events were fatigue, 30% in the standard-dose group compared to 34% in the higher-dose group, headache 24% compared to 28%, and nausea or vomiting 23compared to 28%. They concluded that although there was not a significant decrease in brain metastases after higher-dose PCI, there was a significant increase in mortality. Therefore, they concluded that PCI at 25 Gy over 10 fractions should be the standard of care for SCLC.[66] Although this trial did not address the effects of dose-fractionation for patients with E-SCLC, it is still the most compelling data available regarding the regimen used for PCI for patients with SCLC. While the 25 Gy in a 10-fraction regimen did not meet all the characteristics for the optimal regimen, it was associated with better survival, decreased patient time required, and decreased healthcare costs.[66]

Based on the currently available data, it is recommended that patients with SCLC achieving any degree of response to initial therapy should be offered PCI.[67] The current standard dose-fractionation pattern is 25 Gy over 10 fractions.[67,68] There are also data from a pooled retrospective NCCTG analysis that found that PCI benefits patients who have stable disease after initial therapy. Thus, it appears likely this group of patients benefits from PCI as do those with a favorable response.[67]

MANAGEMENT OF METASTATIC AND RECURRENT DISEASE

Approximately two thirds of all patients with SCLC have extensive-stage disease.[2] The most common sites of extrathoracic metastases are the liver, bone, brain, and adrenal glands.

Initial management of most patients with newly diagnosed ESCLC is four or more cycles of EP. Novel targeted agents are the focus of much research and it is hoped that newer agents will improve outcomes. Second-line chemotherapy often includes topotecan because this was proven superior to best supportive care in patients failing initial therapy.[69]

The Role of Non-CNS Radiotherapy for E-SCLC

RT also has important use for E-SCLC. One role for RT is to palliate bulky intrathoracic disease causing airway compromise, cough, hemoptysis, postobstructive pneumonia, or SVC syndrome. This is often accomplished with a short regimen such as 30 Gy over 10 fractions (or shorter), which will improve symptoms in the majority of patients.

Although the role of TRT is less clear in patients with E-SCLC, there appears a distinct survival benefit to delivering TRT to carefully selected patients. Jeremic et al performed a Phase III study that evaluated chemotherapy with or without TRT in patients with E-SCLC. Patients initially received three cycles of carboplatin and etoposide. Those patients with a CR at distant sites and a PR or better in the chest were randomly assigned to receive either twice-daily TRT (54 Gy in 36 fractions) plus concurrent carboplatin and etoposide followed by two cycles of the same chemotherapy or four cycles of the same chemotherapy without TRT. All patients with a CR at the distant sites also received PCI. Patients who received TRT had significantly better survival than those who did not (median survival time, 17 versus 11 months; 5-year survival rate, 9.1% versus 3.7%; $p = 0.041$).[70] This study revealed improved survival from TRT in carefully selected patients with E-SCLC. It appears that patients who benefit are those for whom the RT encompassed all known residual disease within the body.

The hypothesis that RT can be added to chemotherapy to more effectively treat E-SCLC was evaluated further in a Mayo Clinic Trial. Bonner et al performed a trial that explored the use of RT for both the thoracic and metastatic lesions. This study included an aggressive regimen of seven cycles of an alternating six-drug combination. The first cycle consisted of cyclophosphamide, doxorubicin, etoposide, vincristine, and lomustine. Subsequent cycles used a regimen of doxorubicin alternating with cisplatin.[71] PCI and TRT were given during the chemotherapy. PCI was delivered during the first week of chemotherapy cycles two and three (17 Gy in 5 fractions, each of 3.4 Gy, during each week for a total of 34 Gy in 10 fractions). The TRT was delivered in a split-course fashion during the first week of chemotherapy cycles five and six (20 Gy over 5 fractions, each of 4 Gy, during each week for a total of 40 Gy in 10 fractions). After the seven cycles, patients received 6 Gy in 1 fraction upper hemibody RT followed by 8 Gy in 1 fraction lower hemibody RT. Thirteen patients completed the initial seven cycles. Two of the 20 (10%) patients had fatal hematologic complications after lower hemibody RT. Three (15%) patients had severe peripheral neurologic toxicity, two (10%) had severe central nervous system toxicity, and one (5%) had severe cardiac toxicity. The median survival time was 11.5 months and 5-year survival rate was 16%.

There are valuable lessons to be learned from these data. First, this therapy was toxic. The collective hematologic toxicity from six drugs combined with the TRT, PCI, and sequential

upper and lower hemibody RT resulted in 10% (2 of 20 patients) mortality. Irradiating the entire marrow led to excessive marrow suppression, toxicity, and mortality. Additionally, the PCI regimen (34 Gy in 10 fractions) given during chemotherapy was associated with an unacceptably high risk of leukoencephalopathy.[72] It appears best to administer the PCI after all other therapy because concurrent chemotherapy plus PCI further increases the risk of leukoencephalopathy. Despite the toxicity issues, the finding that the 5-year survival of 16% was much better than other trials for patients with E-SCLC. It is quite possible that RT to the sites of initial disease or areas of residual disease that persist after chemotherapy could be helpful, because failures following chemotherapy alone frequently occur in the sites of original disease and RT lowers the risk of such recurrences. This is the basis of a currently opened RTOG trial 0937, a Phase II trial for patients with E-SCLC and four or fewer distant metastases. This randomized trial compares chemotherapy followed by either PCI (standard arm) or PCI plus TRT and involved field RT to all sites of remaining disease after chemotherapy. The primary endpoint is survival.

The Treatment of Metastases

Patients with brain metastases at diagnosis require cranial RT in their initial management, usually concurrently with the first or second cycle of chemotherapy. The whole-brain RT doses most commonly used for brain metastases range from 20 Gy in 5 fractions to 37.5 Gy in 15 fractions. The majority of patients receive effective palliation as a result.

Patients with a few or solitary primary or recurrent brain metastases can be considered for more aggressive treatment options such as radiosurgery. There is little data addressing specialized therapy such as radiosurgery for patients with SCLC. Sheehan performed a retrospective review of 27 patients with 47 recurrent SCLC brain metastases who underwent radiosurgery.[73] The overall median survival was 18 months after the diagnosis of brain metastases. They concluded that radiosurgery for recurrent SCLC metastases provided effective local tumor control in the majority of patients.

One particular subgroup of patients with E-SCLC included those with disease limited to the chest and the brain only. This group may benefit from the use of chemotherapy, whole-brain RT, and TRT. Kochhar et al identified 30 such patients who initially received cisplatin-based chemotherapy and concomitant whole-brain RT consisting of 36 Gy to 48 Gy.[74] Subsequently, 22 patients also received TRT. The median survival was 14 months. The outcome of patients with E-SCLC with the brain as the sole site of metastases at diagnosis was similar to patients with L-SCLC. Of this cohort, patients who received TRT tended to have a longer median survival (16 months) than those who did not receive TRT or who received it at the time of local disease progression (12 months; $p = 0.3$). This concept of treating E-SCLC with chemotherapy and irradiating all known gross disease probably explains the favorable results in the study of Kochhar et al and the extraordinary 5-year survival rate of 16% achieved in the Mayo Trial reported by Bonner et al.[71] Currently, the RTOG is performing RTOG 0937, previously described, to more fully evaluate the role of RT for carefully selected patients with E-SCLC.

Sites of metastatic involvement may also require palliative RT for effective symptom management. These include painful or weight-bearing bony lesions, symptomatic adrenal metastases, or soft-tissue masses. Lesions causing any debilitating symptoms can be considered for palliative RT.

SVC syndrome may also develop in patients with SCLC. This appears more frequent with this histology than others as a result of a propensity to develop bulky mediastinal adenopathy. Chan et al reported on 76 consecutive patients with SCLC with SVC syndrome,[75] and 93% had improvement in SVC symptoms after chemotherapy compared with 94% after TRT. Additionally, a favorable response was obtained with a wide range of RT fractionation patterns and total doses administered. Those who received chemotherapy and TRT had a longer time to recurrence of SVC syndrome ($p = 0.018$) compared to those who received chemotherapy alone. The early mortality from SVC syndrome was 2%. Chemotherapy or TRT was effective initial treatment in patients with SCLC with SVC syndrome. They also concluded that there is no need to use large radiation fraction sizes for the first few treatments. TRT resulted in more durable palliation than achieved with chemotherapy alone. This study debunked the myth that RT needs to begin emergently within hours. It is preferable to begin chemotherapy quickly and take adequate time for optimal RT treatment planning. This will decrease the normal tissue volumes within the fields and insure that the entire tumor is irradiated.

Management of Recurrent SCLC

The prognosis of any patient with recurrent SCLC is grave, regardless of the site of relapse. Although there are responses noted to second-line chemotherapy, these responses are usually short-lived and often precede rapid tumor progression. Palliative or salvage RT or re-RT (including reirradiating brain metastases) can be of substantial benefit to such patients.

TECHNIQUES OF IRRADIATION

Treatment is dependent on accurate identification of the disease and a clear understanding of its exact distribution with relationship to normal structures. The combination of PET scans and CT imaging are helpful in defining the extent of disease except within the brain. Within the chest, functional imaging (PET) allows better detection of viable tumor within a structure and the CT is better to define the exact extent and location of these structures. Incorporating both PET and CT scans into RT planning can be used to generate smaller, more precise tumor fields that may further decrease toxicity while treating all gross disease with RT. Over time, improvements in imaging allow physicians to more precisely locate and irradiate all sites of disease.

Treatment Volumes and Normal Tissue Considerations

The ability of a patient with L-SCLC to tolerate increasingly aggressive RT regimens and higher total doses during concurrent chemotherapy is in part related to improved TRT target volume selection.[35] There emerged evidence in the 1980s and 1990s that the use of smaller radiation fields did not adversely influence tumor control in patients receiving concurrent cisplatin-based chemotherapy. The fields employed in Intergroup Trial 0096 confined the high-dose volume to the tumor with a 1.5-cm margin, the ipsilateral hilum, and the mediastinum from the thoracic inlet to the subcarinal region. The contralateral hilum and supraclavicular regions were excluded. These treatment volumes have been widely adopted in subsequent clinical trials.

Smaller volumes have the advantage of further sparing of the surrounding normal tissues: lung, esophagus, heart, spinal cord, and bone marrow (Figure 43-1). Optimal sparing is important to decrease the high risk of severe morbidity from therapy. We compiled the toxicity experienced by patients treated on NCCTG 89-20-52, which included concurrent chemotherapy plus either daily or twice-daily TRT. The most common toxicity was hematologic; 90% of patients had grade

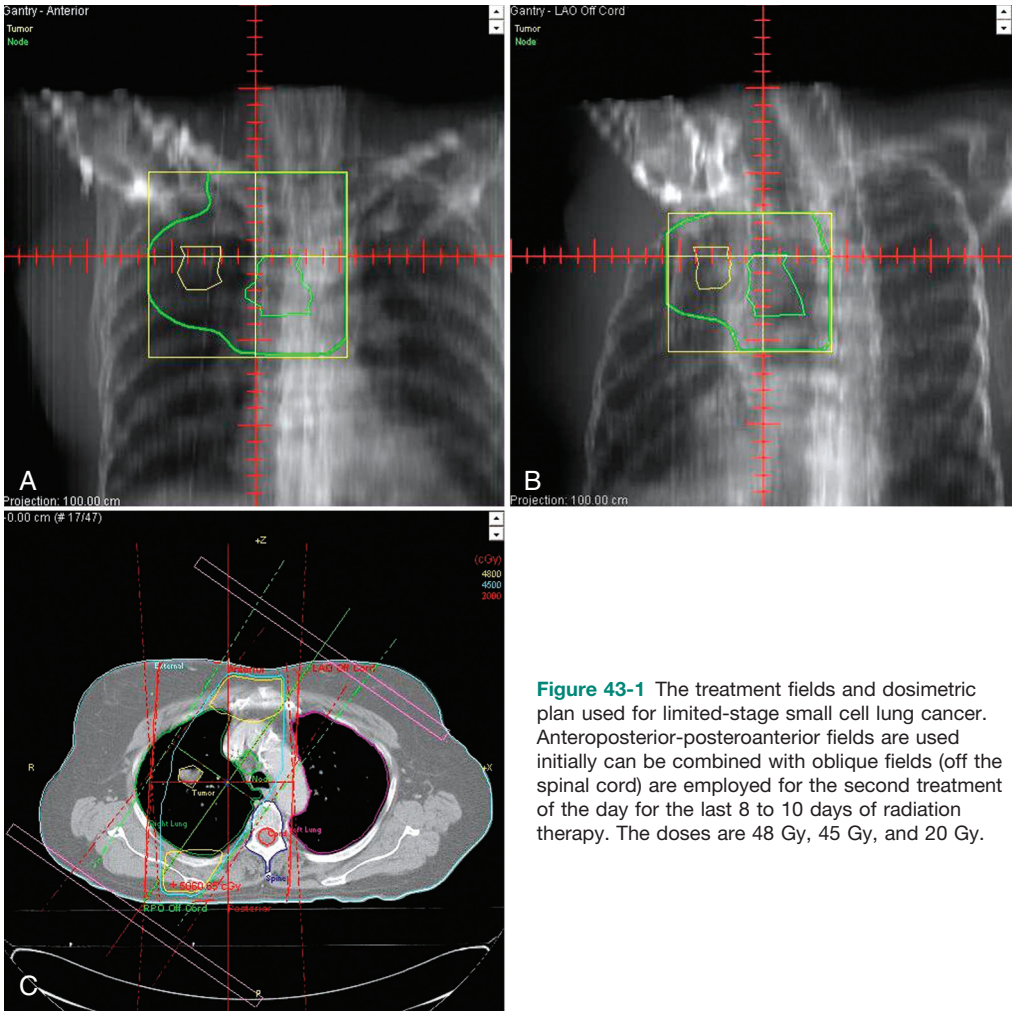

Figure 43-1 The treatment fields and dosimetric plan used for limited-stage small cell lung cancer. Anteroposterior-posteroanterior fields are used initially can be combined with oblique fields (off the spinal cord) are employed for the second treatment of the day for the last 8 to 10 days of radiation therapy. The doses are 48 Gy, 45 Gy, and 20 Gy.

3 or greater (3+) hematologic toxicity and 43% had grade 4+ hematologic toxicity. Forty-seven percent of patients had grade 3+ nonhematologic toxicity and 11% had grade 4+ nonhematologic toxicity. Nausea, vomiting, and esophagitis were the most common nonhematologic toxicities. Fatal toxicity occurred in four patients (2%) of patients.[41] Thus, smaller, more precise fields are needed to deliver therapy more safely. Prospective trials in Europe have evaluated an approach of "involved field" radiotherapy in LSCLC. An initial trial using CT directed radiotherapy fields reported an 11% isolated nodal relapse, whereas isolated nodal relapse was only 3% in a follow-up study that included both CT– and FDG-PET–based disease.[76-78] The current Phase III trial, CALGB 30610, does not employ elective mediastinal radiotherapy, though level 1 evidence regarding elective nodal irradiation is lacking.

RT-induced toxicity is related to dose-volume parameters. In a classic study, Graham et al reported that the risk of grade 2+ pneumonitis was 0% when the V20 (total lung volume that received ≥20 Gy) was <22%, 7% when the V20 was 22% to 31%, 13% when the V20 was 32% to 40%, and 36% when V20 was >40%.[79] The ongoing Phase III study (CALGB 30610) recommends limiting the V20 lung to <40%, although this can be difficult to achieve when bulky disease is present. It is generally accepted that the spinal cord can safely receive 45 Gy to 50 Gy in 1.8 Gy to 2.0 Gy fractions. In most twice-daily TRT regimens employing 1.5 Gy fractions, the spinal cord is limited to 36 Gy to 37 Gy without incident.[41] In the Intergroup 0096 regimen, the oblique off cord fields were used for the second daily treatment for the last 8 to 10 treatments. The TD5/5 (toxic dose to 5% of patients in 5 years) was estimated at 60 Gy for one third of the heart, 45 Gy for two-thirds of the heart, and 40 Gy for the entire heart.[80] Esophagitis is related to the dose of radiation, volume of esophagus irradiated the fractionation schema, and the timing of chemotherapy. Of the patients in the Intergroup Trial 0096 who received twice-daily TRT, 32% had grade 3+ esophagitis compared with 16% for those who received twice-daily TRT ($p = 0.001$).[40] Although esophagitis is uncomfortable, can lead to dehydration, and the need for intravenous hydration or hospitalization, this should not be used as reasons to deny fit patients twice-daily TRT.

Watkins described the factors associated with development of severe acute esophagitis during twice-daily TRT with concurrent chemotherapy in patients with L-SCLC. Twice-daily chemoradiotherapy included 45 Gy at 1.5 Gy twice daily with concurrent platinum-based chemotherapy. The most strongly associated dosimetric variable was the V15 (grade 3 esophagitis rates of 15% versus 64% for V15 <60% versus >60%, respectively).

TREATMENT ALGORITHM, CONTROVERSIES, PROBLEMS, CHALLENGES, FUTURE POSSIBILITIES, AND CLINICAL TRIALS

A proposed treatment algorithm for patients with SCLC is shown in Figure 43-2.

L-SCLC with Good Performance Status and TRT

The management of SCLC is dependent on stage and medical fitness. For patients with good performance status and L-SCLC, the recommended therapy would include concurrent TRT with EP chemotherapy. Specifically, the treatment with the best evidence justifying its use is four cycles of EP chemotherapy with twice-daily TRT beginning early.[31,32] The twice-daily TRT is delivered in 1.5 Gy fractions with an interfraction interval of more than 6 hours to a total dose of 45.0 Gy. This recommendation is based on the Intergroup Trial 0096.[40] The Cancer and Leukemia Group B/Radiation Therapy Oncology Group trial (CALGB 30610/RTOG 0538) and CONVERT trial will help determine which of two TRT regimens is best.

For patients with huge tumors, postobstructive pneumonia, or atelectasis, there may be value in delaying initiation of TRT until a later cycle of chemotherapy. This may be necessary in some cases if the initial tumor volume would require an excessive volume of normal lung to be irradiated. It is unknown if adding TRT improves the outcome of the rare patient with resected L-SCLC. However, chemotherapy is generally administered after resection.

L-SCLC in Special Populations: The Elderly and Those with a Lower Performance Status

Treatment in fit elderly patients (>70 years of age) can be carried out in a manner similar to fit younger individuals. NCCTG 89-20-52 included 263 patients with L-SCLC and an ECOG performance status of <2 who were randomized to daily TRT or split course twice-daily TRT. The outcomes of the younger patients (<70 years old) were compared to the elderly patients (>70 years old). The overall incidence of grade >3 (3+) or grade >4 (4+) toxicity was not significantly greater in elderly patients. One specific toxicity, grade 4+ pneumonitis occurred in 0% of those <70 years compared to 6% of older patients ($p = 0.008$). Grade 5 toxicity occurred in 3 of 54 (5.6%) patients >70 years old compared with 1 of 209 (0.5%) younger individuals ($p = 0.03$). Overall survival was not significantly worse in older individuals; the 5-year survival rates were 22% in younger patients compared with 17% in older patients ($p = 0.14$). Fit elderly patients with L-SCLC can receive combined-modality therapy, if carefully monitored, with a reasonable expectation of 5-year survival.[81]

Patients with lower performance status tolerate the aggressive twice-daily TRT and EP more poorly. However, there is still a likely benefit to concurrent chemoradiation for these patients, particularly if their reduced functional status is as a result of tumor. One alternative would be to deliver daily TRT in 1.8 Gy 2.0 Gy fractions to 50 Gy to 70 Gy, while sparing the spinal cord above 45 Gy to 50 Gy. This could be delivered beginning with the first or second cycle of chemotherapy. Judgment and flexibility are critical when treating very old (≥80 years) or patients who are have poor performance status. It is also reasonable to administer sequential therapy to patients who can not tolerate the rigors of concurrent therapy.

E-SCLC and TRT

Initial management of E-SCLC involves primary chemotherapy (EP), with RT being reserved for brain metastases, bulky and symptomatic intrathoracic disease, and symptomatic bony or visceral metastatic sites. In addition, patients with a good performance status, a CR of metastatic disease, and at least stable disease in the chest following chemotherapy may benefit from the addition of TRT.[70]

Prophylactic Cranial Irradiation for Both E-SCLC and L-SCLC

PCI should be considered for all patients with SCLC who have achieved any degree of favorable response following initial management with chemotherapy or chemoradiation; 25 Gy in 10 fractions is considered the most standard regimen.[66]

Controversies and Clinical Trials

Issues addressed in current clinical trials include the potential benefits of higher dose daily TRT regimens in the management of L-SCLC. In E-SCLC, most research focuses on systemic therapy. However, there is a trial open examining whether patients benefit from the administration of RT to the chest and sites of residual disease plus PCI compared to PCI alone following systemic chemotherapy.

CHAPTER

44 Non–Small Cell Lung Cancer

Henry Wagner, Jr. and Corey Jay Langer

EPIDEMIOLOGY AND PATHOLOGY

An estimated 228,190 new cases and 144,570 deaths from lung cancer occurred in the United States in 2013. Fifteen percent of patients will be alive at 5 years. Because of a decline in smoking rates over the past 40 years, the incidence and death rates in the United States have begun to decline for white men, but they remain stable or are rising in other demographic groups. An increasing percentage of patients with newly diagnosed lung cancer are ex-smokers. In clinical trials, this demographic often constitutes more than half of those enrolled. Although the majority of lung cancers are associated with current or prior tobacco use, lung cancer in persons who have never smoked is often a distinct molecular and clinical entity and accounts for close to 20% of all cases. Lung cancer is an increasing cause of illness and death worldwide, where smoking rates are often much higher than in the United States.

Three histologic types—squamous cell carcinoma, adenocarcinoma (including bronchioalveolar), and large cell undifferentiated carcinoma—comprise non–small cell lung cancer (NSCLC).[1]

BIOLOGIC CHARACTERISTICS

Genetic or epigenetic alterations have been described in NSCLC and in premalignant lung tissues exposed to tobacco smoke. Distinct patterns of genetic and epigenetic modifications have been described for squamous cell and adenocarcinoma. Genomic profiling of lung cancer complements anatomic staging in predicting prognosis and dictating treatment. The biologic subtypes of NSCLC have clinical implications in terms of chemotherapy regimens and targeted therapeutic strategies. Diagnostic biopsies should include sufficient material to allow molecular characterization of the tumor.

STAGING

The TNM system underwent major revisions in 2009. Combined positron emission tomography (PET) using ^{18}fluorodeoxyglucose (^{18}FDG) and computed tomography (CT) is the preferred study for evaluation of the primary tumor and metastatic disease. False-positive rates of 20% to 30% dictate that patients not be denied potentially curative treatment solely on the basis of radiographic findings without histologic confirmation.

PRIMARY THERAPY FOR EARLY-STAGE DISEASE

Anatomic resection, either lobectomy or pneumonectomy, with thorough sampling or formal dissection of hilar and mediastinal nodes remains the preferred treatment in patients with clinical stage IA to IIB NSCLC. Patients with medical contraindications to surgery should be offered radiation therapy (RT), with or without chemotherapy, with curative intent. Hypofractionated stereotactic beam radiotherapy (SBRT) shows promise for lesions up to 5 cm in the absence of nodal spread, with local control and survival rates rivaling those of surgery.

ADJUVANT AND NEOADJUVANT THERAPY

Postoperative RT (PORT) of ipsilateral hilar and mediastinal lymph node reduces the risk of local recurrence in patients with resected node-positive NSCLC. A small survival benefit for patients with N2 disease has been suggested in retrospective analyses, but this remains controversial and has not been adequately tested in prospective trials. PORT is not indicated for patients with N0 or N1 disease. There is a significant survival benefit for adjuvant chemotherapy using platinum-containing regimens (North America and Europe) or tegafur and uracil (Japan), and such therapy should be offered after resection to patients with good performance status with resected stage N1 and N2 disease and strongly considered for those with N0 tumors whose size exceeds 4 cm. For patients with resectable but poor-prognosis disease (stages IIB to IIIA), neoadjuvant chemotherapy or chemoradiation has been investigated. For patients with more advanced mediastinal disease (N2 or N3, selected T4, N0 to N1 with direct mediastinal invasion), either definitive chemoradiation or surgery after induction chemotherapy or chemoradiation are acceptable options with similar overall survival (OS) but differing patterns of failure and morbidity. Brain metastases are common in patients with NSCLC; however prophylactic cranial irradiation (PCI)—although decreasing central nervous system (CNS) failure—has not been shown to improve OS and is not standard therapy.

LOCALLY ADVANCED DISEASE

Most patients with stage IIIB or unresectable stage IIIA disease are treated nonsurgically with irradiation and chemotherapy, with a 10% to 20% long-term survival rate for patients with good performance status and no significant weight loss. Combinations of RT and sequential or concurrent chemotherapy are superior to RT alone. Concurrent chemoradiation yields superior median and long-term survival than sequential therapy.

PALLIATION

External beam irradiation (EBRT) effectively palliates local symptoms or metastases to bone or brain. Hypofractionated regimens are effective and well tolerated. Endobronchial irradiation or photodynamic therapy can relieve obstruction or hemoptysis. Chemotherapy with a platinum-based doublet can extend survival and relieve symptoms and improve quality of life. Molecularly targeted agents are highly active in appropriate patients. Epidermal growth factor receptor–tyrosine kinase inhibition (EGFR–TKI) are the therapy of choice for patients whose tumors harbor EGRF-activating mutations. Likewise, crizotinib has become the standard approach for patients whose tumors harbor ELM4/ALK or ROS1 translocations.

INTRODUCTION

Lung cancer killed an estimated 144,570 men and women in the United States in 2013, more than colon, breast, prostate, and pancreatic cancer combined.[1] More than 80% of these cases were caused by habitual or environmental exposure to tobacco smoke.[2] This common origin makes lung cancer a disease better suited to prevention than treatment. However, non–tobacco-associated lung cancer (NTLC) is not a rare disease; these include about 40,000 cases per year in the United States and an even greater percentage of total lung cancer cases in Asia. NTLC frequently differs at a molecular level from tobacco-associated NSCLC, and these differences have clinical and therapeutic implications.

The reduction of lung cancer deaths in white American men over the past two decades has resulted more from the decrease in cigarette smoking after the publication of the U.S. Surgeon General's report in 1964 than from major advances in the efficacy of therapy or early detection, although this may be changing. Recent data from the National Lung Screening Trial (NLST) have shown reduction of lung cancer deaths with low-dose CT screening of high-risk populations.[3]

Although the results of current therapy are frustrating, they must not be viewed nihilistically. Adjuvant treatment in resected NSCLC has resulted in a modest but statistically significant and clinically meaningful improvement in survival, especially those with nodal involvement. In locally advanced NSCLC, concurrent chemoradiation has led to a substantive increase in long-term survival, particularly in patients with good prognosis with intact performance status (PS) and minimal weight loss. Finally, in advanced or recurrent NSCLC, modern systemic therapy has both prolonged life and enhanced quality of life. These incremental improvements in therapy have helped many individuals diagnosed with NSCLC. Although avoiding tobacco use is the most efficient strategy for reducing lung cancer deaths, it is clearly worthwhile to optimize current therapeutic modalities of surgery, irradiation, and chemotherapy. Even if all current smokers quit smoking this instant, their previous carcinogen exposure would lead to another million or more cases of lung cancer over the next 30 to 50 years. Thus, the need for more effective treatment will continue into the foreseeable future.

Advances in multiple disciplines include tumor biology techniques that enable both identification and selective treatment of particular molecular entities within the broad spectrum of diseases termed lung cancer, imaging and treatment delivery technologies that better identify where to put the dose and deliver it accurately and reproducibly (or adaptively to a target size and shape that is changing over time), and a growing willingness of specialists of all modalities to work collaboratively for their patients' benefit. The development of interventions to facilitate such continuity of care and communication to patients and with other care providers is gaining attention.[4] The key to improving treatment is the integration of diagnostic and treatment modalities by a team whose members are interested in lung cancer and its treatment, well versed in the application of the appropriate modalities, and able to combine them without undue bias.[5,6] This interdisciplinary approach and the expertise, dedication, and collaboration it mandates is the vital to optimizing therapy for our patients. The development of advocacy groups such as the Lung Cancer Alliance and their endorsement by other groups such as the American Academy of Chest Physicians should hasten this becoming the standard of practice, as is already the case for patients with breast and prostate cancers.

ETIOLOGY AND EPIDEMIOLOGY

More than 80% of lung cancer can be attributed to carcinogens in tobacco smoke. Habitual and environmental exposures are clearly linked to lung cancer at levels ranging from descriptive epidemiology, characteristic patterns of oncogene and tumor suppressor gene mutations, and measurement of tobacco-associated carcinogens in the urine of individuals exposed to second-hand smoke.[7-10] It has been speculated that up to a third of lung cancers in those who never smoked may be attributable to secondary exposure.[11] Hecht et al showed that nonsmokers, when exposed to side-stream smoke in concentrations comparable to those found in a smoky room, excreted metabolites of tobacco-specific carcinogens in their urine.[12] Pipe and cigar smokers have lower lung cancer rates than cigarette smokers, but these habits are far from innocuous, particularly in former cigarette smokers, who often continue to inhale.

The risk of lung cancer is related to the amount smoked daily and the duration of smoking, leading to the term *pack-years* as a measure of smoking exposure. When individuals quit smoking, their risk of lung cancer declines over at least a decade but remains higher than that observed in those who never smoked.[13-15] Lung cancer incidence and death rates typically reflect smoking behavior from two to three decades previously. Examination of the respiratory epithelium of former smokers years after quitting shows persistence of telltale patterns of genetic and epigenetic change.[16,17] Once initiated, the process of lung carcinogenesis can proceed without continued smoke exposure. This has led to the ironic observation in the new millennium that the majority of cases of lung cancer are diagnosed in former smokers rather than current smokers.

Current epidemiologic efforts are devoted to better understanding the molecular determinants of risk distal to smoke exposure, including metabolic activation of procarcinogens, degradation and excretion of carcinogens, accurate repair of damaged DNA (or apoptotic execution of cells harboring DNA damage), and other less-well-understood mechanisms that result in the development of lung cancer in some but not all heavy smokers.[18-20] Although no single genetic abnormality has been clearly implicated in causing lung cancer, there is considerable epidemiologic evidence for an inherited component of risk, particularly for cases of lung cancer diagnosed in younger individuals.[21] Polymorphisms in a variety of enzymes involved in the metabolism of potential carcinogens, their detoxification, and in DNA repair enzymes have been associated with risk of lung cancer in a number of small studies of both smokers and nonsmokers but no clear risk pattern has been replicated in large populations.

Smokers with chronic obstructive pulmonary disorder (COPD) are at significantly higher risk for lung cancer than individuals with similar smoke exposure without COPD.[22] It is not known whether this reflects a common behavioral cause (e.g., deeper smoke inhalation, longer smoke retention) in these individuals or if there are differences in metabolism of components of tobacco smoke that increase the risk for both COPD and lung cancer.

Several recent studies have shown that a polymorphism in the nicotinic receptor gene cluster in the chromosome 15q24-25 region is strongly associated both with nicotine dependence and the development of both COPD and lung cancer.[23] Such associations have been seen in European, African, and Asian populations. Whether this locus is directly involved in tobacco carcinogenesis or indirectly mediated through strength of nicotine dependence is not yet clear and both direct and indirect mechanisms may be involved.[24]

In addition to tobacco smoke, many other substances have been implicated in causing lung cancer. Several industrial

chemicals, particularly the chloromethyl ethers, have been associated with lung cancer. Exposure to both asbestos and tobacco smoke produces lung cancer more frequently than either exposure alone. Exposure to inhaled radioactive substances by uranium miners or by individuals living in areas with high endogenous radon levels also increases risk.

Lung cancer has been reported in a number of patients with human immunodeficiency virus (HIV) infection, but there is no strong evidence for a direct causative role. Lung cancer is not particularly common in individuals otherwise immunosuppressed, such as after organ transplantation. Individuals who are HIV positive with lung cancer tend to be younger than other patients, almost always have a history of heavy tobacco use, tend to present with advanced-stage disease (80% stages III and IV), show a predominance of adenocarcinomas, and have a poorer prognosis, even for the minority who present with early-stage disease. The tolerance of these patients to treatment, particularly to aggressive chemoradiation may be compromised by limited hematologic reserve and development of severe mucositis during and after RT.[25]

Although lung cancer was formerly a predominately male disease, its incidence and death rates in women began to rise in the United States in the 1960s, and since 1987, the death rate from lung cancer in women has exceeded that of breast cancer.[26] In the United States, the incidence of lung cancer in men increased through much of the 20th century until leveling off and then starting to decline in the 1980s. In women, the incidence rose steadily through the latter part of the past century but appears to be plateauing in the United States and Europe.

Although most cases of lung cancer occur in individuals with a history of tobacco use, lung cancer in those who have never smoked or in minimal smokers is far from a rare disease. It represents 15% to 20% of lung cancer seen in North America and Europe and up to 40% in parts of Asia. In the United States, 20,000 individuals each year die from non–tobacco-associated lung cancer, which, based on this simple math would make this entity the fifth-most common cause of cancer death. The clinical and molecular characteristics of lung cancer arising in persons who have never smoked or in minimal smokers are generally distinct from those of tobacco-associated lung cancer and warrant separate therapeutic strategies.[27-29]

MOLECULAR BIOLOGY OF LUNG CANCER

The past decade has seen dramatic changes in our understanding of the molecular genetics of lung cancers. Multiple genetic changes have been identified in lung cancers and cell lines derived from them and several distinct pathways of oncogenic development, both for squamous cell and adenocarcinoma, have been proposed.[30-32] The morphologic and clinical differences between the various types of NSCLC are reflected in decidedly different patterns of oncogene and tumor suppressor genes modifications in these disease families, and we are moving to a reclassification of NSCLC along patterns of genomic expression rather than light microscopic appearance. The old category of "large cell undifferentiated" NSCLC is now becoming increasingly infrequent as molecular characteristics of these tumors classify them as squamous or adenocarcinoma.[29-31] To an increasing extent we are moving from an early emphasis on identifying abnormalities in single genes to genomewide analysis and targeting of pathways rather than single enzyme or receptor targets. Although there are no absolute differences or characteristic mutations for either type, in the way that the *BCR-ABL* translocation is relatively pathognomonic of chronic myeloid leukemia, some molecular abnormalities frequent in one histologic type are rare in another.[33-35]

Molecular Changes

RAS

The *RAS* oncogene family contains three members, *HRAS*, *KRAS*, and *NRAS*, which encode membrane-associated proteins involved in mediation of signals arising from binding of ligands to cell membrane receptors such as epidermal growth factor receptors (EGFRs) to nuclear transcription factors.[36] Mutation in several specific sites, including codons 12, 13, and 61, lead to constitutive activation of these signaling pathways. In lung cancer, mutations are most commonly seen in *KRAS*.[37] They are most frequently seen in adenocarcinoma but are also seen in other NSCLC histologies. They are seen almost exclusively in smokers and rarely if ever in those who have never smoked whose tumors contain EGFR mutations. Patients whose lung cancers contain mutated *KRAS* almost never respond to EGFR-TKI, but it is not clear that they are resistant to cetuximab as is the situation in colorectal cancer.[38] The presence of mutated *RAS* genes has been an adverse prognostic factor in resected and advanced lung cancer in most series in which this has been assessed.[39] *RAS* mutations are rare in small cell lung cancer (SCLC), and when detected, they may represent an admixture of NSCLC elements or the development of an intermediate SCLC line.[40]

TP53

Abnormalities in *TP53* function through deletion or mutation of the gene or overexpression of *MDM2* leading to aberrant *TP53* inactivation are among the most common genetically induced changes in human malignancies.[41] Mutations are reported in a high frequency in lung cancer, about 50% of NSCLCs, and 90% of SCLCs.[42] Different patterns of mutation (e.g., ratio of transitions to transversions) are seen in smokers and in persons who have never smoked, suggesting different mutagens. Normal *TP53* plays several key roles in determining cellular response to genetic damage, particularly whether cells enter growth arrest or apoptosis. There have been conflicting reports about the prognostic implications of abnormal *TP53* function in lung cancer. For a number of chemotherapeutic agents and ionizing radiation, cells lacking normal *TP53* function are resistant to apoptotic cell death, although the effect on overall cell survival is controversial.[43-45]

RB1

The *RB1* gene–encoded product (RB) is a nuclear protein that undergoes cyclic phosphorylation and dephosphorylation during the cell cycle under the control of G_1 cyclins.[46,47] RB regulates E2F1 transcription factor activation. Absence of normal function occurs in most SCLCs but only in about 10% of NSCLC lines examined.[48-50]

CDKN2A

Normally, *CDKN2A* (previously designated *p16*) regulates transcription through phosphorylation of the RB1 protein. Abnormalities of *CDKN2A* function are reported in a reciprocal fashion to those of RB1; they are common in NSCLC and rare in SCLC. Because either of these abnormalities can allow uncontrolled transcriptional activation through E2F, it is not surprising that they are not commonly found together.[51] Although mutations in either are common in lung cancer, these mutations have not been correlated with prognosis.

Growth Factors

Abnormalities in normal growth factor signaling pathways have been proposed as a common mechanism for the dysregulated cell growth in cancer. In lung cancer, several clear

examples of this have been demonstrated to exist and have become targets for possible therapeutic intervention.

Epidermal Growth Factor Receptor

EGFR mediates a number of signaling pathways critical for cell growth, survival, and response to cytotoxins, including ionizing radiation and several chemotherapeutic agents. It is overexpressed in a variety of malignancies, and overexpression has been correlated with poorer clinical outcome and resistance to radiation. Clinical attempts to target this pathway have included monoclonal antibodies targeted to the extracellular domain of the receptor (C225, ABX) and low-molecular-weight compounds that bind the adenosine triphosphate (ATP) site and inhibit the tyrosine kinase activity of the receptor. About 10% of patients with NSCLC have mutations involving the ATP-binding pocket of the EGFR, which gives rise to more prolonged signaling activity in response to ligands such as epidermal growth factor (EGF) or transforming growth factor–beta and causes them to bind these inhibitors more tightly.[52-54] Such activation mutations are seen primarily in individuals with no or minimal smoking history and in Asian women and are more common in adenocarcinomas than squamous cell carcinoma. Patients whose tumors have these mutations are likely to have significant objective responses to treatment with compounds that target this pathway, but it is postulated that patients with wild-type, overexpressed EGFR are more likely to show a response of growth restraint but not regression. The presence of specific activating mutations in the tyrosine kinase domain of EGFR, particularly in-frame deletions in exon 19 and single-nucleotide substitutions in exon 21, rather than overexpression of wild-type EGFR, is a better correlate of response to treatment with EGFR-TKI such as gefitinib, erlotinib, or afatinib.[55-57]

ERBB2

Overexpression of *ERBB2* (formally *HER2*) is reported in NSCLC, particularly adenocarcinoma, and it is correlated with decreased survival of patients with resected disease.[58,59] The degree of overexpression is typically much less than seen in cancer of the breast, with few lung cancer patients showing 3+ staining. Trials of monoclonal antibodies directed against *ERBB2* in patients with unselected NSCLC have shown relatively little activity whether used alone or in combination with cytotoxic chemotherapy.[60]

In addition to overexpression of wild-type *ERBB2*, activating point mutations have been described in a number of patients with NSCLC.[61] These patients, about 5% of all with NSCLC or 15% of those with adenocarcinoma, may be more sensitive to therapies directed against ERBB2-mediated signaling and warrant further study with these agents.[56]

EML4-ALK

Recently, fusion genes that produce atypically activated transcription factors or kinases, long known in leukemias and sarcomas, have been described in a number of solid tumors.[62] Fusion of *EML4* and *ALK* has been described in a subset of patients with NSCLC.[63] Patients with *EML4-ALK* are typically young and light smokers or persons who have never smoked with adenocarcinoma. Because these clinical features also are more commonly seen in patients with *EGFR* mutations but patients with *EML4-ALK* mutations are not sensitive to TKIs targeting EGFRs such as gefitinib or erlotinib, it becomes increasingly important to select targeted therapies on the basis of molecular profiling of individual tumors rather than population statistics.[64] Inhibitors of the ALK kinase have shown significant activity both in vitro and in clinical trials and have shown significant improvements in overall response rates and progression-free survival (PFS) in patients with *EML4-ALK* translocations.[65-67]

EARLY DETECTION AND PREVENTION

Fewer than 20% of lung cancer patients in the United States are diagnosed with localized (stage I) disease. The poor survival of patients with symptomatic lung cancer prompted efforts to diagnose the disease in asymptomatic individuals. Until recently these had not shown a significant reduction in lung cancer deaths, but this has changed with reports of the recently completed National Lung Screening Trial.

The U.S. National Cancer Institute (NCI) had sponsored several trials in the 1970s comparing active screening using annual chest radiography and sputum cytology with "routine" medical care.[68,69] These studies showed increased detection of localized disease in the screened populations, with higher rates of resectability, but no decrease in mortality. This led to recommendations from the American Cancer Society to abandon routine screening for lung cancer by the methods used and in the populations studied.

Since the report of these trials, important demographic and technologic changes have occurred. Lung cancer is increasingly a disease of women.[70] Lung cancer has also increasingly become a disease of former smokers. Multiple large centers have reported that more than one half of their patients with lung cancer are former (i.e., more than 1 year since cessation) rather than current smokers.[71] Similar demographics have been observed on clinical trials. This change has had key implications for therapeutic interventions and in the possibility of enlisting this population, which has already demonstrated a high degree of motivation by quitting smoking, in studies of early detection and chemoprevention.

Silvestri et al[72] reviewed the current status of screening for lung cancer in light of this changing demography and proposed 10 essential criteria for a successful screening program: "The disease must have serious consequences and be readily detectable in the preclinical phase. The test should have a high accuracy, detect the disease before a critical point, cause little morbidity, be available and affordable, and result in little overdiagnosis. Finally, treatment for the disease must exist, and it must be effective before symptoms occur, with little risk or morbidity."

Computed Tomography–Based Screening Studies

The availability of fast high-resolution CT has prompted a new round of screening trials.[73] CT is more sensitive in detecting pulmonary nodules in asymptomatic individuals than chest radiography. The percentage of detected nodules ultimately proved to be cancerous has varied considerably in different series, in part because of the background frequency of conditions such as endemic fungal infections that may give rise to benign pulmonary nodules. Most series have shown a shift to earlier stage at diagnosis for screened patients compared with historical controls, which is potentially a marker for improved survival. However, others have argued that tumors detected through screening are likely to have a different and more indolent biology than tumors that present clinically and that only prospective trials can determine whether CT screening reduces overall or tumor-specific mortality. Several large trials of screening CT have been completed in recent years to determine if there is a reduction in overall mortality.

The NLST, which enrolled individuals at risk for lung cancer (30 pack-years or more of smoking history; ages 55 to 75) demonstrated a significant reduction in lung cancer mortality for low dose spiral CT imaging compared to chest x-ray.[74] From August 2002 through April 2004, investigators evaluated

53,454 persons at high risk for lung cancer in 33 separate U.S. medical centers. Participants were randomly assigned to undergo three annual screenings with either low-dose CT (26,722 participants) or single view posteroanterior chest x-ray (26,732). The rate of adherence to screening was more than 90%. The rate of positive screening tests was 24.2% with low dose CT and 6.9% with radiography over all three rounds. A total of 96.4% of the positive screening results in the low-dose CT group and 94.5% in the radiography group were false-positive results. The incidence of lung cancer was 645 cases per 100,000 person-years (1060 cancers) in the low dose CT group compared with 572 cases per 100,000 person-years (941 cancers) in the chest x-ray group (rate ratio, 1.13; 95% confidence intervals [CI], 1.03 to 1.23). There were 247 deaths from lung cancer per 100,000 person-years in the low-dose CT group and 309 deaths per 100,000 person-years in the chest x-ray group, corresponding to a relative reduction in mortality from lung cancer with low-dose CT screening of 20% (95% CI, 6.8 to 26.7; $p = 0.004$). The rate of death from any cause was reduced in the low-dose CT group compared to the radiography group by 6.7% (95% CI, 1.2 to 13.6; $p = 0.02$).

Screening is not innocuous. In addition to the small but finite radiation hazard from CT scans, patients undergoing screening are at risk for complications of further testing and intervention associated with false-positive screen findings. Patients should be made aware of these potential downsides of screening before making decisions to be screened outside the context of a clinical trial. Despite these encouraging results from the NLST trial, there remains concern about the high false-positive rate of initial screen abnormalities and the possibility that some of the screen-detected cancers are indolent and would not have led to clinically evident disease.[75] Patz et al have estimated that about one in five cancers detected by low-dose CT screening in the NLST trial was biologically indolent, rising to 78.9% for bronchoalveolar carcinomas.[76] Because only 1 in 320 screen-detected abnormalities turns out to be a cancer, issues of cost, anxiety, and the rare morbidity and mortality associated with efforts to obtain diagnostic tissue remain of concern and should be part of the discussion with individuals who are considering being screened. Based on current data, a decision to screen individuals in high-risk populations is reasonable so long as the individual understands the benefits and risks of screening, and organizations such as the American Academy of Chest Physicians, the American Lung association, and the U.S. Preventive Services Task Force have endorsed screening programs for the NLST population.

Cytologic and Molecular Screening

Advances in molecular technology offer the promise of detecting malignant changes in exfoliated cells well before morphologic changes appear. Tockman et al have shown that with monoclonal antibody staining using sera developed against SCLC and NSCLC lines, sputum cells showing atypia could predict which patients were going to develop frank malignancy with a lead time of about 2 years.[77] This technique is being studied further in a prospective trial of patients who have undergone resection of a stage I NSCLC and are at high risk for local recurrence and development of a second primary lung cancer. Mao et al reported similar findings using probes for mutations of KRAS and TP53 genes.[78] Mills et al also reported detection of KRAS mutations in fluid obtained at bronchioalveolar lavage.[79] Others have reported the ability to detect EGFR mutations in circulating tumor cells or DNA fragments and the increasing potential of such "liquid biopsies" may greatly enhance our abilities for early detection (or detection of early recurrence) of a variety of solid tumors.[80-82] Sozzi et al have reported on the utility of a microRNA signature in conjunction with CT screening to reduce number of false-positives.[83]

Autofluorescence bronchoscopy has been used to examine the tracheobronchial tree and look for early neoplastic or preneoplastic lesions.[84] This approach complements CT screening, which primarily detects peripheral lesions and has poor sensitivity for small endobronchial lesions.[85]

Chemoprevention

Several classes of compounds have been investigated as candidate agents for lung cancer prevention.[86] Epidemiologic data show a higher incidence of lung cancer in populations with low dietary intake of retinoids and carotenoids. Deficiencies of these agents can lead to squamous metaplasia in animal models. Provision of exogenous vitamin A to animals that have developed metaplasia or atypia can lead to morphologic normalization of the epithelium.

Initial trials of retinoids in patients at high risk for lung cancer suggested reduced second primary lung tumors.[87-89] However, larger, prospective, confirmatory trials testing isotretinoin or retinyl palmitate and *N*-acetylcysteine have failed to confirm the initial promise of earlier trials.[90,91] To further complicate matters, several trials of β-carotene as a chemopreventive agent have observed increased rates of cancer in individuals who continue to smoke.[92]

The epidemiologic correlation between reduced consumption of foods rich in carotenoids and an increased risk of lung cancer in smokers and the laboratory data showing a protective effect of β-carotene against lung carcinogenesis led to two large chemoprevention trials.[93-96] In Finland, a trial of placebo versus β-carotene or α-tocopherol (i.e., vitamin E), or both, showed increased rates of and death from lung cancer in subjects receiving β-carotene. Participants in this trial were predominantly actively smoking males.[97] In the United States, a trial of β-carotene (CARET) was closed early when an interim analysis also showed an increased incidence of lung cancer in the treated arm of the study.[98] The increased risk of lung cancer and death of from cancer persisted even after further administration of β-carotene was discontinued.[99,100]

Selenium is a trace mineral whose presence in the soil varies considerably with geography. Selenium deficiency in animals can produce premalignant changes. Epidemiologic studies have suggested correlation between low dietary intake and cancer of a number of sites. A trial of selenium supplementation versus placebo in subjects with a history of multiple skin cancers did not show reduction in subsequent skin cancers (the primary endpoint), but fewer lung cancer cases were observed in patients randomized to receive selenium.[101] Unfortunately, a confirmatory North American trial in patients with resected stage I NSCLC failed to show any benefit for selenium compared with placebo.[102]

At present, no agent or combination of agents has been proven to delay or prevent the development of lung cancer of any histology in an at-risk population of current or former smokers. The surprising result of increased lung cancer incidence in some retinoid trials as well as the increased risk of diabetes in patients taking selenium in a prostate cancer chemoprevention trial suggest caution rather than therapeutic adventurism.[103] The American College of Clinical Pharmacy (ACCP) currently recommends that no agent be used for lung cancer chemoprevention outside of a clinical trial.[104]

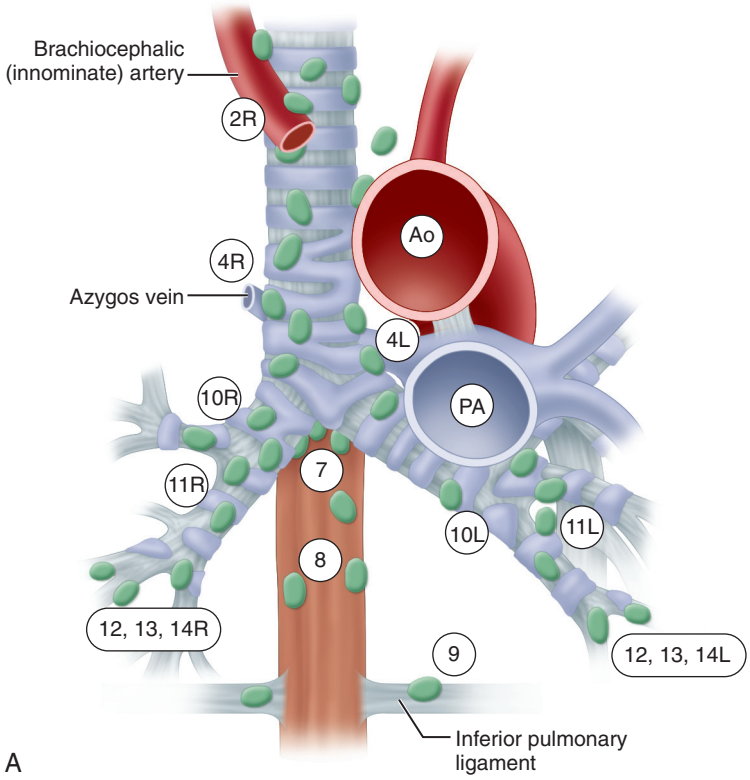
PATHOLOGY AND PATHWAYS OF SPREAD

The respiratory epithelium has a total surface area about the size of a tennis court. It may be divided functionally and pathologically into three zones. From the trachea through the major bronchi the normal lining is made of squamous cells

with interspersed neuroendocrine cells, which appear most commonly at airway bifurcations. Terminal alveoli are lined predominantly with type I and type II pneumocytes. Intermediate bronchi and bronchioles show a transition between squamous and adenomatous lining cells and a corresponding mixture of tumor types. The exposure of this large organ to a common set of inhaled toxins sets in process a widespread set of molecular and subsequent morphologic changes. Slaughter et al, who first observed this phenomenon in patients with multiple primary tumors of the head and neck, referred to this phenomenon as *field cancerization*.[105] Auerbach et al described similar widespread changes in the lungs of smokers with lung cancer, and Saccomano et al described a pattern of progressive degrees of cytologic atypia leading to frankly invasive carcinoma.[106,107] The practical consequence of this is that patients who develop one neoplasm of the upper aerodigestive tract (i.e., head, neck, lung, and esophagus), if treated successfully, remain at substantial risk for developing a second or subsequent primary tumor. For patients with resected stage I NSCLC, this risk is on the order of 2% to 3% per year for at least 10 years after treatment of the first cancer.[90,108,109] It can sometimes be difficult to distinguish second primary tumors from local recurrences or metastases; differences in histology, location, and presence of adjacent mucosal abnormalities have been proposed as criteria. Molecular markers may allow for fingerprinting by characteristic mutations at such sites as *KRAS* or *TP53* (which are known to have different mutational spectra in different parts of the aerodigestive tract), although it still sometimes may be difficult to distinguish between separate primary tumors and clonal variation of a metastasis and most cells in its primary tumor. Recent data have suggested, however, that multifocal lung cancers may share a common clonal origin.[110,111]

In addition to cell type and anatomic stage, a variety of molecular prognostic factors have been proposed to provide further prognostic or predictive information in lung cancer (Table 44-1). These include measures of cell proliferation (e.g., S-phase fraction, proliferating-cell nuclear antigen [PCNA], Ki-67, potential doubling time [T_{pot}]), mutated or overexpressed oncogenes or tumor suppressor genes (e.g., *KRAS, TP53, ERBB2, BCL2*), cell surface antigens (i.e., blood type antigens and their precursors), and induction of angiogenesis. Most of these have been proposed on the basis of small series of patients treated in a nonuniform fashion, and they often are based on univariate rather than multivariate analysis. Proper validation of these will require prospective study in large series of patients staged, treated, and observed in a uniform fashion.[112] It is likely that patterns of expression of multiple markers as assessed by genomic or proteomic analysis will more successfully predict prognosis, as has been shown for breast cancer and intermediate-grade lymphomas.[113,114] Small series have reported the success of such profiling in lung adenocarcinomas, but large validation series in uniformly treated patient groups are awaited.[115] Such profiling may also be useful in determining those patients at greatest risk for specific patterns of metastatic spread, such as to the brain, for whom particular targeted adjuvant therapies such as prophylactic cranial irradiation may have a better risk-to-benefit ratio.

Lung cancer spreads through regional lymphatic vessels within the lung to the hilar and paratracheal nodes, which drain to the supraclavicular fossae and, to a lesser degree, the upper abdomen (Figure 44-1). The patterns of nodal spread are partially predictable on the basis of tumor size, histology, and proximity to central airways. Involvement most often begins with intrapulmonary nodes, extends centrally to the hilum, and then to the mediastinum. However, noncontiguous "skip" metastases are well described. Although nodal involvement can usually be detected by preoperative CT or CT/PET, even for T1 primary tumors, the incidence of clinically undetected nodal metastases can be as high as 15% to 20% for peripheral adenocarcinomas.[116,117]



Hematogenous dissemination is common and is usually associated with nodal involvement, although about 20% of patients with resected T1N0 lesions will experience relapse in distant sites. Nodes that appear normal on routine histology, when examined by immunohistochemical staining for epithelial antigens, contain tumor cells in 15% to 25% of cases.[118] Occult bone marrow metastases in rib resected at the time of thoracotomy are also found by this method, including patients without any evidence of nodal disease.[119] It appears that nodal and hematogenous spread, which usually are associated, may occur independently.

Although nodal drainage is primarily to the ipsilateral hilum and mediastinum, the left upper lobe drains commonly to contralateral paratracheal nodes as well as to nodes in the anterior mediastinum.[120] Direct involvement of visceral and parietal pleura by peripheral tumors puts the entire ipsilateral

TABLE 44-1 Proposed Prognostic and Predictive Factors for Non–Small Cell Lung Cancer

Factor	Comment
Tumor volume	Partially incorporated into new TNM classification
Number of nodal sites	—
Clinically evident nodal involvement	Identified preoperatively as distinct from microscopic nodal involvement
Extranodal extension	May be prognostic for local recurrence and predictive of impact of postoperative radiation therapy on survival
IHC detection of nodal metastases	Nodes negative by H&E but positive by IHC
Histology	Predictive of response and toxicity with some agents
Ploidy	—
Proliferative rate (labeling index, Ki-67, T_{POT})	—
KRAS mutation	Predictive of resistance to EGFR-TKI
3p deletion	—
TP53 mutation or overexpression	—
Angiogenesis (microvessel density)	—
Vascular endothelial growth factor (VEGF) overexpression	—
Epidermal growth factor receptor (EGFR) overexpression and/or mutation	Mutation predictive for response to EGFR-TKI
ERBB2 (HER/neu) oncogene expression and/or mutation	Possibly predictive for response to trastuzumab
EML4-ALK	Predictive for response to ALK-TKI

pleural space at risk for involvement. The true frequency of this is not well known, nor is its clinical significance or appropriate therapeutic response. Several series have reported that intraoperative pleural lavage detects tumor cells in about 10% of patients and that their survival is markedly worse than that of patients with tumors of otherwise similar stage with cytologically negative lavage.[121-123]

Extrathoracic spread differs somewhat among the major histologic types of NSCLC. Early extrathoracic dissemination, particularly to the CNS, is seen more frequently with adenocarcinoma and large cell carcinoma than with squamous cell carcinoma.[124] However, all histologic types are prone to early and widespread extrathoracic metastases, with brain, bone, liver, adrenal, and lung the most commonly involved sites.

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Most patients diagnosed with lung cancer present with symptoms that may be as a result of the primary tumor, its nodal and systemic metastases, or to paraneoplastic syndromes.

Central endobronchial tumors may cause partial or complete airway obstructions, with cough, hemoptysis, postobstructive pneumonia, or dyspnea. Peripheral tumors are often asymptomatic unless they involve the chest wall and produce pain from involvement of intercostal nerves. Tumors that involve the superior pulmonary sulcus may directly involve branches of the brachial plexus with pain and weakness in the shoulder and arm or involve the sympathetic trunk, producing Horner's syndrome with ipsilateral ptosis, miosis, and anhidrosis.

Regional lymph node metastases may compress adjacent structures. Although complete obstruction of main bronchi by extrinsic compression is uncommon, this occurs more readily in distal airways. The superior vena cava is a relatively thin-walled, low-pressure system, and it is vulnerable to compression with significant clinical consequences. The intrathoracic course of the recurrent laryngeal and phrenic nerves is vulnerable to compression by nodal metastases. Patients presenting with hoarseness or who have a fixed elevated hemidiaphragm should be suspected of having such nodal involvement.

Lung cancer can metastasize to a wide variety of extrathoracic sites and produce diverse symptoms. The most frequent symptoms of distant metastatic disease are bone pain and neurologic symptoms from brain metastases. These are not, however, absolute indicators of metastatic disease. Pulmonary hypertrophic osteoarthropathy typically presents with bilateral pain and tenderness in the legs, which are often most tender over the tibias. Bone scintigraphy or CT/PET will show diffuse uptake in these areas, and plain films usually show a characteristic elevation of the periosteum without involvement of cortical bone.

Although focal neurologic symptoms most commonly result from brain metastases, CNS symptoms may also be caused by paraneoplastic cerebellar degeneration or by metabolic disturbances such as hyponatremia resulting from syndrome of inappropriate antidiuretic hormone (most commonly seen in SCLC) or hypercalcemia resulting from secretion of parathyroid-like hormone (most commonly seen in squamous cell carcinoma). Nonspecific decreases in cognitive function compared with age- and gender-matched controls have also been reported in patients with lung cancer before any treatment, particularly in SCLC.[125]

Liver metastases are common but usually asymptomatic unless advanced. Abnormalities in liver function studies are uncommon unless there has been extensive destruction of liver parenchyma, although alkaline phosphatase and bilirubin levels may be elevated by small-volume hepatic or nodal disease blocking the common hepatic or common bile duct. Elevation of the lactate dehydrogenase level is a poor prognostic sign, but it probably reflects overall tumor burden rather than solely the extent of hepatic disease. Adrenal metastases are common, particularly at autopsy, but rarely symptomatic unless large and painful. Symptomatic adrenal hypofunction has been described, but it is infrequent unless both adrenals are involved.

Radiographic Procedures in Staging

As with any other medical test, radiographic staging procedures should be used primarily when their results will lead to a change in choice of therapy. A secondary role is in defining homogeneous groups of patients for clinical research. When used in this manner, the possibility of differences between groups so staged and the more general population of patients must be kept in mind.

Appropriate radiographic procedures for patients with suspected or newly diagnosed lung cancer depend in part on the histologic type of cancer and on the therapeutic options. The otherwise healthy individual who presents for an elective orthopedic procedure and is found to have an incidental 2-cm peripheral lung nodule without any other abnormalities on chest radiography, combined PET/CT of the chest, and routine laboratory studies (e.g., complete blood cell count, chemistry profile including electrolytes, renal, and hepatic function) is unlikely to have any useful information found with further testing. At the other end of the spectrum, the patient who presents with limiting cardiopulmonary disease, substantial recent weight loss, poor performance status, new bone pain, and a large hilar mass requires only an efficient choice of the least invasive means of obtaining a tissue diagnosis and choice of appropriate palliative therapy. Delineation of all sites of metastatic disease in such a setting is an expensive and wasteful application of resources that does not often lead to changes in care or outcome.

Evaluation of the primary tumor is generally best accomplished by CT enhanced with intravenous contrast.[126] The parameters of contrast enhancement (dose, infusion rate, and site of infusion [left side preferred to visualize vessels crossing in the anterior mediastinum]) can make a great difference in the quality of information obtained. It is important to examine the chest using both lung and mediastinal window settings.

Staging of the Mediastinum

Combined PET/CT is the radiographic method of choice for evaluation of the mediastinum.[127,128] The false-positive and false-negative rates are about 20%, however, and this should be considered when planning therapy. In most cases, histologic confirmation of suspected nodal involvement should be obtained before making decisions regarding potentially curative treatment. The accessibility of mediastinal nodes to biopsy under guidance of CT or of endoesophageal or endobronchial ultrasonography makes this a simple, minimally invasive procedure for most patients, with the use of more invasive procedures such as mediastinoscopy or anterior sternotomy (i.e., Chamberlain procedure) reserved for a minority of patients.[129,130] It is critical to personally review diagnostic imaging and not simply rely on written reports. In some cases, a patient is said to have "mediastinal adenopathy" with the implication of unresectable N2 disease, although CT demonstrates the presence of several benign 1-cm nodes. The distribution of size of mediastinal nodes in normal individuals easily includes this range; and of nodes 1.5 cm in the greatest dimension, about 20% will be histologically benign. The percentage of such false-positive results is even higher among patients with obstructing endobronchial lesions or extrinsic bronchial obstruction from hilar nodes and postobstructive infection.

Although there was initially hope that magnetic resonance imaging (MRI) might be superior to CT in differentiating benignly enlarged from malignant mediastinal nodes, this has not been the case. CT, with its better spatial resolution and greater freedom from motion artifact, is the superior modality for imaging the mediastinum. MRI does have a role in evaluation of lesions that involve the lung apex (and possibly the brachial plexus) and medial lesions that abut the vertebrae and may invade the neural foramina. Such involvement may preclude resection and poses a risk for spinal cord compression, and its delineation has important implications for planning radiation therapy.

FDG-PET has good sensitivity and specificity in detecting mediastinal nodal involvement and diseases in extrathoracic metastatic sites.[131-137] PET has greater sensitivity and specificity than CT, but is still imperfect. Nodes that appear involved by PET or CT should be sampled for confirmation of their status when such information will lead to alterations in clinical management, particularly when deciding whether to consider resection. If a negative PET scan is being considered adequate to avoid performing pathologic evaluation of mediastinal nodes, it is important to require that the primary tumor show measurable uptake (often not the case for bronchioalveolar carcinoma), that there not be a central primary tumor whose uptake could obscure small nodes, and that a dedicated PET/CT scanner be used.[138] FDG-PET has also been studied for evaluating the response to preoperative chemotherapy or chemoradiation and for distinguishing between viable tumor and fibrosis in patients who have received RT or chemotherapy, or both, in assessing local disease control in patients treated nonoperatively.[139-146] Regardless, in equivocal situations, mediastinoscopy is still considered the gold standard for evaluation of mediastinal nodes.

Evaluation for Extrathoracic Metastases

The liver and adrenals are common sites of metastasis for NSCLC and are well imaged by CT and PET. Although metastases to the adrenals are common, so are adenomas, and the distinction between these may require biopsy in patients who are otherwise good candidates for curative treatment. Routine bone scintiscans are of limited value. Many patients have abnormal results of bone scintigraphy because of benign degenerative diseases or prior trauma. The likelihood of detecting occult metastatic disease in patients without focal symptoms or elevation in alkaline phosphatase levels is low. PET scan, at this point, has largely replaced bone scans in the evaluation of bone involvement.

The use of total-body PET has been advocated as a cost-effective replacement for CT of the liver and adrenals and radionuclide bone scanning.[127] The typical PET scan does not image the brain, and the high glucose uptake of normal brain tissue will obscure small metastases. It will not replace MRI for this purpose. The typical PET or fused PET/CT does not image the entire skeleton, typically omitting the calvarium and the distal extremities.

Clinically occult involvement of the CNS is common, especially in patients with involvement of mediastinal nodes or other sites of extrathoracic involvement. Scanning of the brain is not indicated for patients with stage IA disease, for which the probability of CNS involvement is about 5%; however, that risk goes up to 15% to 20% for patients with N2 disease.[127] In patients being considered for aggressive chemoradiation with or without surgery, the finding of CNS metastases will lead to major changes in therapy, and scanning is warranted in this situation. Although historically routine brain scanning has not been obtained in patients with extrathoracic metastatic disease in the absence of CNS symptoms, increasingly specific treatments (e.g., bevacizumab) and protocols require brain imaging at the outset before therapy can begin.

The role of CNS imaging in the patient with stage IB to II disease is controversial. Although the false-positive rate of CT and MRI is low and few patients would wrongly be excluded from surgery, the true-positive rate is also low. However, in some series, 10% of patients with stage IB to II NSCLC without neurologic symptoms had metastases demonstrated on enhanced CT.[147] Such a frequency of involvement probably warrants more common CNS imaging as part of routine staging, considering the cost and morbidity of a thoracotomy, which would most likely be futile in the presence of brain metastases.

Tumor-Node-Metastasis Stage Grouping

NSCLC is staged according to the principles of the tumor-node-metastasis (TNM) system. The International Staging System outlined by Mountain in 1986[148] has been the standard for reporting treatment results since that time. The broad outlines of this system are clearly valid. However, several areas emerged that indicated the need for modification of this system, and revisions were implemented in 1997 and again in 2009.[149] The current version is reasonably predictive of outcome, particularly for patients treated surgically (Tables 44-2 and 44-3). This system may not deal so well with anatomic prognostic factors that may be important for nonsurgical treatment.

Tumor volume is not considered an independent prognostic factor except by the proxy of unidimensional measurements. A 1-cm lesion involving the visceral pleura is T2, and a 2.9-cm lesion surrounded by lung parenchyma is T1. It might be expected that the smaller T2 lesion would be more readily controlled by RT than the larger T1 lesion, and available data are in agreement with this expectation. Data from several institutions support the hypothesis that tumor volume, independent of stage, is prognostic for local control and survival of patients with NSCLC treated with RT or chemoradiation.[150-154] Such volumetric measurements can be performed using commercially available RT planning software, although standardization of technique is important to reduce interobserver variability.[155]

There are several reports that size is an important predictor of prognosis in the clinical T1N0 group and directly correlates with the likelihood of microscopic involvement of hilar and mediastinal lymph nodes.[156] This is relevant to treatment strategies that try to reduce the extent of resection or limit the radiation target volume by eliminating elective nodal irradiation (ENI) in these patients and for patients treated with SBRT. Data suggest that only patients with lesions smaller than 1 cm in diameter have a risk of nodal involvement below 10%.

Several of the old TNM stage groups have considerable heterogeneity in outcome.[157] This is true to some degree for patients with stage I disease, where the survival of patients with T1N0M0 disease (~80%) is strikingly better than that of patients with T2N0M0 disease (~60%). It is in the current stage group III that the heterogeneity and need for subgrouping is greatest. This was partially recognized by Mountain,[148] who divided the grouping into IIIA (i.e., no direct tumor invasion of the mediastinum or involvement of contralateral mediastinal or supraclavicular nodes, no pleural effusion) and IIIB (i.e., with one or more of the previous characteristics). This distinction separated a group of patients (IIIA), some of whom could undergo complete resection and have a reasonably favorable prognosis (e.g., T3N1M0), from those with unresectable disease who are often treated palliatively. In patients with stage IIIA or IIIB NSCLC who are treated nonsurgically with radical RT or chemoradiation, the survival differences based on stage are much less striking.[158]

Several other groups have proposed different revisions to the staging system. Based on the European Lung Cancer Working Party data on patients receiving chemoradiation, Berghmans et al proposed separating patients with stage T3 or 4, N3, M0 disease from other factors that predicted better survival than the usual stage IIIA versus IIIB distinction.[159] Andre evaluated patients with resected stage III NSCLC, some of whom had received induction chemotherapy, and found that the number of lymph node levels and clinically detectable nodal metastases (cN2) were adverse prognostic factors.[157]

Although the 2009 modifications introduced to the TNM staging system for lung cancer constitute a clear improvement, they do not deal adequately with a number of the issues that

TABLE 44-2 International Staging System: TNM Classification (2009)

Category	Definition
Tx	Primary tumor cannot be assessed, or tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	A tumor 3 cm or less in greatest dimension, surrounded by lung or visceral pleura, without radiographic or bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus)
T1a	Tumor 2 cm or less in greatest dimension*
T1b	Tumor more than 2 cm but not more than 3 cm in greatest dimension
T2	Tumor more than 3 cm but not more than 7 cm; or tumor with any of the following features†: • Involves main bronchus, 2 cm or more distal to the carina • Invades visceral pleura Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
T2a	Tumor more than 3 cm but not more than 5 cm in greatest dimension
T2b	Tumor more than 5 cm but not more than 7 cm in greatest dimension
T3	Tumor more than 7 cm or one that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium; or tumor in the main bronchus less than 2 cm distal to the carina but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung or separate tumor nodule(s) in the same lobe as the primary tumor
T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, carina; separate tumor nodule(s) in a different ipsilateral lobe to that of the primary tumor
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastases in ipsilateral peribronchial or hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2	Metastases in ipsilateral mediastinal or subcarinal lymph node(s)
N3	Metastases in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
M0	No distant metastases
M1	Distant metastasis
M1a	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural nodules or malignant pleural or pericardial effusion‡
M1b	Distant metastasis

From Goldstraw P: Staging manual in thoracic oncology, Orange Park, FL, 2009, Editorial Rx Press.
**The uncommon superficial spreading tumor of any size with its invasive component limited to the bronchial wall, which may extend proximal to the main bronchus, is also classified T1a.*
†T2 tumors with these features are classified T2a if 5 cm or less or if size cannot be determined and T2b if greater than 5 cm but not larger than 7 cm.
‡Most pleural (pericardial) effusions with lung cancer are the result of tumor. In a few patients, however, multiple microscopic examinations of pleural (pericardial) fluid are negative for tumor and the fluid is nonbloody and is not an exudate. When these elements and clinical judgment dictate that the effusion is not related to the tumor, the effusion should be excluded as a staging element and the patient's disease should be classified as M0.

TABLE 44-3 Stage Grouping and TNM Categories

Stage	TNM Categories
Occult carcinoma	TXN0M0
Stage 0	TisN0M0
Stage IA	T1a,bN0M0
Stage IB	T2aN0M0
Stage IIA	T1N1M0
Stage IIB	T2bN1M0 T3N0M0
Stage IIIA	T1a,bT2a,bN2M0 T3N1-2M0 T4N0-1M0
Stage IIIB	T4N0-2M0 Any T, N3M0
Stage IV	Any T, any N, M1

From Goldstraw P: Staging manual in thoracic oncology, Orange Park, FL, 2009, Editorial Rx Press.

pertain to surgical and nonsurgical therapy. The number of lymph node stations involved, as well as whether involvement is microscopic or macroscopic, has also been found to be of prognostic significance in patients with resected stage IIIA disease, though this assessment may be inconsistent from institution to institution.

Practical treatment decisions for patients with stage IIIA and IIIB NSCLC are often made along the following lines.[160]

GROUP A (old T1-3N2aM0): Involvement of a single mediastinal nodal station found at mediastinoscopy or mediastinotomy or at thoracotomy. The nodal capsule is not breached. In some institutions, patients undergo definitive resection and then are given adjuvant postoperative therapy, whereas others are given preoperative therapy.

GROUP B (old T1-3N2bM0): Involvement of multiple mediastinal nodal stations with potentially resectable disease. Recent trials have compared chemoradiation or chemotherapy as preoperative regimens without providing a definitive answer.

GROUP C (old T1-3N2cM0): Bulky involvement of mediastinal nodes (e.g., seen on a chest radiograph), possibly with superior vena caval compression. Disease is unlikely to be resectable, even with preoperative therapy, but the patient is a candidate for definitive chemoradiation.

GROUP D (old T4aNXM0): Central T4 or N3 disease that can all be encompassed within a reasonable RT portal, limited by lung and spinal cord dose. These patients should be considered for definitive chemoradiation.

GROUP E (old T4bNXM0, now stage IVa): Disease includes malignant pleural or pericardial effusion. Because all known disease cannot be irradiated to a tumoricidal dose, these patients should be treated as other stage IV disease using primary chemotherapy, with irradiation reserved to treat or prevent local symptoms.

Medical Considerations for Surgical Resection: Cardiopulmonary Evaluation

Before undergoing surgery, patients must undergo appropriate cardiopulmonary evaluation to determine their ability to tolerate the operative procedure and the expected reduction in lung function after resection.[161,162] Patients with a history of coronary artery disease should be assessed carefully. Appropriate testing may include a stress test as well as stress radionuclide angiography. Patients in whom coronary artery calcification can be seen on CT should be similarly evaluated.

Pulmonary function evaluation should include determination of lung volumes and flow rates, diffusing capacity, and arterial blood gas analysis. A recommended preoperative workup is outlined in Table 44-4. Some patients with poor baseline pulmonary function the result of extensive bullous disease and poor lung compliance may have improvement in function after combined resection of the tumor and pulmonary dead space.

Patients not meeting criteria for lobectomy should be considered for lesser resections (i.e., wedge or segmental resection) if these appear capable of obtaining negative margins. The Lung Cancer Study Group (LCSG) trial,[163] which randomized patients with stage T1N0M0 NSCLC between lobectomy and more conservative resection, showed significantly better local control for lobectomy and an emergent difference in survival. The role of sublobar resection followed by RT to the tumor bed using intraoperatively placed brachytherapy mesh, was studied by the American College of Surgeons Oncology Group (ACOSOG). Local failure rates were 12.8% and 12.5% with and without brachytherapy, respectively, and staple line failure rates 6.4% and 4.8%, with no benefits seen for brachytherapy in this trial.[164]

PRIMARY THERAPY

Early-Stage Disease

Surgery is the most effective treatment for patients with technically resectable NSCLC, stage IA through IIB. The role of surgery for patients with IIIA (N2) disease is controversial. Several points arise from consideration of the survival of patients with surgically resected disease and the patterns of failure for those with disease that recurs:

- Five-year OS for the most favorable patients, those with small stage T1N0M0 lesions, approaches 80%, not too different from that seen in women with early-stage breast cancer.[165] This refutes the common impression of lung cancer as an intrinsically incurable disease and more correctly focuses attention on early detection.
- Most treatment failures are systemic rather than local (Table 44-5).
- Many patients with compromised pulmonary function can be managed surgically, if they undergo careful perioperative care.[175]
- Complication rates depend on patient (age, physiologic status), disease (e.g., extent of required resection), and technical (e.g., surgical expertise) factors.[176]

Definitive Radiation Therapy

Single-institution reports of results of definitive RT for patients with stage I or II NSCLC who refuse surgery or are deemed inoperable for medical reasons vary in patient selection, RT technique, and outcome (Table 44-6). Some of this variation comes from differing definitions of "medical unresectability," with institutions that consider borderline disease to be unresectable, improving the apparent results of both their surgical and RT series by the Will Rogers effect (i.e., stage migration).[197] However, several general conclusions may be drawn from these series:

1. Some patients with locally confined disease are cured with definitive RT. "Unresectable" is not synonymous with "incurable."
2. Survival of clinically staged patients treated with radical RT is inferior to that of surgically staged patients treated surgically.
3. Survival of these patients decreases with increasing T stage, tumor size (within T stage), and clinical involvement of hilar lymph nodes.

TABLE 44-4 Preoperative Evaluation of Pulmonary Function

Test	Desirable Value	Comment
FEV_1	>1.5 L lobectomy >2 L pneumonectomy >80% predicted	Should obtain regional ventilation and perfusion scans and calculate predicted postoperative FEV_1 in borderline cases
PCO_2	<45 mm Hg	Recent studies suggest that this may not be an independent risk factor
SaO_2	>90%	Further testing indicated if <90%
DLCO	>80% of predicted	Further testing indicated if <80%
VO_2max	>15 mL/kg/min	Values ≥15 mL/kg/min predict low surgical morbidity. Those >10 but <15 are borderline, and the patient's overall clinical status needs to be considered carefully

§Subset of entire series.

4. Even for patients with the most favorable disease status, local control has historically been inferior to that seen with surgery.
5. Even for patients with favorable disease status, distant metastases are a common cause of death.

These observations suggest several strategies to improve treatment outcome. Combining RT with systemic chemotherapy in an attempt to reduce distant relapse and to improve local control is a logical approach to explore, particularly as the toxicity of current chemotherapeutic regimens has decreased. RT time-dose parameters are another fertile ground for clinical trials. Sibley reviewed 10 reports of definitive RT for patients with medically inoperable stage I NSCLC.[194] About 15% of patients were long-term survivors, 25% died of intercurrent disease, 30% died of distant metastases, and 30% died of local failure. Neither time to local failure nor OS correlated with the treatment volume (i.e., primary tumor volume alone or inclusion of elective nodal irradiation), whereas the total tumor dose, in the range of 55 Gy to 70 Gy, did correlate with outcome. This suggested that escalation of the biologic effective dose was a logical approach to improve the RT management of these patients. There is limited experience combining systemic therapy with radiotherapy and potential toxicities need to be considered in patients who are medically inoperable.[198,199]

Stereotactic Body Radiation Therapy

A number of investigators have explored the use of hypofractionated SBRT (also referred to as stereotactic ablative radiotherapy [SABR]) for these patients (see Table 44-5). Both frame-based and frameless systems have been used, with daily tumor localization by orthogonal images, cone-beam CT, and real-time tracking of implanted fiducial markers. Motion resulting from respiration presents a complicating factor not encountered in intracranial stereotactic treatment. Such motion is present in conventional large-field RT, where it is often accommodated by increasing field margins at the expense of treating increasing volumes of normal lung tissue. This is unacceptable for stereotactic large-fraction treatment. A number of approaches have been developed for minimizing respiratory motion through breath-hold and abdominal compression techniques, gating the beam-on time to a particular phase of the respiratory cycle, or tracking the tumor or radiopaque fiducial markers implanted in it and adapting the target volume to the real-time position of the tumor. These approaches continue to evolve, but the results to date are highly promising and suggest that, at least for T1 tumors, the results of SBRT rival those of surgery for local control and survival (see Table 44-5).

The Radiation Therapy Oncology Group (RTOG) has conducted a Phase I/II trial of fractionated SBRT for patients with medically inoperable stage I NSCLC using a regimen consisting of three treatment fractions. Results from this and multiinstitutional trials in Japan and Europe indicate local control rates of about 90% when tumors are treated to a biologically effective dose of 100 biologically effective dose (BED) or greater.[200] A number of different fractionation schemes have been employed, ranging from a single fraction of 34 Gy to three- to five-fraction regimens over 1 to 2 weeks. At present, the optimal dose and fractionation, as well as the optimal dose homogeneity in the target volume remain to be clarified. Dose calculations for the multiple small fields used and tissue heterogeneities are also highly dependent on the calculation model used.[201] There also have been reports of substantial toxicity, particularly with regimens using smaller numbers of fractions, when the high-dose volume includes central

vascular or airway structures or the chest wall.[202,203] Implementation of a program of SBRT requires careful attention to details of patient positioning, treatment planning, and dose calculation to be safe and effective, but this approach, when properly executed, appears to challenge the primacy of surgery in potentially curative treatment of patients with early-stage lung cancer.[204]

There have been at least three attempts to conduct prospective Phase III trials comparing SBRT with surgery for patients with early stage (T1-2N0M) NSCLC; these include an RTOG trial, the ROSEL trial in the Netherlands, and a trial sponsored by Accuray comparing SBRT using the Cyberknife platform with resection.[205] All of these trials failed to meet accrual goals and were closed prematurely. It would appear that despite strong Phase II data supporting the use of SBRT for patients with marginally resectable NSCLC, neither patients nor physicians are at equipoise and willing to randomize patients between surgical and nonsurgical treatments at the present time.

Another therapeutic option that has been explored for medically inoperable patients with early stage NSCLC is radiofrequency ablation (RFA). Local control rates of 50% or more are reported for tumors less than 3 cm. Prospective trials are being conducted to better define the role of this therapy.[206]

Adjuvant Therapy for Early-Stage Disease

Multiple trials since 2000 (IALT, BR10, and ANITA) have demonstrated a survival benefit for adjuvant chemotherapy. Discussing the risks and benefits of adjuvant treatment with patients is difficult. Telling a patient who is recovering from a major surgical procedure that he or she is at high risk for recurrence despite having had a complete resection with no obvious viable tumor remaining is a challenge. Adjuvant treatment with platinum-based chemotherapy is designed to reduce this risk of distant relapse, but the added benefit in long-term survival of roughly 5% overall, although statistically significant, is relatively modest. Moreover, the statistical nuances of disease-free and OS curves escape many patients (Table 44-7). The format in which data are presented (i.e., whether the effect of an adjuvant treatment is expressed as a hazard ratio, a relative survival difference, or an absolute survival difference) can greatly affect a patient's willingness to proceed with adjuvant therapy.[210,211]

Postoperative Radiation Therapy

Several retrospective series published in the 1960s claimed that PORT improved survival of patients with resected NSCLC, particularly if they had nodal metastases.[212-215] This issue has been investigated in several prospective trials that, although methodologically flawed, provide a consensus answer that survival is minimally if at all improved, but local failure is probably reduced with such treatment.

A meta-analysis of 2128 patients treated in nine randomized trials of PORT versus observation concluded that this treatment was associated with a highly significant increase in the risk of death[216] (Figure 44-2). Overall, the risk ratio was 1.21 ($p = 0.001$). The authors concluded that PORT as used in these studies was detrimental and should not be used, at least for the time being. There are several significant differences between the treatment administered in several of the trials included in this meta-analysis and current practice. One fourth of the patients had stage I disease and given patterns of failure PORT would not be expected to be beneficial (see Table 44-7). Details of treatment, including preoperative staging, surgical technique, and radiation dose and dose delivery, differed substantially from current practice. Several of the trials required or allowed daily fraction sizes in excess of 2.0 Gy, with the Medical Research Council (MRC) trial using 2.6 Gy/day and the Slovenian trial using 3.0 Gy/day. Larger fraction sizes would be expected to produce an increase in acute and late complications compared with smaller fractions. Seven of the nine trials also allowed the use of cobalt-60 (^{60}Co) treatment beams, with their poorer depth-dose characteristics than higher energy accelerator beams, and only one study included CT-based treatment planning. Compared with current practice, PORT as used in these trials was outmoded and probably caused excess deaths from cardiac and pulmonary damage. It is notable that in this meta-analysis the increase in risk of death was most marked in those patients with stage I disease and was not significant for patients with N2 disease.

The PORT Meta-analysis Group updated their analysis with the inclusion of one additional trial.[217] The overall conclusions that PORT was detrimental for patients with stage I or II NSCLC and that there was no clear evidence for benefit or detriment for patients with stage III N2 disease were not altered. However, results and updates of several other recent trials were not included in this analysis.[218-220]

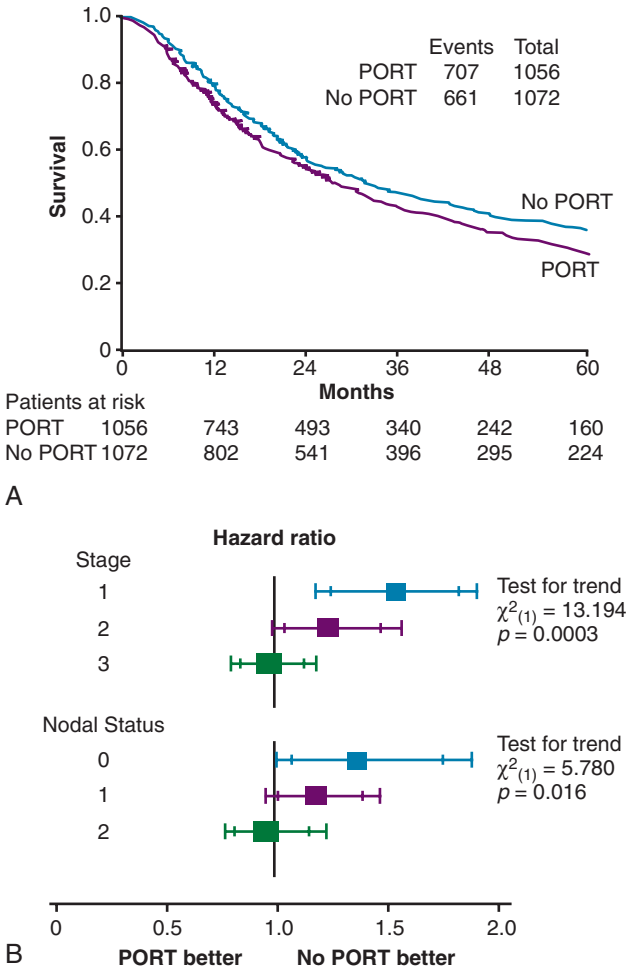

Figure 44-2 **A,** The overall survival curves for all patients analyzed show a significant deleterious effect of postoperative radiation therapy (PORT) on survival. **B,** This deleterious effect varies strongly with extent of local disease (expressed as stage group or N stage), with the hazard function not overlapping with unity for patients with stage groups 1 or N0 disease.
From Burdett S, Stewart L: Postoperative radiotherapy in non–small-cell lung cancer. Update of an individual patient data meta-analysis. Lung Cancer 47:81–83, 2005.

Several studies suggest an improved therapeutic ratio when PORT is delivered with modern techniques. Philips et al[221] reported improved survival and less cardiac and pulmonary toxicity associated with linear accelerator treatment and CT-based treatment planning compared with ^{60}Co therapy. A recent meta-analysis of PORT in N2 disease also suggested linear accelerator-based therapy was associated with the greatest benefit[222] Schraube et al reported calculated complication probabilities for patients receiving postpneumonectomy RT delivered using two-dimensional (2D) or three-dimensional (3D) treatment planning.[223] For equivalent physical doses to the mediastinal nodal target volume, the biologic mean dose to lung and heart and the associated normal tissue complication probabilities were considerably lower with 3D treatment planning. Machtay et al compared the rates of death from intercurrent disease (DID) for patients who had received adjuvant PORT.[224] They observed a 4-year actuarial risk of 13.5%, which was minimally, but not significantly greater than the 10% expected. The total radiation dose was strongly associated with the risk of DID: 2% for doses less than 54 Gy and 17% for 54 Gy and higher doses. Wakelee et al performed a retrospective analysis of DID in the INT 0115 trial, which compared PORT (50.4 Gy if no extracapsular extension, 59.4 Gy if this was documented) to concurrent PORT and chemotherapy with cisplatin and etoposide against that expected based on U.S. vital statistics.[225] The actuarial rates of DID at 4 years were 12.3% for irradiation and 13.7% for irradiation plus chemotherapy (not significant) and no higher than expected given the age and smoking status of the treated patients.

Selection of patients at highest risk for mediastinal recurrence after R0 resection cannot at present be done as accurately as desired. Although the presence of metastases in resected N2 nodes clearly predicts for disease in unresected nodes, the role of extracapsular extension has not been well investigated. One surgical study reported that it predicted for overall relapse in patients treated with surgery alone, whereas in another retrospective review it was found that postoperative mediastinal irradiation appeared to improve OS in patients with resected N2 disease without but not with extracapsular extension.[226,227] Evidence from several institutions indicates that locoregional failure is increasingly common with a higher number of involved N2 nodes and that induction chemotherapy followed by surgery often yields inadequate control of mediastinal disease.[228-231]

The CALGB initiated a Phase III trial of PORT in patients with resected N2 disease in the late 1990s, but only 40 patients accrued before the trial was closed leaving the issue unresolved.[232] Subsequent retrospective data with modern PORT include a review of the U.S. Surveillance, Epidemiology, and End Results (SEER) database indicating that although survival for patients with resected NSCLC was not generally improved by the addition of PORT, it was significantly improved for patients with N2 disease (hazard ratio, 0.855; 95% CI, 0.76 to 0.959).[233] Douillard et al reviewed the results of the ANITA trial in which patients with resected NSCLC, stages I through IIIA, were randomized to either adjuvant chemotherapy (cisplatin/vinorelbine) or observation. The use of PORT was left to individual investigator discretion, based on institutional preference. Although the numbers were small and not protected by randomization to PORT, the results were provocative. PORT was not beneficial for patients with N0 or N1 disease. But for patients with N2 disease, PORT improved both local control and survival whether or not patients received adjuvant chemotherapy, and did not significantly increase the risk of death from intercurrent disease.

If the PORT meta-analysis failed to demonstrate a survival benefit for patients with N2 disease because this benefit was counterbalanced by excess deaths resulting from complications of the RT as given and modern RT is less toxic as the described studies suggest, a trial conducted now might well show a survival benefit. The Institute Gustave-Roussey has coordinated a Phase III Trial of PORT compared to observation for patients with resected N2 NSCLC (the Lung ART trial). Patients may receive preoperative or postoperative chemotherapy. This trial has recently been joined by the EORTC and is scheduled to accrue 700 patients. Its primary endpoint is relapse-free survival (RFS), not overall survival, which allows for a smaller sample size than were overall survival the primary endpoint. As of December 2013 this trial had accrued 226 of the required 700 patients. A Phase III trial is also currently active in China for resected N2 disease, supported by data reported by Dai et al.[234]

A difficult clinical situation is the question of PORT for a patient without proven mediastinal lymph node involvement but whose surgery did not adequately sample or dissect the mediastinum. CT scans done postoperatively may show one or more somewhat enlarged mediastinal nodes, but this may reflect tumor or postoperative infection or inflammation. The use of PET in this setting has been explored by Roberts et al,

TABLE 44-8 Central Nervous System Relapse in Patients with Locally Advanced Non–Small Cell Lung Cancer

who suggested that it might be helpful in directing when to give and when to withhold further therapy.[144] However positive nodes in this setting are not specific and should be considered for biopsy by endoesophageal or endobronchial ultrasonography.

At present adjuvant PORT cannot be recommended on the basis of improved survival but should be considered in selected patients at high risk of local recurrence, particularly when there is involvement of multiple nodal stations in the mediastinum or extracapsular tumor spread. Its use in conjunction with adjuvant chemotherapy is discussed in the next section. For patients with microscopically positive margins after resection the situation is quite different, and concurrent chemoradiation should be considered for residual microscopic disease.

Prophylactic cranial irradiation has been less well evaluated in patients with NSCLC than in SCLC. Three older reported randomized trials of prophylactic cranial irradiation in patients with NSCLC failed to show any survival benefit, but none of them included patients with early-stage, resected disease or even patients thought to be in complete remission after definitive RT (with or without chemotherapy).[235-237] One retrospective series reported benefit in CNS failure rates for prophylactic cranial irradiation in patients with stage III NSCLC treated with an aggressive chemoradiation regimen. The earlier group of patients who did not receive prophylactic cranial irradiation had a CNS failure rate of 46% (13 of 28) compared with 9% (4 of 47) in a subsequent group who received prophylactic cranial irradiation.[238] Others have also reported high CNS relapse rates for patients with stage IIIA/B NSCLC who were aggressively treated (Table 44-8). The RTOG more recently conducted a Phase III trial of prophylactic cranial irradiation in patients with stage IIIA/B NSCLC who had completed all other planned therapy, which included various combinations of surgery, RT, and chemotherapy, and had stable disease or better.[243] The trial had planned to accrue 1058 patients to evaluate a potential relative 20% improvement in OS as its primary endpoint but was closed after enrollment of 356 patients because of slow accrual. Neither overall nor disease-free survival was significantly different between the two arms, but the incidence of brain relapse at 1 year was 7.7% in the prophylactic cranial irradiation arm and 18% in the observation arm. The neurologic effects of PCI in this trial were reported by Sun et al, who noted no change in overall cognitive functioning but a significant decline in memory at 1 year for the PCI group.[244] As control of local and extrathoracic metastatic tumor improves, the potential benefit of PCI may increase, but it cannot be considered standard at this time.

Postoperative Chemotherapy

Early trials of postoperative chemotherapy for patients with resected NSCLC failed to show significant benefit. Many of these were conducted with agents with minimal antitumor activity in this disease, and all were underpowered to detect a modest but clinically worthwhile improvement in survival on the order of 5%. A meta-analysis of all published randomized trials comparing observation with adjuvant chemotherapy showed no overall benefit, but the results differed by type of chemotherapy regimen.[245] Older alkylating agent–based regimens significantly worsened survival by 5%, whereas cisplatin-based regimens gave a 5-year survival improvement of 5%, which approached statistical significance ($p = 0.08$). Although there was considerable heterogeneity of stage, surgical procedure, and planned and delivered chemotherapy, this result suggested that chemotherapy with modest activity for metastatic disease could improve survival in the adjuvant setting, as had been previously demonstrated in breast and colorectal cancers.

Several large trials of adjuvant chemotherapy have been reported since publication of the meta-analysis (Table 44-9). The North American Intergroup conducted a large trial designed to test the efficacy of postoperative chemotherapy in patients with completely resected N1 and N2 NSCLC.[246] PORT was included in both arms to optimize local control, potentially increasing the ability to detect an effect of chemotherapy on systemic metastases. This trial (INT 0115), which enrolled 488 patients, showed no trend or significant difference in survival for the two arms, regardless of whether all 488 entered patients or 368 eligible and evaluable patients were considered. Multivariate analysis showed no benefit for the chemotherapy used in this study (i.e., four cycles of cisplatin and etoposide beginning concurrently with the start of irradiation) for any clinical subset of patients. Concurrent chemoradiation also failed to improve local mediastinal control, compared with RT alone.

The Adjuvant Lung Project Italy (ALPI) accrued 1209 patients with resected stage IA-IIIA NSCLC and randomized them to either observation or to chemotherapy with mitomycin, vindesine, and cisplatin.[247] Forty-three percent of patients also received PORT (after chemotherapy if this was given). There was a survival trend favoring the chemotherapy study arm that did not reach statistical significance.

The International Adjuvant Lung Cancer Trial (IALT) is the largest trial of adjuvant chemotherapy in lung cancer ever conducted.[249] The trial was designed to study 3000 patients, but it closed after enrolling 1867 patients because of declining accrual and evidence of a significant difference between the arms of the trial on interim analysis. Patients were randomized between observation and adjuvant chemotherapy that used cisplatin and an institutional choice of second agents (i.e., etoposide, vindesine, vinblastine, or vinorelbine). RT could be given (by institutional policy) after chemotherapy. There was an overall absolute improvement in the 5-year survival rate of 4% (44.4% versus 40.4%), which was highly significant, was present for all stage groups, and was observed whether patients also received postoperative mediastinal irradiation (not a randomized variable in this trial but done according to institutional preference). Although this trial showed a clear benefit in survival for adjuvant chemotherapy, it did not provide information on patterns of failure.

Two other trials have demonstrated the strong, positive effects of adjuvant chemotherapy. The National Cancer Institute of Canada Cancer Treatment Group (NCIC-CTG) randomized patients with resected stage IB and stage II NSCLC to observation or to adjuvant chemotherapy with cisplatin and vinorelbine.[251] They found a large and significant improvement in OS: 69% versus 54% at 5 years. Despite the availability of effective antiemetic regimens, compliance with this adjuvant chemotherapy regimen was not very good; only about 50% of patients completed all four cycles of this regimen, with variations by age, gender, extent of surgery, and nationality.[253] The CALGB randomized patients with resected stage T2N0M0 NSCLC to observation or to adjuvant therapy with carboplatin plus paclitaxel. The result of this trial was initially positive, with 71% versus 59% survival at 4 years, but the difference became nonsignificant with longer follow-up and the *p* value rose from 0.028 to 0.10.[250]

Douillard et al in the ANITA trial compared a combination of vinorelbine and cisplatin to observation in patients with resected NSCLC and demonstrated a statistically significant survival advantage that has stood the test of time.[248] Eight hundred and forty patients with stage IB-IIIA NSCLC from 101 centers in 14 countries were randomly assigned to observation ($n = 433$) or to 30 mg/m^2 vinorelbine plus 100 mg/m^2 cisplatin ($n = 407$). Postoperative radiotherapy was not mandatory and was undertaken according to individual institution policy. 367 patients in the chemotherapy group and 431 in the control group received their assigned treatment. 301 (36%) patients had stage IB disease, 203 (24%) had stage II disease, and 325 (39%) had stage IIIA disease. Side effects of chemotherapy mainly included neutropenia in 335 (92%) of patients and febrile neutropenia in 34 (9%); seven (2%) toxic deaths were also recorded. After a median follow-up of 76 months (range 43 to 116 months) median survival was 65.7 months (95% CI, 47.9 to 88.5) in the chemotherapy group and 43.7 (35.7 to 52.3) months in the observation group. Adjusted risk for death was significantly reduced in patients assigned chemotherapy compared with controls (hazard ratio, 0.80; 95% CI, 0.66 to 0.96); $p = 0.017$. Overall survival at 5 years with chemotherapy improved by 8.6%, which was maintained at 7 years (8.4%) in follow-up.

Hotta et al[254] published a meta-analysis of trials of adjuvant chemotherapy limited to those trials reported after the Collaborative Group meta-analysis published in 1995. Eleven trials and 5716 patients were analyzed. Trials mandating PORT in both arms (e.g., INT 0115) were excluded. With the exception of several Japanese trials using only tegafur and uracil (UFT), the chemotherapy incorporated was cisplatin plus a variety of other agents, mostly *vinca* alkaloids or etoposide. A significant survival improvement (hazard ratio, 0.872; $p = 0.001$) was seen overall, and in subset analysis this held for the cisplatin-containing chemotherapy and for UFT. The latter results are surprising in view of the rather low response rates (6.3%) seen with UFT in the setting of metastatic disease.[255] Hamada et al also analyzed six published Japanese trials of UFT adjuvant chemotherapy with a highly significant improvement in 5-year OS (absolute magnitude of 5%; $p = 0.01$).[256] Despite the success in Japan, the use of UFT or other fluorinated pyrimidines has not gained wide acceptance in North America or Europe.

A meta-analysis of these recent trials, the Lung Adjuvant Cisplatin Evaluation (LACE) has confirmed an OS benefit for cisplatin-containing adjuvant chemotherapy for patients who are node-positive.[257] There is no clear signal for patients with node-negative tumors, but there is a suggestion of benefit for patients with lesions greater than 4 cm in diameter. Several recent publications with longer follow-up of some of the adjuvant trials have reported conflicting results as to the durability of the benefit of adjuvant chemotherapy. The IALT trial showed survival benefit for the first 5 years but not with longer follow-up, similar to results seen by the CALGB using carboplatin and paclitaxel for earlier stage disease. But the Canadian trial using cisplatin/vinorelbine reported continued benefit beyond 5 years, as did the ANITA trial led by Douillard et al.

Off-study clinical policy currently should recognize the following:

1. Cisplatin-containing doublets have shown modest but statistically significant survival benefit in a number of trials of patients with resected NSCLC and should be considered for all fit patients with resected stage II or IIIA NSCLC and in selected patients with stage IB NSCLC.
2. The benefits are most clearly seen in patients with node-positive tumors and possibly with larger (>4 cm) node-negative tumors.
3. Substitution of carboplatin for cisplatin is not supported by the available data but may be considered for patients with contraindications to cisplatin.

4. Age is not an impediment to treatment or therapeutic benefit, but minimal data exist for patients 75 years of age or older.
5. The role of molecular selection of patients for adjuvant therapy, for example by *ERCC1* expression, is suggested in some retrospective analyses but awaits wider confirmation and the availability of reliable and readily reproducible assays.
6. The role of molecular targeted agents (including cetuximab and bevacizumab), EGFR-TKI (e.g., gefitinib, erlotinib, afatinib) for patients with activating EGFR mutations, crizotinib for patients with EML4/ALK translocations as well as vaccines and other immunomodulators is currently under active investigation but is not established.

Although there are sufficient data to establish adjuvant chemotherapy as standard for most patients with resected NSCLC, with the exception of patients with stage T1N0M0 disease, there are few data on the ability of this therapy to reduce the high rates of local recurrence seen in some patient subgroups. With the failure of CALGB 9734 to accrue adequate numbers of patients, the question of adjuvant RT in combination with or after adjuvant chemotherapy for patients with N2 disease remains unresolved and as noted previously is being addressed in active Phase III trials in Europe and China.

Potentially Resectable Disease: Stages IIIA and IIIB

Preoperative Treatment for Patients with Resectable Non–Small Cell Lung Cancer

Several trials conducted in the 1960s showed that for patients with initially resectable lung cancers, preoperative RT did not improve survival, and for those with initially unresectable disease, it improved resectability, but had no subsequent effect on survival.[258-260] Surgical complications, particularly bronchopleural fistulas, were increased. The approach was largely discarded until recently, when a flurry of trials of preoperative chemotherapy or chemoradiation prompted renewed interest in preoperative RT. Unlike the trials of the 1960s, these trials have used strict criteria for resectability, surgical staging of the mediastinal nodes, and modern attention to RT planning.

Two small, randomized, Phase II trials have been reported from the CALGB and the Lung Cancer Study Group (LCSG).[261,262] Both studies randomized patients with unresectable stage IIIA/B NSCLC to either preoperative RT followed by surgery or preoperative chemotherapy followed by surgery. Postoperative treatment was not specified in the LCSG trial but included RT to varying doses depending on tumor status at time of resection in the CALGB trial. Table 44-10 shows the results of these two trials, as well as those of several other randomized trials that compared immediate resection to induction chemotherapy followed by surgery for patients with stage IIIA NSCLC.[263-266] Results of the trials reported by Roth and Rosell, though quite small, were significantly positive, and the trials were closed early because of survival differences seen on interim analysis, but the LCSG, Japan Clinical Oncology Group (JCOG), and CALGB trials failed to show any difference in survival or resectability between preoperative RT, a strategy that might improve local but not systemic control, and preoperative chemotherapy. The trial by Depierre included patients with stages IB through IIIB; and although it demonstrated a survival benefit for patients with stage IB and IIA/B disease, it did not show a significant difference for patients with stage IIIA disease. Because all of these studies were small, there is no consensus on the optimal management of patients with operable stage IIIA NSCLC. In the United States, many centers advocate the use of preoperative treatment with chemotherapy or chemoradiation, but whether this is superior to resection and postoperative therapy or definitive chemoradiation without surgical resection remains unclear, although a number of theoretical considerations ranging from better patient tolerance to earlier treatment of occult systemic disease favor the preoperative approach.

The Bimodality Lung Oncology Team (BLOT) investigated preoperative therapy in patients with clearly resectable stage IB and II NSCLC using carboplatin and paclitaxel for two or three cycles. Despite a low overall pathologic complete response rate of only 5%, 2- and 3-year survival rates

compared favorably with those of historical controls.[271] The data were sufficiently encouraging to warrant a prospective trial coordinated by the Southwest Oncology Group (SWOG, S9900) comparing surgery alone to induction chemotherapy for patients with stage IB through IIIA disease.[270] Unlike the original BLOT trial, pathologic assessment of the mediastinum was not required. The accrual goal of this trial was over 600 patients, but it was closed early in 2004 because of declining accrual when the positive results of the Depierre trial for preoperative chemotherapy (at least for patients with stage IB and II disease) and the positive IALT trial for adjuvant postoperative chemotherapy for all stages made randomization to the surgery only arm unappealing. Results on the 365 patients entered showed modest benefits in PFS and OS for the induction chemotherapy arm, but these did not reach statistical significance.

A Spanish trial that compared surgery alone to either preoperative or postoperative chemotherapy (the NATCH trial) failed to show a PFS benefit for either timing of chemotherapy, and a meta-analysis of trials of preoperative or postoperative chemotherapy for patients with resectable NSCLC did not find any difference between these strategies with respect to OS.[272] In addition, an indirect comparison meta-analysis of trials of either preoperative or postoperative chemotherapy compared with surgery alone failed to show differences in the hazard ratios for either disease-free or OS between the preoperative and postoperative approaches.[273] However, a more recent meta-analysis performed by the NSCLC Meta-Analysis Collaborative Group, which examined 2385 patients (Stage IB-3A) entered in 15 randomized trials, did show a survival benefit of 5% at 5 years for preoperative chemotherapy.[274]

The role of surgery in patients with stages IIIA and IIIB disease remains controversial. A small RTOG/Eastern Cooperative Oncology Group (ECOG) trial of induction chemotherapy followed by RT or surgery found no difference in outcome but was inadequately powered.[275] The North American Intergroup Trial INT 0139 that randomized patients with pathologic N2 disease to definitive chemoradiation (cisplatin/etoposide concurrent with 61 Gy) or concurrent preoperative chemoradiation to 45 Gy showed better PFS but no OS benefit with the inclusion of surgery; however, an unplanned subset analysis of patients who underwent lobectomy compared with carefully matched patients who were thought to be candidates for lobectomy had they been randomized to the trimodality arm did show a survival benefit.[276] Of note, the surgical mortality rate in this trial was much higher for patients undergoing pneumonectomy, on the order of 23%, which may have nullified any chance of observing an OS benefit. Advocates of surgery argue that better exclusion of patients at poor risk for surgery would have shown an OS benefit, whereas partisans of nonsurgical treatment will point out that there have been significant improvements in radiographic staging (e.g., PET/CT) and RT planning and delivery since this trial was conducted (1994-2001), and that the trial overall failed to show an OS advantage.

In the European Organization for Research in Cancer Therapy (EORTC) trial 08941 patients with stage IIIA (N2) NSCLC received induction chemotherapy with cisplatin/etoposide and responders were randomized between RT and surgery. There was no difference in median or 5-year survival between these approaches.[277]

Neither of these trials, which are the largest published to address the role of surgery for patients with stage IIIA (N2) disease, showed a clear benefit. They do differ considerably in design, and neither meets current standards for staging or treatment delivery. Strong advocates of either surgical or nonsurgical approaches to these patients are unlikely to be convinced by the results.

A German Lung Cancer Group trial of preoperative CT alone or CT plus RT showed no PFS or OS benefit to the irradiation-containing arm of this study.[278] However, PORT was given to the patients in the study arm not receiving preoperative RT. The overall resectability rate in the trial was low, only about 50%, in a population that was composed of about two thirds of patients with stage IIIB disease. By including RT in both arms of the trial, the issue becomes one of timing rather than amount of treatment, and the similarity in overall outcome is perhaps not surprising.

Betticher et al reported on 90 patients with stage IIIA N2 NSCLC given induction chemotherapy with cisplatin and docetaxel, of whom 75 underwent resection, with 59 R0 resections (i.e., microscopically negative margins).[279] The overall median survival was 27.6 months and 33 months for patients who were resected. Among patients with resected disease, 50% experienced relapse (10 local, 10 local plus distant, and 18 distant only). The pathologic complete response (CR) rate in this trial was 19% of patients who underwent resection. An RTOG neoadjuvant (RTOG 0412) trial took the Betticher regimen and added RT in one arm to determine whether preoperative RT in this setting could improve local control, but this trial closed prematurely because of low accrual.

Several trials have shown that those patients faring best after preoperative treatment with chemotherapy or chemoradiation were those with pathologic sterilization of mediastinal nodes but not necessarily of the primary tumor. This has prompted trials evaluating higher preoperative radiation doses. The RTOG (RTOG 0229) has demonstrated that 60 Gy concurrent with weekly carboplatin and paclitaxel in carefully selected patients could be delivered with acceptable toxicity, a high resectability rate and more than 50% mediastinal nodal clearance.[280]

If sterilization of mediastinal lymph nodes is a useful criterion in selecting patients for surgery, how can this best be assessed preoperatively? CT is not particularly helpful, and it is not clear that early PET, done to allow resection within 4 to 6 weeks after neoadjuvant therapy, can discriminate between dead or dying cells or radiation-induced inflammatory changes at this early point. Biopsy by either endobronchial ultrasound (EBUS) or mediastinoscopy ultimately may be the gold standard, but using the presence or absence of residual nodal involvement after definitive chemoradiation to make therapeutic decisions is hazardous: to begin, results may be unreliable in the setting of radiation therapy (XRT) induced inflammation or fibrosis; secondly, a subset of patients with viable nodes after chemoradiation may still be cured by surgical resection.

Unresectable Stages IIIA and IIIB Disease

There are few good prospective data exploring the role of radiation dose on local control and survival in patients with NSCLC. In the 1980s it was believed by many authorities that local control could be achieved in about one half of patients treated to doses to 60 Gy given in 30 fractions over 6 weeks. However, the data on which that assumption was based (RTOG 73-01) indicated failure of local progression at time of systemic progression or death, which almost certainly overestimates long-term local control rates in an era when neither CT nor CT/PET was used to assess local control.[281] Patients were randomized to 40 Gy, 50 Gy, or 60 Gy given as a continuous course at a dose of 2 Gy/day and to a fourth arm of 40 Gy given by split course (i.e., 20 Gy in five fractions, a 2-week break, repeated dosage). The 50-Gy and 60-Gy arms showed modest improvement in local control and survival compared with the 40-Gy split or continuous arms, but this advantage was lost after 2 years. The lack of durable benefit for the higher doses may be the result of a number of factors: (1) poor local control even at higher doses, (2) the lack of CT treatment

planning, and (3) the use of posterior spinal cord blocks that shielded mediastinal lymph nodes. Patterns of failure in this trial were reported in terms of crude risk of clinically detected local failure: 33% with 60 Gy and 44% to 49% with 40 Gy.

It is incorrect to assume that local control is achieved in 67% of patients with 60 Gy. Le Chevalier et al[282-284] reported actuarial local control of only 17% to 20% at 1 year, in patients assessed radiographically and bronchoscopically after definitive RT to a dose of 65 Gy in 26 fractions in 6.5 weeks either alone or preceded or followed by chemotherapy with cyclophosphamide, cisplatin, lomustine, and vindesine. This percentage fell to about 10% at 4 years. In addition to its necessity for cure, local control is also important for quality of life because even patients dying of systemic disease are benefited if they can avoid the complications of local disease progression, such as airway obstruction with dyspnea or postobstructive infection, hemoptysis, compression of mediastinal structures such as the superior vena cava and phrenic or recurrent laryngeal nerves, or pain from chest wall invasion.

Several strategies have been investigated to improve local control. One approach uses chemotherapeutic agents or biologic response modifiers in conjunction with irradiation, and several of these appear to be effective. Another involves surgery after induction therapy with chemotherapy, RT, or both, a strategy that is undergoing investigation in the Phase III trials discussed in the preceding section. Strategies involving modification of radiation time dose and fractionation have also been explored, falling into the general categories of accelerated hyperfractionation and classic hyperfractionation.

COMBINING RADIATION THERAPY AND CHEMOTHERAPY

One risk of multimodality therapy of lung cancer is the potential for extending the time from initial presentation to the start of definitive local treatment. Several reports have shown inconsistent effects of time to treatment on average and long-term survival of lung cancer patients. This may stem in part from starting patients with a disease with a poor prognosis on simple palliative treatment quickly, with more delay for both thorough staging and planning of more complex treatment for patients treated with curative intent. In the study by Wang et al, no benefit in average survival was seen, but there was a significant association between shortened time to treatment and survival for patients who lived more than 5 years, about 10% of the entire population.[285]

Chemotherapy and RT can be combined in several ways. One can try to achieve additive cytotoxicity by treating the known local disease with RT and the local and systemic disease with chemotherapy. Such an approach is epitomized by the use of induction chemotherapy before local treatment with RT or surgery. This strategy may allow greater sparing of normal tissue by virtue of smaller RT target volumes or lesser resections performed on the postchemotherapy tumor volume. Another approach is to administer RT and chemotherapy concurrently in the hope of shortening the overall time of treatment and avoiding delay of starting either modality, in effect, turning off the "metastatic engine." Both approaches have proven superior to RT alone in prospective trials conducted in the 1980s and 1990s. Concurrent therapy has more acute toxicity (myelosuppression and esophagitis), but its superiority to sequential therapy has been demonstrated in additional trials. At least six randomized trials comparing the sequential and concurrent use of chemotherapy and RT for patients with stage IIIA/B NSCLC have been reported (Table 44-11). Although all trials addressed the same general question of sequencing, they differed in many details. Different chemotherapy regimens with different toxicity profiles were used. The number of cycles of induction chemotherapy administered before RT varied from two to four. It is not clear in these trials whether the prechemotherapy or postchemotherapy tumor volume was taken as the gross tumor volume or whether treatment planning was completed before the start of chemotherapy.

Some of these trials demonstrated a clear-cut advantage for concurrent chemoradiation; others did not. However, meta-analysis of individual patient data, confirmed the superiority of concurrent rather than sequential irradiation and chemotherapy.[291] An alternate interpretation is that the overall treatment time is key and that this is intrinsically shorter for concurrent regimens. With protraction of the overall treatment time, accelerated repopulation of the tumor, which may have begun during chemotherapy, may outpace the ability of daily fractionated radiation to kill remaining tumor clonogens. Data from the U.K. Continuous Hyperfractionated Accelerated Radiation Therapy (CHART) trial and ECOG 2597 are consistent with this hypothesis. The median survival for the ECOG sequential chemotherapy followed by accelerated irradiation arm was 20.3 months compared with 14 months for patients receiving conventional irradiation after chemotherapy.[292]

Similarly, the CHART trial showed a clear-cut survival advantage for continuous hyperfractionated XRT given three times a day compared to conventional once-daily XRT over a

longer period. The CALGB has reported a trial comparing induction chemotherapy with carboplatin and paclitaxel followed by concurrent chemoradiation with initial concurrent therapy. Unlike the Locally Advanced Multimodality Protocol (LAMP) trial, this was planned as a Phase III comparison. This large cooperative group trial failed to confirm the earlier Phase II results, with somewhat disappointing median survival times of 11.4 months for the initial concurrent regimen and 14 months for induction followed by concurrent therapy (p = 0.154) though it should be noted that this trial allowed enrollment of patients with more than 5% weight loss.[293]

The SWOG conducted a Phase II trial employing consolidation with docetaxel rather than additional cycles of cisplatin plus etoposide after concurrent irradiation with cisplatin plus etoposide (EP/XRT) in patients with stage III unresectable NSCLC. Median survival was 26 months, and the 3-year survival rate was 37%. In a prior SWOG trial exploring continued cisplatin plus etoposide as consolidation, the median survival time was 15 months and 3-year survival was 17%.[294] This is a striking difference, but it should be noted that these two studies were conducted in different treatment eras, with potentially different staging, patient allocation, and treatment planning. The Hoosier Oncology Group (HOG) attempted to confirm the SWOG results in a Phase III trial comparing EP/XRT alone to EP/XRT followed by three cycles of consolidation with docetaxel, but this study showed no survival benefit for consolidation therapy with docetaxel despite a significant increase in toxicity and hospitalization.[295]

Before the results of the HOG trial the SWOG incorporated consolidation docetaxel as part of their standard treatment regimen in a trial testing the role of maintenance gefitinib in unselected patients whose EGFR mutation status was not already identified. This trial showed significantly poorer disease specific and OS in the patients receiving gefitinib compared to placebo, for reasons that are not fully understood.[296] One possible explanations includes the development of more aggressive phenotypes (e.g., *MET* mutation) because of the selective pressure of gefitinib. In addition, molecular testing was not routinely performed on tumor specimens, so an unappreciated negative selection bias might have prevailed. For this reason, a recently initiated Intergroup trial (RTOG 1306) will test induction therapy for 3 months with either erlotinib followed by definitive chemoradiation in patients with documented activating mutations of EGFR or crizotinib followed by definitive chemoradiation in patients with documented ALK translocations.

At present, however, there is no established role for additional chemotherapy or targeted therapy after concurrent radiation and systemically dosed chemotherapy for patients with stages IIIA and IIIB NSCLC. In patients who receive radiosensitizing doses of chemotherapy during XRT, it is common to deliver one or two cycles of full-dose chemotherapy after completion of concurrent RT, but this is a strategy that has never been prospectively compared to observation alone after completing chemotherapy and concurrent XRT.

INTEGRATION OF MOLECULAR TARGETED AGENTS WITH RADIATION THERAPY

Identification of radioresistant cells in human tumors has led to several approaches to sensitize them while not altering the radiation response of normal tissues. Tumor cells may be resistant because of the local environment (e.g., hypoxia) or because of genetic changes (e.g., mutations in *TP53* or *KRAS*). Past strategies have attempted to reverse environmental hypoxia without great success, but some newer agents show promise. Several approaches that exploit specific tumor genetic changes are also being explored.[297,298]

Epidermal Growth Factor Receptor Inhibitors

Exposure of cells to ionizing radiation induces phosphorylation of EGFR and activation of its kinase activity in much the same fashion as binding of ligands such as EGF or transforming growth factor-α. This leads to activation of several signaling cascades with resultant increased cellular proliferation, decreased apoptosis, and stimulatory effects on neoangiogenesis and DNA repair.[299-302] Inhibition of these processes through anti-EGFR monoclonal antibodies, expression of a dominant-negative truncated version of EGFR, or low-molecular-weight compounds that bind to the ATP site of EGFR and block its kinase activity can result in significant radiosensitization of a number of cell lines in vitro and in vivo.[303,304] A Phase III trial comparing RT with or without the anti-EGFR antibody C225 in patients with squamous cell carcinoma of the head and neck, which commonly overexpresses EGFR, has demonstrated clinically significant improvements in local control and survival.[305] Similar trials in NSCLC using monoclonal antibodies (e.g., C225) and the low-molecular-weight tyrosine kinase inhibitors (TKIs) erlotinib and gefitinib have been conducted.

The RTOG conducted a Phase II trial investigating the combination of cetuximab with concurrent weekly carboplatin and paclitaxel and radiation to 63 Gy that showed acceptable toxicity and an encouraging median survival of about 22 months. Unfortunately, RTOG 0617, one of the largest studies ever conducted in LA-NSCLC, failed to demonstrate a survival benefit for the addition of C225 to standard chemoradiation compared with radiation alone, although a post-hoc analysis suggested that patients with heightened EGFR expression (H scores exceeding 200) might enjoy a survival advantage with the addition of C225.[306] To date, there are no mature Phase III trials showing a survival benefit for EGFR TKIs in combination with XRT or chemoradiation. Several groups have shown that objective regressions of NSCLC in response to treatment with EGFR TKIs occur almost exclusively in patients with specific point mutations in the ATP-binding region, which are present in only a minority of patients, though relatively more common in women, never smokers, East Asians, and those with adenocarcinoma.

The incremental activity of bevacizumab in combination with chemotherapy in patients with metastatic NSCLC and theoretical considerations and demonstration in colorectal cancer of increased tumor perfusion after bevacizumab treatment prompted interest in its combination with chemoradiation for patients with stage III NSCLC and limited SCLC. Several small trials were conducted using concurrent treatment, with disturbing reports of life-threatening hemoptysis as well as formation of tracheobronchial fistulas, prompting early trial closure.[307] Such combinations, and by extrapolation other strategies combining RT or chemoradiation with antivascular agents, should be approached with caution and only in the context of a clinical trial.

Radiation Dose and Fractionation

In North America, dose and fractionation for curative treatment of patients with unresectable NSCLC has generally been 1.8 Gy to 2.0 Gy per fraction, one fraction per day, 5 days per week, to a total dose of 60 Gy to 65 Gy. Such a low total dose has been recognized as unlikely to achieve a high rate of local control, but simple dose escalation using conventional radiation techniques was limited by acute and late toxicity to normal tissues. Several series have challenged this assumption by using conformal treatment planning and quantitative evaluation of doses to various normal tissues. Retrospective data

from the University of Michigan found a relationship between radiation dose and survival for patients with stage III NSCLC, which was seen both for patients receiving irradiation as a single modality as well as those undergoing concurrent or sequential chemoradiation.[308] Some of these trials have also limited the target volume by eliminating ENI.[152,190] Others have treated more traditional elective volumes, at least to doses of 50 Gy or so for possible microscopic disease.[309] These trials have clearly demonstrated the feasibility of dose escalation substantially above what had been previously believed limiting, to at least 74 Gy to 78 Gy. Retrospective review suggests improvement in clinical outcome, particularly in patients with bulky disease, with higher doses of XRT.[310] Whether these doses truly result in better local control and survival when used as a component of combined-modality therapy remains to be demonstrated in prospective trials.

The RTOG recently completed a randomized Phase III trial (RTOG 0617) in patients with stages IIIA/B NSCLC comparing 60 Gy to 74 Gy in combination with concurrent and consolidation chemotherapy (with or without cetuximab in a second randomization) to address the dose question.[311] In both trial arms only gross disease was targeted; there was no ENI. Unfortunately, the high dose arm unexpectedly and paradoxically sustained inferior survival and impaired control compared to the standard dose. The reasons for this remain unclear and an assessment of possible differences in treatment planning between the two arms is ongoing.

The use of altered fractionation schedules is an attempt to exploit differences between tumor and normal tissues in the fraction-size dependence of their radiation sensitivity.[312] Several variations on standard fractionation have been proposed and evaluated:

- *Hyperfractionation:* The use of small fractions (e.g., 100 cGy to 120 cGy) given two or more times each day to allow a higher total dose to be delivered within the tolerance of late effects to normal tissues.
- *Accelerated fractionation:* Reduction of the overall treatment time to decrease tumor cell proliferation during RT, increasing the probability of local control for a given dose. This may reduce the effects of repopulation and acquired resistance.
- *Concomitant boost:* Another approach to reduce proliferation during treatment is to begin with conventional fractionation but accelerate with twice-daily treatment during the last 2 or 3 weeks of treatment when accelerated repopulation increases.
- *Continuous hyperfractionated accelerated RT:* In a combination of the previous two methods, fraction size is decreased but overall time significantly shortened, typically by treating with three fractions per day.

In addition to these strategies, many other approaches have been proposed and tested. Some regimens feature accelerated fractionation in two courses with an intervening treatment break. Although the dose rate during the weeks of treatment is increased, when the break is taken into account, the overall rate of dose delivery is often only minimally greater than with conventional fractionation.

Hyperfractionation

The RTOG conducted a series of trials exploring the use of altered fractionation in NSCLC.[313,314] The first groupwide trial (RTOG 81-08) evaluated acute toxicity of several radiation dose levels using fractions of 1.2 Gy given 4 to 6 hours apart. Dose to the initial large volume encompassing known and electively treated tissues was always 50.4 Gy, whereas the dose to known disease was increased from 50.4 Gy to 60 Gy, 69.6 Gy, and 74.4 Gy. This was a dose-seeking and toxicity study, but comparison of the group of patients treated to 69.6 Gy with contemporaneous controls from other trials (RTOG 78-11 and 79-17) suggested a late survival benefit (8.3 ± 4.0% versus 5.6 ± 1.5% survival at 5 years). After this, in RTOG 83-11 the total dose was increased in two sequential randomizations from 60 Gy to 79.2 Gy.[315] Late toxicities were similar in all trial arms, and OS did not differ between arms. However, when a favorable subset of patients was analyzed, identified retrospectively by the CALGB criteria of good performance status and minimal weight loss, the 69.6-Gy arm appeared superior to other arms and to 60 Gy in 6 weeks as featured in other RTOG trials (13 months on median survival time [MST], and 1- and 2-year survival rates of 56% and 29%, compared with 9 months on RTOG 83-21, and 1- and 2- year survival rates of 35% and 10%, respectively). The higher-dose arms did not show this benefit, although they were not associated with greater reported toxicity, which might have offset a better therapeutic effect.

An Intergroup RTOG/ECOG trial made two comparisons: conventional RT alone or preceded by induction chemotherapy (as in CALGB 8433) and, as a third arm, the 69.6-Gy, twice-daily regimen, which seemed to have had the best therapeutic index of various dose levels tested in prior RTOG trials. This study confirmed the benefit for induction chemotherapy, previously observed by the CALGB trial using an identical regimen, with a statistically significant survival advantage for induction vinblastine and cisplatin compared to standard RT alone.[316,317] The twice-daily arm was numerically superior to daily fractionation, but the differences did not reach statistical significance.

The North Central Cancer Treatment Group (NCCTG) conducted a trial of similar design. Instead of using a continuous twice-daily regimen, they employed a split-course regimen of 1.5 Gy given twice daily for 20 fractions over 2 weeks, a 2-week break, and another 1.5 Gy given in 20 fractions.[318] The total dose was 60 Gy in 20 fractions, but the overall time was no shorter than with conventional fractionation. This was compared with standard fractionation of 60 Gy in 30 fractions over 6 weeks. A third arm combined the twice-daily split-course regimen with concomitant cisplatin plus etoposide chemotherapy. Accrual to this trial was slow, and it was closed short of the planned sample size. The results trended in favor of the twice-daily arm (with or without chemotherapy) for freedom from progression and survival. For patients with nonsquamous histology, survival was significantly improved ($p = 0.02$). In the NCCTG trial, freedom from local progression was better for the twice-daily regimen with or without concomitant chemotherapy, although this did not quite reach statistical significance ($p = 0.06$).

In RTOG 83-01, 11% of patients experienced significant treatment interruptions.[319] Compared with those completing treatment in the planned timeframe, survival at 2 and 5 years was significantly lower for those with treatment interruption (24% versus 13% at 2 years; 10% versus 3% at 5 years). Similar detrimental effects of treatment protraction have been reported for other trials of XRT alone as well as concurrent chemoradiation.[319,320] However, the length of treatment was not determined randomly and may reflect other prognostic factors. Survival differences, like the benefit for hyperfractionation, were seen only for the subset of patients with good performance status and minimal weight loss.

Accelerated Fractionation: CHART, HART, and CHARTWEL Regimens

Saunders et al compared an accelerated regimen called continuous hyperfractionated accelerated radiation therapy (CHART) to a conventional regimen of 60 Gy in 30 fractions in a mixed group of patients who had locally advanced (stages IIIA/IIIB) or medically unresectable (stage I or II) disease.[321,322]

The CHART regimen consisted of 54 Gy given in 36 fractions (three times daily) over 12 consecutive days (weekends included). The interfraction interval was 6 hours. Results showed a survival advantage (30% versus 20% at 2 years; $p < 0.001$) for the CHART regimen, with local control also significantly improved. Modifications of this regimen that increased total dose, shortened interfraction interval to 4 hours, and omitted weekend treatments (HART in the United States[323] and CHARTWEL in the United Kingdom[324]) have reported similar encouraging results in Phase II trials.

ECOG conducted a trial of HART compared with standard daily fractionation in patients with stages IIIA and IIIB NSCLC (E2597).[292] Patients received two cycles of induction chemotherapy with carboplatin and paclitaxel and were then randomized to conventional RT or to HART. The study was powered to show an improvement in median survival from 14 to 21 months, but it was closed early because of slow patient entry. The results, a median survival of 21 months on the HART arm and 13 months on the standard arm, are provocative, and seem to mirror those observed in the RT only trials, but the difference did not reach statistical significance in this underpowered trial. One recent meta-analysis comparing hyperfractionated and accelerated trials to conventional fractionation has shows benefit but at the expense of increased esophageal toxicity.[325]

Physical Considerations in Fractionation Trials

Many of the previously discussed trials evaluating radiation dose and fractionation were performed before the routine use of CT, PET/CT and 3D planning, let alone intensity-modulated radiation therapy (IMRT) in lung cancer treatment. Given the limitations of the imaging of that era, there was considerable uncertainty about the extent of disease and the adequacy of its coverage, particularly with the use of lateral and oblique beams. If a different proportion of the total dose is administered through anterior-posterior/posterior-anterior and oblique beam arrangements in the two fractionation regimens and the rate of tumor miss was greater for oblique than for anterior-posterior/posterior-anterior beams, it was reasonable to expect a difference in local control based on technique independent of any difference because of fractionation. Even in trials incorporating fairly straightforward patient eligibility criteria and irradiation technique requirements, errors in staging and field size or placement were roughly 15%. Because more complex techniques were typically used in the hyperfractionated regimens that gave a higher total dose, the net effect might have been to mask a possible biologic benefit of the higher-dose regimen. The use of large fields and ENI also increased acute toxicity. The role of accelerated fractionation to smaller target volumes in patients with CT/PET staging (PET was not performed in the majority of patients in CALGB 39904) is worthy of further study and has given promising results in some early trials.[196]

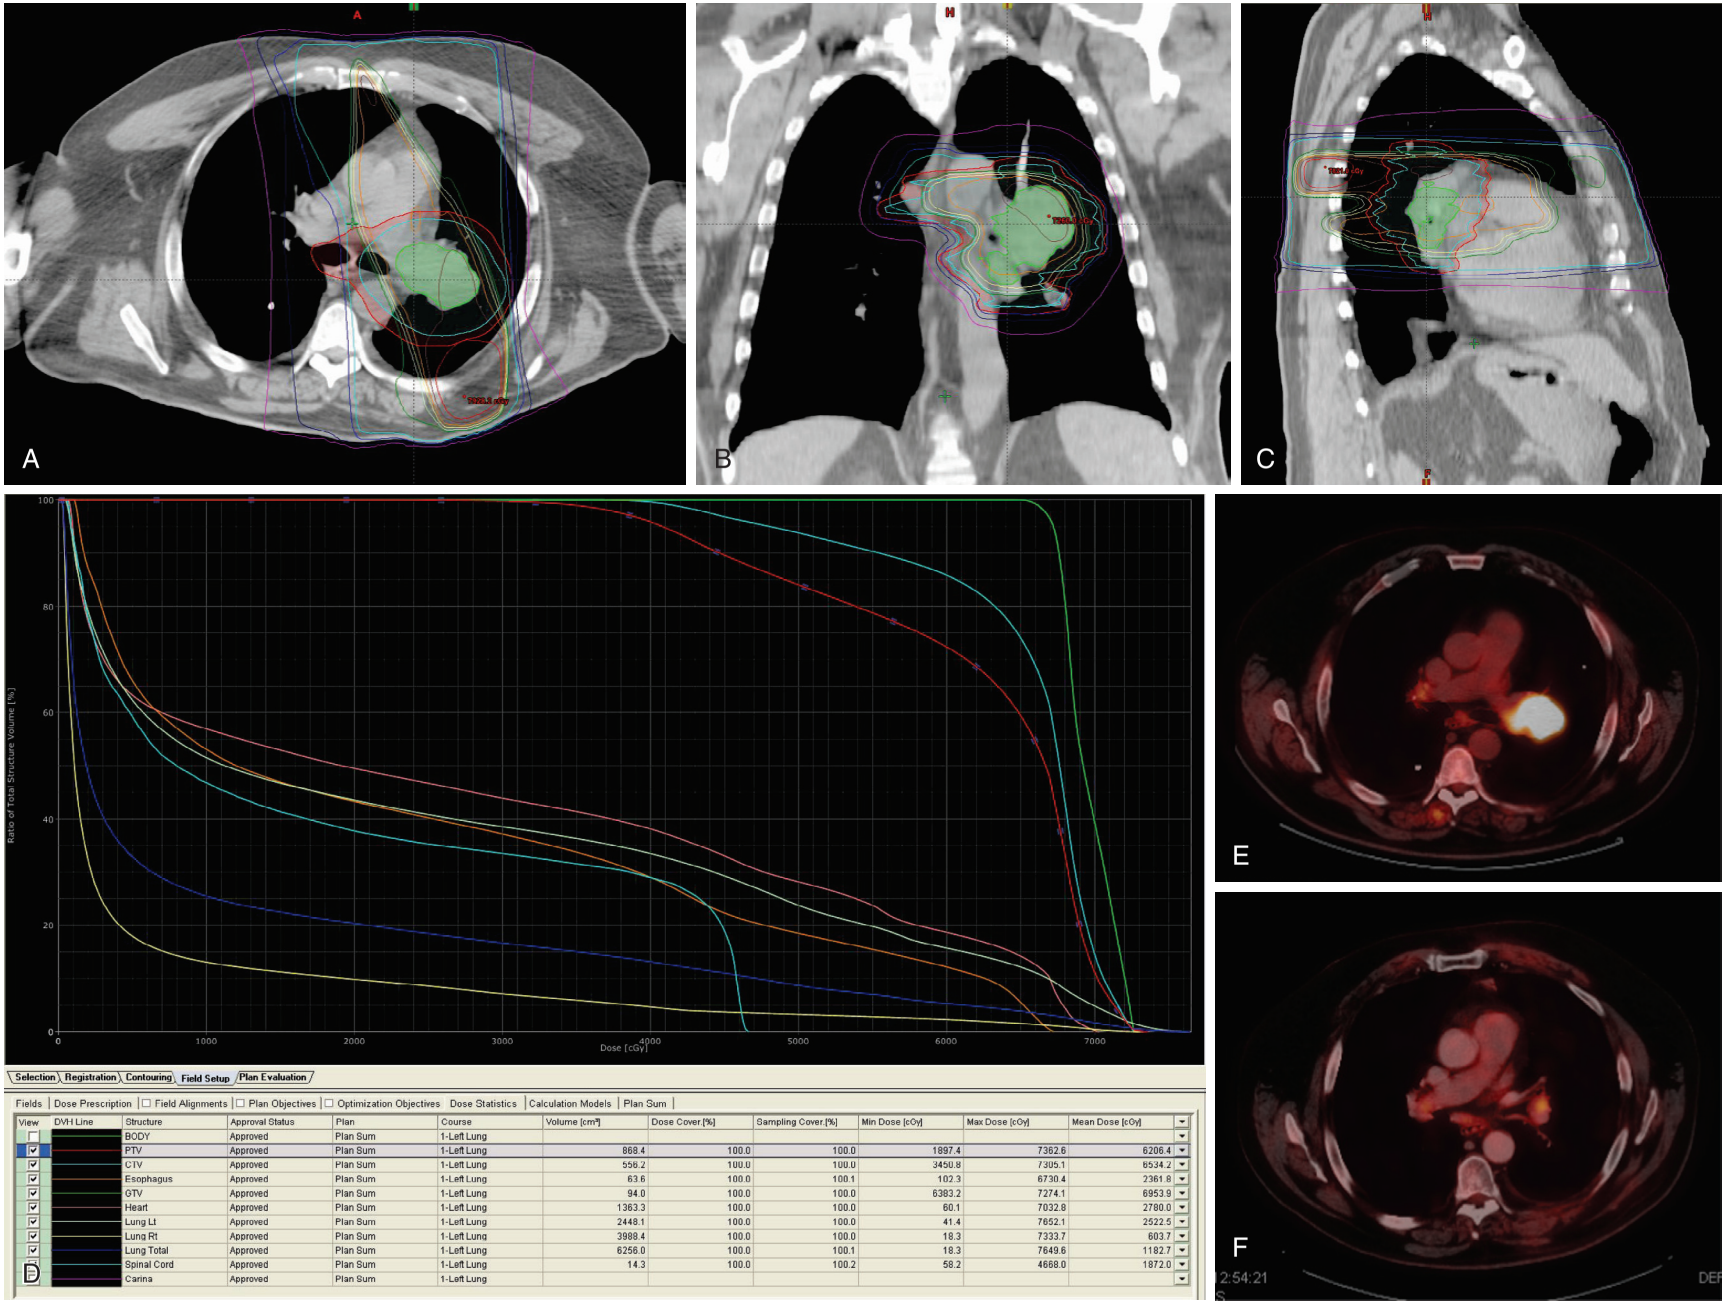
Evaluation of Local Control

Most trials of altered fractionation have attempted to evaluate patterns of failure. Assessing local control in irradiated NSCLC is difficult for several reasons:

- Difficulty in distinguishing between recurrence from fibrosis
- Variable assessment of local control after relapse in other sites
- High rate of early death from systemic relapse and intercurrent disease

Some of these difficulties can be dealt with statistically through methods such as reporting failures in terms of competing risks. In addition, PET is helpful, though not foolproof, in distinguishing scar from tumor. Current estimates of postirradiation local control, short of resection, should be considered approximations at best.

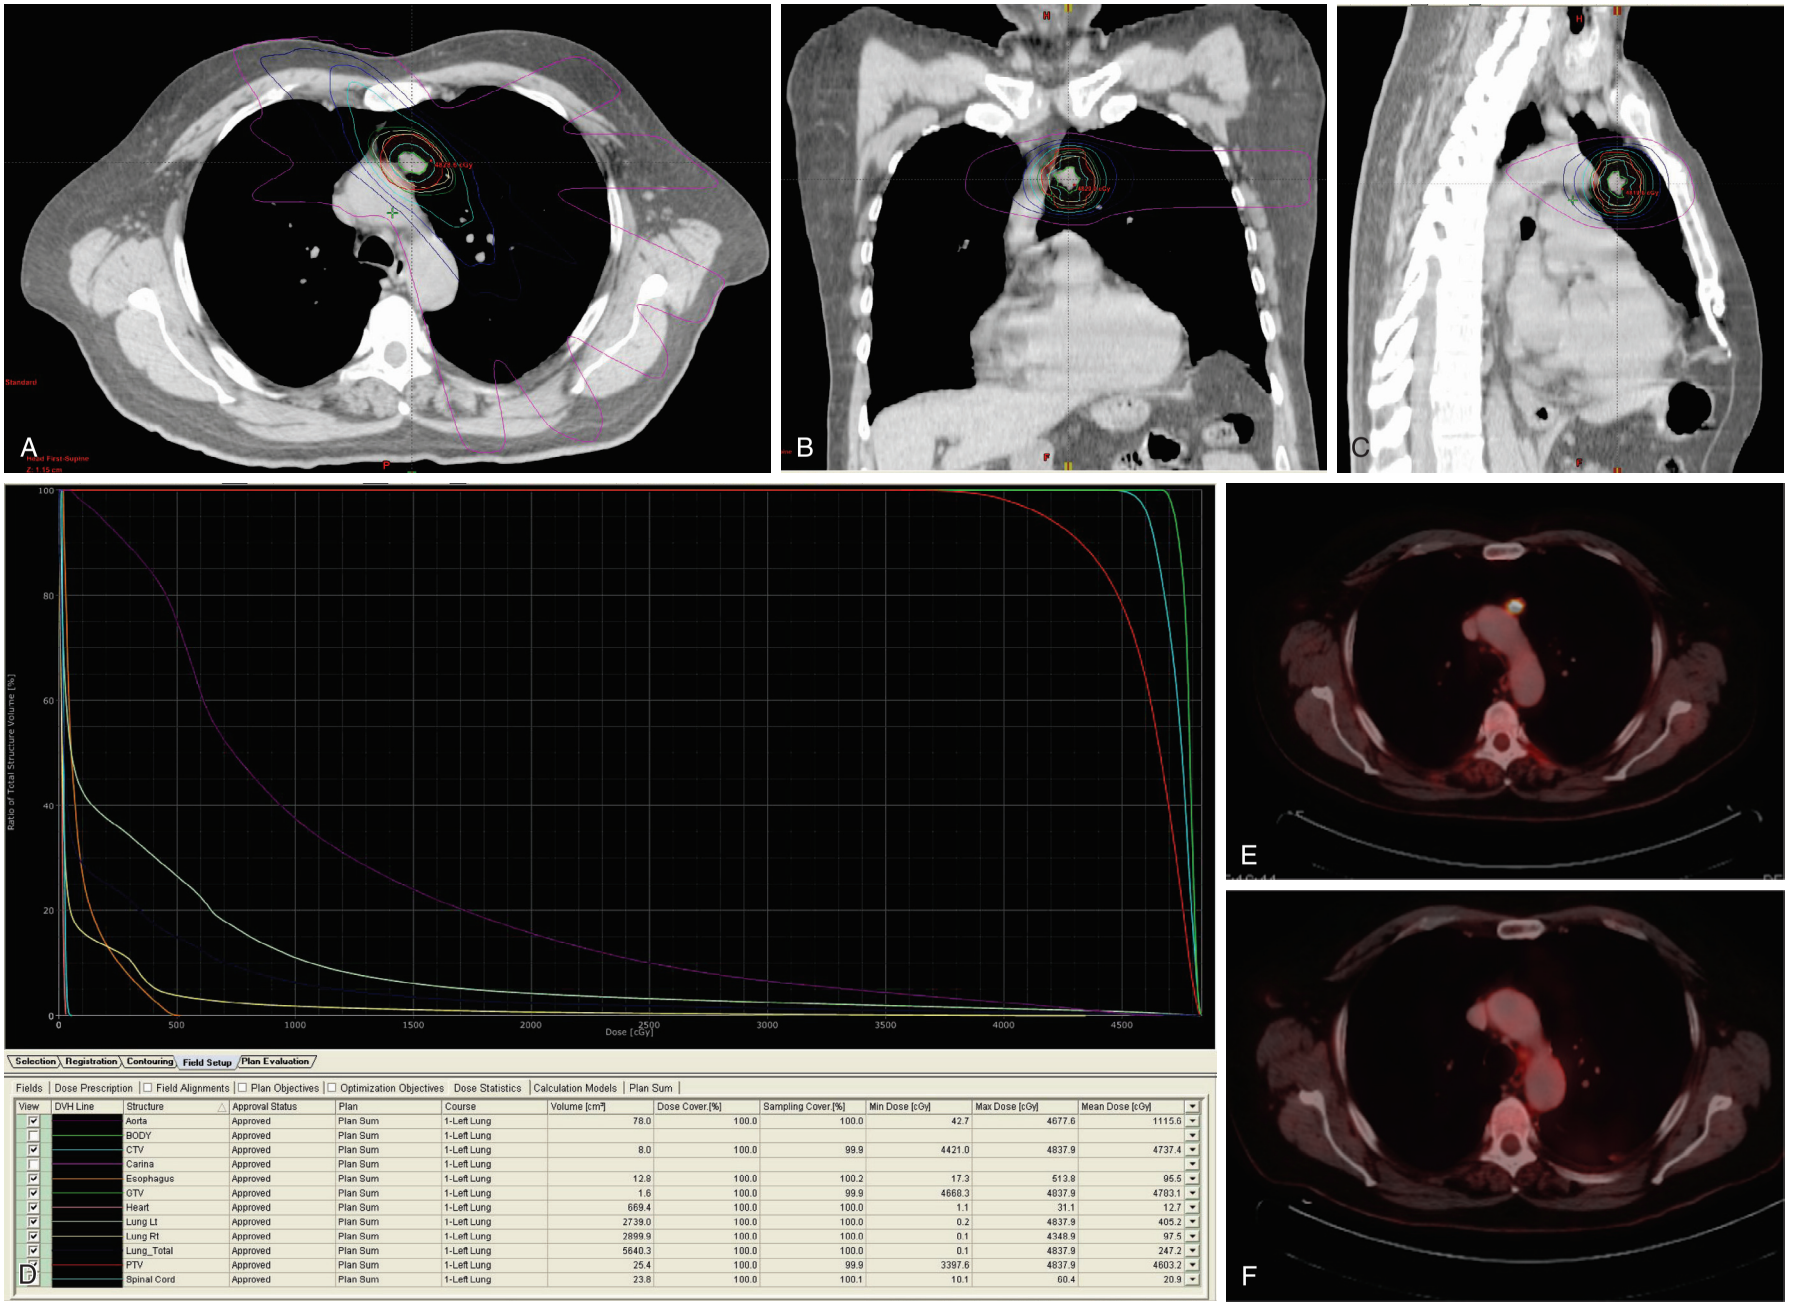
RADIATION THERAPY TECHNIQUE



Positioning and Immobilization

Patients are generally positioned supine during treatment, with the torso supported and partially immobilized using custom devices such as Alpha Cradles or VacLoc bags or using adjustable wingboards. Positioning the arms above the head allows for more options using lateral or oblique beam angles, but care must be taken to allow the arms to fit in the gantry (typically 70 cm or 80 cm) of CT scanners used for image acquisition. Prone positioning may seem appealing for patients with tumors located posteriorly in the chest, but it may result in greater motion of intrathoracic structures with respiration. In the absence of more formal respiratory arrest (deep breathing and breath-hold) or respiratory gating techniques, patients should be instructed in quiet, steady respiration during treatment and planning. Wu et al found that the predominate effect of respiration was on translation of the tumor position rather than rotation or deformation of the tumor volume.[326] Others have reached similar conclusions.[327,328]

When cone-beam CT scans are used for positional matching there are often several organs that can be used for the primary match, whether this be done manually or automatically. Higgins et al have investigated image registration using matches made on the spine, carina, and tumor in a series of 30 patients with lung cancer with four different individuals performing the matches and found that reproducibility was greatest for automatic matching on the carina and worst for manual matching on the tumor.[329] Automated matches took an average of 1 minute, manual ones, 4 minutes. With this technique and their definition of target volumes (clinical target volume [CTV] = gross tumor volume [GTV] + 5 mm, ITV = CTV_{inhale} + CTV_{exhale}; planning target volume [PTV] = internal target volume [ITV] + 5 mm) they reported no geographic misses using any of the registration techniques. One way of improving direct matching on the tumor is the use of implanted fiducials. There remain limitations to this technique; peripheral lesions are often difficult to reach bronchoscopically, and percutaneous CT-guided placement poses a risk of pneumothorax.[173,330]



Definition of Target Volume

Traditional treatment volumes for patients with stages IIIA/B NSCLC have been based on principles of covering the known volume of the primary tumor and its nodal metastases and on the "elective" irradiation (ENI) of nodal echelons at risk for microscopic involvement.[331] This initial volume was treated to a dose appropriate for microscopic disease, usually in the range of 45 Gy to 50 Gy, and then areas of known disease were boosted to a total of 60 Gy to 65 Gy. Such an approach typically treated large amounts of normal tissue, including lung, heart, and spinal cord, to a high dose. Current approaches that restrict the target volume to known disease and try to avoid the transit of opposed beams through normal tissue can produce dose distributions that better conform to the target volume but may treat larger volumes of normal tissue, albeit to lower dose.[332-334] Figures 44-3 and 44-4 show isodose curves and dose-volume histograms for a patient with a stage T3N0M0 squamous cell carcinoma of the left lung for two different treatment plans, one with and the other without ENI. The development of appropriate dose-volume-effect nomograms, with and without chemotherapy, for clinically important normal tissues, including lung, esophagus, heart, and spinal cord, is an active area of clinical research.

Figure 44-4 Isodose curves **(A, B, C)**, dose-volume histogram **(D)**, and pretreatment **(E)** and 3-month posttreatment **(F)** PET/CT scans of a patient with a T1N0 NSCLC treated by stereotactic radiation therapy. Treatment was prescribed to the 85% isodose line, and dose was 4800 cGy in five fractions over 2 weeks. Because of the proximity of the tumor to the aorta, the dose plan was intentionally made nonspherical to reduce the volume of aorta receiving a high dose, with more dose going into a clinically less critical volume of lung. At 3 months after treatment the patient had achieved a complete metabolic response, and at 6 months he continued without evidence of disease or toxicity.

As larger target volumes are treated, it becomes more difficult to limit doses to normal tissue tolerances, and there is a reciprocal relation between the volume of the target and the dose to which the target can be safely treated. The spinal cord, because of its intolerance of damage to even a short section, is probably an exception to this dose-volume relationship. Late esophageal stricture formation probably falls in this category as well, because even a short length of stricture can be quite symptomatic, but it is of less clinical importance because of the effectiveness of esophageal dilatation. If we wish to improve local control by increasing radiation dose, it follows that we need to consider reducing target volume. Several trials have demonstrated the feasibility of such an approach and the impossibility of major dose escalations when large target volumes are used.[335-338]

Modeling studies have suggested that meaningful improvements in local control and potentially in survival can be achieved by dose escalation within the range of what is achievable with present-day techniques so long as target volumes are limited, typically with the reduction or elimination of ENI. Even greater dose escalation is feasible with active breathing control or other respiratory gating techniques.[339] Unfortunately Phase III data from RTOG 0617, which found poorer local control and survival in patients treated to 74 Gy versus 60 Gy, indicate that this theoretical benefit is not yet presently achievable in the clinic.

The issue of ENI in NSCLC has been hotly debated in the past decade and is now beginning to be illuminated by data from Phase II and Phase III trials. Yet at the same time that we are retreating from routine ENI for patients receiving definitive chemoradiation many are also advocating postoperative mediastinal irradiation for patients with resected N2 disease. Is this inconsistent? Perhaps, but a reasonable argument can be made for both positions. In patients treated definitively without resection of the primary tumor, the greatest bulk of disease and the site at greatest risk of failure remains at the primary site. If this is not controlled, the benefit of eradicating microscopic disease in adjacent nodes is moot. Most of these patients will develop tumor progression either locally or distantly before microscopic regional nodal disease will grow sufficiently to be scored a regional failure, let alone become a clinical problem for the patient. But in the postoperative setting, where all macroscopic intrathoracic tumor has been resected, the implications of residual microscopic disease can become much greater and may warrant more extensive elective treatment.

A distinction between intentional and incidental ENI should also be considered. Several studies have shown that when clinically uninvolved hilar and mediastinal lymph node stations are not specifically targeted in the treatment plan, they may receive nonnegligible doses that may be significant for controlling small-volume metastatic disease.[320,340,341] Doses to the mediastinum adequate to control microscopic disease has also been recently reported for patients treated with SBRT for T1-2N0M0 tumors.[342]

One randomized trial reported by Yuan et al has attempted to address the issue of ENI directly, although its design was confounded in that the involved-field and ENI arms intentionally received different radiation doses of 68 Gy to 74 Gy and 60 Gy to 64 Gy.[343] Response and local control were better in the higher-dose involved-field arm. Survival was also better with a significant improvement at 2 years, though not at other time points. Unfortunately, the trial did not address the issue of whether ENI to 60 Gy, boosting macroscopic disease to 74 Gy, would have been superior to the 74 Gy involved-field arm. Further prospective studies of appropriate target volume are clearly indicated as both systemic therapy and the way in which we deliver RT can be improved.

Once the decision is made as to the volume that warrants treatment, it must be delineated in the treatment planning system. Several studies have addressed the correlation between tumor volume as measured from surgical specimens with that measured by imaging techniques such as CT or PET/CT. Pioneering studies by Giraud showed microscopic extension of tumor cells for several millimeters beyond the CT-demonstrated tumor border for resected lung tumors and that this differed for squamous and adenocarcinoma.[344] More recent studies are extending this approach to tumor volumes obtained by PET/CT in an attempt to determine optimal standard uptake value cutoffs so that the GTV_{PET} and the GTV_{PATH} match more closely.[345] General issues concerning the benefits and challenges of incorporating PET/CT in RT treatment planning have been reviewed by Ford et al.[346]

One attempt to reduce the individual variability in target volume contouring has been the addition of FDG-PET/CT information to the usual CT-based contouring process, with either manual incorporation of this information or direct registration of the PET data with the planning CT scan. Several studies have shown that the contoured volume changes in about one third to half of cases, both by inclusion of nodes not significantly enlarged but FDG avid and by exclusion of non–FDG-avid regions in the lung thought to represent atelectasis rather than tumor. However, not all of these changes have been verified histologically, and there is particular uncertainty in knowing where to draw discontinuous tumor/nontumor contours in a region of continuously decreasing standard uptake value at the interface between tumor and atelectasis.[346-349] There are also reports that both interobserver and intraobserver variation in contouring of the GTV is reduced with the incorporation of data from PET/CT scans.[350-352] It is clear, however, that the greater sensitivity of PET/CT for the detection of distant metastases and the attendant stage migration of patients thought initially to have stages I to III disease, who, in fact, have stage IV NSCLC will artificially improve the apparent outcome of treatment of patients with localized NSCLC.

Bradley et al reported on an RTOG Phase II trial that compared radiation treatment plans derived with and without the use of PET/CT data, which showed a net reduction in target volumes, with an average reduction of 12.5 cm^3. This led to a reduction in mean lung dose from 19 Gy to 17.8 Gy ($p = 0.06$) and of V20 from 32% to 30.8%. With a median follow-up of 12.9 months the rate of failure in nontargeted nodal regions was 2%. These results are likely to be sensitive to the details of the contouring protocols used for both CT and PET/CT contouring. Several groups have shown that the contoured volumes and their correspondence to the pathologic tumor volume is highly dependent on the chosen threshold values.[353,354]

Individualized Radiation Dosing

Several groups have reported trials of adaptive radiation therapy for patients with NSCLC in which the target volume for the last portion of treatment is modified based on the response of the tumor to earlier fractions, as assessed by regression of the tumor on CT or CT/PET imaging.[355] This approach can allow increase in delivered dose while staying within normal tissue tolerances if there is substantial tumor regression in the first several weeks of treatment and early and promising results have been reported.[356,357] The RTOG 1106 is exploring this approach in LA-NSCLC after showing its feasibility in limited institution Phase I/II trials.

Another approach modifies the radiation prescription for each patient to achieve a predetermined probability of normal tissue toxicity. Thus, patients with smaller primaries and regional nodes could be treated to a higher dose than patients with larger target volumes while having the same risk of

complications. Such as approach, termed *individualized isotoxic accelerated radiotherapy* (INDAR) has been combined with concurrent chemotherapy with encouraging results in Phase I/II trials.[358,359]

Beam Energy

Careful dosimetry has indicated that in regions of electronic disequilibrium, as seen in going from low-density lung to higher-density tumor, the use of high-energy photons can lead to significant underdosing of tumor cells at such interfaces or of microscopic extensions of tumor into lung.[360,361] This problem is reduced but not eliminated, particularly for small fields, with lower photon energies (6 MV to 10 MV). With multiple-beam conformal and IMRT plans there is little reason to use higher energies.

Proton beam RT is just beginning to be explored in the treatment of lung cancer. Early clinical experience has been reported in treating patients with stage III disease, and both clinical reports and modeling studies for its use in SBRT for early-stage disease have been published.[362-364] Although the virtual dosimetric and early clinical reports are encouraging, caution should be exercised in adopting proton beam RT in the setting of a tumor when both uncertainty as to the extent of disease and interfraction and intrafraction motion may make overstrict definitions of the target volume hazardous. On the other hand, use of proton beams to limit the volume of lung receiving relatively low but still toxic doses (e.g., V5) may be advantageous so long as the PTV is not made excessively restricted. The RTOG will spearhead a Phase III trial comparing proton beam XRT to photon beam XRT in the context of chemoradiation for LA-NSCLC (ClinicalTrials.gov Identifier NCT01993810). In both arms the target volume will receive a dose of 70 Gy.

Choice of Beam Direction

Traditional 2D treatment-planning schemes typically treated the tumor and regional nodes with opposed anterior and posterior portals until spinal cord tolerance was approached and then used lateral or oblique beam angles, sparing the cord but treating substantial volumes of lung to a relatively high dose.[365] The general planning approach accepted these high doses but attempted to limit the volume of normal lung receiving them. An alternative approach is to avoid the use of opposed beams, increasing the total number of beams used, and in some cases, using noncoplanar beams. The net result of these strategies is to increase the volume of lung receiving some radiation dose but to keep this well below lung tolerance, except in the immediate vicinity of the tumor. Particularly when the target volume is small, a higher degree of heterogeneity of dose (e.g., hot spots) can be accepted within the target volume if this allows better sparing of normal tissue. These considerations, although valid for all patients with lung cancer, are particularly important for those who are unable to undergo resection because of poor pulmonary function. Low dose exposure (~V5) to large segments of the lung are of concern when using multiple fields for treatment of locally advanced disease. Some investigators are also exploring the possibility of optimizing beam placement through relatively nonfunctional portions of lung (e.g., those involved with extensive bullous disease or postobstructive atelectasis) and minimizing dose to functional lung parenchyma.[366,367]

TOXICITY OF THORACIC IRRADIATION AND COMBINED-MODALITY THERAPY

Treatment of patients with aggressive multimodality therapy requires attention to and management of a variety of acute and chronic toxicities.[368] These involve local toxicities such as esophagitis and pneumonitis and systemic considerations such as myelosuppression (Table 44-12). Acute toxicities during RT may compromise the ability of patients to complete treatment without interruption, and late effects limit the total dose that can be given.

TABLE 44-12 Common Toxicity Criteria of Particular Importance in Lung Cancer

Toxicity	Grade 1	Grade 2	Grade 3	Grade 4	Grade 5
Cough	Mild symptoms; nonprescription intervention indicated	Moderate symptoms, medical intervention indicated; limiting instrumental ADL	Severe symptoms; limiting self-care ADL	—	—
Definition: A disorder characterized by sudden, often repetitive contraction of the thoracic cavity, resulting in violent release of air from the lungs and usually accompanied by a distinctive sound.					
Dyspnea	Shortness of breath with moderate exertion	Shortness of breath with minimal exertion; limiting instrumental ADL	Shortness of breath at rest; limiting self-care ADL	Life-threatening consequences; urgent intervention indicated	Death
Definition: A disorder characterized by an uncomfortable sensation of difficulty breathing.					
Pneumonitis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic: medical intervention indicated; limiting instrumental ADL	Severe symptoms; limiting self-care ADL; oxygen indicated	Life threatening respiratory compromise; urgent intervention indicated (e.g., tracheotomy or intubation)	Death
Definition: A disorder characterized by inflammation focally or diffusely affecting the lung parenchyma.					
Esophagitis	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered eating/swallowing, oral supplements indicated	Severely altered eating/swallowing; tube feeding, TPN, or hospitalization indicated	Life-threatening consequences; urgent operative intervention indicated	Death
Definition: A disorder characterized by inflammation of the esophageal wall.					

Data from Common Toxicity Criteria: Cancer Therapy Evaluation Program, Version 4.03, 14 June 2010.
ADL, *Activities of daily living;* IV, *intravenous;* TPN, *total parenteral nutrition.*

Risk factors for radiation pneumonitis include radiation dose and lung volume treated and compromise in the patient's baseline pulmonary function.[369] Patients with lower lobe tumors are more likely to have pneumonitis, probably because of the greater lung volume treated. Although the effect of most chemotherapeutic agents on pneumonitis is not well defined, there is an increased risk associated with the use of mitomycin C, gemcitabine, irinotecan, and possibly taxanes. The etoposide/cisplatin regimen in combination with XRT features one of the lowest rates of pneumonitis. Newer immunologic strategies, such as monoclonal antibodies targeting PD1 and PDL1, are also associated with pneumonitis, though these agents have not yet been studied in the context of definitive chemoradiation.

Another approach to reducing lung toxicity is to take advantage of the regional and individual variations in lung function and preferentially place beams through lung parenchyma that is not particularly functional, sparing as much functional (as opposed to merely volumetric) lung parenchyma as possible. This approach was first proposed by Marks et al using simple ventilation-perfusion lung scans.[366,367] Although this approach has not yet made much clinical impact, further studies using both single-photon emission computed tomography (SPECT) and hyperpolarized ^{3}He-MRI to map regional lung function as well as the increasing availability of software to fuse such functional imaging with CT obtained for treatment planning suggest that the time may be right for wider evaluation of the true degree of lung function sparing that can be achieved with such techniques and whether it is of clinical benefit.[370]

The number and variety of dosimetric parameters that have been associated with pulmonary toxicity suggests that no single parameter is adequate to characterize treatment plans and the necessity of reviewing the entire dose-volume histogram in evaluating a plan for toxicity, just as we have appreciated the need to review the entire set of isodose curves in evaluating the adequacy of tumor coverage rather than simply relying on the dose-volume histogram.[371] To date, V_{20} and the mean lung dose are currently the best and most widely used predictors of lung tolerance. It should be kept in mind that the data on which these formalisms are based is largely with daily fractions in the 180 cGy to 200 cGy range in patients not receiving concurrent chemotherapy. Extrapolation beyond these conditions should be done with caution. It is well recognized that the radiation is not acting on a uniform biologic substrate, but efforts to identify genetic or phenotypic changes associated with increased sensitivity of normal tissues to radiation have, until recently, met with little success. With the ability to perform genomewide association studies as well as evaluate a wide variety of intermediate processes in the development of radiation toxicity it may be possible in the future to develop plans based not only on physical dose distributions but also on individual tumor and normal tissue radiosensitivity.[372,373]

Management of Toxicity

Management of patients with moderately severe radiation pneumonitis symptomatic with cough and dyspnea has generally included suppression of cough with codeine or benzonatate and the use of oral corticosteroids such as prednisone to reduce acute inflammation in the hope of decreasing late fibrosis. In patients with symptomatology or hypoxia, prednisone is generally dosed initially at 1 mg/kg with a taper based on symptom improvement.

Esophagitis is common in patients who receive concurrent RT and chemotherapy or accelerated fractionation regimens. Management with a soft diet, use of topical analgesics such as lidocaine or diphenhydramine, and systemic narcotics is helpful. Particularly in patients treated with curative intent, the presence of moderate to severe acute esophagitis should prompt aggressive supportive therapy, including enteral or parenteral feeding when indicated, rather than a treatment interruption, which can jeopardize local control.[374]

Amifostine, a thioester that is actively taken up by normal tissues but enters most tumor cells only by passive diffusion, can protect normal tissues to some degree against radiation mucositis and the renal and bone marrow toxicity of chemotherapeutic agents such as cisplatin.[375-377] Preliminary results of a Phase III trial enrolling patients with head and neck cancers demonstrated a delay in time of onset and reduction in maximal severity of oral mucositis, and Phase II data for lung cancer were promising.[378] However, in a Phase III trial in patients receiving induction chemotherapy followed by concurrent chemotherapy and twice-daily RT, statistically significant differences were not demonstrated in objective measures of esophagitis and only borderline differences were noted in patient self-assessment. Weight loss was significantly less common in the amifostine group, although the magnitude of the difference in average weight loss (3.4% versus 4.7%) is of questionable clinical relevance.[379]

Myelitis is the most feared complication of thoracic irradiation, but it is rare with current radiotherapeutic techniques. The tolerance dose (TD5/5) for the thoracic spinal cord has been estimated at about 50 Gy, but it may be higher than this. With the use of multiple fractions per day, however, repair of damage is not complete in 6 hours, and the total cord dose should be lowered for twice- or thrice-daily regimens.

Late normal tissue effects of radiation have until recently been thought to be irreversible. Changes in our understanding of fibrosis have indicated that this is a dynamic process, undergoing continued tissue remodeling long after irradiation and have raised hopes that fibrosis may be reversed after the fact by disruption of ongoing cytokine cascades.[380] Animal studies and limited human trials with amifostine and vitamin E have suggested some ability of these agents to modify fibrosis in lung and subcutaneous tissue but more definitive studies are needed.

Attempts to improve the therapeutic ratio of treatment for patients with stage III NSCLC must address treatment efficacy and toxicity. Efforts to adopt new uniform criteria for reporting acute and late toxicities, shown in Table 44-12, should facilitate these efforts. These considerations are of great importance as long as the clinical gains achieved with aggressive treatments are modest.

PALLIATION OF LOCAL AND SYSTEMIC DISEASE

Several recent publications have highlighted the limited understanding of many patients with stage IV cancer of the goals of their treatment, whether palliative radiation therapy or chemotherapy (Table 44-13).[381,382] The reasons for this range from patient hopefulness to physician hesitancy to be upfront about the reasonable expectations from therapy. Palliation is a worthy goal on its own, and early implementation of formal palliative management on a regular basis has been shown to improve not only quality of life but also actually extend survival in patients with advanced NSCLC.[383] Early involvement of the palliative care team is important for optimal patient care.

Chemotherapy

The introduction of cisplatin and carboplatin ushered in an era of modestly effective and clinically beneficial chemotherapy for NSCLC. Chemotherapy has demonstrated benefit in

TABLE 44-13 Palliative Management of Local Expressions of Systemic Metastatic Disease

Syndrome	Presentation	Management
Brain metastases	Headache; nausea or vomiting; altered mental status; focal motor, sensory, or cerebellar deficits; focal or generalized seizures	Corticosteroids; whole-brain irradiation. Consider resection or radiosurgery of oligometastatic disease in patients whose other sites of disease are controlled or indolent. Avoid prophylactic anticonvulsants that are ineffective and have their own potential toxicities. Caution patients about driving.
Spinal cord compression	Back pain (early); motor or sensory deficits, loss of sphincter control (late)	Emergency evaluation by contrast-enhanced MRI; high-dose corticosteroids; local radiation or surgical decompression
Pleural effusion	Dyspnea; chest pain	Thoracentesis and pleurodesis with doxycycline, bleomycin, or talc
Pericardial effusion	Dyspnea; syncope	Emergency evaluation by cardiac ultrasound to exclude atrial collapse; pericardiocentesis or pericardiectomy. Avoid diuretics.
Superior vena cava obstruction	Dyspnea; facial and neck swelling; distention of superficial chest wall veins	Corticosteroids; mediastinal irradiation Concurrent chemotherapy if good performance status
Bone metastases	Pain; may be asymptomatic	Analgesics, radiation therapy. Consider prophylactic orthopedic intervention for weight-bearing bones. Consider use of bisphosphonates or RANK ligand inhibitors.

patients with metastatic disease, in patients with locally advanced disease when given together with RT, and in the adjuvant and neoadjuvant treatment of patients with localized disease. For the past 30 years, chemotherapy combinations containing a platinating agent and a second drug have results in palliation of patients with metastatic disease and, in combination with RT or surgery, have increased cure rates for patients with locally advanced disease or early stage NSCLC. From literally hundreds of clinical trials,[384-386] several general conclusions may be drawn:

1. Doublet therapy with cisplatin or carboplatin and a second active agent is superior to single-agent therapy, and single agents are superior to best supportive care.
2. The addition of a third conventional cytotoxic agent increases toxicity without significantly improving response rates or survival.
3. A variety of second-generation (vinblastine, etoposide) and third-generation (vinorelbine, gemcitabine, paclitaxel, docetaxel, pemetrexed) drugs produce broadly similar response rates and survival, although each of the third-generation agents in combination with platinum have generated statistically significant albeit clinically modest improvements in OS compared to second-generation combinations. Among the third-generation agents, given the minimal differences in response rates and survival, the choice between regimens is generally based on the particular toxicity spectrum (hematologic, renal, neuropathy), the patients preexisting comorbidities, and scheduling convenience (weekly versus every 3 weeks). Several trials have compared various third-generation agents in combination with cisplatin or carboplatin and not found meaningful differences in outcome.[387]
4. In nonsquamous histology, in combination with cisplatin, pemetrexed has clearly demonstrated superior survival compared to gemcitabine in the first-line treatment of patients with advanced NSCLC,[388] and superior survival in the maintenance setting compared with intravenous (IV) placebo. Conversely, gemcitabine in combination with cisplatin proved superior to pemetrexed/cisplatin in patients with squamous cell histology. These histology-specific differences in outcome may well be as a result of differences in expressions of relevant target enzymes (e.g., thymidylate synthase for pemetrexed, ribonucleotide reductase for gemcitabine). Choosing a drug regimen based on histology is likely a temporary surrogate for a more sophisticated individualized therapy based on genomic, proteomic, and metabolomic profiling of individual tumors.[389-391]
5. When used at equivalent doses, cisplatin and carboplatin show similar activity. Cisplatin regimens may produce slightly higher response rates but minimal differences in OS. In the United States, there is a tendency to use carboplatin when treating patients for palliation and cisplatin in the adjuvant and neoadjuvant settings. In locally advanced NSCLC, at least one Japanese study showed little difference in long-term outcome for XRT in combination with cisplatin-based therapy (MVP) compared to XRT in combination with weekly carboplatin/paclitaxel or carboplatin/irinotecan.[392]
6. Virtually all patients who respond to first-line chemotherapy will experience relapse, and the role of second-line therapy for these patients is becoming increasingly well defined. Docetaxel, pemetrexed, and erlotinib are each approved by the Food and Drug Administration (FDA) for the second-line treatment of patients whose disease has progressed on first-line platinum-based regimens. In addition, several recent trials have suggested that switching to a different agent (e.g., pemetrexed, erlotinib) for maintenance after response or stabilization on initial chemotherapy may prolong remission and survival in selected patients, although the routine use of such maintenance chemotherapy is controversial.[393] One concern regarding the trials that claim benefit for immediate maintenance therapy is that patients in the control arm of these trials were not routinely crossed over to the maintenance agent at the time of disease progression. In the trial of pemetrexed reported by Ciuleanu et al, only 67% of the patients in the control arm received poststudy chemotherapy, and fewer than 20% received pemetrexed.[394] Therefore, this trial has not clearly shown that immediate maintenance with pemetrexed is superior to a policy of close observation after initial chemotherapy with routine delayed use of pemetrexed at the time of disease progression. Such a policy would require close follow-up but might be preferred by some patients, particularly if initial treatment was toxic.

The availability of agents with diverse mechanisms of action and the increasing feasibility of genomic and proteomic profiling of individual tumors is rapidly moving us to an era of personalized medicine in lung cancer as well as other malignancies. The molecular heterogeneity of NSCLC is giving rise to new clinical trial designs in which patients, particularly

those with adenocarcinoma histology, first undergo molecular analysis to determine which of several targeted therapies would be most appropriate.[395,396] In this regard, an EGFR TKI (erlotinib, gefinitib, afatinib) is indicated in the first-line treatment of patients with an EGFR mutation based on multiple prospective Phase III trials showing a major relative risk (RR) and PFS advantage compared with standard platinum-based chemotherapy. By the same token, patients whose tumors harbor EML4/ALK or ROS1 translocations warrant therapy with crizotinib. For now, these assays are based on tumor biopsies. The ability to identify and quantitate genomic changes in tumor by analysis of either circulating tumor cells or circulating cell-free DNA may greatly facilitate such analyses by reducing the need for invasive biopsy procedures.[80,81,397] Such "liquid biopsies" are being developed first in the treatment of patients with metastatic disease, in whom their sensitivity approaches 100%, but may yield even greater value when applied to patients with earlier-stage disease.[83] Such developments will require better characterization of the molecular determinants of radiosensitivity of tumor and normal tissues and their patient-specific modification by chemotherapeutic agents, which may or may not be the same as for these agents when used without RT.

Data from SWOG 0003 and the Japanese Four-Arm Cooperative Study showed clinically significant ethnic differences in chemotherapy tolerance. These trials had generally similar outcomes, except for 1-year survival, but despite a lower dose of paclitaxel in the Japanese trial (200 mg/m^2 versus 225 mg/m^2), Japanese patients had twice the incidence of neutropenia.[398] Data also were available for population variations in the rate of glucuronidation of irinotecan metabolites among racial and ethnic groups. What in the past had been puzzling differences between national trials may herald the development of metabolically individualized treatment regimens.[399] One example of this is a polymorphism in BIM, which confers resistance to EGFR TKI and is seen in about 15% of East Asians but is rare in European or North American patients.[400]

Management of the Patient with Oligometastatic Disease

Although the majority of patients with stage IV NSCLC have widespread metastatic disease and a poor survival, an occasional patient will present with only one or a small number of evident metastatic sites. Such oligometastatic disease presents in 5% to 10% of patients (depending in part on how carefully additional metastatic sites are sought after the first one is identified). Management of these patients is controversial. Most will do poorly, but a few will fare quite well with aggressive treatment to all known sites of disease. Khan et al reported long-term survival of 5 of 23 such patients and have argued that these patients may constitute about 6% of all new patients with NSCLC in the United States and that with aggressive treatment 1500 to 2000 patients per year could experience long-term disease-free survival.[401] Even in patients who will not be cured, the effective palliation or prevention of symptoms from bulky intrathoracic disease by local RT may improve both quality of life and survival. In this regard the difference between patients with stages III and IV disease is one of degree rather than kind.[402]

Treatment of the patient with otherwise early-stage NSCLC with a solitary brain metastasis is the best example of this phenomenon. With aggressive therapy, including surgical resection of the lung primary and the brain metastasis, these patients in some cases have a good outcome, far better than that typically observed in patients with stage IV disease.[403] Some are even cured.

Palliative Radiation Therapy

For patients with advanced NSCLC who are candidates for neither surgery nor chemoradiation with curative intent and who lack symptoms requiring immediate RT, it is not clear that there is benefit to early RT rather than waiting for symptoms and treating palliatively at that time. One randomized trial that compared these two approaches in 230 patients found no differences in OS, activity level, or psychological distress. Patients randomized to deferred RT started RT a median of 125 days from randomization.[404] This strategy allows for a window of opportunity in which to offer either a conventional or investigational chemotherapeutic regimen to patients with good performance status and with measurable or evaluable nonirradiated lesions.

The radiation dose required for effective palliation of symptoms has been the subject of several randomized trials and reviews (Table 44-14). For most patients there seems little

TABLE 44-14 Palliation of Symptoms of Non–Small Cell Lung Cancer with External Beam Irradiation or with Multiagent Chemotherapy

§Data from Tummarello D, Graziano F, Isidori P, et al: Symptomatic, stage IV, non–small cell lung cancer (NSCLC). Response, toxicity, performance status change, and symptom relief in patients treated with cisplatin, vinblastine, and mitomycin C. Cancer Chemother Pharmacol 3:249–253, 1995.

benefit, in either survival or relief of specific symptoms, with increased doses; the typical 20 Gy in 5 fractions or 30 Gy in 10 fractions are quite reasonable. Shorter regimens of 1 or 2 fractions have also been used with success, especially in patients with end-stage disease where a longer course of treatment can constitute a substantial proportion of the patient's anticipated survival. For selected patients with good performance status, little metastatic disease burden or metastatic disease that has responded well to chemotherapy, there may be a modest benefit for higher doses of thoracic RT, although this is not clear from published data and higher doses may produce more acute toxicity, particularly esophagitis.[405,406]

Most patients with lung cancer have symptoms from their intrathoracic disease. RT has long been the mainstay of treatment for such patients, with relatively high rates of palliation for irritative or obstructive symptoms such as cough and for hemoptysis, but poorer results for symptoms of nerve compression such as recurrent laryngeal and phrenic paralysis (see Table 44-13). In the United States, common practice has been to treat such patients to doses of 30 Gy to 35 Gy in 10 to 15 fractions over 2 to 3 weeks. In the United Kingdom, several randomized trials conducted by the Medical Research Council (MRC) compared such schedules with shorter regimens of 17 Gy in 2 fractions 1 week apart or a single fraction of 10 Gy with equally good palliation of symptoms and survival and toxicity no greater than with more fractionated treatment (see Table 44-14). Such schedules are particularly attractive for patients who may otherwise have to travel substantial distances or remain hospitalized for the duration of their RT. They provide good symptom management while limiting the use of medical resources and reducing disruption of the schedules of the patients and their caregivers. For patients with better performance status, however, more fractionated schedules have resulted in modest improvements in survivals compared with 1- or 2-fraction schedules.[407,408]

The most common sites of locally symptomatic metastases of NSCLC are bone and brain. These can be palliated in most patients with relatively brief courses of RT, typically 2 weeks in the United States and two fractions in the United Kingdom (see Table 44-14). In appropriate situations, resection of solitary CNS metastases, particularly larger cystic ones unlikely to respond well to radiation therapy or radiosurgery, or orthopedic stabilization of metastases to weight-bearing bones should be considered. For patients with one to three CNS metastases, stereotactic radiosurgery in addition to whole-brain radiation therapy (WBRT) improves radiographic and clinical response and, for patients with a single metastatic lesion, improves survival.[409] It has been suggested that for these patients, WBRT can be omitted in their initial management and used only if needed subsequently, without a detrimental effect on survival.[410,411] A concern with this strategy is that the risk of subsequent CNS events is rather high in these patients (30% to 60%), and the psychological morbidity of multiple brain metastases and their treatment may be substantial. This issue has been addressed in several randomized trials.[412-415] The majority of data from both retrospective reviews and prospective trials have indicated that the addition of WBRT to local treatment (either resection or radiosurgery) reduces the rate of relapse in the brain (both at the site of the initially treated metastasis and other intracranial sites) without appreciably impacting survival. In the EORTC trial, the rate of death from intracranial progression was reduced. In the M. D. Anderson trial, however, survival was significantly shorter in the patients randomized to receive WBRT. This was attributed by the investigators to the significantly greater rate of neurocognitive deterioration. An alternative explanation is that in this small trial, with a total of just 58 patients, a potential imbalance in prognostic factors led to poorer survival in the patients randomized to WBRT and that their neurocognitive functioning deteriorated rapidly as they approached death. The optimal approach in this situation remains controversial and clearly needs to be individualized.

Bone metastases are common and are often painful and debilitating. A high index of suspicion, early imaging, and consultation between appropriate medical, radiation, and surgical oncologists is essential to reduce the adverse effects of skeletal-related events, such as pain, fracture, and spinal cord compression. For lesions without risk of fracture short-course palliative RT, such as 8 Gy in a single fraction, has been shown to be as effective and considerably less expensive and more convenient compared to longer fractionated courses such as 30 Gy in 10 fractions but it results in a higher frequency of retreatment.[416] The use of bisphosphonates (e.g., zoledronic acid) and RANK ligand inhibitors (e.g., denosumab) appears to reduce the incidence of skeletal-related effects as well as delay their onset.[417]

Reirradiation of thoracic tumors, either the primary site or vertebral metastases, may be appropriate in selected cases where there is no evidence of distant dissemination and pressing local symptoms. By using IMRT, it is possible to deliver doses on the order of 70 Gy while limiting reirradiation of the spinal cord to 20% to 25% of this.[418] SBRT has also been used for reirradiation of localized recurrence with acceptable toxicity and evidence of good early responses.[419]

In past years, chemotherapy for palliation of specific symptoms was thought to be inferior to irradiation. Trials of new chemotherapeutic regimens typically reported response rates and survival, but infrequently reported palliation of specific symptoms or effects of treatment on quality of life. More recent trials have addressed these issues and have shown that with a number of platinum-containing chemotherapy regimens, the rates of clinical improvement and symptomatic palliation were about twice as great as the rates of Response Evaluation Criteria in Solid Tumors (RECIST)-specified objective response (Table 44-15). This suggests that for patients with widely metastatic disease and good performance status, an initial trial of chemotherapy should be offered, with RT reserved for nonresponding lesions. RT should be employed early in patients with metastases to weight-bearing bones, impending spinal cord compression, or caval or major airway obstruction. Because of the increased risk of neutropenic sepsis in patients with lobar or main-stem bronchus obstruction, attempts to open such obstructed airways with external beam or endobronchial irradiation, laser excision, or stent placement are desirable before chemotherapy.

One shortcoming of clinical research has been the conduct of a large number of clinical trials of similar design. The power of these trials is limited, and to obtain statistical significance, it has been necessary (e.g., the role of PCI in SCLC, impact of platinum-containing chemotherapy on survival of patients with metastatic NSCLC) to combine data from multiple individual trials in meta-analyses. When done with care, this process can complement the results of large randomized trials as well as provide hypotheses for further testing.[420] But given the burgeoning number of new agents we are faced with the prospect of large numbers of promising but inconclusive small trials without clear direction for changing therapy. This will be further complicated by the individualization of therapy required to target distinct molecular lesions in individual tumors, unless the magnitude of effects in these cases is so dramatic (as in treatment of gastrointestinal stromal tumors with imatinib) that definitive trials will require few patients. Such individualized therapy holds the promise of treatments that are more effective and less toxic, but implementing them will require major changes in the way we fund and perform diagnostic procedures, molecular

TABLE 44-15 Recommended Therapy for Patients with Non–Small Cell Lung Cancer Who Are Good Risks

Clinical Stage	Primary Therapy*	Adjuvant Considerations
T1N0M0	Resection (usually lobectomy)	If pathologic N0, no adjuvant therapy is indicated. Should be considered for trials of early detection and chemoprevention
T2N0M0	Resection (usually lobectomy)	Postoperative adjuvant chemotherapy†
T1-2N1M0	Resection (consider preoperative chemotherapy)	Postoperative adjuvant chemotherapy†
T3N0-1M0	Resection (consider preoperative chemotherapy)	Postoperative adjuvant chemotherapy†
T1-3N2M0	Resection followed by adjuvant chemotherapy ± mediastinal irradiation‡	Single N2 node found at intraoperative mediastinoscopy
T1-3N2M0	Induction chemotherapy or chemoradiotherapy and resection or definitive chemoradiotherapy	Multiple N2 nodes or single node with extranodal extension identified before thoracotomy
T1-3N3M0	Definitive chemoradiotherapy	Chemoradiotherapy clearly superior to standard radiation therapy alone; local control remains poor. With conventional fractionation, use concurrent rather than sequential chemoradiation.
T4N1-3M0	Definitive chemoradiotherapy	Consider preoperative radiochemotherapy and resection for patients with T4N0M0 lesions, especially those of the superior sulcus.§
T1-4N0-3M1	Symptomatic palliative treatment with radiation and/or chemotherapy	Consider more aggressive therapy for primary and metastatic disease, including resection for patients with T1-3N0M1 lesions with a solitary lesion in the brain or adrenal, particularly if responsive to initial chemotherapy.

**Patients who are good risks are characterized by adequate cardiopulmonary function, ECOG PS ≤1, weight loss ≤5%. Patients not meeting these criteria may still be suitable for therapy but should be evaluated with particular care.*

†Regimens with demonstrated efficacy in this setting include cisplatin or carboplatin and a second agent such as etoposide, vinorelbine, paclitaxel, docetaxel, or gemcitabine.

‡Adjuvant postoperative radiation to the mediastinum, if given, should be carefully planned to avoid excessive cardiac and pulmonary treatment and limited to a dose of 45 Gy to 50 Gy (1.8 to 2.0 fractions) with a possible boost to a small field if there is known extracapsular extension or adherence of nodal metastases to adjacent unresected structures.

§For preoperative chemoradiation, radiation doses in the range of 45 Gy to 50 Gy are best established using concurrent chemotherapy with cisplatin/etoposide or carboplatin/paclitaxel.

analysis of tumors, as well as the ways in which we conduct clinical trials and develop new drugs. This may be particularly true in trials using multiple investigational agents being developed by different drug companies.[113] These will need to be balanced with societal needs to control healthcare expenditures by various means including limitation of reimbursement to evidence-based therapies. These goals, although not necessarily in conflict, will require careful codevelopment for successful implementation.[421,422]

Although there is great popular interest in and use of natural, holistic, complementary, and alternative methods of cancer therapy and prevention, it is our responsibility to present our patients with data, not merely hope often born of desperation, and to assess such approaches honestly, openly, and critically.[423-425] No such approach has been shown to impact lung cancer incidence or survival in unselected populations, and as previously noted, trials have shown that supplementation with β-carotene could increase the risk of lung cancer in smokers. Although there should be no prejudice against investigating therapies that arise from alternative sources or belief systems neither, should there be any hesitation to hold them to strict standards of clinical investigation in randomized clinical trials.[426]

CONTROVERSIES

The past several decades have witnessed a clear demonstration of modest survival improvements for patients with LA-NSCLC when they were treated with careful combinations of RT and chemotherapy. Also new tools for tumor imaging and radiation dose delivery may allow us to escalate tumor dose with manageable normal tissue toxicity and will enable us to determine whether this dose increase can result in improved local control and survival. Several reasonable guidelines for stage-specific therapy may be proposed based on good-quality evidence from prospective clinical trials (see Table 44-15). There remain a number of basic questions about the role of RT that have not been addressed or answered by current clinical research:

1. Should ENI be reduced or eliminated for patients in early-stage disease, in whom the probability of nodal disease is low, or in patients with bulky primary disease that is not likely to be controlled with current chemoradiation? Is there an intermediate subgroup of patients with a reasonable probability of primary tumor control and substantial risk of regional nodal metastases for whom elective nodal treatment improves survival? Would a strategy of fractionated RT to the elective nodal volume combined with SBRT to primary lesions with a reasonable probability of microscopic nodal metastases be of value?
2. Will adjuvant chemotherapy effective against occult M1 disease also eradicate microscopic nodal disease, or will there be an ongoing role for adjuvant mediastinal irradiation to improve both local control and survival, especially in those who undergo resection of N2 nodes?
3. Is the superiority of concurrent versus sequential combinations of RT and chemotherapy the result primarily of selective radiosensitization or of shortening the overall treatment time? If overall time rather than concurrency is the critical factor, alternate strategies to shorten time without exposing tissues to overlapping toxicities of concurrent treatment, such as induction chemotherapy followed by accelerated RT or rapidly interdigitated therapy (e.g., RT during the week with chemotherapy on the weekend), may warrant investigation.
4. What is the role of surgery in patients with advanced stages IIIA(N2) and IIIB disease? If sterilization of mediastinal lymph nodes is useful in selecting patients for surgery, how

can this best be assessed preoperatively? Will increasing radiation dose to the mediastinum to increase the rate of sterilization of mediastinal nodes translate to increased survival, even though it does not necessarily affect systemic disease?

5. Does close follow-up benefit patients with NSCLC after surgical or nonsurgical therapy, or does it merely shorten the measured disease-free survival without extending OS or improving quality of life? There is marked variation in current clinical practice after curative resection.[427] Most recurrences are detected clinically; asymptomatic recurrences are most commonly detected by routine chest radiographs or CT. OS does not seem significantly affected, and close follow-up does not clearly improve survival. However, many of these studies were conducted at a time when chemotherapy was less effective and active second-line and third-line agents had not been identified. The high rate of second primary lung cancers in these patients is a strong argument for close surveillance.
6. How is local tumor control best evaluated in patients not undergoing surgical resection? Several investigators have demonstrated that assessment based on CT measurement of tumor size, whether evaluated unidimensionally as in the RECIST, by traditional bidimensional measurements, or by volumetric assessment, does not correlate particularly well with clinical outcome. Assessment by ^{18}FDG-PET has correlated better with endpoints such as pathologic response at surgery or survival, but postirradiation inflammatory changes and infection may also cause persistently increased FDG uptake. There may be benefits in functional imaging with other agents that more directly detect image cell proliferation or apoptosis.[428]
7. How can we best assess the efficacy of SBRT in good performance status patients with stage I NSCLC when neither they not their physicians have been supportive of randomized trials?
8. To what degree will molecular profiling of individual tumors and the normal tissues in which they arise lead to individualization of dose and fractionation in radiation therapy, as it is starting to lead to individualized chemotherapy?[35,429,430]

CONCLUSIONS

The past several years have seen modest progress in the treatment of patients with NSCLC, particularly in the combination of local and systemic modalities of treatment. Staging has become more accurate with the introduction of FDG-PET; and although this does not improve treatment per se, it allows a better match between a patient's true extent of disease and the ideal treatment for the patient's tumor. Adjuvant chemotherapy for most resected patients (excluding those with stage T1N0M0 disease) has demonstrated a modest but statistically significant and clinically meaningful survival benefit of similar magnitude to those seen with other adult solid tumors such as breast or colorectal cancer.

Better imaging and treatment planning technologies for RT, including adaptation for tumor motion, herald a new era of treatment precision and the ability to explore dose escalation in a more meaningful fashion than previously. As more effective systemic treatment agents are introduced, we may reasonably expect modest gains in survival. This progress is real, can be achieved with acceptable cost, and should be made widely available to patients with unresectable disease. These gains should not blind us to the fact that prevention of this disease is far better than its treatment and that detection and treatment of early-stage disease is far better than the best chemoradiation for advanced disease. Basic research and clinical trials assessing smoking prevention and cessation, chemoprevention, and early detection in smokers and the growing population of former smokers who remain at high risk for lung cancer must remain high priorities to produce a major reduction in deaths from this disease. Funding for basic and clinical research in lung cancer, which currently is less than a fourth of that expended on other malignancies (expressed as dollars per death), must be increased if we are to continue to make progress against this devastating disease. (Table 44-16).

CHAPTER

45 Cancer of the Esophagus

A. William Blackstock, Jr. and Suzanne Russo

INCIDENCE

Esophageal cancer is the eighth-most common cancer worldwide and is endemic in Asia, South and East Africa, and Northern France. Esophageal cancer accounts for approximately 1% of cancers in the United States and is associated with an 85% mortality rate. In 2012, 17,460 (13,950 men and 3,510 women) in the United States were diagnosed with esophageal cancer, resulting in approximately 15,000 deaths (12,040 men and 3030 women).

BIOLOGIC CHARACTERISTICS

The predominant histologic types are squamous cell carcinoma and adenocarcinoma. Major prognostic factors are local tumor extent, presence of nodal involvement or distant metastases, and pathologic response to therapy. Approximately 15% to 30% of adenocarcinomas and 5% to 13% of squamous cell carcinomas overexpress Her-2/neu.

STAGING EVALUATION

Staging evaluates the extent of primary tumor, involvement of lymph nodes, and presence or absence of metastases. Staging evaluations should include a history and physical examination, blood count and chemistries, endoscopy with biopsy, 18-fluorodeoxyglucose positron emission tomography (FDG-PET) with computed tomography (CT) imaging and endoscopic ultrasound (EUS).

DEFINITIVE THERAPY

Surgical resection is the primary therapy for resectable esophageal cancer. Cure rates of 60% to 80% are achieved in the rare patient found to have disease confined to the esophagus without nodal involvement. Preoperative chemoradiation (for resectable squamous and adenocarcinomas of the esophagus) and perioperative chemotherapy (for distal and esophagogastric adenocarcinomas) significantly improve survival in patients with more advanced locoregional disease amenable to surgical resection. Concurrent chemoradiation therapy provides a significant improvement in overall survival and local control over radiation alone for both squamous and adenocarcinomas. There is no demonstrated benefit to escalation of radiation dose in this setting.

Postoperative chemoradiation has demonstrated a survival benefit for patients with stage IB-IV, M0 resected gastroesophageal junction and gastric adenocarcinomas who have not received preoperative therapy compared to surgery alone. Chemotherapy alone in the preoperative setting has demonstrated a small survival advantage over surgery alone.

PALLIATION

Patients with unresectable esophageal cancer causing obstruction or bleeding may obtain palliation with concurrent chemotherapy and radiation. In patients with poor performance status who cannot tolerate systemic therapy, external beam radiation or brachytherapy is a reasonable option for palliation of dysphagia. Esophageal stenting should also be considered. Radiotherapy is also used for palliation of symptomatic distant disease such as bone or brain metastases. Intraluminal brachytherapy with or without the addition of external beam irradiation is occasionally used for palliation.

INTRODUCTION

The diagnosis and management of esophageal cancer continues to evolve. Advances in the operative and postoperative management and rational applications of multimodality therapy have produced modest improvements in survival rates over the last 25 years.[1] In this chapter, we review biologic and epidemiologic factors associated with esophageal cancer. We also discuss review the rationale for and results of combined-modality approaches, as well as the use of palliative therapies. We conclude with a summary of current treatment recommendations and a discussion of several important clinical trials in progress.

ETIOLOGY AND EPIDEMIOLOGY

Esophageal cancer is the eighth-most common cancer worldwide[1] and is endemic in developing nations with wide variations in prevalence between low- and high-incidence regions (Asia, South and East Africa, and Northern France).[2] In 2012, 17,460 patients (13,950 men and 3510 women) in the United States were diagnosed with esophageal cancer, resulting in approximately 15,000 deaths (12,040 men and 3030 women).[3] The incidence of esophageal cancer continues to rise and has increased 5% over the last 2 years in contrast to 2010, when 16,640 Americans were diagnosed with esophageal cancer, and there has been a 14.6% increase in incidence over the previous 5 years.[4,5] Esophageal cancer represents only approximately 1% of new cancers in the United States, but approximately 85% of patients die of their disease without significant overall improvement over the last 25 years.[3-5] In 2008, esophageal cancer was the fifth leading cause of death in males age 40 to 79.[3]

Esophageal cancers are histologically classified as either adenocarcinoma or squamous cell carcinoma. Both squamous cell and adenocarcinomas are more common in males, however the incidence of squamous cell carcinoma is declining in North America and Western Europe as the incidence of adenocarcinoma of the distal esophagus and gastroesophageal junction is increasing, currently representing approximately 70% of all esophageal carcinomas in the United States.[6] Squamous cell carcinoma remains dominant in endemic regions and underdeveloped parts of the world.[6-8]

TABLE 45-1 Incidence of Adenocarcinoma of the Esophagus

Investigator	Years	Adenocarcinoma (%)
Smithers[14]	1936-1951	7.3
Hesketh/Conn. Register[12]	1983-1986	22.9
Birgisson[15]	1987-1994	73.5
Steyerberg[16]	1991-1999	52.0
Brown[6]	2000-2004	61.1*

*White males and females only.

Data from the Surveillance Epidemiology and End Results (SEER) program of the National Cancer Institute demonstrated that the incidence of esophageal cancer in white males steadily increased by 45% in the United States between 1975 and 2004, with the incidence of adenocarcinoma increasing by 463%, and the incidence of squamous cell carcinoma declining by 50% during the same time period.[6] In contrast, the overall incidence of esophageal cancer has remained constant among white females, although there have been similar trends observed with a 335% increase in the incidence in adenocarcinomas and a 29% decline in the incidence of squamous cell carcinomas.[6,9] The incidence of squamous cell carcinoma has shown a significant decline in black males beginning in 1992,[10] but it remains the most common cell type among blacks in the United States,[11] despite the twofold to threefold increase in incidence of adenocarcinomas in black males and females. Interestingly, a review of the New England tumor registries[12] demonstrated that the incidence of adenocarcinoma has increased even when tumors located at the esophagogastric junction have been excluded, and data from the National Cancer Institute's SEER database (1973-2001) found no evidence of histologic reclassification of esophageal squamous cancers or anatomic reclassification of adenocarcinomas of the gastric cardia to explain this trend.[13] Table 45-1 reflects recent changes in the prevalence of adenocarcinoma of the esophagus over the span of several decades.

Racial disparities have been observed in the esophageal cancer population. Males who are black are more likely to present with advanced or metastatic disease, resulting in a survival rate that is 60% of that for males who are white.[3,4] In a multivariate regression analysis controlling for age, gender, marital status, tumor histologic type, and tumor location, black race was associated with worse survival rates. In this study analyzing SEER data, when the tumor status, surgical technique, and radiotherapeutic modality were added to the model, race was no longer significantly associated with survival rates.[11] Provocative data from Steyerberg[16] and others[17,18] also suggested that the underuse of potentially curative surgery may, in part, explain the poorer survival rates observed for patients who are black with locally advanced disease because a population-based analysis showed that once data had been corrected for treatment received, there was no difference in survival rates between patients regardless if they were white or black. It has been postulated that the increased incidence of disease and increased mortality rates observed in patients who are black are reflections of socioeconomic status and dietary risk factors but not ethnicity. Squamous cell carcinoma remains the most common histologic type among males who are black[11] and may be associated with worse outcomes, facts that could explain some of the observed racial disparities in survival rates.[12] In one population-based study there appeared to be a risk for developing esophageal cancer in patients who are black beyond what could be attributed to alcohol and tobacco use.[19] The reasons for the apparent racial difference in risk from the same level of alcohol and tobacco use could be associated, in part, with increased mutations in the *TP53* gene in esophageal cancers found in patients who are black, as reported by Baron et al.[20]

PREVENTION AND EARLY DETECTION

The use of tobacco is an established risk factor for squamous cell carcinoma of the esophagus and also for adenocarcinoma, but to a lesser extent[21]; smoking cessation reduces the risk of only squamous cell carcinoma, however.[22-24] In addition, patients with both squamous cell and adenocarcinomas of the esophagus are at increased risk of developing second primary cancers, including lung and head and neck malignancies, which are also correlated with tobacco use.[25,26] Alcohol consumption has been shown to be a risk factor for squamous cell carcinoma but not adenocarcinoma.[21,27] Other environmental factors associated with the development of squamous cell cancers include thermal injury and exposure to nitrates and potentially carcinogenic nitrosamines, asbestos fibers, or water contaminated with petroleum products.[28-30] In addition, the presence of human papillomaviruses (HPV-16 and HPV-18) may be risk factors for the development of cancers of the esophagus.[31]

Obesity and high body mass index (BMI) have been established as strong risk factors for development of esophageal adenocarcinoma but not squamous cell carcinomas.[27,32,33] Those individuals who are in the 75% highest BMI range have a 7.6-fold increased risk of developing adenocarcinoma of the esophagus compared to those with lower BMIs.[34,35] Obesity-related comorbid illnesses that contribute to the development of esophageal cancer include gastroesophageal reflux disease (GERD) and type 2 diabetes. One study demonstrated that the presence of type 2 diabetes was associated with an increased risk of developing esophageal, among other cancers, whereas treatment with metformin reduced the risk.[36] Diet affects both types of esophageal carcinomas, with increased intake of fruits and vegetables associated with a reduced incidence of cancer.[37] Lifestyle changes, including weight loss and exercise, postulated to reduce the risk of developing esophageal adenocarcinoma, are currently being investigated.

GERD predisposes to Barrett's esophagus and both are associated with an increased risk of adenocarcinoma of the esophagus, with severe long-standing disease.[22,38-41] The incidence of GERD appears to be increasing in the United States. Barrett's esophagus is known to be associated with GERD and is a precursor lesion for esophageal adenocarcinoma, although most Barrett's lesions do not proceed to carcinoma. The normal squamous mucosa is damaged by chronic GERD and is replaced by columnar metaplasia in Barrett's esophagus that predisposes to malignancy.[42] A 30% to 60% increased risk of development of esophageal adenocarcinoma has been demonstrated in patients with Barrett's esophagus.[40] Long-standing GERD, length of Barrett's esophagus, male gender, age, and hiatal hernia size are strongly associated with high-grade dysplasia[43-45] and are thought to be a predictor for development of adenocarcinoma in patients with Barrett's esophagus. The risk of development of esophageal malignancy increases from 4% in patients with Barrett's esophagus with low-grade dysplasia to 59% in patients with high-grade dysplasia.[46] Biomarkers such as aneuploidy and loss of heterozygosity of p53,[47-49] cyclin D1,[50] and P16[51] have been associated with increased risk of progression from high-grade dysplasia to adenocarcinoma, whereas p53 expression has been correlated with treatment response.[49]

Medical management of Barrett's esophagus is designed to control GERD symptoms using proton pump inhibitors (PPIs) and histamine receptor antagonists. Patients with Barrett's esophagus with high-grade dysplasia should undergo surgical

resection or alternative local strategies, such as endomucosal resection (EMR), cryoablation, radiofrequency ablation (RFA), or photodynamic therapy (PDT).[52] Some have postulated that the use of pharmaceutical agents for the treatment of GERD (i.e., antisecretory agents and therapies to relax the lower esophageal sphincter) have precluded necessary surveillance required for the detection and management of Barrett's esophagus and is therefore related to the recent increase in the incidence of Barrett's esophagus–associated adenocarcinomas.[53] Nonetheless, efforts continue to improve early detection of Barrett's esophagus. Endoscopy is performed on patients with severe symptomatic GERD, especially those with a family history of esophageal cancer or Barrett's esophagus, and can evaluate progression of metaplasia to dysplasia or carcinoma, but the rate of progression is fairly low.[54] Guidelines of the American College of Gastroenterology currently recommend surveillance every 3 years for patients without dysplasia until none is detected on two consecutive endoscopies, as confirmed by biopsy. If high-grade dysplasia is discovered, followup endoscopy should be performed at 3 months to rule out adenocarcinoma and repeated each 3 months thereafter.[55]

The use of chemopreventive agents are under investigation. Nguyen[56] reported the results of a retrospective observational study of 344 patients with Barrett's esophagus demonstrating that prescription use of PPIs is associated with a reduced risk of high-grade dysplasia or cancer with adjustment for gender, age, and the length of duration of Barrett's esophagus and the use of nonsteroidal antiinflammatory drugs (NSAIDs) or aspirin resulted in a nonsignificant trend toward a lower incidence of high-grade dysplasia and cancer.[56] A meta-analysis demonstrated that the use of NSAIDs decreases the risk of both squamous cell carcinoma and adenocarcinoma, with odds ratios of 0.58 and 0.67, respectively.[57] Similar results were reported in a prospective cohort study.[58] Currently, there is a large multicenter, randomized controlled clinical trial (AspECT) evaluating the long-term chemopreventive effect of esomeprazole with or without aspirin.[59]

Dysplastic lesions as well as carcinomas of the esophagus have been shown to overexpress the cyclooxygenase-2 (COX-2) enzyme.[60-62] COX-2 expression is correlated with the proliferative activity in dysplastic lesion and was found to be increased, in a stepwise fashion, with the transition from normal esophageal tissue to low-grade dysplasia to high-grade dysplasia, suggesting that COX-2 is involved in the early stages of carcinogenesis and that interruptions in the dysplasia-carcinoma sequence could be an important part of a chemoprevention strategy.[63] In a recent animal study, celecoxib was shown to significantly decrease the risk of Barrett's esophagus and prevent the development of esophageal adenocarcinoma in a rat surgical model with mixed reflux of acid and duodenal juice.[64] COX-2 may be an effective selective target of chemoprevention for adenocarcinoma of the esophagus in humans but requires further clinical evaluation.

The human epidermal growth factor receptor 2 (*HER-2*) gene or HER-2 protein expression has been associated with the development of esophagogastric and gastric adenocarcinomas.[65] The Her-2/neu oncogene is overexpressed or amplified in preneoplastic lesions and may indicate an increased risk of developing esophageal adenocarcinoma among patients with Barrett's esophagus.[66] Chemoprevention with targeted therapies, such as trastuzumab, are being investigated.[67]

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

The HER2/neu oncogene is overexpressed in esophageal cancers (15% to 30% of adenocarcinomas and 5% to 13% of squamous cell carcinomas)[68-70] and has been associated with tumor invasion, lymph node metastases, and poor prognosis.[66,68,71] Her-2/neu positivity is identified in 21% of gastroesophageal tumors compared to 33% of gastric tumors.[72] Typically both immunohistochemistry and fluorescence in situ hybridization (FISH, which expresses the ratio between the number of copies of the Her-2 gene and the number of chromosome 17 centromeres) are used to test to identify HER-2 overexpression. However gastric cancer cells demonstrate incomplete HER-2 membrane staining in a basolateral pattern and increased tumor heterogeneity compared to breast cancer cells, which may lead to underestimation of HER-2 overexpression using standard techniques.[73,74] Hence, Hoffman et al developed a modified HER-2 scoring system using 10% stained area cut-off for resected specimens, and no cut-off for biopsies to better identify patients with gastroesophageal and gastric cancers that would be candidates for anti-HER-2 therapy.[75] This method was validated and subsequently used in the Trastuzumab for Gastric Cancer Trial (ToGA) trial.[73,76] HER-2 testing with immunohistochemistry using the modified scoring system is currently recommended for all patients with metastatic esophagogastric or gastric adenocarcinomas at the time of diagnosis. FISH is reserved for confirmation of equivocal immunohistochemistry results (2+), although some institutions routinely perform both tests on all patients.

Overexpression of the epidermal growth factor receptor (EGFR) is found in both esophageal squamous cell carcinomas and esophageal adenocarcinomas, as well as their precursor lesions, such as squamous dysplasia and Barrett's esophagus.[77-79] Overexpression of EGFR on immunohistochemical testing occurs in approximately 80% of patients with esophageal adenocarcinoma and squamous cell carcinoma.[80] Additionally, amplification of the *EGFR* gene has been detected by FISH analysis in 8% to 30% of esophageal adenocarcinomas.[81,82] Clinical studies have shown that increased EGFR expression is associated with an overall decrease in survival rates in patients with esophageal cancer.[83] Ongoing trials continue to evaluate the efficacy of EGFR inhibitors, erlotinib[84-86] and cetuximab,[87-91] in addition to chemotherapy in patients with advanced disease.

Vascular endothelial growth factor (VEGF) expression levels and microvessel density are significantly higher in cancerous tissues compared with normal tissues and Barrett's dysplastic tissues.[92,93] VEGF expression has been correlated with tumor differentiation, depth of invasion, and lymph node metastases.[94,95] VEGF is overexpressed in 30% to 60% of esophageal cancers, and studies have demonstrated a correlation between high levels of VEGF expression, advanced stage, and poor overall survival rates.[96-102] A meta-analysis of 1,453 patients from 19 studies has correlated VEGF overexpression in Asian patients with esophageal carcinoma with poor prognosis, especially for those with squamous cell histology; however no correlation was observed for non-Asian patients.[103] Ongoing clinical trials are evaluating the potential benefit of the addition of VEGF inhibitors to chemotherapy for patients with advanced tumors.[104-106]

COX-2 is another molecular target that has significance in cancer development and progression, and inhibition of COX-2 activity results in enhanced radiosensitization of tumor tissue but not normal tissue.[107,108] Selective COX-2 inhibition has been shown to directly inhibit tumor neovascularization.[109] The combination of these effects suggests potential enhancement of selective tumor targeting by COX-2 inhibition.

Mutations in the p*53* gene are present in up to 80% of esophageal cancers. Interestingly, the mutations for squamous tumors, which are in A-T base pairs, are different from the mutations usually seen in adenocarcinomas.[110] Data from Montesano[110] indicate that the mutations common to

squamous tumors are correlated with smoking. Mutations in the *p53* gene are an early event in the carcinogenic process. There is no concordance between *p53* gene mutations and the accumulation of the p53 protein nor are *p53* gene mutations independently predictive of clinical outcome.[111] In vitro data showed that wild-type p53 protein levels increased after chemotherapy.[111,112] Despite this correlation, p53 is not currently used in clinical practice.

Additional molecular abnormalities include cyclin D1, a cell cycle-regulating protein involved in the G_1 phase to S phase transition. Overexpression of cyclin D1 has been observed in approximately 30% to 40% of esophageal adenocarcinomas and squamous cell carcinomas.[113] Inactivation of the *p16* gene, a tumor suppressor gene, occurs in a significant number of esophageal cancers,[51] and restoring p16 expression appears to inhibit the proliferation and tumorgenicity of esophageal cancers.[112] These represent but a few of the potential molecular targets for directing therapies in future clinical studies.

PATHOLOGIC FINDINGS AND PATHWAYS OF SPREAD

The predominant histologic types of esophageal cancer are squamous cell carcinomas and adenocarcinomas and should be established by biopsy for staging and treatment purposes. Approximately 20% of esophageal squamous tumors involve the upper "cervical" esophagus, although the majority is found in the middle esophagus, defined as the segment of esophagus from the aortic arch to the inferior pulmonary vein and usually representing the segment at 25 cm to 32 cm from the incisors. The remaining 30% of squamous tumors are found in the distal esophagus (at 33 cm to 42 cm from the incisors). In contrast, more than 90% of adenocarcinomas are found in the distal esophagus and gastroesophageal junction. Other malignant histologic types are unusual but include adenosquamous, mucoepidermoid, and adenoid cystic tumors and malignant tumors with endocrine differentiation (small cell cancers). Histologic review of esophagectomy specimens with early-stage disease revealed little difference between the rate of submucosal spread and the rate of lymph node metastasis for squamous cell carcinomas and adenocarcinomas.[114]

The esophagus is a hollow tube approximately 25 cm in length that extends from the pharynx to the stomach and consists of three parts: the cervical, thoracic, and distal esophagus. The cervical esophagus lies just left of the midline behind the larynx and trachea. The upper portion of the thoracic esophagus passes behind the tracheal bifurcation and left main stem bronchus, and the lower thoracic esophagus runs behind the left atrium. The distal esophagus is an area approximately 6 to 8 cm in length merging into the gastroesophageal junction. Adenocarcinomas of the esophagogastric junction are classified into three types based anatomic location and the epicenter of the tumor.[115] The current classification system identifies tumors 1 cm to 5 cm above the esophagogastric junction as distal esophageal tumors (Siewert Type 1), those tumors with the epicenter or mass located within 1 cm proximal and 2 cm distal to the esophagogastric junction are classified as true carcinomas of the cardia (Siewert Type 2), and subcardial tumors with epicenter located 2 cm to 5 cm distal to the esophagogastric junction (but may be infiltrating the esophagogastric junction) are classified as Siewert Type 3.[115] In addition to the Siewert classification, the revised American Joint Committee on Cancer (AJCC) staging system specifies that tumors that meet the criteria for Siewert Types 1 and 2 are classified as adenocarcinomas of the esophagus for the purposes of staging.[116] Those meeting criteria for Siewert Type 3 are classified as gastric cancers.[116]

In the esophagus, mucosal lymphatics merge with a submucosal plexus, which then merges with lymphatic channels in the muscularis. These channels communicate with an extensive network of cooperating lymphatics that extend longitudinally throughout the esophagus and eventually drain into nodal groups as cephalad as the internal jugular lymph nodes and as caudal as the celiac lymph nodes. The nodal groups at risk for involvement in cancers of the cervical esophagus include the supraclavicular and upper paratracheal nodes. The nodes at risk for gastroesophageal tumors include the pulmonary ligament, paracardial, left gastric, common hepatic, splenic, and celiac nodes. The esophagus lacks a serosal surface and is only separated from adjacent structures by a loose connective tissue, the adventitia. The adventitia provides little barrier to local spread, and as a consequence, tracheoesophageal and esophagobronchial fistulas develop in 5% to 10% of patients with cancer of the esophagus.

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

More than 90% of patients present with progressive and worsening dysphagia often resulting in significant weight loss. Other findings include odynophagia, chest pain, cough, and fever associated with possible respiratory fistulas, hoarseness associated with tumor involvement of the recurrent laryngeal nerve, and melena resulting from intraluminal bleeding.

Patients with newly diagnosed esophageal cancer should undergo a complete history and physical, physical examination, upper endoscopy with biopsy, complete blood count, serum chemistries, coagulation studies, and a contrasted CT scan of the chest and abdomen. An endoscopic ultrasound (EUS) with or without fine-needle aspiration (FNA) and 18-FDG–positron emission tomography (PET; FDG–PET) or PET/CT are also recommended. Her-2/neu testing is also recommended. The initial workup identifies patients with locoregional cancer and those with metastatic (M1) disease. In patients with locoregional disease who are deemed fit for surgery, cardiac and pulmonary function as well as nutritional status should be evaluated. Jejunostomy or nasogastric feeding tubes may be considered for those patients in need of nutritional support. A gastric feeding tube is not recommended. Laparoscopic staging of the peritoneum with washing can be considered for adenocarcinomas, if there is no other evidence of distant metastases.

The TNM staging system for esophageal cancer according to the AJCC is based on the pathologic review of pathologic specimens of patient undergoing primary surgical treatment for esophageal cancer without adjuvant therapy.[116] The AJCC staging manual, seventh edition, is shown in Box 45-1. This staging system incorporates a risk-adjusted analysis of the data generated by the Worldwide Esophageal Cancer Collaboration (WECC) for more than 4,500 patients, which correlates decreased survival with squamous histology, increasing depth of invasion, involvement of regional nodes, and presence of distant metastases.[117] Esophageal cancers are staged according to the histologic subtype, depth of invasion, presence of regional lymph nodes or distant metastatic disease, and grade and location of tumor. Some difficulties have arisen because this is a surgical staging system and many patients are now treated initially without resection, making accurate pathologic staging impossible. Patient outcomes are correlated with surgical pathologic stage and do not take into account the impact of adjuvant therapy. Other limitations of this staging system include inclusion of the proximal 5 cm of the stomach,

BOX 45-1 TNM Staging of Esophageal Cancer[15]

Histologic Grade

G1	Well differentiated
G2	Moderately differentiated
G3	Poorly differentiated
G4	Undifferentiated

Cancer Location

Upper thoracic	20 cm-25 cm from incisors
Middle thoracic	>25 cm to 30 cm from incisors
Lower thoracic	>30 cm to 40 cm from incisors
Esophagogastric junction	Includes cancers whose epicenter is in the distal thoracic esophagus, esophagogastric junction, or within the proximal 5 cm of the stomach (cardia) that extends into the esophagogastric junction or distal thoracic esophagus (Siewert III). These stomach cancers are stage grouped similarly to adenocarcinoma of the esophagus

Primary Tumor

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	High-grade dysplasia
T1	Tumor invades lamina propria, muscularis mucosae, or submucosa
T1a	Tumor invades lamina propria or muscularis mucosae
T1b	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades adventitia
T4	Tumor invades adjacent structures
T4a	Resectable tumor invading pleura, pericardium, or diaphragm
T4b	Unresectable tumor invading other adjacent structures, such as aorta, vertebral body, trachea

Regional Lymph Nodes

Nx	Regional nodes not assessed
N0	No regional lymph node metastasis
N1	Metastasis in one to two regional lymphnodes*
N2	Metastasis in three to six regional lymphnodes*
N3	Metastasis in seven or more regional lymph nodes*

Distant Metastasis

MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

STAGE AND PROGNOSTIC GROUPINGS FOR ESOPHAGEAL CANCER

Adenocarcinoma

Stage 0	Tis, N0, M0, grade 1 or X
Stage I A	T1, N0, M0, grades 1-2 or X
Stage I B	T1, N0, M0, grade 3
	T2, N0, M0, grades 1-2 or X
Stage IIA	T2, N0, M0, grade 3
Stage IIB	T3, N0, M0, any grade
	T1-2, N1, M0, any grade
Stage IIIA	T1-2, N2, M0, any grade
	T3, N1, M0, any grade
	T4a, N0, M0, any grade
Stage IIIB	T3, N2, M0, any grade
Stage IIIC	T4a, N1-2, M0, any grade
	T4b, any N, M0, any grade
	Any T, N3, M0, any grade
Stage IV	Any T, any N, M1, any grade

Squamous Cell Carcinoma

Stage 0	Tis, N0, M0, grade 1 or X, any location
Stage I A	T1, N0, M0, grade 1 or X, any location
Stage I B	T1, N0, M0, grades 2 or 3, any location
	T2-3, N0, M0, grade 1 or X, lower esophagus or X
Stage IIA	T2-3, N0, M0, grade 1 or X, upper and middle esophagus
	T2-3, N0, M0, grade 2 or 3, lower esophagus or X
Stage IIB	T2-3, N0, M0, grade 2 or 3, upper and middle esophagus
	T1-2, N1, M0, any grade, any location
Stage IIIA	T1-2, N2, M0, any grade, any location
	T3, N1, M0, any grade, any location
	T4a, N0, M0, any grade, any location
Stage IIIB	T3, N2, M0, any grade, any location
Stage IIIC	T4a, N1-2, M0, any grade, any location
	T4b, any N, M0, any grade, any location
	Any T, N3, M0, any grade, any location
Stage IV	Any T, any N, M1, any grade, any location

**Regional lymph nodes include any paraesophageal node extending from cervical nodes to celiac nodes.*

emphasis on number of involved nodes, rather than size or location relative to the primary tumor, and failure to discern between resectable and unresectable disease.[116] Diagnostic tools are used to evaluate local extent of primary tumor (EUS, endoscopy), identify and quantify lymph node involvement (EUS), and identify metastatic disease (FDG-PET).

EUS performed before therapy evaluates the depth of tumor invasion (T) and presence of enlarged or abnormal regional (mediastinal and perigastric) lymph nodes (N).[118,119] Preoperative EUS results in accurate T stage in 59% of patients and 82% accuracy in patients with transmural tumor extension.[120] EUS has been reported to be 87% accurate for detecting mediastinal nodal disease,[121] which is improved when confirmed by EUS-guided FNA[122-125]; however EUS is inadequate for objective pathologic response evaluation after neoadjuvant chemoradiation.[126,127] Combining diagnostic studies improves staging accuracy. One study compared CT, EUS, and EUS-FNA for preoperative lymph node staging and found EUS-FNA to be more sensitive than CT (83% versus 29%) and more accurate than both CT and EUS (87% versus 51% and 74%, respectively).[125] Review of CT or PET-CT imaging before EUS staging is recommended to identify obstructing tumors that may increase the risk of perforation and identify areas concerning for nodal involvement before the procedure. In addition thoracoscopic staging can be used to further increase the accuracy of tumor penetration and lymph node staging to 88%, as demonstrated in a cooperative group trial of patients undergoing subsequent surgery.[128]

The importance of staging for the selection of surgical candidates cannot be overstated. Cancers confined to the epithelium and muscularis mucosa and without nodal involvement are defined as stages I and II. In a clinicopathologic review of

165 patients with esophageal cancer treated with resection only, Holscher et al[129] observed 0% lymph node metastases in patients with disease confined to the mucosa compared with 18% for tumors with submucosal spread. The 5-year overall survival rate reported for patients with node-negative disease was 63%. Lymph node involvement was shown to be a strong independent predictor of poor survival following surgery alone. Tumors invading the adventitia or surrounding structures have a worse outcome, and there is almost always associated nodal involvement.

The addition of FDG-PET to standard staging techniques has improved the detection of occult metastatic disease[130-134] and can result in up to 15% upstaging from M0 to M1 compared with CT and EUS.[131] In a meta-analysis reported by van Westreenen, FDG-PET showed limited sensitivity (0.51) and reasonable specificity (0.81) for the detection of locoregional metastases.[135] This study also demonstrated detection of distant lymphatic and hematogenous metastasis with a sensitivity and specificity of 0.67 and 0.97, respectively.[135] Taken in total, these data are compelling and have resulted in an increasing use of FDG-PET for the routine staging of patients with esophageal cancer.

Investigation of gene profiling[136] and biomarkers[137] to improve patient selection for surgical therapy is currently being investigated and may improve prognostic stratification in the future.

PRIMARY THERAPY

The management of patients with esophageal and esophagogastric junction cancers requires the expertise of several disciplines and support infrastructure. Treatment decisions should be made in an environment that fosters a multidisciplinary collaboration.

Single-Modality Therapy

Surgery

In 1913, Dr. Franz Torek[138] used a transpleural approach to perform the first successful resection of an esophageal carcinoma reconstructed with an external rubber esophagus. With improvements in anesthesia, subsequent surgeons used mainly a transthoracic approach with primary esophagogastric anastomosis, and in 1933, Ohsawa[139] reported extended survival rates in 8 of 20 patients who had a resection. In 1938, Adams and Phernister[140] were the first Western surgeons to successfully adopt the Japanese transthoracic technique. The results of these studies, however, revealed a discouraging 5-year survival rate of 5% to 10%.

Esophagectomy should be performed in high-volume centers by experienced surgeons for best results.[141] One standard option includes a transthoracic resection, or Ivor-Lewis procedure,[142] which allows better access to lesions in the upper two thirds of the esophagus and complete visualization of the esophagus. For distal tumors, this approach allows for resecting a substantial proximal margin and placing the anastomosis high in the chest (above the azygos vein), a technique that is thought to result in fewer anastomotic leaks and less postoperative reflux. The initial laparotomy is for exploring the abdomen for distant disease and mobilization of the stomach. The second incision is a thoracotomy incision for exposure and dissection of the esophagus. After tumor resection, the stomach is pulled through the hiatus for an intrathoracic anastomosis. An alternative transthoracic approach is the McKeown esophagogastrectomy (right thoracotomy followed by laparotomy and cervical anastomosis).[143]

The transhiatal procedure is an alternative to the transthoracic approach that uses abdominal and left cervical incisions, where the procedure is performed through the abdominal incision and the gastric conduit is drawn through the posterior mediastinum and the esophagogastric anastomosis is exteriorized in the cervical incision.[144] The esophagus is removed via blunt dissection and continuity is reestablished with a cervical esophagogastric anastomosis, which eliminates an anastomosis in the chest and the risk of a leak producing mediastinitis. The advantages for this technique include eliminating the morbidity associated with a thoracotomy.

Another acceptable approach is the left transthoracic or thoracoabdominal esophagastrectomy, which is a technique sometimes used for distal esophageal cancers that uses a contiguous left thoracic and abdominal incision through the eighth intercostal space.[145] The esophagogastric anastomosis is performed in the left chest superior to the pulmonary vein.

At present, there are no definitive data to suggest that one technique is superior to the others and long-term survival is not different between the two approaches.[146] In one review of 210 patients treated with either a transthoracic resection (n = 172) versus a transhiatal resection (n = 38), an increased incidence of tumor perforation (18%) and injuries to the recurrent laryngeal nerve (13%) following the transhiatal approach was observed.[147] Another retrospective study of 238 patients observed increased rates of wound infections, pneumothorax, and hospital mortality for patients treated with transthoracic resection.[148] In contrast, Stark et al[149] observed increased rates of respiratory complications and hospital mortality following transhiatal resection. Others have identified little or no difference in overall complication rates or operative mortality rates between the two surgical approaches.[150,151] These findings are consistent with a meta-analysis reported by Hulscher et al[152] who observed that the 5-year survival rate with surgery alone was approximately 20% after both transthoracic and transhiatal resections.

Surgery remains a major component of treatment for resectable disease and is usually performed with curative intent following adequate staging and pretreatment nutritional support. There has been a marked reduction in surgical morbidity and mortality with improvements in staging techniques, patient selection,[153] perioperative care and surgical experience, but improvements in cancer control have been modest. Moertel[154] reviewed 18 older surgical series involving 4109 patients treated with resection and found a 5-year overall survival rate of 9.6% (range, 3% to 20%).

Regional lymph node involvement results in a worse outcome following esophagectomy.[155,156] One study demonstrated a 31% overall survival rate for all patients undergoing resection; only 13% of patients with nodal disease were alive at 5 years versus 44% for patients who were node-negative.[157] Another study demonstrated similar results with 5-year survival rates after surgery alone at 57% for patients who were node negative and 15% for node-positive disease.[158] Other investigators found that no patient with more than 30% regional nodal tumor involvement was alive at 5 years, whereas 45% of patients with less than 30% nodal disease were alive at 5 years.[129] These data indicate that in the limited cohort of patients who present without regional nodal involvement, many will do well with surgery alone, but patients found to have nodal disease are rarely treated successfully with surgery alone.

The optimum number of lymph nodes to be removed and examined at the time of resection is unclear. One retrospective analysis demonstrated that the number of lymph nodes removed at the time of surgery was an independent predictor of survival time and that the optimal threshold for this survival benefit was removal of 23 nodes.[159] Another study suggested at least 18 lymph nodes should be removed.[160] The largest retrospective analysis analyzed the SEER database for

29,656 patients with esophageal cancer and found that patients with more than 12 lymph nodes examined had a significant reduction in mortality compared to those without examination of lymph nodes. Those with 30 or more lymph nodes examined demonstrated the lowest mortality.[161] A report from the WECC database evaluating 4627 patients undergoing esophagectomy alone demonstrated increased survival with greater extent of lymphadenectomy in patients with pathologic pN0M0 staging.[156] However, extent of lymphadenectomy may only be prognostic because one study demonstrated that extent of lymphadenectomy did not predict survival in patients undergoing surgery alone for esophageal cancer.[162]

Esophagectomy remains the standard of care for high-grade dysplasia and superficial cancers; however, surgical morbidity and mortality may be substantial for patients who are medically unfit. More recently, minimally invasive esophagectomy (MIE) and endoscopic treatments have become treatment options for selected patients with early-stage localized esophageal cancer. MIE strategies include laparoscopic-assisted, thoracoscopic, or limited thoracotomy Ivor-Lewis or McKeown esophagectomies. A recent meta-analysis using data from 10 studies to evaluate the effects of MIE versus open esophagectomy on outcome demonstrated trends in favor of MIE, with reductions in morbidity, pulmonary complications, anastomotic leakage, mortality, length of hospital stay, operating time, and blood loss compared to open esophagectomies.[78,163-166] MIE is useful in older patients who are at increased risk for operative morbidity.[167] However, not all patients are candidates for minimally invasive procedures, especially those who have undergone prior abdominal surgery or who have bulky tumors or lymph nodes difficult to resect. No randomized trials have assessed whether MIE improves outcome compared with open esophagectomy. However, in the absence of prospective trials with adequate followup MIE remains investigational.[168,169]

The goal of EMR and ablative therapies is eradication of Barrett's esophagus and removal of the associated dysplasia (Tis) or early malignancy (well to moderately differentiated T1a tumors without evidence of lymphovascular invasion). EMR of Barrett's esophagus and high-grade dysplasia occasionally results in a diagnosis of esophageal cancer. Although EMR of visible lesions can be effective, there is a high rate of recurrence. EUS staging before EMR is recommended in the setting of high-grade dysplasia or early carcinoma.[170] All focal nodules should be resected rather than ablated and Tis and high grade dysplasia should be fully characterized for presence of nodularity, lateral spread, and multifocal disease. Patients with Tis or selected T1a tumors are candidates for curative therapy with EMR. EMR is considered therapeutic for completely excised moderately differentiated tumors <2 cm in diameter without evidence of invasion beyond the muscularis mucosa or lymphovascular spread. For patients with tumors in the submucosa or deeper, or evidence of lymph node involvement, esophagectomy remains the standard surgical treatment.

Data regarding the role of surgery in patients treated with definitive concurrent radiation and chemotherapy is presented in the section regarding combined modality therapy.

Ablative Therapies

Endoscopic ablative procedures (cryoablation, RFA, and PDT) are mainly used for Barrett's esophagus or dysplasia. Balloon-based RFA results in complete remissions in the majority of patients with Barrett's esophagus or high-grade dysplasia.[171] Endoscopic cryoablation is also an effective therapy in this setting.[172] PDT has been reported to provide local control in early esophageal cancers arising from Barrett's esophagus, ranging from 17% to 100%, and high-grade dysplasia, ranging from 75% to 100%.[173-175] There are no randomized studies that compare ablative therapies to EMR. Recurrence rates using ablative treatments are higher than with esophagectomy and require close endoscopic surveillance and retreatment in some patients. Ablative therapies may also be useful in achieving long-tem palliation of dysphagia, anorexia, or malnutrition.[176,177]

Chemotherapy

Esophageal cancer has a distant failure rate of more than 70%. A large number of chemotherapy agents have been evaluated for response (Table 45-2), but the response rates remain low, with only about 20% of patients having an objective response to a variety of single agents. Combination chemotherapeutic regimens have shown a higher response rate, the best responses being seen in patients receiving multiagent chemotherapy regimens (Table 45-3). Despite increased response rates, the duration of response is typically short and comparable to that seen with single-agent chemotherapy. New agents including targeted therapies remain under investigation.

Targeted Biologic Therapies

HER-2/NEU

Overexpression of HER-2/neu has been reported to range from 0% to 52% in squamous cell carcinomas of the esophagus

TABLE 45-2 Single-Agent Activity in Chemotherapy of Esophageal Cancer*

Drug	No. Patients	Complete Response Rate or Partial Response Rate (%)	Median Duration of Response (mo)

**Response as determined by radiographic or endoscopic methods.*

and 0% to 73% in adenocarcinomas.[201] The ToGa trial screened tumors from 3807 patients with advanced gastric (80%) or esophagogastric (20%) cancer, and 22.1% were found to be Her-2/neu-positive. In this trial 594 patients with Her2/neu positive cancers were randomized to receive either chemotherapy (5-fluorouracil or capecitabine and cisplatin) alone or the same chemotherapy with trastuzumab resulting in improved survival for those patients with Her-2/neu positive (IHC 2-3+ or FISH+) tumors treated with trastuzumab. Median overall survival was 16 months for those patients receiving trastuzumab with IHC 2-positive and FISH-positive or IHC 3-positive tumors compared to 11.8 months for those who did not.[73] Trastuzumab emtansine (T-DM1) is a conjugated antibody to a potent microtubule inhibitor. T-DM1 has demonstrated efficacy in esophagogastric cancer cells and xenograft models.[202] A Phase II/III trial is planned using a taxane with or without T-DM1 in patients with refractory esophagogastric cancer.

EGFR

Up to 80% of esophageal adenocarcinomas and squamous cell carcinomas demonstrate increased EGFR expression, which is associated with decreased overall survival.[82] Multiple trials with tyrosine kinase inhibitors of anti-EGFR antibodies have failed to suggest utility for these agents in advanced disease for either adenocarcinoma or squamous cell carcinoma. The potential application of these agents combined with radiotherapy is discussed in the section on combined modality therapy.

VEGF

High levels of VEGF expression have been correlated with poor overall survival rates in patients with esophageal cancer.[94,96-100] The impact of VEGF inhibition in combination with chemotherapy in patients with esophageal cancer is under evaluation, but impact on survival remains unclear. Recently reported results from Phase III studies in advanced gastric (including gastroesophageal junction) cancers have not demonstrated a survival benefit for the addition of bevacizumab to systemic chemotherapy, although improved progression-free survival was observed.[203,204]

Sorafenib is a tyrosine kinase inhibitor of VEGFR1-3, Raf-1, Braf, and PDGFR1. It has been studied in combination with docetaxel and cisplatin in advanced gastric and esophagogastric junction cancer demonstrating a 41% response rate and 13.6 month median survival.[198]

COX-2

COX-2 is another molecular target that has been shown to have significance in cancer development and progression in dysplastic lesions of the esophagus, with COX-2 level increasing in the early stages of carcinogenesis of esophageal adenocarcinoma.[63] Selective inhibition of COX-2 has been shown to alter the development and progression of cancer in clinical trials.[205] In addition, inhibition of COX-2 activity results in enhanced radiosensitization of tumor tissue but not normal tissue.[107,206] Selective COX-2 inhibition has also been shown to directly inhibit tumor neovascularization.[107,108,206,207] The combination of these effects suggests potential enhancement of selective tumor targeting by COX-2 inhibition. Studies combining COX-2 inhibition with neoadjuvant chemotherapy and radiation have demonstrated tolerability but failed to demonstrate an improvement in the pathologic response over standard neoadjuvant combined-modality treatment.[208-210]

New Targets

Hepatocyte Growth Factor/Mesenchymal Epithelial Transition Factor (Hgf/Met). cMET (mesenchymal–epithelial transition factor) and its ligand, HGF are potential therapeutic targets in esophagogastric cancer. MET tyrosine kinase activation is mediated by HGF binding and multiple downstream signal transduction pathways (Ras, mTOR, STAT3, PI3K and

NF-κB)[211,212] and can promote angiogenesis.[213,214] MET signaling is altered by receptor or ligand overexpression as well as gene amplification in some gastric and esophagogastric tumors.[213-217] MET gene mutations may be sporadic or hereditary.[213,218,219] Only 2% of esophagogastric adenocarcinomas contain the MET amplification, which is associated with advanced stage disease.[220] Crizotinib is an orally available small molecule inhibitor of MET and ALK. In a small study of patients with esophagogastric with MET amplification treated with crizotinib, a 30% response rate was observed.[220] Another strategy to target the MET pathway is Rilotumumab, a human monoclonal antibody to HGF. A randomized Phase II study has demonstrated an improved median survival with the addition of rilotumumab to epirubicin, cisplatin and capecitabine (ECX) in patients with gastric/esophagogastric disease with greater than 50% of cells staining positive for MET by immunohistochemistry.[221] MET expression is predictive of both poor overall prognosis and response to anti-HGF antibody therapy.[221] A Phase III study is planned for first-line therapy in patients with esophagogastric adenocarcinoma with high MET expressing tumors using rilotumumab.

Heat Shock Protein 90 (Hsp90). HSP90 binds to nucleotide binding sites as a chaperone protein resulting in the release of important client proteins, which include wild-type and activated signaling proteins of B-RAF, KIT, EGFR, HER-2, PDGFR, and KIT. Hsp90 inhibition results in alterations in the structure of these proteins and subsequent ubiquitination and degradation.[222] In a study of human esophageal cell lines, inhibition of Hsp90 with 17-allylamino-17-demethozygeldanamycin (17-AAG) resulted in decreased proliferation and survival, and synergistic effect with radiation.[223] A Phase II study of a small molecule inhibitor of Hsp90, STA9090, in patients with metastatic esophagogastric cancer is completed and results are pending (NCT01167114).

Radiation Therapy

Historical series reported results using external beam radiation alone for the treatment of patients with esophageal cancer, mostly those who refuse surgery or those with unresectable tumors (T4). The outcome following primary radiation therapy alone in the treatment of clinically localized esophageal cancer remains poor, with a 2-year survival rate of approximately 10% to 20% and a 5-year survival rate of approximately 5%[224-226] (Table 45-4). Several autopsy studies demonstrate that 50% to 89% of patients harbor both local and undetected distant disease.[227] Review of the literature examining patterns of failure following irradiation alone demonstrate local failure rates of 50% to 91% following doses greater than 50 Gy.[228,229] Attempts to increase total radiation dose have failed to improve outcome for these patients. In the Radiation Therapy Oncology Group (RTOG) 85-01 trial, all patients in the radiation alone arm who received 64 Gy at 2 Gy per fraction delivered with conventional techniques died of cancer within 3 years following treatment.[230,231]

Twice-a-Day Radiation

Building on the encouraging data of twice-daily radiotherapy in other tumor sites, a number of researchers have investigated its usefulness in esophageal cancer. Kikuchi et al observed an encouraging 5-year cause-specific survival rate of 31.5% for 60 patients receiving twice-a-day concomitant boost radiation therapy alone,[239] while Zhao et al reported on the feasibility of late-course accelerated hyperfractionated radiotherapy for early-stage esophageal carcinoma (41.4 Gy in 5 weeks, followed by a 2-week course of twice-daily irradiation at 1.5 Gy per fraction; cumulative dose of 67 Gy to 70 Gy). The investigators observed an encouraging 5-year local control rate of 85%.[240] Another study reported a 5-year survival rate of 33% for patients treated with definitive late-course accelerated radiotherapy alone to 68.4 Gy.[237] The addition of chemotherapy appears to improve outcome for patients treated with hyperfractionated radiation as demonstrated by Girvin et al who treated patients with twice-a-day preoperative irradiation plus concurrent 5-fluorouracil, cisplatin, and vinblastine and observed a remarkable complete response rate of 79%.[241] Data from a larger series using a similar concurrent regimen of 5-fluorouracil plus cisplatin and twice-daily irradiation did not confirm the findings of Girvin, however. In the series reported by Yu et al, a local tumor control rate of 94% was reported with an alternating schedule of cisplatin and 5-fluorouracil with twice-daily irradiation on alternating weeks (1.8 Gy to 2 Gy to 60 Gy), but the regimen was associated with significant grade-5 acute toxicity.[242] The use of twice-daily irradiation is currently restricted to clinical trials.

Combined-Modality Therapies

Combined-modality therapy has been adopted for the treatment of esophageal cancer because of the poor survival rates associated with patients treated with surgery or radiation alone and has now become standard for the treatment of non-metastatic disease, except for the earliest lesions.[243]

Surgery with Neoadjuvant or Adjuvant Chemotherapy (without Radiation)

The rationale for the use of chemotherapy before either surgery or chemoradiation includes the early treatment of subclinical distant disease while the primary tumor is also being treated, administering the drug when the patient can best tolerate the toxicities. In addition to the hope that both local and distant control rates might improve, there is also hope that this approach might identify patients who would respond to additional chemotherapy for control of minimal residual disease.

Although a number of studies evaluating preoperative chemotherapy have demonstrated good response rates, only a few randomized studies have been reported. The most robust experience comes from the Medical Research Council Oesophageal Cancer Working Group.[244] In this study, 802 previously untreated patients with resectable esophageal cancer were randomized to receive either two cycles of cisplatin plus 5-fluorouracil followed by surgery or surgery alone. The

median survival time was 16.8 months for patients randomized to chemotherapy compared with 13.3 months for patients who underwent surgery alone. The 2-year survival rate was also improved for patients randomized to chemotherapy (43%) versus surgery alone (34%) and at a median followup of 6 years, survival remained higher for those patients treated with preoperative chemotherapy (23% versus 17%).[245] Lesser improvements in median survival times have been demonstrated in other randomized studies.[191,246-248]

In striking contrast are the data from Kelsen et al from the Intergroup trial (INT 0113).[249,250] Four hundred sixty-seven patients were randomized to surgery alone versus induction chemotherapy (three cycles of cisplatin/5-fluorouracil chemotherapy) followed by surgery. With a median follow-up time of 55.4 months preoperative chemotherapy decreased the incidence of R1 resections, but produced no significant differences in survival.[250] An individual patient databased meta-analysis has demonstrated a small but significant difference (4%) in overall and disease-free survival favoring preoperative chemotherapy over surgery alone.[251] A larger meta-analysis of 1981 patients from nine randomized trial also showed a survival benefit for patients treated with preoperative chemotherapy.[252]

The utility of postoperative chemotherapy alone has also been studied in a limited fashion. A multicenter Phase II trial evaluated four cycles of adjuvant paclitaxel and cisplatin chemotherapy; the 3-year survival rate was encouraging at 42%, but most patients (76%) had failure at distant sites.[253] The Japan Clinical Oncology Group reported the results from 242 patients with squamous cell carcinoma of the esophagus who underwent transthoracic esophagectomy with lymphadenectomy and were then randomized to either observation or two courses of cisplatin plus 5-fluorouracil chemotherapy. Although an improvement in the 5-year disease-free survival rate was seen for patients receiving the adjuvant chemotherapy (55% versus 45%), a slight improvement in overall survival rate was observed (61% versus 52%).[254] These results were not different from those observed in a 205-patient Phase III trial showing no benefit with the addition of adjuvant cisplatin and vindesine chemotherapy to surgery.[255] We currently recommend that patients receive adjuvant chemotherapy only as part of a clinical trial.

There is a growing interest in perioperative chemotherapy for the treatment of resectable esophagogastric cancer. The MAGIC trial randomized 503 patients with esophageal (25%; 14% lower esophagus, and 11% esophagogastric junction) or gastric (75%) adenocarcinomas to receive pre- and postoperative chemotherapy (epirubicin, cisplatin, and 5-fluorouracil). The perioperative chemotherapy group was found to have less advanced nodal involvement (84% versus 70.5%) and a greater proportion of early stage (T1-T2) tumors (51.7% versus 36.8%) than the surgery alone group, and chemotherapy improved 5-year survival rates (36% versus 23%, respectively).[256] A similar approach was taken by the FNCLCC/FCCD trial in which patients with adenocarcinoma of the lower esophagus or esophagogastric junction (75%) or proximal stomach (25%) were treated with perioperative 5-fluorouracill and cisplatin. The 5-year disease-free (34% versus 19%) and overall survival (38% versus 24%) rates were improved for patient receiving perioperative chemotherapy.[257] These studies have established perioperative chemotherapy as a viable option for patients with resectable adenocarcinoma of the distal esophagus or esophagogastric junction.

Neoadjuvant Radiation Followed by Surgery (without Chemotherapy)

Early attempts to improve local control and survival rates combined radiation and surgery. At the Memorial Sloan Kettering Cancer Center from 1956 to 1966, 85 patients were treated with preoperative radiation and surgery, with 47 patients ultimately going on to resection. The overall crude 5-year survival rate was 6% and the median survival rate was 14 months. No tumor was seen in the surgical specimen in 7 (14%) of the tumors resected.[228] One study compared the outcomes for patients who underwent staging laparotomy, gastrostomy, and nutritional supplementation before preoperative radiation (20 Gy to 25 Gy in four to five fractions) followed by a total esophagectomy with the outcomes for patients who underwent either irradiation or surgery alone. The 3-year survival rate was 27% for patients treated with combined therapy versus 22% for those treated with surgery alone and 6% with irradiation alone,[258] but updated data showed a 5-year survival rate of 13% for the combined-modality cohort.[259] Others report a 5-year survival rate of 25% for patients receiving 50 Gy preoperatively versus 14% for patients treated with surgery alone.[260]

These studies, however, were all retrospective reviews that did not allow direct comparisons of treatments. Prospective randomized trials evaluating outcomes for patients treated with either surgery alone or preoperative irradiation demonstrated no benefit to the addition of preoperative radiotherapy; reported 5-year survival rates ranged from 9.5% to 45% for the preoperative radiation and surgery group and from 11.5% to 25% for patients treated with surgery alone.[261-264] To date, randomized trials have not demonstrated a survival advantage for either preoperative or postoperative radiation alone.[264-266] Table 45-5 summarizes the results of randomized trials comparing radiation alone followed by surgical resection to surgery alone.

Primary radiotherapy or preoperative radiation therapy should be restricted to palliation for patients who are medically unable to receive chemotherapy as part of their treatment course.

Chemoradiotherapy

Numerous single institutions and cooperative groups have investigated the use of concurrent chemotherapy and radiotherapy in the management of patients with localized esophageal cancer, either as definitive treatment or as preoperative therapy. A significant body of information suggests that chemotherapeutic agents such as 5-fluorouracil, cisplatin, mitomycin C, gemcitabine, irinotecan, oxaliplatin, and paclitaxel

have a greater than additive effect when used in combination with radiation therapy. In addition, there is a growing body of evidence that incorporation of targeted therapies in to treatment regimens may enhance radiosensitization. Therefore, most studies testing multimodality therapy have used these agents in a concurrent schedule. The mechanism of the interaction between irradiation and chemotherapeutic agents is complex and not entirely understood.

Definitive Concurrent Chemotherapy and Irradiation

Table 45-6 reports the results of several nonrandomized trials employing concomitant chemotherapy and radiation therapy for the definitive treatment of esophageal cancer. Generally, the most successful treatment regimens have combined infusional 5-fluorouracil with either mitomycin C or cisplatin.

Randomized data have shown benefit in patients treated with definitive concurrent chemoradiation (Table 45-7), resulting in local control rates ranging from 24% to 67% (Tables 45-8 and 45-9).

The most important contemporary trial is that of Herskovic et al (RTOG 85-01).[230] One hundred and twenty-one patients were randomized to either 50 Gy with concurrent chemotherapy with 5-fluorouracil (1000 mg/m^2 for 4 days) and cisplatin (75 mg/m^2) versus 64 Gy alone. At 5 years, 27% of the combined-modality patients were alive versus none of the patients in the irradiation-only group.[280] The median survival time for the combined-modality arm was 14.1 months versus 9.3 months for the irradiation-alone arm.[280] These results are important because they not only demonstrate a survival advantage with combined-modality therapy but also show that the survival advantage cannot be obtained by simply substituting a higher radiation dose in place of chemotherapy.

There was a suggestion of a radiotherapy dose-response relationship from early (nonrandomized) studies at Wayne State University, as patients treated to 5000 cGy (concurrent with a 5-fluorouracil plus cisplatin regimen) appeared to have longer median survival than patients treated to 3000 cGy with the same chemotherapy (see Table 45-6).[274] INT 0123,

randomized patients with unresectable esophageal cancer to receive the same chemotherapy (5-fluorouracil and cisplatin) with either 64.8 Gy or 50.4 Gy. In this study there was no significant difference in median survival times (13 months versus 18.1 months), 2-year survival rate (31% versus 40%), or locoregional failure rate (56% versus 52%) between the high-dose and standard-dose treatment arms, respectively; however there was a higher treatment-related mortality rate (10% versus 3%) in the patients assigned to the high-dose radiation arm, which did not seem to be related to the higher radiation dose.[274] The trial was stopped after an interim analysis. The reason for the lack of benefit in the high-dose arm is unclear, but there was a significant prolongation of the treatment time because of toxicity breaks when correcting for the number of radiation treatments as well as a significantly lower 5-fluorouracil dose delivered when compared with the low-dose arm.[274] Results of these studies have established 50.4 Gy as the standard dose for definitive chemoradiation in esophageal cancer.

The improvement in survival rates in the combination trials seems related at least in part to an improvement in local control rates. Tables 45-8 and 45-9 show the crude patterns of failure from several definitive chemoradiation trials. These data suggest that combined-modality therapy produced a shift in the pattern of failure, from a local failure rate of 50% to 90% for irradiation alone to 20% to 50% with combined-modality therapy. RTOG 85-01 reported a crude local persistence or recurrence rate of 44% for patients treated with chemoradiation versus 64% for the irradiation alone group. The 2-year actuarial local failure rate was reduced from 68% to 43% and the rate of distant metastases was reduced from 70% to 25% with combined-modality therapy.[230]

Many chemotherapy agents have been investigated in an attempt to improve outcomes. RTOG 0113 was a randomized Phase II study for patients who were unwilling to have surgery or were medically unfit for surgery, who were randomly assigned to receive either induction treatment with 5-fluorouracil, cisplatin, and paclitaxel and then 5-fluorouracil plus paclitaxel with 50.4 Gy of irradiation or induction with paclitaxel plus cisplatin and then the same chemotherapy with 50.4 Gy of irradiation. Unfortunately, both arms were associated with high morbidity rates, and the study did not meet its 1-year survival end point.[281] Others have demonstrated efficacy of carboplatin and paclitaxel with concurrent definitive chemoradiation in esophageal cancer.[282,283] Definitive chemoradiation with cisplatin and docetaxel has been shown to result in a high response (98%), local control (60%), and 3-year survival (37%) rates in patients with squamous cell carcinoma.[204] A recent Phase II trial randomized patients to either FOLFOX (leucovorin, 5-fluorouracil, oxaliplatin) or 5-fluorouracil and cisplatin with concurrent definitive radiation resulting in improved outcome for those treated with FOLFOX (3-year OS 18.2 months versus 17.4 months; median OS 20.2 months versus 17.5 months, respectively).[284] An optimum regimen for concurrent chemoradiation has not been established, though active cooperative group prospective trials have adopted paclitaxel and carboplatin or FOLFOX-based regimens as standard therapy concurrent with radiotherapy.

A number of targeted agents have been incorporated into chemoradiation trials with attempt to improve outcome. Trastuzumab in addition to cisplatin, paclitaxel, and concurrent radiation followed by maintenance trastuzumab has demonstrated safety and a promising 3-year survival rate of 47% for patients with esophageal adenocarcinomas that overexpress HER-2.[285] Based on this encouraging safety and efficacy data, RTOG 1010 (NCT01196390) is studying the addition of trastuzumab to chemoradiation in patients with HER2-positive operable locally advanced adenocarcinoma of the esophagus and esophagogastric junction. Results of a randomized Phase III trial (RTOG 0436; NCT00655876) of cisplatin, paclitaxel, and radiation therapy with or without cetuximab in locally advanced, nonsurgically treated esophageal cancer were recently presented, and the addition of cetuximab did not improve OS regardless of histology.[286] A smaller prospective study (SWOG 0414) evaluating cetuximab with concurrent cisplatin, irinotecan, and radiation demonstrated poor tolerability of the regimen with treatment-related mortality approaching 10% resulting in early study closure.[287] The SCOPE1 study (NCT00509561) randomized Phase II/III study showed the addition of cetuximab to chemoradiotherapy resulted in both greater toxicity and worse survival.[288] These results give caution to the use of targeted agents outside of a clinical trial.

An important concern regarding the use of combined-modality therapy is treatment toxicity. In the Wayne State University series, 5 of 20 patients required hospitalization for intravenous hydration and nutritional support, and 38% developed pulmonary compromise (thought to be secondary to receiving bleomycin plus irradiation) that required corticosteroids.[273] The overall irradiation dose appears to be important, as has been reflected in data from Sauter et al.[289] In a study of 30 patients receiving concurrent chemotherapy and irradiation (60 Gy), only 67% of patients were able to complete the irradiation schedule as planned and only 18 of the 30 patients were able to proceed to resection.[289] Coia et al[279,290] reported a 56% incidence of moderate to severe acute toxicities, whereas the researchers of RTOG 85-01 found that side effects were severe in 44% of patients and life-threatening in 20% of patients in the combined-modality arm versus 25% and 3% in the radiation only group, respectively.[230] Most of the toxicity was hematologic, along with significant esophagitis and stomatitis. Although only 1 of 61 patients in the combined-modality group died of acute toxicity, only 50% of patients completed all four cycles of chemotherapy.[230]

Definitive Sequential Chemotherapy and Irradiation

The usefulness of sequential chemotherapy followed by a course of definitive radiation therapy alone has been

evaluated on a limited scale. One study evaluated patients treated with sequential cisplatin/bleomycin chemotherapy for three courses followed by definitive thoracic irradiation and resulting in a partial response rate of 52% and a complete response rate of 16% as determined by CT scanning and endoscopy, with 1-year and 4-year survival rates disappointing at 20% and 8%, respectively.[291] Similarly, patients treated with two cycles of induction cisplatin-vindesine-bleomycin chemotherapy followed by definitive radiotherapy results in a discouraging 15% OS rate at 5 years.[292] A more recent Phase II sequential study reported by Sharma et al,[293] testing multiple cycles of 5-fluorouracil plus cisplatin followed by a definitive course of irradiation (60 Gy), was equally disappointing, with a median survival time of 39 weeks. This approach has generated relatively little interest as it does not take advantage of the probable benefit of concurrent chemoradiotherapy.

Definitive Induction and Concurrent Chemotherapy and Irradiation

A number of investigators have tested induction chemotherapy followed by definitive irradiation and concurrent chemotherapy, mostly in the preoperative setting.[294-301] One report in the nonoperative setting evaluated 45 patients with locally advanced disease treated with three cycles of induction 5-fluorouracil and cisplatin followed by two additional cycles of chemotherapy delivered concurrently with irradiation to 64.8 Gy. Although the median survival time was an encouraging 20 months, six patients died from treatment-related toxicity.[302,303] The impact of induction chemotherapy on the therapeutic ratio for patients receiving definitive concurrent chemoradiotherapy has not been well studied.

Preoperative Chemoradiation

Preoperative chemoradiation followed by surgery is the most commonly used treatment approach for patients with esophageal carcinoma. The Southwestern Oncology Group (SWOG) and the Radiation Therapy Oncology Group (RTOG), based on pilot data from Wayne State University, performed two similar Phase II trials using concurrent chemotherapy and irradiation followed by planned resection in patients with squamous cell carcinoma of the esophagus. In the SWOG study, 113 patients with initially resectable tumors received treatment with infusional 5-fluorouracil plus cisplatin with concurrent irradiation to a dose of 30 Gy. The overall operability rate was 63%, and the overall resectability rate was 49%. The median survival time was 12 months, with 16% of patients alive at 3 years.[304] Of the 41 patients entered in the RTOG preoperative trial of concurrent irradiation plus 5-fluorouracil and cisplatin, 7.5% were alive at 3 years.[305] For patients with esophageal adenocarcinoma, preoperative chemoradiation followed by surgery has been the subject of numerous clinical trials. Data from the University of Michigan and Duke University report 5-year survival rates of 34% and 27%, respectively.[269,306]

Although chemotherapy before preoperative chemoradiation has been included in several regimens, there are no randomized clinical trials at this time that demonstrate benefit over concurrent chemoradiation without induction chemotherapy. A renewed interest in this approach has come about recently with exploration of early PET scans to assess the response.[307,308] Currently, the CALGB is evaluating a response-adapted strategy using induction chemotherapy with early FDG-PET imaging followed by chemoradiation, with concurrent chemotherapy selection based on the response to initial chemotherapy (CALGB 80803—NCT01333033). In this study patients receive either modified FOLFOX (leucovorin, 5-fluorouracil and oxaliplatin) for three 14-day courses or carboplatin and paclitaxel for two 21-day courses. Patients then undergo PET/CT scan. Patients with responsive disease (tumor metabolic activity decreased by ≥35%) receive three additional courses of FOLFOX and concurrent radiotherapy or weekly radiosensitizing doses of concurrent carboplatin/paclitaxel with concurrent radiotherapy. The primary endpoint of this study is pathologic complete response rate of PET/CT nonresponders within each treatment group.

The next generations of chemoradiation trials attempted to incorporate more novel chemotherapeutic agents. The results of a 46-patient Phase II study of irradiation and concurrent cisplatin, 5-fluorouracil, and paclitaxel demonstrated a pathologic complete response rate of 45% for the 40 patients able to undergo resection. The overall median survival time was 34 months, with 37% of patients alive at 5 years.[309] Urba et al reported results from a Phase II trial using preoperative cisplatin, paclitaxel, and twice-daily irradiation, with 90% of patients able to undergo surgery and a 19% complete pathologic response rate. Survival data compared favorably with other previously reported combinations, with a median survival time of 24 months.[310] Oxaliplatin has also been evaluated in combination with 5-fluorouracil–based chemotherapy with or without irradiation in the neoadjuvant setting. Data suggest that a course of preoperative oxaliplatin and concurrent chemotherapy with protracted venous infusion of 5-fluorouracil with irradiation (50.4 Gy) is an active regimen in locally advanced esophageal cancer, resulting in rates of 81% for complete radiologic response and 38% for complete pathologic response.[311] More recent studies demonstrated promising complete pathologic response rates of up to 63%,[312] but excessive treatment-related deaths were encountered. Currently, it is thought that concurrent irradiation and containing-containing regimens are not acceptable because of excess toxicity.[312,313]

The addition of targeted agents to chemoradiation in the neoadjuvant setting is under investigation. One treatment strategy evaluated the benefit of the addition of bevacizumab to preoperative chemoradiation using carboplatin, paclitaxel, and 5-flurouracil in stages I to III esophageal or esophagogastric junction cancer (95% adenocarcinomas). A pathologic complete response rate of 29% was observed, similar to regimens not containing bevacizumab.[314] Ilson et al evaluated the efficacy chemoradiation with bevacizumab in patients with Siewert I/II adenocarcinoma of the esophagus. The treatment regimen consisted of induction chemotherapy with cisplatin, irinotecan, and bevacizumab followed by concurrent chemotherapy with cisplatin, irinotecan, and bevacizumab concurrent with radiation therapy. Surgery was followed by adjuvant bevacizumab. A pathologic complete response was observed in only 12% and progression-free and OS were 14 and 30 months, respectively.[315] Given the lack of improvement in the pathologic complete response rate in these Phase II compared with historical controls, there is no role for bevacizumab with chemoradiation for esophageal cancer outside of clinical trials.

Chemoradiation with cetuximab has been extensively studied in the Phase II setting. The Swiss Group for Clinical Cancer Research (SAKK) 75/06 trial evaluated treatment with induction cisplatin, docetaxel, and cetuximab followed by radiation therapy with concurrent cisplatin and cetuximab in 28 patients with operable esophageal cancer resulting in a pathologic complete response rate of 32%.[316] Another study evaluated cetuximab, paclitaxel, and cisplatin in combination with radiation therapy in 60 patients and a pathologic complete response rate of 27% was observed.[317] These studies were not associated with unacceptable toxicity. In contrast, ECOG 2205 evaluated a neoadjuvant regimen of cetuximab combined with 5-fluorouracil, oxaliplatin, and radiation but because of an excess of acute respiratory deaths (ARDS), the study was closed.[318]

Results from several nonrandomized trials employing using various chemotherapeutic and targeted therapies in the setting of preoperative chemoradiation are shown in Table 45-10.

The question of whether combined preoperative radiotherapy and chemotherapy is superior to preoperative chemotherapy was addressed in a Phase III study in patients with locally advanced esophagogastric junction adenocarcinomas. A higher pathological complete response rate and uninvolved lymph node rate was observed in those patients treated with combined modality therapy compared to those receiving only chemotherapy (15% versus 2% and 64% versus 37%, respectively). Although the study was closed early because of poor accrual, there was a trend for 3-year survival rate in favor of the combined-modality group (47% versus 27%, $p = 0.7$).[300]

Preoperative Chemoradiation versus Surgery Alone

Preoperative chemoradiation is the most common treatment approach for patients with esophageal carcinoma and is currently considered standard of care. Although earlier randomized trials comparing surgery alone with chemoradiation followed by surgery for the treatment of resectable esophageal cancer have shown conflicting results[325-330] four meta-analyses have demonstrated that chemoradiation results in improved survival[252,331-333] and decreased local recurrence compared to surgery alone.[331,333] In addition, preoperative chemoradiation has been reported to result in increased pathologic response rates compared with preoperative chemotherapy without radiation (28% versus 4%, respectively) in patients with locally advanced esophageal cancer,[334] while pathologic complete response to neoadjuvant therapy has been associated with an improvement in overall survival in some series[334] but not in others.[335]

In a nonrandomized study of preoperative chemoradiation and surgery versus surgery alone, Vogel et al[336] reported an OS advantage for patients receiving multimodality therapy, with 36% alive at 5 years versus 11% for surgery alone. Urba et al also reported a 3-year survival advantage for those patients receiving preoperative concurrent chemoradiation compared with surgery alone (30% versus 16%, respectively), although not nonstatistically significant.[208] Walsh et al conducted a randomized study of patients treated with two 5-day courses of 5-fluorouracil given on weeks 1 and 6 and cisplatin with concurrent (40 Gy) irradiation, delivered before surgery compared with patients who underwent surgery alone. The reported (actuarial) survival rates favored patients receiving combined-modality therapy, with 32% alive at 3 years versus 6% who underwent surgery only[330]; however, this trial has been criticized for the unusually low survival rate in the surgical arm. In contrast, no survival advantage was observed for patients receiving preoperative chemoradiation versus surgery alone in a randomized study reported by Bosset.[325] This study, however, used a unique irradiation and chemotherapy schedule: irradiation was delivered via a split course, and over the span of 2 weeks, a total dose of 37 Gy in 3.7-Gy daily fractions was delivered. The chemotherapy consisted of cisplatin given prior to each week of irradiation. Patients were taken to surgery 2 to 4 weeks after completing the preoperative regimen.[325] The lack of benefit and increased toxicity observed for the combined-modality arm may have been predicted with the application of large radiation fractions, the inclusion of a planned treatment break, an inadequate recovery period between the preoperative therapy and surgery, and the use of single-agent chemotherapy.

The U.S. Gastrointestinal Intergroup trial attempted to further evaluate the role of preoperative chemoradiation therapy compared to surgery alone but was stopped before completion because of poor accrual. Nonetheless, Tepper et al[327] reported the results from this trial (CALGB 9781) for the 56 patients who were enrolled before the trial closed. A median survival time of 4.48 years versus 1.79 years in favor of trimodality therapy and a 5-year survival rate of 39% versus 16% in favor of trimodality therapy were demonstrated on an intent-to-treat analysis.[327] Despite the low accrual rate, the observed difference supportive trimodality therapy as an appropriate standard for resectable esophageal cancer.

The Phase III CROSS trial randomized patients with resectable esophageal cancer (75% adenocarcinomas) to preoperative weekly radiosensitizing carboplatin and paclitaxel with concurrent radiation (41.4 Gy at 1.8 Gy per fraction) or surgery alone and demonstrated improved median and 5-year survival in the chemoradiation arm compared to the surgery arm (49 months versus 24 months, and 47% versus 34%, respectively). The pathologic complete response rate was higher for squamous cell carcinomas compared to adenocarcinomas, but histology was not prognostic for survival. The study included 368 patients (23% squamous cell; 75% adenocarcinoma; and 2% undifferentiated) with 178 patients randomized to neoadjuvant chemoradiation. R0 resection was achieved in 92% of the patients receiving neoadjuvant chemoradiation compared with 69% of those who proceeded directly to surgery. A pathological complete response was achieved in 47 of 161 patients (29%) who underwent resection after preoperative therapy. The results of this trial were statistically significant and present convincing data supporting trimodality therapy for patients with resectable esophageal cancer.[329]

A recently reported meta-analysis of more than 1000 patients enrolled in nine randomized trials evaluating preoperative chemoradiation versus surgery alone revealed a 0.66 survival odds ratio at 3 years in favor of patients receiving preoperative therapy.[333] Three other meta-analysis also demonstrate a similar survival advantage to trimodality therapy compared to surgery alone.[252,331,332] Table 45-11 summarizes the randomized trials comparing the results of preoperative chemoradiation followed by surgery to surgery alone.

Preoperative Chemoradiation versus Definitive Chemoradiation

Bedenne et al[337] have reported the results of a study comparing preoperative chemoradiation followed by surgery versus definitive chemoradiation. In this randomized Phase III trial, patients with locally advanced esophageal cancer received two cycles of induction 5-fluorouracil plus cisplatin with radiotherapy, either delivered via standard fractionation (46 Gy in 4.5 weeks) or over a split course. Patients were then randomized between surgical resection versus completion of definitive chemoradiation to 61 Gy. The 2-year survival rates and median survival times were not different, at 34% and 17.7 months for patients in the preoperative arm versus 40% and 19.3 months for patients randomized to definitive chemoradiation ($p = 0.56$).[337] In a related German study, patients with locally advanced squamous carcinoma of the esophagus received induction chemotherapy followed by a randomization to either chemoradiotherapy (40 Gy) followed by surgery or definitive chemoradiotherapy. The analysis of the 172 randomized patients showed the overall survival rates to be equivalent; the survival rate at 3 years was 31% for patients randomized to combined-modality therapy versus 24% for patients treated with definitive chemoradiation.[338]

A study from the Minnie Pearl Cancer Research Network reflects the difficulties associated with studies that randomize patients away from a surgical intervention. In this study, patients with locally advanced esophageal cancer were to receive a course of preoperative chemoradiation followed either by surgery or by completion of the definitive chemoradiation regimen. One-hundred and ninety-four patients were entered, but only 57 patients actually proceeded with the treatment to which they were randomized. When all patients were considered, the survival rates were similar; the 3-year survival rate for patients undergoing resection was 35% versus 31% for patients receiving definitive chemoradiation.[323]

The data, taken in aggregate, suggest that the results with definitive chemoradiation are comparable to those observed with treatment strategies that incorporate preoperative chemoradiation and surgery. However, compared to data from historical control patients undergoing planned esophagectomy 4 to 6 weeks after completion of chemoradiation, patients undergoing salvage esophagectomy following definitive chemoradiation experienced increased rates of operative death and complications, including the need for prolonged intubation or longer stays in the intensive care unit and hospital and increased anastomotic leaks. Salvage esophagectomy, nonetheless, has demonstrated a 25% 5-year survival rate in a subset of patients with stage T1-T2, N0 tumors, who undergo R0 resection, and those with a prolonged time to recurrence.[339]

Postoperative Chemoradiation

Prospective and retrospective analyses have demonstrated a survival benefit to the addition of postoperative chemoradiation in patients with node-positive esophageal cancer who have undergone esophagectomy.[340-342] SWOG 9008/INT-0116[341] reported a 3-year disease-free survival of 37% for patients with node-positive disease receiving postoperative chemoradiation compared to 24% for patient who did not. SWOG 9008/INT-0116 investigated the benefit of postoperative chemoradiation following surgery in patients with stage Ib-IV, M0 resectable adenocarcinoma of the esophagogastric junction or stomach in a prospective randomized trial. In this trial 556 patients (20% esophagogastric junction) were randomized to receive surgery alone or surgery followed by postoperative chemoradiation (5-fluorouracil plus leucovorin for one cycle followed by concurrent chemoradiation during cycles two and three, followed adjuvant 5-fluorouracil plus leucovorin following completion of chemoradiation). Patients treated on the postoperative chemoradiation arm experienced improved 3-year overall survival (50% versus 41%) and relapse-free survival (48% versus 31%) rates compared to those treated with surgery alone. There was also a decrease in local failure observed in this group (19% versus 29%). However, high rates of hematologic and gastrointestinal toxicities were associated with this treatment regimen resulting in 17% discontinuation of treatment. Despite the significant number of patients who did not complete the treatment, survival benefits have persisted after more than 10 years of followup and the results of INT-0116 have established postoperative chemoradiation as a standard of care for patients with completely resected adenocarcinoma of the esophagogastric junction or stomach.[341] Based on these results, postoperative chemoradiation is considered an acceptable treatment strategy for patients with stage Ib-IV, M0 distal esophageal and esophagogastric junction tumors who undergo resection.

The Significance of Pathologic Complete Response to Neoadjuvant Chemoradiation

Compared with historical unimodality series, failures locally and distantly have markedly decreased with the advent of multimodality therapy (Table 45-12). In general, preoperative irradiation and chemotherapy produce complete pathologic response rates of 20% to 50% (an average of approximately 30%) (Table 45-13). Pathologic complete response to neoadjuvant therapy has been associated with an improvement in OS in some series,[334] but not in others.[335] In the SWOG study, patients who had no evidence of disease at the time of surgery, when compared with all patients who had resection, had a projected 3-year survival rate of 45% versus 14%, and a median survival time of 32 months versus 14 months, respectively.[304]

A similar survival advantage was demonstrated by investigators from the University of North Carolina where median survival time for patients with no evidence of disease at resection was 37 months compared to 13 months for patients with residual tumor.[319] Similarly, in the University of Michigan series, the median survival time was improved for patients without evidence of residual disease at the time of surgery compared to the entire cohort (70 versus 29 months, respectively).[343] Although survival rates were higher in patients who had no disease in the surgical specimen in the University of Michigan and University of North Carolina series, there were long-term survivors among patients with residual disease, suggesting that the addition of surgery, at least in a subset of patients, can produce additional cures after chemoradiation therapy. A retrospective review was performed using a recursive partitioning analysis for 276 patients who received chemoradiation before esophagectomy. These results supported the idea that a pathologic complete response predicted for improved survival rates compared with patients with residual disease, but was less prognostic than the presence of nodal disease and metastases.[344]

Nodal status following neoadjuvant chemoradiation has also been demonstrated to be a predictive factor for survival rates. Gaca et al[349] performed a retrospective analysis of 28 patients with a complete pathologic response and found that patients who were node-negative, regardless of T stage, experienced improved median disease-free survival rates compared with patients with stage N1 nodes. They also found that preoperative tumor stage, patient age, tumor location, or the presence of Barrett's esophagus did not independently predict OS on univariate analysis. Multivariate analysis showed that only posttreatment nodal status, and not posttreatment tumor status, predicted disease-free survival.[349]

Assessing Residual Disease Following Neoadjuvant Chemoradiation

There are no reliable methods to predict pathologic complete responders following neoadjuvant. The use of preresection endoscopy was not useful for determining the tumor response; although 77% of patients were reported to have had a clinical complete response (by endoscopy) preoperatively, 41% of these patients had residual tumor in the pathologic specimen.[319] The inaccuracy of endoscopy in discerning the response after preoperative chemoradiation has been further confirmed in a study from Roswell Park and is important because it suggests that a strategy of initial chemotherapy plus radiation therapy with surgery saved for patients with incomplete clinical response may not be successful.[350]

FDG-PET as an indicator of complete response has also been evaluated.[297,351-353] Tumors with low pretreatment standard uptake unit values, defined as less than 4.5, are less likely to show evidence of treatment response after chemoradiation. A higher likelihood of nodal and pathologic complete response has been demonstrated in tumors with pretreatment SUV_{max} values greater than 4.5. Patients with tumors in both low and high pretreatment SUV_{max} groups demonstrate similar survival rates.[353]

PALLIATION

Oncologists can produce palliation with irradiation alone by using external beam radiation doses ranging from 30 Gy in 2 weeks to 50 Gy to 60 Gy over 6 weeks (Table 45-14). Wara et al[354] reported on 103 patients who completed therapy with 50 Gy to 60 Gy, with 89% having symptomatic improvement and 66% maintaining relief for 2 months or more. The average duration of palliation was 6 months. The dysphagia usually improved near the end of therapy, and almost all patients reported an arrest of their previous symptom progression.[354] Similar data report a 60% to 88% improvement in dysphagia with radiation doses of 50 Gy or higher.[355,356] Concurrent chemoradiation may also be used for palliation of dysphagia (Table 45-14). Studies demonstrate a rate of up to 88% improvement in swallowing, with the median time to improvement being 2 weeks with durable relief of symptoms.[290] Aggressive concurrent irradiation potentially increases complications in patients with incurable disease and a limited life span, but it may offer a more effective means of palliation.

When considering brachytherapy in esophageal cancer, one must keep in mind both the biologic characteristics of the disease and the physics of brachytherapy. Esophageal tumors are rarely confined to the mucosa or the muscular wall, and they generally extend outside the walls of the esophagus and have a high incidence of nodal spread. The physics of brachytherapy are such that the dose is primarily delivered within a radius of approximately 1 cm from the applicator. Therefore, it is quite unlikely that this approach will be effective for curative therapy of most esophageal carcinomas because of inadequate therapy to much of the tumor. It may, however, be useful for palliation where the central disease is producing the symptoms and can be effectively treated with brachytherapy. Several small series have demonstrated that intracavitary irradiation in the appropriately selected patient is a safe and

effective method of palliation resulting in local control rates of 25% to 35%. Harvey et al reviewed 22 patients treated with either 20 Gy in three fractions of low-dose-rate brachytherapy versus 12.5 Gy in one fraction of high-dose-rate brachytherapy and found that both modalities resulted in equally effective palliation of dysphagia.[359] Accelerated treatments are especially suitable for patients in poor physical condition or with a short life expectancy; however, the incidence of stricture and fistula formation increased with the brachytherapy fraction size (9.5% for fractions <500 cGy, 20% for fractions between 500 cGy and 800 cGy, and 38% for fractions >800 cGy). In a randomized trial by Sur et al, there was no reported difference in local control or survival between palliative external beam radiotherapy or high-dose rate brachytherapy.[360] Brachytherapy as an intraluminal boost has also been evaluated in RTOG 85-01 in which patients with unresectable esophageal cancer received 50 Gy with concurrent cisplatin and 5-fluorouracil followed by a brachytherapy intraluminal boost. Although the local failure rate was 27%, there were a significant number of grade-3 to grade-5 toxicities, and the cumulative incidence of fistulas was 18% per year.[361] The benefit of brachytherapy added to chemoradiation or external beam radiation alone remains unclear.

TOXICITY FROM IRRADIATION

Benign Strictures Resulting from Irradiation

Unfortunately, benign strictures can result from irradiation of esophageal cancers, causing a worsening of symptoms. The incidence of benign stricture is estimated at 12% to 30% in patients treated with irradiation alone. Strictures usually develop 4 to 6 weeks after therapy.[290,362,363] In 25 patients treated with concurrent irradiation and chemotherapy, Coia et al observed a 12% incidence of benign strictures that responded to one or two dilations.[290]

Tracheoesophageal Fistula

The development of a malignant fistulous tract between the esophagus and airway (trachea or bronchus) is not uncommon in midesophageal lesions because of the anatomic location of the two structures. Most fistulae involve the trachea, but they can also involve either a main stem, lobar, or segmental bronchus. Involvement of the trachea with tumor can lead to fistula formation during irradiation because of necrosis of the tumor or the natural progression of the disease. It is estimated that the incidence of this complication is 5% to 10% of patients with esophageal cancer. In general, excision, bypass, or intubation has been recommended in an attempt to prevent further contamination of the airway. The median survival time following these limited measures can be as brief as 6 to 10 weeks, with the procedures themselves resulting in a mortality rate of 10% to 32%.[364]

Many oncologists accept the fact that irradiation of a fistula worsens the condition because healing may be compromised by irradiation. However, Burt et al found that the survival rate for patients with an untreated fistulous tract was 4% at 6 months and 1% at 1 year compared to 15% and 5% in patients treated with irradiation, respectively.[365] Treatment of radiation-induced fistulae can be challenging. Yamado et al reported on 14 patients with fistulae secondary to esophageal cancer who were treated with primary irradiation. Closure of the fistula occurred in 5 of 8 patients whose fistulae developed before or during irradiation. In two of these cases, the closure lasted over the long term, but for patients who developed fistulae during irradiation, resolution was less likely.[366] Gschossmann reported on a 10-patient series from the Mayo Clinic with fistulae developing during treatment and observed that the severity of the fistulae did not increase with therapy and the median survival time was 4.8 months.[367]

Although it has been speculated that development of radiation-induced fistulae may impact patient outcome, there is also a growing body of evidence supporting the safe use of chemotherapy with or without irradiation in managing patients with a tracheoesophageal fistula. Malik et al observed an objective response and closure of the fistulae in two patients treated with chemoradiation and concluded that the presence of a fistula should not exclude a patient from receiving combined-modality therapy.[368] At present, it is difficult to determine whether aggressive combined-modality therapy will increase treatment-related morbidity in patients who present with airway or esophageal fistulae or develop them shortly after starting therapy. Once the diagnosis of a fistulous tract into the airway is documented and the process is stabilized, planned curative therapy for selected patients with localized disease is recommended, especially if the fistula is relatively small.

IRRADIATION TECHNIQUES

The recommended dose for preoperative therapy is 41.4 Gy to 50.4 Gy delivered over 4 to 5 weeks, using 1.8-Gy to 2-Gy daily fractions. The recommended dose for postoperative radiation 45 Gy to 50.4 Gy is recommended. When definitive irradiation is used concurrently with sensitizing chemotherapy without surgery, a total dose of approximately 50 Gy to 54 Gy is recommended as lower doses may not be adequate. For inoperable tumors of the cervical esophagus, 60 Gy to 66 Gy may be appropriate.

The irradiation of esophageal cancer presents a challenge to radiation oncologists because these tumors are situated deeply in the mediastinum and are surrounded by several vital structures. The mucosa of the esophagus is mostly squamous epithelium, and the acute mucosal reaction can be substantial. Acute odynophagia and dysphagia are common, usually developing 10 to 14 days after the initiation of therapy. The esophagitis is self-limiting, but without nutritional support, the acute mucosal reaction may force a delay in completing treatment. Patients should be closely monitored and aggressive supportive care should be provided for the management of radiation-induced acute toxicities to avoid unnecessary treatment interruptions. Consideration of feeding jejunostomy, nasogastric feeding tube, or intravenous hydration should occur in case of inadequate caloric intake or dehydration.

Portions of the upper airway, trachea, bronchi, lung parenchyma, and pleura are unavoidably irradiated during therapy. The pulmonary parenchyma is highly susceptible to radiation injury, with clinical lung damage reported at total fractionated doses in the range of 20 Gy. However, the likelihood of clinical injury relates strongly to the baseline pulmonary status of the patient, as well as the amount of lung in the irradiation field. It is not uncommon for patients with esophageal cancer to have chronic obstructive lung disease, which affects the amount of normal lung that can be safely irradiated. The risks of permanent lung injury and late pneumonitis are also volume-related.

If the heart is irradiated, complications involving the pericardium and myocardium can result. Irradiation of the pericardium can result in both acute and chronic pericarditis. The former is an uncommon complication of thoracic irradiation that usually develops within the first posttreatment year. It is often associated with viral infections, which makes diagnosis difficult. Although it has been reported at doses in the range of 20 Gy to 40 Gy, acute pericarditis generally occurs with

substantially higher doses. Chronic pericarditis typically develops more than 1 year after treatment and is related to volume treated.

Irradiation of the myocardium can result in an interstitial fibrosis that decreases cardiac function. This phenomenon is also related to the volume of irradiated heart and a total dose that exceeds 40 Gy. Data have associated irradiation of the myocardium with an acceleration of coronary arteriosclerosis and sudden cardiac death in young persons. Because the vast majority of patients with esophageal cancer are older and have a limited prognosis, myocardial injury is not a significant clinical problem at present time.

Other rare complications of esophageal irradiation include the risk of rib fractures, damage to the brachial plexus, and spinal cord injury, which is potentially the most devastating side effect. In general, it is safe to treat the spinal cord with irradiation alone to a cumulative dose of 45 Gy to 50 Gy delivered in standard single daily fractions of 180 cGy to 200 cGy.

The difficulty in controlling esophageal tumors with irradiation relates to the frequent extension of tumor through the thin esophageal wall, the involvement of vital mediastinal structures, including large vessels and the trachea, and the threat of perforation; the frequent spread of tumor through submucosal lymphatics, ultimately involving long segments of the esophagus; the spread of tumor to regional lymph nodes; the presence of metastatic disease in a high percentage of patients (either occult or clinically apparent disease); and the generally poor nutritional status of patients at presentation. Esophageal tumors can extend submucosally in the cephalo-caudad direction for a significant distance from the primary tumor. In 1962, Miller[369] reported a 15% incidence of longitudinal microscopic tumor spread at greater than 6 cm from the primary lesion and an incidence of regional nodal involvement of 40% to 70%.

For lesions of the cervical esophagus, irradiation fields must take into account tumor spread into mediastinal, supraclavicular, and low anterior cervical lymph nodes. The supraclavicular nodes are generally electively treated in patients with high thoracic tumors but not in those with middle or distal thoracic tumors. Although there is a significant incidence of involvement of the celiac axis lymph nodes, little information supports routine treatment of this nodal group for patients without evidence of tumor involvement, especially if this necessitates a substantial extension of the irradiation field.

The typical irradiation field extends approximately 4 cm to 5 cm above and below gross tumor, with a field width of approximately 8 cm. The size of the tumor dictates the exact field width needed to obtain adequate mediastinal nodal coverage and to adequately cover the primary tumor mass. CT simulation and three-dimensional treatment planning techniques are recommended. When four-dimensional CT planning or other motion management is available, margins may be reduced to account for motion control. Intravenous or oral contrast should be used to facilitate target and normal tissue localization. The gross tumor volume (GTV) includes the primary tumor and the involved regional nodes as identified by CT, PET/CT, barium swallow, or EUS. The clinical tumor volume (CTV) includes areas at risk for microscopic spread and elective node regions depending on the location of the primary tumor. The planning target volume (PTV) includes the tumor plus a cephalo-caudad margin of 4 cm to 5 cm and a radial margin of 2 cm. Efforts to reduce radiation dose to surrounding normal tissue should be made.

If conventional two-dimensional radiation planning is used, patients are initially treated with anterior-posterior treatment fields to 36 Gy to 40 Gy in 1.8 Gy to 2 Gy daily fractions to limit the dose to the heart and spinal cord. The treatments then continue, avoiding the spinal cord, with either oblique or lateral fields, to a total dose of 45 Gy to 50 Gy. An alternative approach is to treat through the entire course with multiple fields that limit the dose to the spinal cord to a total dose of 45 Gy to 50 Gy.

The use of three-dimensional conformal radiation is recommended and dose volume histograms (DVH) should be generated and used as predictors of normal tissue complications. Custom blocking may be used to limit the volume of normal tissue receiving radiation. Recommended normal tissue constraints for treatment planning purposes included liver (no greater than 60% volume should receive more than 30 Gy), kidneys (no greater than 60% of one kidney should receive more than 20 Gy), spinal cord (maximum dose 45 Gy), heart (efforts to keep minimal dose to the left ventricle), and lungs (no greater than 20% volume should receive more than 20 Gy and 40% volume greater than 10 Gy). Figure 45-1 represents a three-dimensional CT-based plan demonstrating radiation treatment for a distal esophageal tumor.

Intensity-modulated radiation therapy (IMRT) may be appropriate in selected cases and has the potential of reducing the amount of radiation delivered to surrounding normal tissues. Wu et al[370] compared IMRT plans with forward and inverse three-dimensional conformal irradiation plans for 15 patients with midesophageal cancers and demonstrated that the IMRT plans generated the most conformal high-dose distribution around the planning target volume while delivering a lower mean lung dose and mean heart dose. Others have demonstrated similar findings comparing the ability of three-dimensional therapy and IMRT to deliver simultaneous integrated boost, dose-escalation in upper esophageal locations. Lower V20 and V30 volumes in the lung were consistently demonstrated in the IMRT plans.[371] An additional study explored the potential advantage of IMRT in distal esophageal cancers, resulting in a significant reduction in the mean lung dose, V10, and V20, without a significant reduction in the cardiac dose from the three-dimensional conformal plans.[372] Because the actual use of IMRT plans has not been well studied, care needs to be taken to avoid the risk of unexpected normal tissue toxicities resulting from the low-dose regions, especially in the lungs, being widely spread into normal tissue. Figure 45-2 represents an IMRT CT-based plan demonstrating radiation treatment for a distal esophageal tumor. Figure 45-3 is a dose-volume histogram showing the dose distribution differences for surrounding normal structures between a three-dimensional treatment plan and an IMRT treatment plan for the same patient. Considerations of tumor/target motion are of particular importance when IMRT is used. A full discussion of motion management considerations is found in the chapter on non–small cell lung cancer.

Proton beam therapy (PBT) is a promising modality for the management of thoracic malignancies, including esophageal cancer. A series of 62 patients treated with PBT and concurrent chemotherapy either definitively or preoperatively at M. D. Anderson Cancer Center from 2006 to 2010 evaluated toxicity associated with this treatment approach. With a median radiation dose of 50.4 Gy (range 36 Gy to 57.6 Gy), few toxicities were observed. The most common acute toxicities encountered were grade-2 to grade-3 esophagitis (46.8%), fatigue (43.6%), nausea (33.9%), anorexia (30.1%), and radiation dermatitis (16.1%). Two cases of grade-2 and grade-3 radiation pneumonitis occurred. There was no apparent impact on subsequent surgery in the preoperative cohort. There were significantly fewer local regional recurrences in the preoperative group (3 of 29) than in the definitive group but there were no differences in distant metastases or OS between the two groups.[373] Although the clinical outcomes are encouraging, a prospective comparison with traditional radiation techniques is warranted.

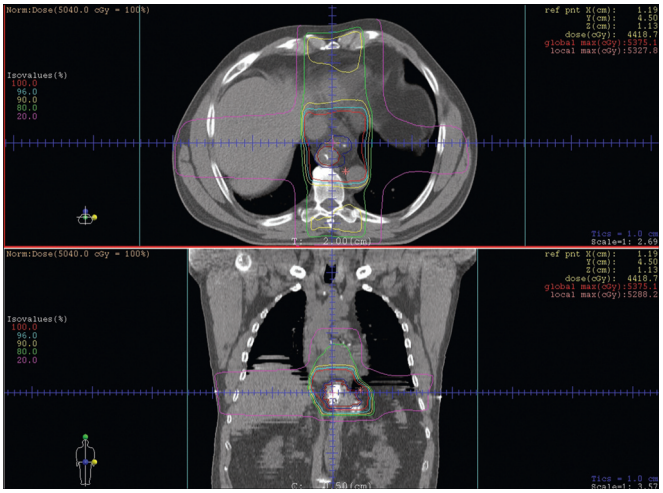

Figure 45-1 Three-dimensional treatment planning for a patient with distal gastroesophageal junction cancer. Axial and sagittal representations illustrate the dose distribution when the initial clinical target volume encompassing 5 cm of esophagus proximal to the tumor and 2 cm distal into the stomach is treated to 45 Gy using an AP/PA technique. An opposed lateral technique is used to boost the tumor and 2-cm margins to 50.4 Gy.

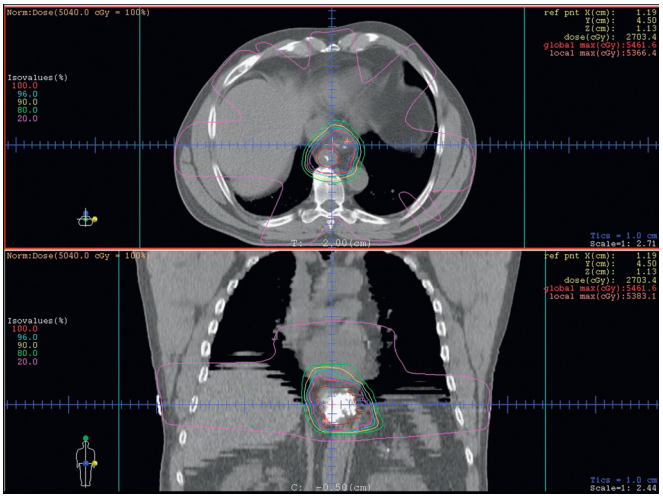

Figure 45-2 Intensity-modulated radiation treatment planning for a patient with distal gastroesophageal junction cancer. Axial and sagittal representations illustrate the dose distribution when the initial clinical target volume encompassing 5 cm of esophagus proximal to the tumor and 2 cm distal into the stomach is treated to 45 Gy to initial clinical target volume, followed by a boost to the tumor plus 2 cm to 50.4 Gy.

Other changes in treatment planning are being pursued with improved tumor localization. One study compared CT-based tumor volumes to PET/CT-based tumor volumes and demonstrated a change in target volumes for 84% of patients, with 48% with minor differences and 36% with major differences. These discrepancies were mostly in celiac or distant mediastinal lymph node involvement, resulting in a change in length of the tumor volume in 56% percent of patients.[374] It should be recognized that significant changes in treatment volumes may also increase treatment-related toxicity. Caution should be exercised in determining the exact size of a tumor from a PET/CT scan because the apparent size is determined heavily by the settings on the computer. FDG-PET

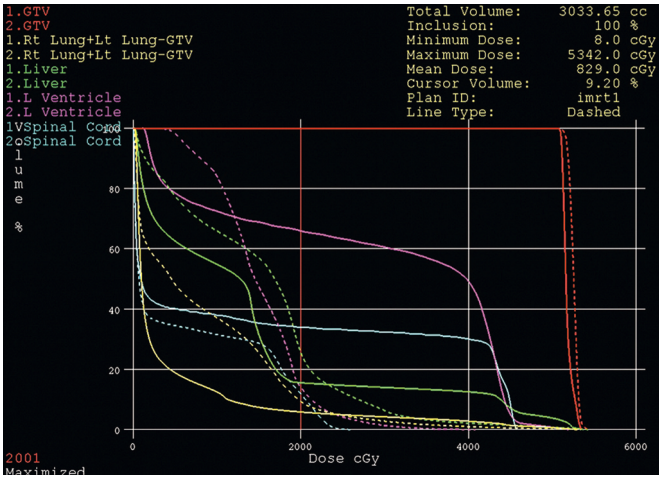

Figure 45-3 Dose-volume histograms compare dose delivered to surrounding normal tissues resulting from the three-dimensional treatment plan illustrated in Figure 45-1 *(solid lines)* and a seven-field intensity-modulated radiation therapy (IMRT) treatment plan *(dashed lines)* designed to treat the same volumes to the same dose (45 Gy to the initial clinical target volume, followed by a boost to the tumor plus 2 cm to 50.4 Gy). Note that mean doses of normal tissue are reduced, whereas the volumes of normal tissue receiving lower radiation doses (V10) increase for the IMRT plan compared with the three-dimensional conformal plan for all structures.

is perhaps most useful in finding areas of unexpected disease and determining the precise location of known lesions.

TREATMENT ALGORITHM, CONTROVERSIES, AND FUTURE POSSIBILITIES

Although surgery alone remains the standard of care in the management of early-stage localized esophageal cancer, combined-modality approaches have an important role for the typical patient with a locally advanced tumor. Figure 45-4 describes an algorithm for the treatment of esophageal cancer.

Today, the treatment of this disease requires a multimodality approach by the surgeon, radiation oncologist, and medical oncologist and a clear understanding of the interactions and toxicities associated with these modalities. Combined chemoradiation either as definitive therapy or in the preoperative setting is considered standard of care. The complications associated with multimodality therapy are significant and must be considered. Data supporting alternative treatment strategies including perioperative chemotherapy and preoperative chemotherapy followed by selective use of chemoradiation are emerging. Minimally invasive surgical techniques are promising options in selected patients. IMRT and improved tumor targeting may assist in reducing treatment-related morbidity. The use of FDG-PET response to direct therapy may be further explored depending on the results of the ongoing CALGB 80803 trial (NCT01333033) evaluating a response-adapted strategy using early FDG-PET imaging for treatment selection. We continue to evaluate novel treatment strategies using new systemic therapies, targeted agents, and radiation techniques to improve patient outcomes. We await the results of RTOG 1010 evaluating the addition of trastuzumab to chemoradiation in patients with operable, locally advanced adenocarcinoma of the esophagus and esophagogastric junction with HER2 positivity (NCT01196390).

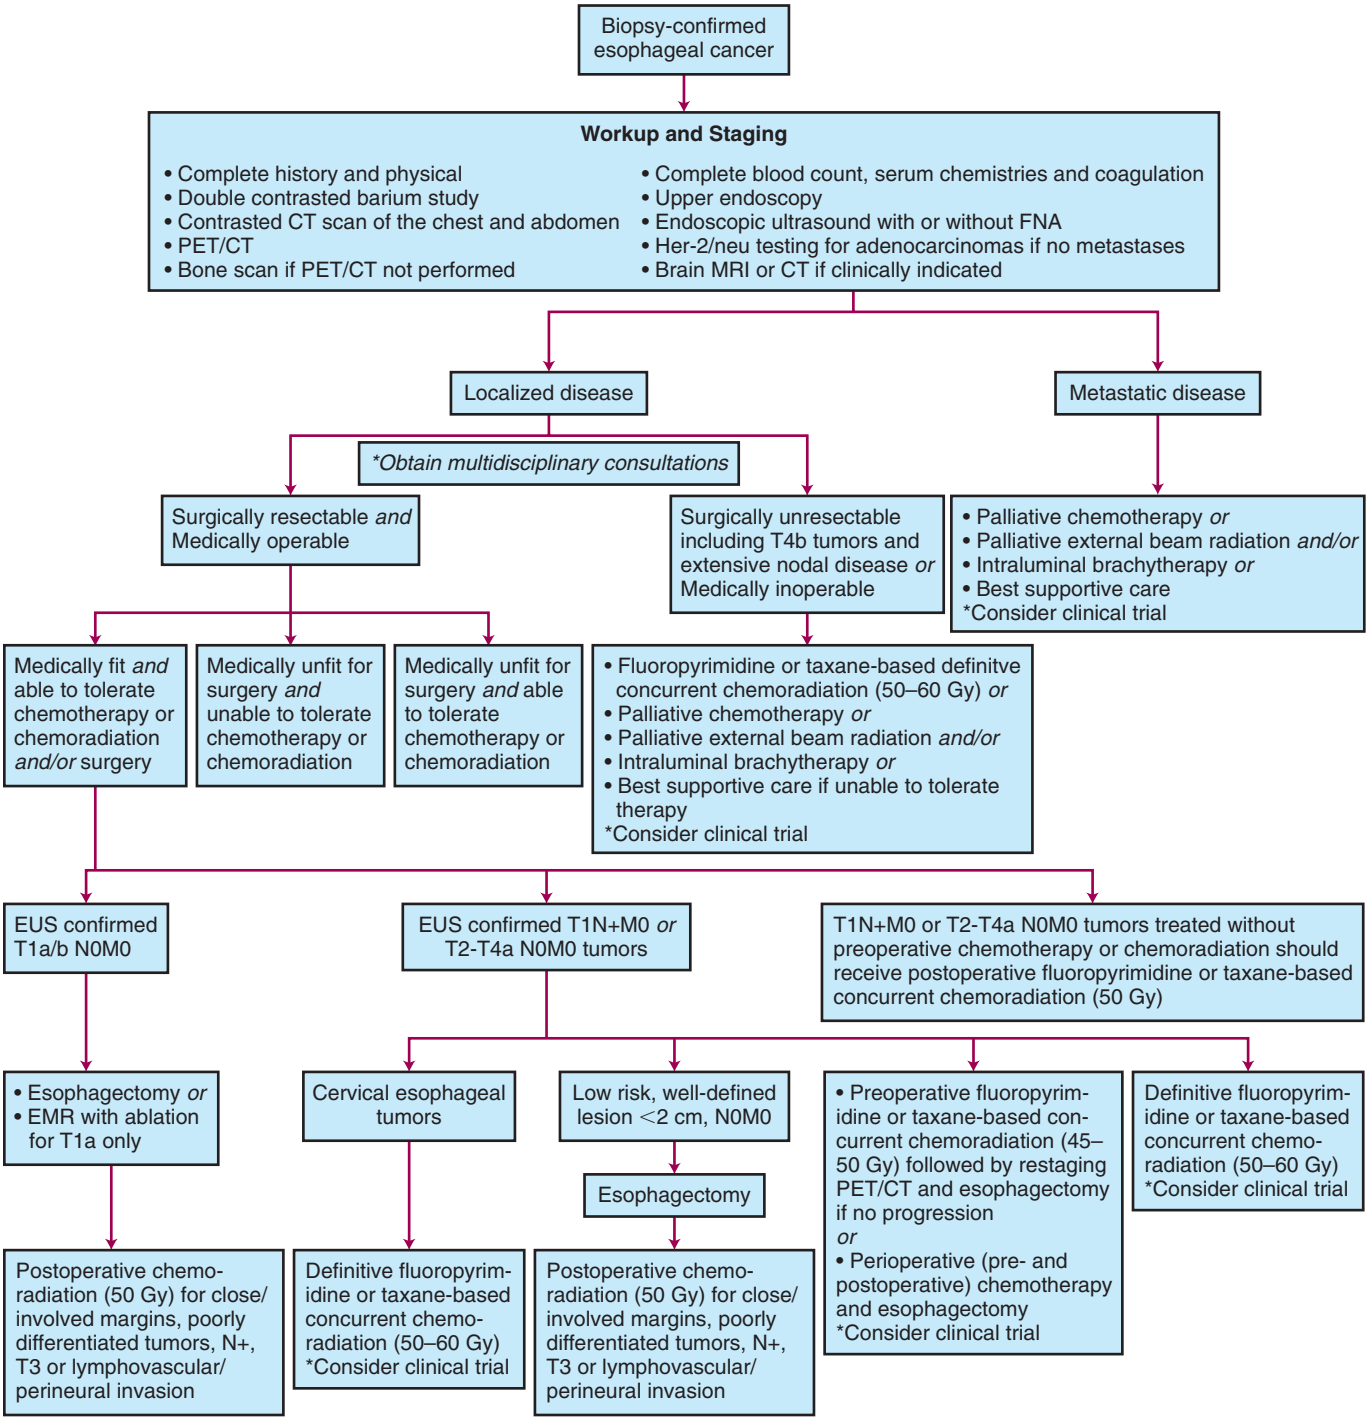

Figure 45-4 Treatment algorithm for newly diagnosed esophageal cancer. Treatment options for esophageal cancer are based in location and stage of the tumor, as well as surgical resectability and medical fitness of the patient. A multidisciplinary approach to the treatment of cancer usually includes combination therapy consisting of surgery and perioperative chemotherapy or chemoradiation, except in early stage, node-negative disease. Standard of care chemotherapy consists of fluoropyrimidine-or taxane- based regimens. Other chemotherapeutic regimens and/or targeted therapies should be considered on clinical trial. *CT,* Computed tomography; *EMR,* endomucosal resection; *EUS,* endoscopic ultrasound; *FNA,* fine-needle aspiration; *MRI,* magnetic resonance imaging; *PET,* positron emission tomography.

CHAPTER

46 Uncommon Thoracic Tumors

Jing Zeng, Ramesh Rengan, and Charles R. Thomas, Jr.

INCIDENCE

The overall incidence of thymoma in the Unites States is 0.15 cases per 100,000 persons.[1] Thymoma is the most common tumor of the anterior mediastinum, accounting for 30% of anterior mediastinal lesions and 20% of all mediastinal tumors in adults.

Between one and two cases of carcinoid tumor of any site occur per 100,000 people in the United States. The rate for bronchopulmonary carcinoids is 0.6 per 100,000 persons.[2] Pulmonary carcinoids make up almost 30% of all neuroendocrine tumors.[3]

The incidence of malignant pleural mesothelioma (MPM) is 10 cases per million people. The incidence is increasing, and the disease is classically seen in patients exposed to asbestos.[4] Based on the predicted 30-year to 40-year lag in presentation from the time of exposure to asbestos, it is expected that mesothelioma rates will continue to rise in the United States until approximately 2020.

BIOLOGIC CHARACTERISTICS

Thymomas tend to be slow-growing tumors with an indolent natural history. Histologically benign, they are capable of local and regional invasion and have a marked tendency for local recurrence. The two most important prognostic factors are invasiveness and completeness of surgical resection.

Pulmonary carcinoids generally are nonfunctional, but they can secrete physiologically active substances, leading to paraneoplastic syndromes. Biologic behavior ranges from indolent to aggressive. Prognostic factors are atypical histologic findings, nodal involvement, and the presence of symptoms at presentation.

MPM is aggressive, and local disease progression is the main cause of symptoms and death. It spreads by direct extension and seeding in the pleural space. Local recurrence is the predominant pattern of failure.

STAGING EVALUATION

Patients with suspected thymoma require routine screening blood work and chemistry testing, but diagnosis is usually based on clinical radiographic findings. Historically, biopsy confirmation of an anterior mediastinal mass was avoided because of concerns about needle tract seeding.[5,6] Treatment without biopsy confirmation remains controversial. The value of neoadjuvant therapy cannot be properly assessed without a pretreatment biopsy.[7] Image guided fine-needle aspiration biopsy is useful, though a core biopsy increases accuracy.[8] Bronchoscopy, video-assisted thoracoscopic surgery, mediastinoscopy, or anterior thoracoscopy also may help to yield a diagnosis before resection.

Pulmonary carcinoid requires a similar workup. Transbronchial biopsy or computed tomography (CT)- or ultrasound-guided fine-needle aspiration biopsy may establish the diagnosis preoperatively. The role of positron emission tomography (PET) scans remains controversial because of the relatively low glucose uptake of carcinoid tumors.[9,10]

Patients with suspected mesothelioma should be asked about a history of asbestos exposure. CT of the chest is needed. Although thoracentesis, percutaneous fine-needle aspiration, or ultrasound-guided core biopsy may yield the diagnosis, the most accurate method is video-assisted thoracoscopic biopsy.

PRIMARY THERAPY

Complete en bloc surgical resection is the treatment of choice for all thymomas, except in rare advanced cases with extensive intrathoracic or extrathoracic metastasis.

Curative resection of localized primary lung carcinoids is the treatment of choice. Endoscopic laser ablation may be used to palliate tumor obstruction, improve atelectasis, and reduce inflammation before resection.

Pleurectomy and extrapleural pneumonectomy (EPP) are extensive surgical procedures for mesothelioma. Patients require careful assessment to ensure that the operation will be tolerated physiologically. More recently, the role of EPP in mesothelioma has been called into question, and some advocate for pleurectomy as the primary surgical treatment.[11]

ADJUVANT THERAPY

Encapsulated, noninvasive, stage I thymomas do not require adjuvant postoperative radiation therapy. Radiation therapy can be an effective adjuvant therapy for invasive thymomas. It is unclear whether all stage II thymomas benefit from adjuvant radiotherapy (RT).[12-14]

Typical carcinoids usually do not require adjuvant therapy after resection. Certain symptoms, including flushing, can be relieved by pharmacologic agents such as octreotide.[15] Adjuvant RT has been used in patients with large tumors (>3 cm), positive nodes, positive margins, atypical histologic findings, residual disease, and inoperable disease.

For mesothelioma, high-dose postoperative RT can dramatically reduce ipsilateral thoracic failures. Postoperative irradiation should include the entire volume immediately adjacent to the pleural space, but it is technically difficult to deliver.

LOCALLY ADVANCED DISEASE

Preoperative RT and primary RT alone have each been advocated in patients with thymoma with unresectable advanced disease. Chemotherapy may produce an improvement in overall survival (OS) rates. Chemoradiation may be appropriate for some patients with locally advanced unresectable malignant thymoma.

RT has been used adjuvantly or to palliate symptoms from locally advanced or metastatic carcinoids.

EPP followed by irradiation or systemic chemotherapy may reduce the risk of relapse and provide better local control of mesothelioma than surgery alone.

PALLIATION

RT can provide effective palliation in patients with symptomatic metastatic or unresectable disease.

THYMIC TUMORS

The thymus gland is a bilobed lymphoepithelial organ located in the anterior mediastinum, behind the sternum and in front of the great vessels. In early life, the thymus functions in T-lymphocyte differentiation and maturation and releases T lymphocytes into the circulation. It weighs 12 g to 15 g at birth and 40 g at puberty, and during adulthood, it slowly involutes and is largely replaced by adipose tissue. The thymus is composed of an outer cortex consisting primarily of epithelial cells, degenerated keratinized epithelial cells (Hassall's corpuscles), myoid cells, thymic lymphocytes ("thymocytes"), and B lymphocytes, which form rare germinal centers.[16]

Although various tumors and cysts can arise in the thymus, tumors of the thymus are uncommon. Most thymic tumors arise in the epithelial cells of the thymus. They account for approximately 50% of anterior mediastinal masses.[17,18] The most common thymic tumors are thymoma, thymic carcinoma, and thymic carcinoids. Thymomas, 90% of which are found in the anterosuperior mediastinum, are commonly associated with myriad paraneoplastic syndromes. They are the most common tumor found in the anterior mediastinum.[18,19] Thymomas are associated with an exuberant lymphoid component composed of immature cortical thymocytes. Although they appear benign histologically, they may exhibit invasive behavior clinically.

Thymic carcinomas (i.e., type C thymomas) also arise in the thymic epithelium, but they have a higher propensity for capsular invasion and widespread metastases, especially those with features of high-grade malignancy. The histologic subtypes include clear cell, sarcomatoid, and anaplastic carcinoma. Low-grade thymic carcinomas (well-differentiated squamous cell carcinomas, basaloid carcinomas, and mucoepidermoid carcinomas) are characterized by a relatively more favorable clinical course, with a lower incidence of local recurrence and metastasis.[20,21]

Neuroendocrine tumors of the thymus are rare, accounting for less than 5% of all neoplasms of the anterior mediastinum. Like carcinoids at other sites, they are thought to originate from endodermal cell (or foregut cellular) precursors. Unlike carcinoids in other locations, most thymic carcinoids behave aggressively, often invade locally and commonly metastasize to regional lymph nodes.[22] Approximately 50% of patients may develop endocrine abnormalities.[23]

Etiology and Epidemiology

The etiology of thymic tumors is largely unknown. There is a reported association between Epstein-Barr virus (EBV) infection and tumors of the thymus. For instance, thymic diseases are more common in far Eastern countries, where the incidence of EBV infection is high.[24,25] Defective viral genomes have been isolated in patients with lymphoepithelioma-like thymic carcinoma.[24,26-28] Childhood thymus irradiation has been linked to the development of thymic tumors,[29] and familial cases have been reported, suggesting a possible relationship with cytogenetic abnormalities.[30,31] In an analysis of secondary or concomitant neoplasms in 1495 patients with acute lymphoblastic leukemia enrolled in two consecutive multicenter protocols, an increased risk of solid tumors was identified.[32] Although the histologic characteristics of these second malignant tumors varied, thymoma was among the solid tumors identified in adult survivors of acute lymphoblastic leukemia. Among patients with primary thymic carcinoid tumors, up to 30% had multiple endocrine neoplasia type 1 or 2.[33,34] Other studies have reported a distinctive chromosome abnormality involving translocation of fragments of chromosomes 15 and 19 [t(15:19)(q15:p13)] in thymic carcinoma, particularly in young adults and pediatric patients with high-grade thymic carcinoma.[35-37] Deletion of the short arm of chromosome 6 is associated with benign thymomas.[38] Aberrations involving chromosome 6 suggest that several putative tumor suppressor genes may contribute to the pathogenesis of thymoma.[39]

TABLE 46-1 World Health Organization Classification of Thymic Epithelial Tumors

Type	Pathologic Classification	Prognosis
A	Medullary thymoma Spindle cell thymoma	Benign clinical course
AB	Mixed thymoma	
B1	Lymphocyte-rich thymoma Lymphocytic thymoma Predominately cortical thymoma Organoid thymoma	Moderately malignant clinical course
B2	Cortical thymoma	
B3	Epithelial thymoma Atypical thymoma Squamoid thymoma Well-differentiated thymic carcinoma	
C	Thymic carcinoma	Highly malignant clinical course

In a small study of 37 cases, most World Health Organization (WHO) type A thymomas (Table 46-1) did not show any chromosomal aberration, whereas type B3 thymomas and thymic carcinoma (i.e., type C thymoma) shared some genetic aberrations, including the loss of chromosome 6 and the gain of chromosome 1q.[40] The loss of chromosome 6, on which the human leukocyte antigen locus and some of the tumor suppressor genes have been identified, and the gain of chromosome 1q, to which growth promoter genes have been mapped,[40-42] may play a role in tumorigenesis and pathogenesis of the paraneoplastic autoimmunity characteristics of thymoma. Such chromosomal aberrations have been implicated in a variety of human neoplasms.[43,44]

The true incidence of thymoma is unknown, and the annual incidence in the United States has not been well defined. The SEER program reported a thymoma incidence of 0.13 to 0.15 per 100,000 people.[1] Although thymomas are uncommon, they are the most frequently diagnosed mediastinal masses, representing approximately 30% of anterior mediastinal lesions and 20% of all mediastinal tumors in adults.[17-19,45-47] Most patients with thymoma are between the ages of 40 and 60 years, with a median age of 52 years and an equal overall gender ratio.[48-51] Thymomas are less common in children, accounting for approximately 15% of anterior mediastinal masses.[19,48-51]

Thymic carcinomas are distinct from invasive thymomas both pathologically and clinically.[52] They account for 5% to 36% of all thymic neoplasms.[53-56] The wide range in incidences reflects differences and changes in the pathologic classification of this rare tumor. Patients with thymic carcinoma are typically middle-aged or elderly, and there is a slight male predominance. Thymic carcinoids represent less than 5% of anterior mediastinum lesions[57,58] and typically affect middle-aged men.[21]

Prevention and Early Detection

A small subgroup of cases are associated with thymic irradiation during childhood, EBV infection (associated with

lymphoepithelioid thymic carcinoma), or familial cytogenetic abnormalities; the etiologic factors for most thymic tumors are unknown, however, and there is no known mechanism for prevention. Thymomas are characterized by an indolent growth pattern with a tendency toward local invasion. Thymomas are associated with autoimmune disorders, particularly myasthenia gravis, in 30% to 45% of cases.[59,60] Most thymic tumors are discovered incidentally because of abnormalities observed on routine radiographs or during evaluation for myasthenia gravis. Approximately 10% to 15% of patients with myasthenia gravis have benign or malignant thymomas.[61-65] Thymic carcinomas and carcinoids are commonly detected incidentally. They are locally invasive and are found to have metastasized to regional lymph nodes and distant sites in up to 30% of patients at diagnosis.[22,54,66]

Biologic Characteristics and Molecular Biology

Patients with thymoma may have dysregulation of the lymphocyte selection process associated with abnormal proliferation, autoimmunity, and immunodeficiency. Thymoma-associated autoimmune disease involves an alteration in circulating T-cell subsets.[67-69] Up to 70% of thymomas may be associated with paraneoplastic syndromes.[55] Various autoantibodies have been described.[70,71] In addition to T-cell defects, B-cell lymphopenia has been observed in thymoma-related immunodeficiency along with hypogammaglobulinemia (i.e., Good's syndrome).[72,73]

Factors influencing the different biologic behaviors of thymoma subtypes are poorly understood. Some pathologic features, such as altered expression of TP53 and BCL2,[74,75] counts of argyrophilic nucleolar organizer regions,[76,77] proliferating cell nuclear antigen, matrix metalloproteinases, and Ki-67 index,[77,78] are associated with biologic behavior, clinical stage, and prognosis.[79] There is a tendency for up-regulation of adhesion and costimulatory molecules.[80-83] Altered TP53 expression may be implicated in the initial stages of tumorigenesis, and increased expression of epidermal growth factor (EGF) and epidermal growth factor receptor (EGFR) may play a role in thymoma genesis.[84] A decreased OS time is predicted by Src kinase and TP53 co-expression.[85] It has been proposed that a deficiency in the autoimmune regulator *(AIRE)* gene has an oncogenic effect on thymomas. AIRE expression is lacking in approximately 95% of thymomas; therefore loss of AIRE expression may provide a potential mechanistic link for the well-recognized association of autoimmunity with thymoma.[86,87]

Thymic carcinomas possess overt features of malignancy similar to those of carcinoma arising in any other organ, with a higher propensity for capsular invasion and metastases than invasive thymomas. Paraneoplastic syndromes occasionally exist with well-differentiated lesions.[88,89] Most variants of thymic carcinoma are highly lethal, producing frequent metastases to regional lymph nodes, bone, liver, and lung.[90-92] Thymic carcinomas may express high levels of EGFR,[84,93,94] but *EGFR* gene mutations are rare.[95] Tumor and serum levels of vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF) can be elevated,[96,97] and correlations among such growth factors, angiogenesis, and invasiveness have been observed.[97-99] Thymic carcinoma has been associated with increased expression of epithelial membrane antigen, cytokeratin subtypes, and TP53 protein.[75,100-104] Somatic *KIT* gene mutations are present in some thymic carcinomas but not in thymomas.[105,106] Increased expression of CD70 may serve as a marker for thymic carcinoma.[107] Other surface antigenic molecules, such as CD5 and CD99, have aberrant expression in thymic carcinoma.[108-110] Cytoplasmic phosphorylated AKT serine 473 and insulin-like growth factor-1 receptor (IGF-1R) are expressed in a higher proportion of recurrent tumors and more aggressive subtypes according to the WHO staging system. IGF-1R was associated with a worse progression-free survival time.[111,112] Thymic carcinomas can be distinguished from lung carcinomas by negative expression of thyroid transcription factor-1[100] and a distinctly different cytokeratin profile.[113] Additionally, although mutations in the *TP53* gene are common in lung carcinoma, *TP53* gene mutation was not found in any of seven examined thymic carcinomas.[105] The combination of c-KIT, CD5, and cells such as β5t thymic cortical environmental marker cells, cortical thymocytes, and thymic cortical dendritic macrophages can be used to distinguish thymic carcinoma from Type B3 thymoma or lung squamous cell cancers.[114]

Thymic carcinoids have a malignant clinical course with a poor prognosis, frequently worse than carcinoids of the gastrointestinal tract. They may secrete peptides, amines, kinins, prostaglandins, or other substances. In a study of 80 patients with thymic carcinoids, 74% were male, 72% had related symptoms, 6% had Cushing's syndrome, and 16% had other endocrine abnormalities.[115] Even after complete resection, recurrence is common (36% to 87%).[22,115,116] OS rates were only 28% and 10% at 5 and 10 years, respectively.

Pathology and Pathways of Spread

There is no direct correlation between the histopathology of thymomas and their malignant potential.[48,117,118] However, an accurate histologic diagnosis is still crucial in patient management.

The histologic diagnosis of thymoma can be difficult, and a variety of systems have been proposed. The WHO classification, developed in 1999 and revised in 2004, is the most widely accepted. Tumors with true malignant cytologic characteristics are considered to be thymic carcinomas rather than thymomas. Invasive thymomas invade the capsule macroscopically or microscopically, with typically "bland" cytologic characteristics of thymic epithelial cells admixed with mature lymphocytes. The term *invasive thymoma* should be used instead of malignant thymoma to denote the tumor's predilection for capsular invasion.

Grossly, thymomas are nodular, multilobulated, and firm. They may contain cystic spaces, calcification, or hemorrhage and may be neatly encapsulated, adherent to surrounding structures, or invasive. Thymomas generally have epithelial and lymphatic cells. They are classified as predominantly epithelial, predominantly lymphocytic, mixed lymphoepithelial, or spindle cell type. Morphologically, thymoma cells are rather large and may be round, oval, or spindle shaped with vesicular nuclei and small nucleoli. The cytoplasm is often eosinophilic or amphophilic. Thymic neoplasms arise from epithelial cells (Figure 46-1). The lymphocytic component is mostly normal-appearing mature lymphocytes. Some of the other microscopic features that may be seen in thymomas include Hassall's corpuscles, keratinizing squamous epithelium, rosettes, glands, cysts, papillary structures, and germinal centers. Immunohistochemistry is often helpful in making the diagnosis. Thymomas typically stain positive for thymic epithelial markers, including cytokeratin, thymosin β3 and α1, and epithelial membrane antigen.

Thymic carcinoma histologic characteristics are more diverse. The tumor is cytologically malignant, and most commonly have squamous cell histologic findings. Other subtypes include lymphoepithelioma-like carcinomas, clear cell carcinomas, sarcomatoid carcinomas, adenosquamous carcinomas, mucoepidermoid carcinomas, adenocarcinomas, and basaloid squamous cell carcinomas.[21] Their histologic appearances are not different from carcinomas in other sites.[119]

BOX 46-1 Paraneoplastic Diseases Associated with Thymoma

- Addison's disease
- Carcinoid syndrome
- Chronic mucocutaneous candidiasis
- Cushing's syndrome
- DiGeorge syndrome
- Erythroid and neutrophil hypoplasia
- Hashimoto's thyroiditis
- Hyperparathyroidism
- Hyperthyroidism
- Hypertrophic osteoarthropathy
- Hypogammaglobulinemia
- Lambert-Eaton syndrome
- Lupus erythematosus
- Myasthenia gravis
- Myocarditis polyarthropathy
- Myotonic dystrophy
- Myotonic dystrophy scleroderma
- Nephrotic syndrome
- Pancytopenia
- Panhypopituitarism
- Pemphigus
- Pernicious anemia
- Polymyositis
- Polyneuritis
- Red cell aplasia
- Rheumatoid arthritis
- Sarcoidosis
- Sjögren's syndrome
- Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
- Ulcerative colitis
- Whipple's disease

The histologic features of thymic carcinoids are identical to carcinoid tumors in other organs. Unlike thymomas, they are rarely encapsulated. Immunohistochemically, they may stain positively with CAM 5.2, low-molecular-weight cytokeratins, chromogranins, synaptophysin, and leucine-7.[115]

The predominant pattern of spread of thymomas is by direct invasion into adjacent organs. The degree of encapsulation and the invasion of adjacent tissues define malignancy for these tumors rather than the histologic appearance.[120] Approximately 50% of cases in surgical series are noninvasive.[18,48-50,121,122] Thymomas may metastasize as implants on pleural surfaces or pulmonary nodules, but they rarely metastasize to extrathoracic areas.[123] When thymomas metastasize, the most common site is the pleural cavity, where they form plaques, malignant pleural effusions, and diaphragmatic masses. Invasion into the superior vena cava, brachiocephalic vein, lung, and pericardium may be observed.[124]

Thymic carcinomas invade locally, often involve the pleura and mediastinal nodes, and sometimes spread regionally to the cervical and axillary lymph nodes.[125] Distant metastases to the lungs, liver, brain, and bone also occur. Distant metastases to bone, liver, or skin occur in 30% to 40% of cases of thymic carcinoids,[23] and they may be seen in 70% of patients within 8 years from initial diagnosis.[126]

Clinical Manifestations and Patient Evaluation

Approximately 30% to 40% of patients with thymic neoplasms are asymptomatic and the tumors are discovered incidentally.[51,59,123,127] Clinical symptoms vary greatly, depending on the size of the tumor and effect on adjacent structures, but they are usually those of a mediastinal mass producing cough, chest pain, dyspnea, hoarseness, superior vena cava syndrome, and symptoms related to tumor hemorrhage.[21,128,129] Patients may also have dysphagia, fever, weight loss, and anorexia.

Some thymomas present with symptomatic paraneoplastic syndromes; the most common is myasthenia gravis, which is seen in approximately 45% of patients.[59] Box 46-1 lists other syndromes.[19,59,61,120,130] Thymic carcinoids may also be associated with Cushing's syndrome, Eaton-Lambert syndrome, syndrome of inappropriate secretion of antidiuretic hormone (SIADH), and hypercalcemia,[23] but the classic carcinoid syndrome is rare. The causes of these syndromes remain obscure, although autoantibodies have been demonstrated, mostly in thymoma patients.[70,71,131]

Myasthenia gravis is an autoimmune neuromuscular junction disorder characterized by the presence of anti-acetylcholine receptor antibodies, which cause an acetylcholine receptor deficiency at the motor end plate. The disease is characterized by rapid exhaustion of voluntary muscular contractions, with a slow return to the normal state.[130,132] Myasthenia gravis is

common with thymoma but rare in thymic carcinoma. Patients with thymoma and myasthenia gravis may have an increased operative mortality rate, and most surgical deaths are attributed to myasthenic crisis. Death of patients with thymoma and myasthenia gravis is commonly caused by complications of myasthenia gravis, whereas in patients without myasthenia gravis, death often is attributed to local progression of tumor.[122]

Prognostic Factors

The two most important prognostic factors for thymoma are invasiveness (stage) and completeness of surgical resection.[49,51,133-135] Capsular invasion is commonly used as the basis for designation as benign or malignant. Tumor size (>10 cm) and the presence of symptoms also have prognostic value.[46,136,137] Patients with complete or radical excision have significantly improved survival times over those with subtotal resection or biopsy only.[133,138] Although almost all noninvasive thymomas can be totally resected, the ability to achieve a complete resection in invasive cases varies from 58% to 73%.[62,133,139] Older series reported a poor prognosis associated with myasthenia gravis,[6,49,50] but several modern series have failed to confirm this observation.[134,135,140-142] Myasthenia gravis may even confer a survival advantage because neuromuscular symptoms may lead to earlier discovery of a small thymoma.[136,143,144] After thymectomy, patients with myasthenia gravis have attenuation of the severity of symptoms over time but not necessarily complete resolution of them.[145-147] About 50% of patients with pure red cell aplasia have thymoma, and about 10% of patients with hypogammaglobulinemia have thymoma. Patients with red cell aplasia, hypogammaglobulinemia, and lupus erythematosus appear to have a poorer prognosis.[122,136,142,143]

Although the degree of tumor invasiveness is strongly related to stage and prognosis, there are data to support the prognostic significance of the histologic findings, independent of tumor stage.[141,148,149] The historical classification proposed by Marino and Muller-Hermelink categorized thymoma as cortical, mixed, and medullary types.[150] Thymomas arising from the epithelial cells of the cortex were classified as cortical thymomas, and those arising from the medullary spindle cells were classified as medullary thymomas. According to the Marino and Muller-Hermelink data, cortical thymomas have a more aggressive course than medullary thymomas and are more likely to be associated with myasthenia gravis. Of note, thymic carcinomas were categorized as a separate entity.

In 1999, the WHO published a classification including six subtypes of thymic tumor, based on the relative proportion of epithelial and lymphocytic cells (see Table 46-1). This is the most widely accepted histologic classification system, and the WHO cell type is an independent prognostic factor.[149,151-153] A retrospective study of 324 patients found that patients with WHO types A, AB, and B1 had a 100% disease-specific survival rate without RT and therefore did not benefit from adjuvant RT.[154] There was no survival difference for cell types B2 and B3 with or without adjuvant RT. Reiker et al,[155] noted that survival rates of patients with types A, AB, B1, and B2 were better than for type B3, and that type C had the lowest OS. The prognostic value of the subtype of type B thymomas has been examined in one series that found no differences in recurrence or survival rates among the three subtypes of type B, but all patients who recurred had stage III disease, indicating that the Masaoka stage was predictive.[156] The risk of myasthenia gravis increases progressively with WHO type from A (~20%) to B3 (~60%).[87]

Paraneoplastic syndromes occasionally exist with well-differentiated thymic carcinomas.[88,89] However, clinical features have not proved useful as prognostic indicators.[149] As with thymomas, total resection and stage at presentation are important prognostic factors for thymic carcinoma.[22] Extensive lymph node dissection (>10 nodes) is needed to accurately stage patients, and disease-free survival (DFS) can be as high as 90% in N0 patient with extensive nodal dissection, whereas patients with node-positive disease can have DFS on the order of 33%.[157]

Recently, a nine-gene assay has been developed that divides thymomas into high and low risk of metastasis, with 10-year metastasis-free survival of 77% and 26%, respectively.[158] This product is available commercially.[159]

Diagnostic Workup for Thymic Tumors

The diagnostic workup of a patient with an anterior mediastinal mass begins with a thorough history and physical examination. Particular focus should be given to detect signs and symptoms that may suggest myasthenia gravis, such as fatigue, diplopia, ptosis, and dysarthria. Constitutional symptoms such as fever, chills, and weight loss are more suggestive of lymphoma. Routine screening blood work and chemistry testing may give clues to the presence of associated syndromes. In the case of suspected Cushing's syndrome, seen in 1% to 2% of patients, a dexamethasone suppression test and urinary cortisol level should be obtained, although some carcinoids can be suppressed, making diagnosis difficult. The differential diagnosis, in addition to thymic lesions, includes germ cell tumors, lymphomas, and thyroid proliferative disorders. Serum alpha-fetoprotein and beta-human chorionic gonadotropin levels should be obtained in young men if a non-seminomatous germ cell tumor is suspected.[160-162] Exclusion of metastases from extrathymic primary tumors is important.

The chest radiograph often demonstrates a hilar mass (Figure 46-2). CT scan with contrast defines the characteristics of a mediastinal lesion, as well as its relation to or invasion of other mediastinal structures.[163,164] Thymic tumors are usually homogeneous, well-demarcated lesions with a round or lobulated shape, and occasionally have calcification (Figure 46-3).[165,166] The presence of fat planes between the tumor and adjacent structures suggests localized disease. Pleural involvement may be seen in advanced disease. The radiographic presence of both an anterior compartment mass as well as "drop" metastases to the pleura is highly suggestive of the diagnosis. Thymic carcinomas often contain calcifications, cysts, or necrosis on imaging.[167] A nomogram has been developed by Marom et al,[168] using CT characteristics to predict the Masaoka stage (Figure 46-4). In the absence of symptoms and signs, extensive radiographic imaging is unnecessary. Magnetic resonance imaging (MRI) has not been superior to CT scanning.[169,170]

The role of PET has not been well established as FDG (fludeoxyglucose) uptake in thymomas is variable. However, PET/CT can help distinguish thymomas from thymic carcinomas, as well as help predict WHO grade.[171-174] A report of 51 patients found that FDG uptake was higher in patients with thymic carcinoma than thymoma, and type B3 thymomas had higher uptake than lower histologies (A through B2).[173] Similar results were seen in 47 patients from Italy, where SUV max and ratio of SUV max to tumor size correlated with WHO grade and Masaoka stage.[174] However, a series of 58 patients from Japan found that while SUV max can differentiate between thymic carcinoma and thymoma, there was no difference between the low- and high-risk thymoma groups.[171] High uptake of FDG also appears to correlate with the degree of tumor invasiveness,[175-177] and may be helpful in identifying nodal and distant metastasis.[172]

Patients presenting with a thymic mass need a histologic diagnosis before definitive therapy. CT- or ultrasound-guided fine-needle aspiration biopsy can establish the diagnosis

TABLE 46-2 Masaoka Staging System for Thymoma

Stage	Description
I	Macroscopically completely encapsulated with no microscopic detectable capsular invasion
II	Macroscopic invasion into surrounding mediastinal fatty tissue or mediastinal pleura or microscopic invasion into the capsule
III	Macroscopic invasion into surrounding organs (e.g., pericardium, great vessels, lung) or intrathoracic metastases, or both
IVA	Pleural or pericardial implants or dissemination
IVB	Lymphogenous or hematogenous metastases

Adapted from Masaoka A, Monden Y, Nakahara K, et al: Follow-up study of thymomas with special reference to their clinical stages. Cancer 48:2485–2492, 1981.

preoperatively[178] with a sensitivity and specificity of 87% to 90% and 88% to 100%, respectively, for thoracic neoplasms.[179] When larger tumor samples are required to distinguish between lymphoma and lymphoid-predominant thymoma, core-needle biopsy provides sufficient specimens with an overall sensitivity of 96% and specificity of 100%.[179] Bronchoscopy, video-assisted thoracoscopic surgery, mediastinoscopy, or anterior thoracoscopy may help yield the diagnosis before resection, especially if enlarged lymph nodes are present.[160,180,181] The potential risk of breaching the capsule, leading to spillage and seeding of tumor cells during biopsy, has been debated and remains unsettled.[6,182,183]

Staging

Bergh et al introduced the first clinical staging system for thymoma in 1978.[184] Their staging system was subsequently modified by Masaoka in 1981 and is the most widely accepted (Table 46-2).[133] It is based on pathologic findings at time of surgery.

A separate, simplified staging paradigm was proposed by Suster and Moran.[185] Stage I lesions are localized and encapsulated; stage II lesions are locally invasive; and stage III lesions have nodal, visceral, or distant metastasis. A tumor-node-metastasis (TNM) staging system was proposed by Tsuchiya[186] but is not widely accepted. There is no formal American Joint Committee on Cancer (AJCC) staging system for thymoma.

Treatment

Surgery for Thymoma

Surgery is the mainstay of therapy in resectable cases. However, adjuvant or neoadjuvant radiation therapy plays an important role in subtotally resected or unresectable cases. Many patients who present with symptoms of myasthenia gravis benefit from a thymectomy.[134] Consequently, surgical resection alone for stage II thymomas is a reasonable approach.[12,13] In general, surgical resection for thymoma carries low risks of morbidity and mortality; most surgical deaths can be attributed to a myasthenia gravis crisis, but the risk can be minimized with appropriate perioperative management, including plasmapheresis, in selected situations.[122,187] After an encapsulated thymoma without associated myasthenia gravis is removed without disturbing the integrity of the capsule, recurrences are rare.[49,62,188,189]

Successful surgical treatment of locally invasive thymoma depends on the completeness of resection.[190] Consequently, the surgeon should remove as much of the lesion as possible, including surrounding mediastinal fat, possibly to include an extended thymectomy.[191] However, resection of an involved phrenic nerve is controversial, and surgeons advocate debulking alone, leaving both phrenic nerves intact if there is bilateral phrenic nerve involvement because of the respiratory morbidity from resection. When complete resection is not possible, a debulking operation should be considered, because good long-term results can be achieved when such surgery is followed by postoperative radiation therapy.[122] Only about one fourth of patients with stage IVA disease have resectable disease.[59] Surgical approaches have varied from discrete resection of pleural metastases to en bloc mediastinal dissection with EPP.[192] A few small single-institution series have suggested that EPP may improve local control rates.[192-194] The conventional surgical approach for thymoma resection uses an open sternotomy. There has been recent interest in using a VATS thymectomy, with encouraging results, especially for smaller and noncystic tumors.[195-198] The surgeon should delineate the extent of the tumor, specify the areas of invasion, and identify the areas of positive or questionable margins and residual disease with metallic clips to assist future radiation therapy planning.

Radiation Therapy for Thymoma

Although the role of adjuvant irradiation for invasive thymomas has never been tested in a prospective, randomized fashion, there is general agreement that RT is an effective adjuvant therapy for invasive thymomas,[199] and most retrospective studies have reported improvements in local tumor control and survival rates after adjuvant irradiation.[65,116,137,138,144,146] However, patients with encapsulated, noninvasive stage I thymoma should not receive postoperative RT after complete resection because the recurrence rate is approximately 0% to 2%.[65,115,193-195]

There is controversy about whether postoperative RT should be used for completely resected invasive thymomas. A meta-analysis of 22 studies with 592 patients with completely resected stage II or III thymoma found no reduction in recurrence after adjuvant RT,[200] but it is difficult to draw firm conclusions, given the selection bias in retrospective series. Berman et al reported a single-institution retrospective cohort comparison of 74 patients with stage II thymoma after complete surgical resection.[14] Patients who were thought to be at high risk for local recurrence were referred for adjuvant RT. The rate of locoregional recurrence was 8% in patients who were observed versus 0% in the RT group ($p = 0.15$). The researchers concluded that no benefit of postoperative RT was observed in patients with stage II thymoma as a group; however, a higher-risk subset of these patients may benefit from adjuvant therapy.[14] Kondo and Monden reported a multiinstitutional, retrospective study of 1320 patients with thymic epithelial tumors and found no significant difference in the recurrence rates between two groups with stage II or III thymoma,[22] one of which underwent surgery alone and the other surgery plus adjuvant irradiation. This observation may reflect the fact that most of the patients underwent complete resection (100% with stage II disease and 85% with stage III disease); as has been pointed out by the study authors, the recurrence rates they found were lower than in previous reports.

Although some studies showed no benefit from adjuvant RT,[12,13,154,201] the recurrence rates of surgery alone, even with complete resection, may approach 30%.[121,136] A SEER study of 901 patients showed a 10% absolute improvement in 5-year OS rates but no statistical difference in cause-specific survival rates in patients with stages II to III disease.[201] Conversely, another SEER study of 476 patients with stage III disease saw

improved DFS but not OS in patients receiving adjuvant RT.[202] In a study of 141 patients with thymoma, Nakahara et al reported a 5-year survival rate of 92% for patients with stage II disease and 88% for patients with stage III disease who were treated with postoperative irradiation.[139]

Histology may impact the role of adjuvant irradiation. A series of 188 patients with type B3 thymoma found that Masaoka stage and adjuvant radiation were independent prognostic factors for OS in patients with stages III and IV.[203] After complete resection, invasive thymomas still carry a poorer prognosis than noninvasive tumors.[50,204,205] Survival rates continue to fall with long-term follow-up.[140] The 5-year and 10-year survival rates for well-encapsulated thymomas without invasion are more than 90%, and for invasive thymomas, the rates range from 30% to 70%.[6,121,133,139] The 5-year survival rates according to Masaoka stage are 83% to 100% for stage I disease, 86% to 98% for stage II disease, 68% to 89% for stage III disease, and 50% to 71% for stage IV disease.[22,133,206,207] The approximate 10-year survival rates are 80%, 78%, 47%, and 30%, and the 15-year rates are 78%, 73%, 30%, and 8% for stages I to IV, respectively.[207] Table 46-3 provides a summary of treatment results.

In cases with gross fibrous adhesions of the tumor to the pleura at the time of surgery or microscopic invasion of the pleura on histologic studies, there is an increased risk for recurrence. Haniuda found that patients with fibrous adhesion to the mediastinal pleura without microscopic invasion benefited most from postoperative radiation therapy.[210,217] The recurrence rates, with and without adhesion to the mediastinal pleura, were 36% and 0%, respectively. In another study,[218] patients with resected stage II thymoma had recurrence rates of 8% and 29%, respectively, with and without adjuvant radiation therapy. Although postoperative radiation therapy may decrease local recurrence, it does not appear to decrease the incidence of subsequent pleural dissemination that may occur outside of radiation fields; in fact, the pleura is the most common site of failure after radiation.[214] This may be a reflection of the natural pattern of spread of this disease. Extended radiation fields to include the entire pleura significantly increases the normal tissue toxicity and is not routinely employed.

Anecdotal studies have demonstrated good local control of thymomas treated with primary irradiation. Of 23 patients treated with irradiation alone, 8 had complete regression, 10 had partial regression, and 5 had no regression of disease.[49] In a report by Marks et al, tumor was controlled in all nine cases treated with megavoltage irradiation.[219] The average follow-up was 5.5 years (minimum, 30 months). Ariaratnam et al observed tumor control in 8 of 11 patients with malignant thymoma with a minimum follow-up of 2 years.[220] Two of the three patients who died had received only 30 Gy in 3 weeks to the mediastinum. Overall, irradiation as monotherapy may result in local control rates of approximately 65% and 5-year survival rates of 40% to 50%.[205,211,221]

With the increasing availability of proton radiation therapy, there is a potential for an improved therapeutic ratio in radiation therapy for thymomas by taking advantage of the proton dose distribution. Figura et al present a case of stage III thymoma treated with adjuvant radiation, showing that compared with intensity-modulated radiation therapy (IMRT), proton radiation lowered esophageal dose by 55%, heart dose by 28%, lung dose by 37%, and generalized normal tissue dose by 59%.[222] However, there was a 27% (1.9 Gy) increase in breast dose. Although dedicated studies of thymoma are lacking, multiple studies evaluating tumors in the mediastinum have found lower doses to normal structures, including heart, spinal cord, esophagus, and whole-body radiation dose with the use of protons.[223-225]

Locally Advanced Thymoma and Palliation

For patients with stage III to IV disease, the evidence supporting the use of postoperative radiation therapy is robust. Urgesi et al reported no in-field recurrences in a study of 33 patients with completely resected stage III thymoma treated with postoperative irradiation.[135] Curran et al reported a 53% 5-year actuarial mediastinal relapse rate in patients with stages II and III disease after surgery alone, compared with 0% after total resection and irradiation and 21% after subtotal resection or biopsy and irradiation.[226] Similarly, in a study of 70 patients with Masaoka stages III to IV thymoma, the relapse rate for patients receiving postoperative radiation therapy was reduced from 50% to 20%, and most disease (80%) recurred outside of the irradiated field.[227]

Preoperative radiation therapy has been advocated for unresectable or marginally resectable thymomas.[49,228-230] Several small studies assessing preoperative radiation therapy for extensive disease found a decrease in tumor burden at the time of surgery, with response rates as high as 80%, and described a theoretical decrease in the potential for tumor seeding during surgery.[121,122,209,231] Onuki et al found that a dose of 12 Gy to 20 Gy given to 21 patients with stage III thymomas resulted in a 76% response rate, with more aggressive WHO histologic subtypes having a less robust volume reduction.[231] Preoperative chemoradiation has also been tested in locally advanced thymic tumors with favorable results. Korst et al found that in a group of 22 patients with 71% Masaoka stage III or IV disease with aggressive histology (62% B3 thymoma or thymic carcinoma), two cycles of cisplatin and etoposide concurrent with 45 Gy led to a 77% R0 resection rate and 14% R1 resection rate.[232] These series demonstrated that preoperative irradiation facilitated total or subtotal resection of the invasive thymoma mass by reducing the tumor volume.[228]

Primary radiation therapy as the definitive treatment has been advocated in nonsurgical candidates or patients with unresectable advanced disease. In a study of 12 patients who presented with unresectable tumors and were treated with primary radiation therapy, 7 patients were alive 1 year 8 months to 5 years 1 month later.[233] Similar outcomes were reported for 31 patients with unresectable stage III or IV disease.[234] Five-year survival rates of 53% to 87% and 10-year survival rates of 44% were reported for patients with advanced thymoma receiving irradiation after biopsy only or incomplete resection.[211,221] Urgesi reported the use of radiation therapy alone in 21 patients with intrathoracic recurrences of thymoma.[235] The 7-year survival rate of 70% was similar for those treated with irradiation alone and those treated with surgery and adjuvant therapy. However, the retrospective nature of these studies, small number of patients, differing amounts of clinical disease, and variations in radiation doses and techniques are significant confounding variables.

Preoperative and primary radiation therapy alone has fallen out of favor. Because of the improved response rates to chemotherapy, most patients with advanced disease are treated with a combined-modality approach. Other therapies, such as cryotherapy, have been attempted, and could have efficacy.[236]

Chemotherapy for Thymoma

In general, thymomas are chemosensitive tumors, but chemotherapy is reserved for locally advanced or metastatic disease. However, there are no prospective, randomized trials comparing different chemotherapeutic agents.[205] Platinum-based regimens have commonly been used, with response rates of more than 50% with the application of cisplatin-based combination chemotherapy.[237] Some of the commonly employed combinations are cisplatin, doxorubicin, and cyclophosphamide (PAC),

TABLE 46-3 Summary of Adjuvant Therapy Results of Thymoma

with reported overall responses in excess of 70%,[238-240] and cisplatin, doxorubicin, vincristine, and cyclophosphamide (ADOC).[241] In a study by Fornasiero,[242] 37 patients with stage III or IV thymoma were treated with ADOC, with an overall response rate of 92% and a 43% complete response rate. Loehrer studied 23 patients with localized but unresectable thymomas treated with PAC followed by radiation therapy.[238] The overall objective response rate was 70%, with five complete responders. The estimated 5-year DFS rate was 54%, with a median survival time of 93 months. Multivariate analysis demonstrated that chemotherapy was associated with an improvement in OS rates for patients with stages III and IV disease. Similar results with combination PAC have been reported in Taiwan; all responders had overexpression of the topoisomerase 2α gene, but patients with no detectable expression progressed with treatment.[243]

Targeted Agents for Thymoma

Because thymic tumors harbor a number of molecular aberrations, this has encouraged the use of targeted agents.[244,245] Although EGFR overexpression is common in thymic tumors,[246] patient exhibit limited partial and complete response.[247,248] Patients with thymic carcinomas also have higher serum VEGF and bFGF than controls,[96] although patients with thymoma and controls show no difference. However, low response rates have been seen with bevacizumab and erlotinib.[248] Similarly, KIT overexpression has led to testing imatinib, which shows no substantial activity.[249,250] Early case reports with sorafenib and sunitinib show some activity, although this remains to be validated,[251,252] A retrospective series of mTOR inhibitors showed 60% stable disease or partial response, but this remains to be validated prospectively.[253]

Combined-Modality Therapy for Thymoma

The role of chemotherapy as an adjuvant therapy after resection has not been established, but there is anecdotal evidence that combining chemotherapy with irradiation with or without surgery can be effective with acceptable toxicity in selected cases.[254-257] It has also been shown that neoadjuvant chemotherapy and then surgery, followed by additional chemotherapy and irradiation, may improve the resectability and survival rates of patients with locally advanced disease.[257,258]

In a Phase II study of 22 patients with unresectable thymoma treated with induction PAC resection, adjuvant irradiation, and consolidative chemotherapy, there was a 77% response rate to chemotherapy, a 95% 5-year OS rate, and a 79% 7-year OS rate.[240] A trial from the Japanese Clinical Oncology Group reported on 23 patients with unresectable stage III thymoma treated with weekly dose-dense cisplatin, vincristine, doxorubicin, and etoposide and found no deaths from toxicity, but only 57% were able to complete chemotherapy as planned.[259] Thirteen of the patients were able to undergo resection, with nine R0 resections. With a 62% response rate, efficacy of the dose-dense regimen was no better than with conventional chemotherapy.[238,240]

In a study by Macchiarini, all 7 patients with stage III invasive thymoma treated with neoadjuvant cisplatin, epirubicin, and etoposide were able to undergo surgical resection.[256] Four had complete resections, and three had incomplete resections. Shin reported that 9 of 11 patients with unresectable stages III and IV thymoma were able to undergo complete resection after induction chemotherapy consisting of cyclophosphamide, doxorubicin, and cisplatin.[255] All 9 patients were given additional postoperative radiation therapy and chemotherapy. Of these patients, 7 were disease free at a median follow-up time of 43 months. Wright reported on 10 patients with stages III to IVA thymoma treated neoadjuvantly with two cycles of cisplatin and etoposide and concurrent irradiation followed by surgery.[260] Eight patients had R0 resections, and the 5-year survival rate was 69%.

Treatment of Thymic Carcinoma

Although the optimal treatment of thymic carcinoma is unclear, surgical extirpation remains the cornerstone of therapy, and in most published studies, surgery has been followed by adjuvant radiation therapy.[20,66,261-263] Because many series are gathered over decades, it has been difficult or impossible to control for the changes in pretreatment tumor imaging, surgical techniques, and thoracic radiation therapy planning and delivery, all of which may contribute to the inconsistent results in the literature. A prescriptive dose range has yet to be identified, with most studies using 40 Gy to 70 Gy at 1.8 Gy to 2 Gy per fraction, but in general, doses of 45 Gy to 55 Gy are used in the adjuvant setting, whereas 60 Gy or more is used for definitive irradiation. Although a survival benefit has not been seen, there is a trend toward improved survival and local control rates with adjuvant therapy.[20,262] No dose-related survival advantage has been established, although a relationship between dose and local control rates has been demonstrated.[264]

In a series of 26 patients treated with surgery and postoperative irradiation, Hsu et al observed a 77% 5-year OS rate,[262] with respective 82% and 66% survival rates for completely resected and subtotally resected cohorts. With a median dose of 60 Gy (range, 40 Gy to 70 Gy), an excellent 5-year local control rate of 91% was observed. For a cohort of 40 patients receiving definitive or adjuvant radiation therapy, Ogawa et al reported an absence of local recurrence for those with complete resection and radiation doses greater than 50 Gy.[20] Kondo and Monden reported the largest retrospective,[22] comparative study and found no statistically significant survival benefit from the addition of adjuvant irradiation to surgical resection, although no definitive conclusions could be made because of subgroup sample size limitations and the retrospective nature of the study.

Although local control rates are increased with irradiation, a survival benefit remains to be demonstrated. For patients with any question of clinical resectability, neoadjuvant platinum-based chemotherapy is a reasonable treatment consideration.[265] For patients with early stage cancer with completed resected disease, there is some thought that adjuvant radiation is not indicated.[266] Table 46-4 summarizes some of the treatment results of thymic carcinoma.

Treatment of Thymic Carcinoid

Complete surgical resection is the preferred method of treatment, although recurrence and distant metastases are common.[22,272,273] A SEER analysis of 160 patients found that the median survival time was 79 months in patients who had surgical resection compared with 26 months in those who did not have surgery.[273] Patients who received irradiation had a worse OS rate, but patients who received irradiation were more likely to have advanced disease. In a study of 40 patients, the recurrence rate was 64%, even though 35 of the 40 patients had a complete resection,[22] and the 5-year survival rate was 84%. Despite a lack of conclusive evidence, incomplete resections followed by irradiation or chemotherapy, or both, may improve local control rates without significantly increased morbidity and mortality rates.[58,126,274,275] However, distant metastases occur in approximately 30% of patients.[276] The long-term prognosis is poor, with an overall 5-year survival rate of 0% to 31%.[272,277]

Techniques of Irradiation

High-energy (>10-MV) x-rays usually are preferred for irradiation. A CT scan is indispensable for adequate treatment planning. Clips placed at the time of surgery denoting the extent

TABLE 46-4 Summary of Thymic Carcinoma Treatment Results

Study	Year	No. Patients	Treatment	Radiation Therapy Dose	Local Control Rate (%)	5-year OS	Comments
Blumberg et al[66]	1998	43	TR/SR ± Ch/RT	—	52 (CR)	65% (35% at 10 years) 68% (TR) 62% (SR)	Masaoka stage was not prognostic, but invasion of innominate vessel was prognostic
Chang et al[261]	1992	16	TR/SR/BX ± Ch/RT		77	31% (median, 30 mo)	Better survival rate was seen with squamous type
Hsu et al[262]	2002	26	TR/SR ± RT	40 Gy-70 Gy	91 (OS)	77% (OS) 82% (TR) 66% (SR)	Masaoka stage was prognostic; very good local control rate observed with surgery + RT
Kondo and Monden[22]	2003	186	TR/ST/BX ± Ch/RT	—	49 (TR)	50.5% (OS) 66.9% (TR) 30.1% (SR) 24.2% (BX) *Subgroups:* 72.2% (TR alone) 73.6% (TR + RT) 46.6% (TR + Ch/RT) 81.5% (TR + Ch)	Largest number of patients gathered from multiple institutions in Japan; total resection was the most important factor in survival rate; RT did not improve results for completely resected tumors
Liu et al[267]	2002	38	TR/SR/BX ± Ch/RT	—		27% (MS, 24 mo)	Grade, stage, and resectability were predictors of survival rates
Lucchi et al[265]	2001	13	TR/SR ± Ch/RT	45 Gy-60 Gy	46 (OS)	61% (MS, 38 mo)	100% objective tumor response with induction chemotherapy but small study
Nakamura et al[268]	2000	10	BX + Ch ± RT	6 Gy-56 Gy	0	0% (MS, 11 mo)	Poor survival rate for unresectable disease; median chemotherapy response was only 6 mo
Ogawa et al[20]	2002	40	TR/SR/BX ± Ch/RT	10 Gy-70 Gy (mean, 50 Gy)	100 (TR + RT)	38% (28% at 10 years)	Long-term study; better survival and local control rates with complete resection + RT (12 of 16 patients versus 1 of 24 patients)
Shen et al[216]	2013	43	TR/SR ± Ch/RT	45 Gy-64 Gy (mean, 51.4 Gy)		61% at 7 years	Thymic carcinomas are more likely to present with advanced Masaoka stage than thymoma
Roden et al[269]	2013	29	TR/SR/BX ± Ch/RT	—		36%	Weight loss is associated with worse survival
Okereke et al[270]	2012	16	TR/SR ± Ch/RT	—	88	63% (MS, 57 mo)	Long-term survival can be achieved with R0 resection
De Montpreville et al[271]	2013	37	TR/SR/BX ± Ch/RT	—		67% at 3 years (MS, 94 mo)	Lymph node dissection should be systematic when resection is performed

of resection in completely resected tumors or outlining regions of residual disease are useful in guiding postoperative irradiation. The planning target volume (PTV) should include the gross tumor volume (GTV) and the thymus, if any, and the tumor bed with a 1.5-cm to 2-cm margin. A four-dimensional breathing scan, if available, should be used to determine tumor motion and can be used to create an internal target volume (ITV) or to plan for radiation-coordinated breathing control, which can provide superior sparing of normal lung.[278] Areas of suspicious subclinical disease and regional lymphatics are commonly included in the field. However, treatment of the entire mediastinal and supraclavicular nodal basin prophylactically is not advised because of the low incidence of lymph node involvement and a higher normal tissue complication rate.[279,280] A SEER database analysis of 1334 patients from 1973 to 2005 by Fernandes et al found no increase in long-term cardiac mortality rates or rates of secondary malignant tumors for patients treated with RT compared with patients treated with surgery alone.[281]

Conventional port arrangements may include two opposed anteroposterior ports (weighted 2:1 or 3:2), wedged-pair techniques, and other multiple-field arrangements. Given the advanced technical capabilities available, three-dimensional conformal RT (3DCRT) or IMRT should be considered to provide dose homogeneity and allow better sparing of normal critical structures. Figure 46-5 shows a postoperative radiation therapy field with multileaf collimators shaping the surgical tumor bed. Figure 46-6 shows a plan with IMRT. The isodose lines more closely conform to the PTV. The risks of side effects depend on normal tissue tolerance, surrounding critical organs, prior treatments, irradiation dose, other concurrent therapies, and the general health of the patient.

Various dose and fractionation schemes for thymoma have been reported.[205,282] Although one retrospective study did not find any relationship between radiation dose and local control rates,[209,264] others have found that radiation dose was a significant prognostic factor for local control, with good results reported when doses higher than 40 Gy were used for subclinical disease.[213,283] Retrospective data from Zhu found a 5-year survival rate of 82% in patients given greater than 50 Gy,[215] compared with 70% for doses less than or equal to 50 Gy. The most important prognostic factors were Masaoka stage and extent of resection.

Postoperative doses of 45 Gy to 55 Gy given by conventional fractionation have been used effectively in most cases.[121,136,202,214,235] The dose to the spinal cord should be limited to 45 Gy and can be accomplished using oblique mediastinal fields or IMRT. For patients with gross residual disease, doses of 60 Gy or more are probably required,[213,234] but higher doses correlate with higher risks of complications.[284] IMRT may facilitate delivery of high doses to gross tumor while respecting dose limits to organs at risk.[285]

Treatment Algorithm and Controversies

The initial treatment for thymic tumors is surgery if the disease is resectable. Adjuvant irradiation or chemotherapy should be considered for patients with features indicating a high risk for recurrent disease and those with an unresectable or inoperable tumor. Optimal treatment must be customized, and the following guidelines should be considered:

1. Pathologic stages I to II thymoma (WHO types A, AB, B1, B2, B3) should not receive adjuvant therapy after a complete thymectomy (R0 resection, negative margins). Adjuvant RT may be considered in patients with B2 and B3 disease. If observation without RT is decided on, patients with B2 and B3 disease should be closely observed with biannual or annual CT scans.
2. Patients with pathologic stage II thymoma (WHO types A, AB, B1, B2, B3) with less than a complete thymectomy (as outlined in guideline 1) may benefit from postresection thoracic irradiation. A dose of 50 Gy to 66 Gy (depending on the amount of residual disease) can usually be safely administered.
3. Pathologic stage II thymic carcinoma (WHO type C) can be treated with multimodality adjuvant therapy, which includes concomitant chemoradiation with or without

consolidation chemotherapy after a complete thymectomy (R0 resection, negative margins).

4. Pathologic stages III to IVA thymic neoplasms (WHO types A, AB, B1, B2, B3, C) are treated with multimodality adjuvant therapy (as outlined in guideline 3) even after a complete thymectomy (R0 resection, negative margins).
5. Clinically unresectable stages III to IVA thymic neoplasms are treated with neoadjuvant chemoradiation, followed by sequential thymectomy, postoperative thoracic irradiation, and consolidation chemotherapy.

PULMONARY CARCINOID TUMORS

Neuroendocrine lung tumors have a spectrum of clinical behaviors and include typical carcinoids (the most indolent type), atypical carcinoids, large cell neuroendocrine tumors, and small cell lung carcinomas (the most aggressive type).[286] The term *carcinoid* was originally defined as a carcinoma-like lesion without malignant characteristics by Oberndorfer in 1907.[287] Pulmonary carcinoids used to be known as bronchial adenomas because they were believed to be benign, but they are now recognized as malignant because of their potential to metastasize. Pulmonary or bronchial carcinoid tumors are typically low-grade malignant neoplasms that arise from neuroendocrine cells of the amine precursor uptake and decarboxylation (APUD) system that have migrated from the embryonic neural crest. These cells are the Kulchitsky (enterochromaffin) cells, which are located in the basal layer of bronchial epithelium.[288,289] Approximately 25% of carcinoids are located in the respiratory tract, which is the second-most common site after the gastrointestinal tract. Pulmonary carcinoids are frequently centrally located and confined to the main or lobar bronchi.[290] These tumors are rare, and their biologic behavior mostly depends on their histologic characteristics.

Etiology and Epidemiology

The cause of pulmonary carcinoid is unknown, and no environmental risk factors have been identified. Carcinogens that are associated with lung cancer have not been consistently associated with pulmonary carcinoids,[291] although a few studies revealed a higher frequency of smokers with atypical carcinoids.[292-294] Some of the neoplastic cells express mutant retinoblastoma *(RB1)* or mutant *TP53* gene products, and they show occasional loss of heterozygosity, especially in atypical carcinoids.[295] In atypical carcinoids, there is also a high frequency of molecular alterations and inactivation of tumor suppressor genes, such as the *TP53, RB1, CDKN2A* (previously designated *p16*), and *CDKN2D* (previously designated *p19*) genes. Most familial pulmonary carcinoids have been reported in patients with multiple endocrine neoplasia type 1 (MEN 1). In cases of atypical and typical lung carcinoids, there is a characteristic allelic loss within the region of 11q-13, which harbors the *MEN1* gene, a tumor suppressor gene.[296-300] Other frequently detected genetic alterations in lung carcinoids, especially atypical carcinoids, include losses of 3p, 5p, 9p, 10q, and 13q.[297,300] Ki-67 expression in more than 5% of nucleoli is a poor prognostic factor for survival.[301]

The annual incidence of carcinoid tumors is one or two cases per 100,000 people in the United States.[2,291] For

bronchopulmonary carcinoids, improved diagnostic tools have led to an increase in incidence from 0.6 to 1.35 per 100,000 people/year.[3,302] Carcinoid tumor of the lung represents about 3% of all lung malignant tumors, with an equal frequency in men and women,[3,291] approximately 3500 new cases were reported in 2004.[303,304] Bronchial carcinoids are the most common primary lung tumor in children, typically presenting in late adolescence. Typical carcinoids are about four times more common than atypical carcinoids. Data from the SEER program of the National Cancer Institute have shown a trend of relative increase of pulmonary carcinoids.[291,302]

Prevention and Early Detection

There is no known preventive measure for pulmonary carcinoids. Carcinoids are detected like other space-occupying tumors. The most common findings on a chest radiograph include a hilar mass with occasional atelectasis. Functioning carcinoids are suspected on the basis of the symptoms and signs, and the diagnosis is confirmed by demonstrating increased urinary excretion of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA). Thyroid transcription factor-1 is expressed in 80% of metastatic pulmonary carcinoids but not in intestinal carcinoids, and it may be of value in the workup and diagnosis of pulmonary carcinoids.[305,306]

Biologic Characteristics and Molecular Biology

Carcinoid tumors occur sporadically and are thought to arise from neuroendocrine cells. The WHO classification of lung neuroendocrine tumors describes two different subtypes of carcinoids, typical and atypical, with distinctive clinical behaviors and different prognoses.[304,307] Based on the criteria proposed by Travis,[286,307] the spectrum of neuroendocrine tumors also includes large cell neuroendocrine carcinoma and small cell lung carcinoma.

Although most pulmonary carcinoids are nonfunctional, some secrete a variety of physiologically active substances, leading to paraneoplastic syndromes, including carcinoid syndrome, Cushing's syndrome, and acromegaly.[288] Serotonin (5-hydroxytryptamine [5-HT]) is a frequently encountered vasoactive substance released by carcinoid tumors. Other substances, including corticotropin, histamine, dopamine, substance P, neurotensin, prostaglandins, and kallikrein, have been reported.[308-313]

The biologic behavior of these tumors varies depending on the histologic characteristics. Typical carcinoid tumors of the lung have a better prognosis than other primary lung cancers, with a 5-year survival rate greater than 90%. For atypical carcinoids, 5-year survival rates range from 25% to 75%.[314-319]

A population-based study of more than 1400 patients from Europe showed a 5-year OS rate of 78% for pulmonary carcinoids as a whole.[320] Although typical carcinoids have an indolent clinical course, atypical carcinoids behave more aggressively, with nodal involvement in 20% to 60% of cases and a higher rate of distant metastases. Figure 46-7 shows a right-sided hilar atypical carcinoid tumor with associated mediastinal adenopathy. The recurrence rates and stage at presentation are higher than for typical carcinoids. The proliferation rates, as assessed by MIB-1 and Ki-67, are also higher than for typical carcinoids.[304,321,322]

Pathology and Pathways of Spread

Carcinoids are thought to be derived from different embryonic divisions of the gut and are classified accordingly. Foregut carcinoids are often found in the lungs, bronchi, and stomach,

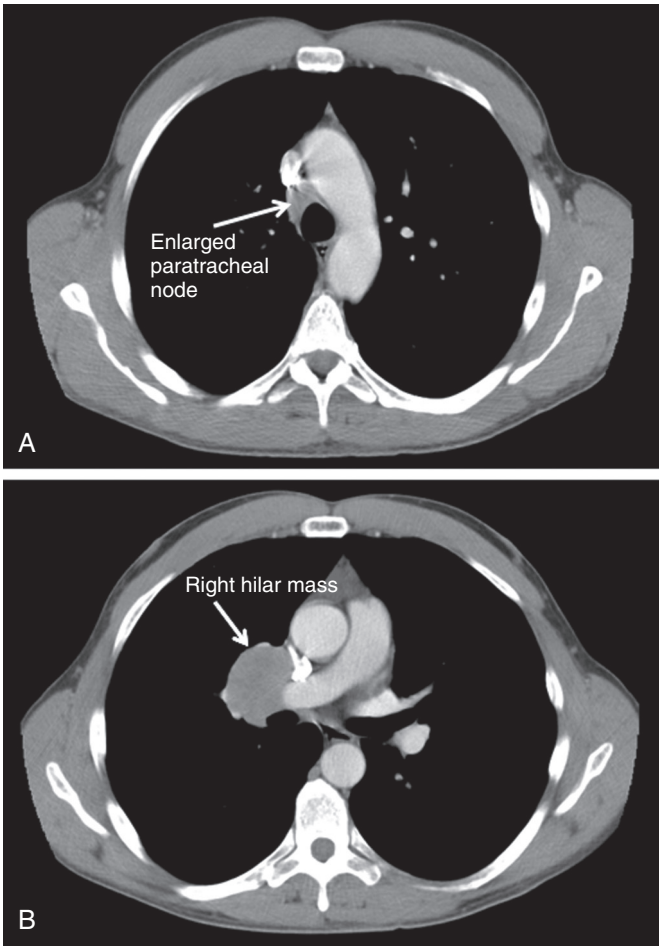

Figure 46-7 Atypical carcinoid. **A,** The preoperative CT scan shows a right hilar mass. **B,** There was also right paratracheal adenopathy. Lymph node involvement is seen more commonly in atypical carcinoid than typical carcinoid.

and midgut and hindgut tumors are seen in the small and large intestines. Histologically, they may stain positive with silver or Grimelius stains, cytokeratin 7 and 11, neuron-specific enolase, synaptophysin, carcinoembryonic antigen, and chromogranin; there is no marker exclusive to carcinoids, however.[305,321,323] Microscopically, they are characterized by small uniform cells and the presence of numerous membrane-bound, neurosecretory eosinophilic granules containing a variety of hormones and biogenic amines in the cytoplasm. Most pulmonary carcinoids (70% to 90%) are typical carcinoids or well-differentiated neuroendocrine tumors, which are characterized by small cells with well-rounded nuclei; atypical carcinoids (10% to 30%), or poorly differentiated neuroendocrine tumors, have malignant histologic features of increased nuclear atypia with high mitotic activity (more than two mitoses per 10 high-power fields), lymphovascular invasion, nuclear pleomorphism, and areas of necrosis.[307,323-326]

It is sometimes difficult to establish the specific diagnosis of carcinoid because of small biopsy samples or to differentiate atypical carcinoid from small cell lung carcinoma without immunohistochemical tests.[307,327-329] Well-differentiated carcinoids are often indolent, with a relatively low risk of nodal or distant metastasis of 3% to 15%.[303,326,330-332] Atypical carcinoid may have an aggressive clinical course, with frequent organ metastases.[295,333,334] The risk of nodal metastasis, frequently to mediastinal lymph nodes, is 30% to 57%.[303,335,336] Distant

metastases occur in more than 20% of patients.[303] The most common sites of distant metastasis include liver, bone, adrenal glands, brain, skin, and soft tissue.[304,317,337-339]

Clinical Manifestations, Patient Evaluation, and Staging

Median age at diagnosis for pulmonary carcinoid tumors is around 64 years.[3] Carcinoids in children are rare.[340] Between 70% and 80% of these tumors are located centrally near the hilum within the tracheobronchial tree and may produce a variety of clinical symptoms and neuroendocrine manifestations.[341,342] About 25% of patients present with symptoms such as recurrent pneumonia, cough, hemoptysis, or chest pain. Carcinoids are vascular tumors and can bleed secondary to bronchial irritation. Hyperparathyroidism may be seen. At least 50% of pulmonary atypical carcinoid tumors present in the periphery of the lung.[343] Patients with peripheral lesions may be asymptomatic, and their lesions are usually discovered incidentally.[319,344]

Carcinoids may produce various amines and polypeptides with corresponding signs and symptoms, often precipitated by emotional upset, food ingestion, or alcohol. The serotonin metabolite 5-HIAA, which is excreted in urine, acts on smooth muscle to produce bronchoconstriction or diarrhea, colic, and malabsorption. Histamine and bradykinin, through their vasodilator effects, cause flushing. The release of such vasoactive substances into the systemic circulation can cause the *carcinoid syndrome*, characterized by episodic flushing, typically of the head and neck; asthmatic wheezing; abdominal cramps with recurrent diarrhea resulting in malabsorption syndrome; and valvular heart disease, including right-sided endocardial fibrosis, leading to pulmonary stenosis and tricuspid regurgitation.[345] Bronchial carcinoids generally have low serotonin content because the tumor cells lack the aromatic amino acid decarboxylase enzyme and cannot make serotonin and its metabolites. Hence, the secretion of 5-hydroxytryptamine (5-HTP) is increased and 5-HIAA urinary excretion is normal. Lesions of the left side of the heart, which have been reported with bronchial carcinoids, are rare because serotonin is destroyed during passage through the lung. Some patients complain of decreased libido and impotence. However, the incidence of carcinoid syndrome or other paraneoplastic syndromes, including Cushing's syndrome and acromegaly, is no more than 3% to 5% of cases, and these syndromes mainly occur in patients with larger tumors (>5 cm) or metastatic disease.[346] Paraneoplastic syndromes in the absence of lymph node or distant metastases do not affect the prognosis.[344,347] Levels of human chorionic gonadotropin and pancreatic polypeptide are occasionally elevated.

Patients with a suspected lung mass require a thorough history and physical examination. Routine blood tests and chemistry tests may give clues to the presence of associated syndromes (Table 46-5). The differential diagnosis, in addition to bronchopulmonary carcinoid, includes lung carcinoma and metastasis from an extra-pulmonary primary tumor. CT and bronchoscopy are two of the most valuable diagnostic procedures. Up to 80% of carcinoids manifest with type 2 somatostatin receptors, and the receptors can be targeted by radioactive octreotide or pentetreotide. Somatostatin receptor scintigraphy with indium-111–radiolabeled octreotide (^{111}In-octreotide) has demonstrated reliable uptake in primary tumors and been used to detect early recurrence.[348-350] FDG-PET scans are often normal.[9,10,292,351]

Transbronchial biopsy or CT- or ultrasound-guided fine-needle aspiration biopsy may establish the diagnosis. Bronchoscopy, video-assisted thoracoscopic surgery, or mediastinoscopy may help yield a diagnosis before resection, especially if enlarged lymph nodes are present. Three-quarters of bronchopulmonary carcinoids are centrally located and are amenable to a bronchoscopic biopsy.

The prognostic factors are atypical histologic findings, staging, and the presence of symptoms at the time of presentation.[340-342,348,351] A high mitotic rate, tumor size larger than 3.5 cm, and female gender have also been implicated as prognostic factors for patients with atypical pulmonary carcinoids.[293] There is no specific staging system for pulmonary carcinoids, but the AJCC lung cancer staging system (TNM) is commonly used. In an analysis of 513 carcinoid tumors from the International Association for the Study of Lung Cancer (IASLC) and 1619 cases from the SEER database, TNM staging was found to correlate with survival.[353]

Treatment

Primary Therapy

Curative resection is the treatment of choice.[304,338,339,354,355] After complete resection, the long-term results are generally excellent.[303,338,341,354] Conservative surgical resection, consisting of wedge or segmental resection, is the preferred therapy for localized pulmonary carcinoids.[356,357] Patients with central lesions may require bronchial sleeve resection or sleeve lobectomy.[355] Endoscopic laser ablation is not considered curative but may be used to alleviate tumor obstruction, improve atelectasis, and reduce inflammation before resection.[331] Intraoperative nodal evaluation should be performed, and if the

results are positive, complete nodal dissection is indicated. Because of higher rates of local recurrence in patients with atypical carcinoids, a more extensive surgical procedure, such as lobectomy or pneumonectomy with nodal dissection, should be considered.[304,338,339,356] Patients may present with metastatic or unresectable disease, however, and curative resection may not be obtainable. Debulking and other cytoreduction procedures may be of benefit in gastrointestinal carcinoids,[358,359] but these procedures are of uncertain benefit for patients with pulmonary carcinoids.

Medical Treatment

Certain symptoms, including flushing, can be relieved by pharmacologic agents. Ondansetron, one of the specific 5-hydroxytryptamine-3 (5-HT3) antagonists, provides sustained symptomatic relief in patients with carcinoid syndrome.[360] Somatostatin analogs are potent inhibitors of neuropeptide release and gut exocrine or endocrine function. These analogs are effective in relieving symptoms by binding to somatostatin receptors (mainly, receptor 2),[361] which are present in approximately 80% of carcinoids, leading to inhibition of hormone secretion.[362,363] Octreotide and lanreotide, long-acting analogs of somatostatin, are the drugs of choice. The response rate is about 70% for symptomatic improvement, and there is a more than 50% reduction in urinary 5-HIAA secretion, with a median duration of response of 12 months. Data suggest that these somatostatin analogs may have a direct antitumoral effect, with stabilization of tumor growth and reduction of tumor size in patients with carcinoids of various sites.[361,362]

More recently, peptide receptor radionuclide therapy with radiolabelled somatostatin analogues have shown promise in clinical trials. 90Y-DOTATOC (90Y-edotreotide) has an yttrium-90 (90Y) atom with high binding affinity for somatostatin receptors.[364] Two trials with 39 and 90 patients with progressive/metastatic neuroendocrine tumors have shown symptom improvement in 63% to 74% of patients, although it is unclear what the response rate would be in pure bronchial carcinoid.[365,366] 177Lu-DOTATATE (177Luoctreotate) can be given therapeutically but also can be used for imaging and dosimetry after therapy.

Radiation Therapy

There are no prospective trials that address the use of adjuvant therapy for patients with bronchopulmonary carcinoids. In general, typical carcinoids do not require adjuvant radiation therapy or chemotherapy after curative resection.[303,338,341,354,367] A series of 25 patients (12 typical and 13 atypical tumors) with node-positive bronchial carcinoids treated at the Memorial Sloan Kettering Cancer Center (MSKCC) found no survival benefit from postoperative radiation therapy.[290] Recurrence and survival rates appeared to depend on cell type rather than nodal status. In another study of 163 patients (including three fourths of patients with typical carcinoids, most of which were stage N0), however, the prognosis depended on the presence and extent of nodal involvement rather than histologic subtype.[318] The role of adjuvant radiation therapy is unsettled because of the retrospective nature of studies and the small number of patients.[293,333,368] However, adjuvant radiation therapy has been used in patients at high risk for locoregional recurrence, including those with large tumor size (>3 cm), positive nodes, positive margins, atypical histologic findings, residual disease, and inoperable disease.[326,333,368,369]

Palliative radiation therapy can be considered in patients with metastatic typical or atypical pulmonary carcinoids. Tumor-targeted irradiation with radioactive somatostatin analogs (^{111}In-octreotide or ^{131}I-metaiodobenzylguanidine [^{131}I-MIBG]) has been used, often as second- or third-line therapy.[369-371] The results are inconclusive, with occasional long-term survivors reported.

Chemotherapy

Unlike chemotherapy for small cell lung cancer, systemic chemotherapy has produced only limited success in patients with metastatic carcinoid tumors.[369] Although no effective chemotherapeutic regimen has been established, aggressive treatment with adjuvant systemic chemotherapy is recommended in high-risk patients with stage III atypical or metastatic carcinoid.[335] Several trials have shown response rates of 21% to 33% with various combinations of doxorubicin, streptozocin, cyclophosphamide, etoposide, and fluorouracil in patients with metastatic carcinoids.[335,372-375] Patients with atypical carcinoids treated with cisplatin and etoposide appear to have a higher response rate than patients treated with other regimens.

Targeted Agents

mTOR mutations occur in about 15% of pancreatic neuroendocrine tumors.[376] Everolimus, an oral mTOR inhibitor, is approved for use in advanced pancreas neuroendocrine tumors.[377] Everolimus plus octreotide was tested for advanced carcinoid tumors, and appeared to improve progression-free survival (PFS). Neuroendocrine tumors exhibit angiogenesis and increased vascularity.[378] Bevacizumab and sunitinib have been tested in advanced neuroendocrine tumors, with bevacizumab exhibiting a more favorable toxicity profile.[379-382] Although Phase II data has been encouraging, Phase III data are pending.[379,383]

Locally Advanced Disease and Palliation

For patients with locally advanced or metastatic disease, surgery is generally limited to those whose metastases are confined to one site amenable to local resection.[359,384] Radiation therapy has been used successfully to palliate symptoms in patients with locally advanced or metastatic disease.[385] Local control and symptomatic relief can be achieved in most patients with 4000 cGy to 5000 cGy. Endoscopic resection and laser photoablation have been used for palliation of symptoms.[331] Somatostatin analogs alone or in combination with chemotherapy or interferon-alpha may be considered for symptomatic treatment or tumor stabilization.[386]

Results of Therapy

Patients with typical carcinoid tumors treated with surgery alone have a good outcome. However, patients with atypical pulmonary carcinoid tumors and regional lymph node metastases are at high risk for recurrent disease and have worse survival rates when they are treated with surgical resection alone.[334] The 5-year OS rate ranges from 78% to 100% for all resected pulmonary carcinoids, 90% to 100% for typical carcinoids, 25% to 69% for atypical carcinoids, and 18% to 38% for metastatic carcinoids.[330-332,334,336,339] Ten-year rates are 10% to 20% lower than 5-year rates. Some of the published results are summarized in Table 46-6. Although the role of adjuvant radiation therapy as part of multimodality treatment is undefined, adjuvant irradiation may improve the outcome of high-risk patients with atypical carcinoid tumors, positive nodes, or positive margins.[337] The National Comprehensive Cancer Network (NCCN) recommends adjuvant therapy for stages II and III atypical carcinoids.[387]

Irradiation Techniques

The same general principles of thoracic irradiation apply to irradiation of pulmonary carcinoids. High-energy (>10-MV) x-rays are preferred with a CT scan for treatment planning. As in treating other tumors, surgical clips denoting the extent of

resection or outlining regions of residual disease are useful in guiding postoperative irradiation. The PTV should include the gross or residual tumor volume and tumor bed with a 1.5-cm to 2-cm margin. Depending on the histologic and surgical findings, areas of suspicious subclinical disease and regional lymphatics are included. Treatment field arrangements may resemble the typical lung tumor fields. There are no consistent guidelines regarding dose and fractionation regimens. Postoperative doses of 45 to 58 Gy delivered in 1.8 Gy to 2 Gy per day have been reported (see Table 46-6). For patients with gross residual or unresectable disease, a higher total dose may be justified as long as the dose to other critical structures does not exceed the tolerance of normal tissues.

Treatment Algorithm and Controversies

Surgery is the primary treatment for typical and atypical pulmonary carcinoids. Although conservative resection has resulted in low recurrence rates and excellent long-term survival rates for patients with well-differentiated pulmonary carcinoids, the adequacy of such resection in patients with atypical carcinoids has not been settled. More extensive surgical procedures, with higher treatment-related morbidity rates, have been advocated by some investigators.[335,393] Adjuvant radiation therapy or systemic chemotherapy may be considered even for patients with early-stage disease because of the high incidence of regional and distant failure.[333] Palliative irradiation should be considered for those with symptomatic disease.

MESOTHELIOMA

MPM is an aggressive malignant disease, and local disease progression is the main cause of symptoms and death. Disseminated disease is usually reported only very late in the course of MPM.[394-398] MPM spreads by direct extension and seeding throughout the pleural space, including fissures, diaphragmatic and pericardial surfaces, through the chest wall, and into the mediastinum, peritoneum, and lymph nodes. The major problem for patients with MPM is poor local disease control in the thorax. Aggressive surgery alone, even in carefully selected patients with early-stage disease, has not improved the 2-year survival rate of 10% to 33%.[396,397,399] Combined-modality treatment suggests improved local control and survival rates,[399-401] but local recurrence is still the most common site of first relapse.[402]

Even after EPP, the diffuse nature of most malignant mesotheliomas and the manipulation of the exposed tumor during surgery put the entire ipsilateral chest cavity, diaphragm insertion, pericardium, mediastinum, and bronchial stump at high risk for local recurrence. The hemithorax and mediastinum have an irregular shape and are adjacent to critical structures, such as the spinal cord, liver, kidneys, esophagus, heart, and contralateral lung. Conventional irradiation of the hemithorax and mediastinum is limited by the ability of these organs to tolerate radiation[397,402,403] and by the total volume of tissue being irradiated.

Etiology and Epidemiology

MPM has an incidence of approximately 10 cases per million people per year in the United States.[404] The incidence has been increasing and represents a significant clinical problem in populations exposed to asbestos. The Center for Lung Cancer and Related Disorders estimates approximately 3000 new cases of MPM per year, with a peak incidence of approximately 4000 per year expected to occur in about 2025. The incidence is rising as a result of the long latency between asbestos exposure and clinically apparent disease; most cases occur more than 20 years after exposure. The median age at diagnosis is approximately 60 years.

Approximately 90% of mesothelioma cases can be attributed to prior asbestos exposure. This is typically an occupational exposure (e.g., construction work, automotive brake repair, boiler work, shipbuilding), and it explains the approximately 90% male predominance. However, other sources of exposure may include a spouse or parent asbestos worker. Even a history of living near asbestos-using businesses, such as automotive shops (from brake linings) or cement manufacturers (which may have added asbestos), can increase the risk of mesothelioma. Patients from certain regions of the world (e.g., central Turkey, Western Australia) also have endogenous environmental asbestos exposure. There is no direct association between mesothelioma and smoking, but smoking greatly increases the risk when there is also asbestos exposure.[405] Radiation exposure has been shown to be causatively linked to mesothelioma, with an increased incidence identified in adults with previous thoracic radiation treatment.

Clinical Evaluation and Staging

Dyspnea, chest pain, cough, and weight loss are common presenting symptoms of MPM. All patients should be asked about their history of asbestos exposure. Pulmonary function tests demonstrate a restrictive pattern resulting from "trapping" of the lung or chest wall involvement. MPM has a tendency to grow along tracks of previous chest tubes. All sites of previous instrumentation should be identified and examined for evidence of tumor seeding. Such chest wall progression may manifest as pain, a nodule, or an ulcer. Particularly when transthoracic extension is identified, the axillary and supraclavicular lymph nodes should be palpated for involvement. Sometimes, scoliosis can occur because of ipsilateral lung volume loss.

Imaging

A chest radiograph should be used for initial evaluation. Careful attention should be paid to the presence of pleural effusions or calcified pleural plaques. Nodular irregularities often can be identified. Sites of rib tenderness should be evaluated for direct tumor extension, although chest pain is more often attributable to involvement of the endothoracic fascia.

Contrast-enhanced CT of the chest is the mainstay of radiographic staging. Circumferential pleural thickening, an irregular pleural contour, or contraction of the ipsilateral hemithorax are common findings. Invasions of the diaphragm or chest wall are difficult to detect in early cases, so CT may underestimate the extent of disease. Miliary disease can be present on the undersurface of the diaphragm or peritoneum and remain undetected by imaging. MPM tends to manifest late in the disease course, often with large masses and pleural effusions. Pleura-based irregular masses are common, particularly in dependent regions. The interlobar fissures are often involved. MPM can invade adjacent structures, such as the chest wall, mediastinum, great vessels, vertebral body, or heart. Mediastinal and hilar lymph nodes can be involved with tumor, but the pattern of spread is often different from that of non–small cell lung cancers. MPM spreads to the lower paraesophageal nodes (level 8), pulmonary ligament nodes (level 9), and diaphragmatic nodes much more commonly than lung cancers. Pericardial effusions and ascites can also be seen on CT, and they should be evaluated pathologically before any attempt at curative resection. The anteromedial extent of tumor, particularly extension across the midline, should be determined before surgery. Because surgery obliterates the costomediastinal space, the anterior pleural reflection cannot be accurately delineated on postoperative studies.

The utility of MRI in the staging of mesothelioma is controversial. MRI may slightly more accurately predict the extent of invasion into the chest wall, diaphragm, and great vessels. The finding of chest wall invasion should not preclude surgery, however, as long as the region of invasion can be removed with a limited chest wall resection. Invasion to the peritoneal surface of the diaphragm cannot always be appreciated without invasive staging. FDG PET/CT scanning has been applied to mesotheliomas because they tend to avidly take up FDG. Sensitivity and specificity of 90% or more has been reported and is helpful in distinguishing between benign pleural thickening and MPM.[406-408] Furthermore, PET/CT, when compared with CT, in a series of 35 patients, upstaged tumors and therefore prevented unnecessary surgery in 40% of patients.[409]

Invasive Staging

The diagnosis of mesothelioma can be difficult because of the relative rarity of the disease and the cytologic similarity to more common metastatic neoplasms, such as adenocarcinoma. Thoracentesis is often the first procedure performed to obtain diagnosis, but it has a diagnostic sensitivity of only 32%.[410] Percutaneous fine-needle aspiration biopsy similarly has low diagnostic sensitivity, although ultrasound-guided core-needle biopsy has been reported to improve accuracy.[411] Before beginning multimodality treatment, accurate preoperative staging is necessary. Historically, an open pleural biopsy has been the gold standard.[412] More recent data has shown that thoracoscopic biopsy should be the preferred method for obtaining tissue for diagnosis.[413-415] Diagnostic thoracentesis is an alternative, though it has a lower yield than video-assisted thoracoscopic surgery.[416]

Mesothelioma has a tendency to track along sites of chest wall violation, and tumor may recur at previously placed thoracoscopy port sites if they are not excised at the time of definitive surgery. Limiting the number of port sites at the time of video-assisted thoracoscopic surgery and placing the port sites where they are easily excised help to reduce local chest wall recurrence. When it is difficult to establish entrance into the pleural space, it is preferable to perform a limited open biopsy of the parietal pleura by extending the port site incision slightly, rather than to perform a formal thoracotomy. A thoracotomy performed for diagnosis significantly compromises potentially curative surgery.

Unfortunately, preoperative assessment of mesothelioma tumor stage is less than ideal. Although CT, PET, and MRI are reasonably accurate in defining tumor volume within the thorax and chest wall and in identifying sites of distant disease, they are less successful in determining tumor involvement at two critical sites: contralateral mediastinal nodal involvement and tumor invasion through the diaphragm. Tumor involvement at either site negates resection, and therefore an accurate assessment of these areas is necessary before performing EPP. Some experienced clinicians obtain pretreatment laparoscopy with peritoneal lavage and cervical mediastinoscopy in all patients considered for resection. At the M. D. Anderson Cancer Center, of 118 patients with MPM who were clinically and radiographically determined to have resectable disease, laparoscopy and peritoneal lavage revealed transdiaphragmatic or peritoneal involvement in 12 (11%) of 109 patients and mediastinoscopy identified positive contralateral nodes in 4 (4%) of 111 patients. Overall, 15 (13%) patients were identified with occult advanced disease and spared unnecessary EPP.

Staging

The AJCC seventh edition staging system for mesothelioma is shown in Table 46-7 and is based on the International Mesothelioma Interest Group (IMIG) staging system. The staging systems are useful only after surgical staging, and no clinical staging system has been developed.

Several important prognostic markers have been identified for MPM. Metastases to any nodal station predict a worse outcome. However, unlike non–small cell lung cancer, it is not clear that mediastinal metastases reflect a worse prognosis than hilar or intrapulmonary nodal metastases. The completeness of resection is also prognostic. Patients with R1 or R2 resections have been reported to have a worse outcome in some series.[417]

Another poor prognostic marker is nonepithelioid histologic findings. Epithelioid histologic characteristics are found in 50% of cases. Pure epithelioid mesothelioma may be difficult to distinguish from metastatic adenocarcinoma of the lung, so immunohistochemistry or electron microscopy is essential.[418] Patients with sarcomatoid (10% of patients), mixed (30% of patients), and desmoplastic tumors fare much worse than patients with epithelioid histologic types.[226,419,420] Thrombocytosis and high levels of platelet-derived growth factor may also predict a worse outcome. Several reports suggest that serum levels of mesothelin are elevated in most patients at diagnosis and that they fall after surgery. Serum mesothelin may be a marker for tumor recurrence.[421] Good prognostic factors include young age, early-stage disease, performance status of 0 to 1, lack of chest pain, and presence of symptoms for longer than 6 months.[420]

Treatment

Surgery

Pleurectomy

Pleurectomy for treatment of MPM has been advocated by many surgeons even though cytoreduction is not as complete as that achieved with EPP. Pleurectomy is effective in allowing expansion of the trapped lung and reduces the likelihood of recurrent pleural effusion. A large retrospective study of 663 patients actually showed improved OS rates with pleurectomy as compared with EPP. Patients treated with pleurectomy and decortication had a higher rate of local recurrence of disease, whereas patients undergoing EPP had greater surgical morbidity and mortality rates.[422] The ability to administer postoperative external beam radiation therapy may be compromised after pleurectomy, leading some centers to explore the addition of photodynamic therapy (PDT).

Extrapleural Pneumonectomy

Many centers of expertise consider EPP to be the operation of choice for mesothelioma because it achieves the greatest[423] degree of cytoreduction and may allow for safer delivery of adjuvant therapy compared with pleurectomy. A review of 34 studies of EPP for patients with MPM found a perioperative mortality rate of nil to 11.8% and a median OS time of 9.4 months to 27.5 months. Without adjunctive therapy, EPP has been associated with recurrence rates as high as 80%. Studies including EPP as part of multimodality therapy have reported local recurrence rates of between 40% and 50%, with local recurrence as low as 13% (7 of 55 patients) in one study using 54-Gy hemithoracic irradiation after EPP.[424]

EPP is an extensive surgical procedure, removing the ipsilateral lung along with the parietal pleura, pericardium, and most of the hemidiaphragm, so patients require careful assessment preoperatively to exclude the presence of locally advanced or distant disease (which would preclude resection) and meticulous cardiopulmonary screening to ensure that the operation can be tolerated physiologically. Surgical staging of the mediastinum and abdomen (with washings) should be

TABLE 46-7 TNM Staging of Mesothelioma

PRIMARY TUMOR (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor limited to the ipsilateral parietal pleura, with or without mediastinal pleura and with or without diaphragmatic pleural involvement
T1a	No involvement of the visceral pleura
T1b	Tumor also involving the visceral pleura
T2	Tumor involves each of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following: 1. involvement of diaphragmatic muscle 2. extension of tumor from visceral pleura into underlying pulmonary parenchyma
T3	Locally advanced but potentially resectable tumor. Tumor involving all of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following: 1. Invasion of the endothoracic fascia 2. Invasion into mediastinal fat 3. Solitary completely resectable focus of tumor invading the soft tissues of the chest wall 4. Nontransmural involvement of the pericardium
T4	Locally advanced, technically unresectable tumor. Tumor involving all of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following: 1. Diffuse extension or multifocal masses of tumor in the chest wall, with or without associated rib destruction 2. Direct transdiaphragmatic extension to the peritoneum 3. Direct extension to mediastinal organs 4. Direct extension to the contralateral pleura 5. Direct extension into the spine 6. Extension to the internal surface of the pericardium with or without a pericardial effusion or tumor involving the myocardium
REGIONAL LYMPH NODES (N)	
NX	Regional nodes cannot be assessed
N0	No regional lymph node metastasis

performed when assessing patients for EPP. In general, patients should have adequate cardiac function (i.e., ejection fraction >40% and no reversible ischemia on radionuclide imaging) and have an estimated postoperative forced expiratory volume in 1 second (FEV_1) value of greater than 0.8 L/min, or 30% of predicted. The ideal patient is young, with epithelial histologic typing and a good performance status and without lymph node involvement. Even in centers with extensive experience with carefully selected patients, EPP has a high rate of complications.[425] Because of the extremely poor prognosis of the sarcomatoid subtype, EPP may be less of a consideration for this histologic group.[426]

A recent multicenter randomized trial in the United Kingdom compared EPP plus adjuvant radiation to radiotherapy without EPP, in patients with mesothelioma that had no evidence of disease progression following three cycles of platinum-based chemotherapy.[11] Out of 50 patients randomized, 24 were assigned to EPP, and 16 of 24 patients satisfactorily completed EPP. The hazard ratio for OS between EPP and no EPP was 1.9 (p = 0.082). Median survival was 14.4 months in the EPP group and 19.5 months in the no EPP group. Quality of life appeared similar between the two groups. Authors concluded that EPP appears to offer no benefit and may possibly harm patients. On the other hand, a large retrospective experience including 540 patients from Australia showed EPP to be associated with improved survival on multivariate analysis.[427]

Chemotherapy

Reviews describe modest success with several chemotherapeutic agents in MPM.[428,429] Reported response rates of more than 25% have been obtained with methotrexate (37%),[430] gemcitabine plus cisplatin (48%),[431] pemetrexed plus carboplatin (25%),[432] pemetrexed plus cisplatin (38%),[433] mitomycin plus cisplatin (26%),[434] raltitrexed plus oxaliplatin (26%),[435] and doxorubicin plus cisplatin (28%).[436] The British Thoracic Society performed a randomized trial to assess the role of chemotherapy in palliation.[437] Patients were randomized to active symptom control or one of two chemotherapy regimens (i.e., mitomycin C, vinblastine, and cisplatin or vinorelbine alone). They found that active symptom control with chemotherapy provided better palliation of chest pain and shortness of breath than active symptom control alone.

The combination of cisplatin plus the antifolate pemetrexed has a well defined role in patients with advanced mesothelioma[438]; 456 patients were randomized to cisplatin alone versus

cisplatin and pemetrexed. The median survival time was 12.1 months for the pemetrexed plus cisplatin arm and 9.3 months for the cisplatin alone arm ($p = 0.020$). Toxicity was dramatically reduced by the addition of vitamin supplementation, but this did not influence the effectiveness of therapy. Time to progression was improved from 3.9 months to 5.7 months by the addition of pemetrexed ($p = 0.001$). The response rate was 17% for cisplatin alone compared with 41% for combined treatment.

Combination cisplatin and pemetrexed has also been studied as part of multimodality therapy in localized disease. Krug et al reported the results of a multicenter Phase II trial of neoadjuvant pemetrexed plus cisplatin followed by EPP and irradiation for MPM, with a promising median survival time of 29.1 months and a 2-year survival rate of 61.2%.[439] For patients who cannot tolerate cisplatin, carboplatin plus pemetrexed is moderately active and has an acceptable toxicity profile.[432,440,441] Pemetrexed-based chemotherapy is currently incorporated as part of the treatment regimen, either before or after surgery, for patients treated with EPP.[427] An alternative approach of hyperthermic intraoperative cisplatin has been used following EPP, with an MPM recurrence rate of 51% and an ipsilateral recurrence rate of 17%.[442]

Rationale for Irradiation

Although technical challenges remain, several lines of evidence suggest that radiation therapy can be effective in treating mesothelioma. First, mesothelioma cell lines are not particularly radioresistant in vitro, and they have radiosensitivities similar to those of non–small cell lung cancer.[443,444] Second, some evidence suggests a dose-response relationship for symptom palliation, such that doses greater than 40 Gy seem more effective than lower doses.[395,445] This dose-response relationship suggests that clinically significant cell killing results from modest radiation doses. Third, modest radiation doses can dramatically reduce the local failure rate at thoracotomy or other instrumentation sites. Thus, postoperative irradiation may be effective in reducing locoregional recurrence and potentially improve survival rates.

Curative Radiation Therapy

Radiation Therapy Alone

Irradiation alone is not considered curative given the extent and distribution of disease and the proximity of the pleural surface to many dose limiting structures. Radiation therapy without surgery is best considered a palliative treatment.

Radiation Therapy Combined with Surgery

Several groups have reported promising outcomes for MPM patients treated with surgery and irradiation, with or without chemotherapy.

Radiation Therapy after Pleurectomy or Decortication

A study performed between 1982 and 1988 at Helsinki reported high rates of pulmonary toxicity and pulmonary function deterioration in 34 patients (29 after partial pleurectomy) treated with high doses of adjuvant hemithorax radiotherapy (55 Gy to 70 Gy).[446,447] A larger experience from MSKCC[448] included 123 patients treated with pleurectomy or decortication from 1974 to 2003 with adjuvant external beam RT[449]; 54 patients also received an intraoperatively placed ^{125}I or ^{192}Ir boost to gross disease, and a subset of patients received ^{32}P. Photon and electron fields were combined to treat the superficial chest wall and spare the underlying lung. Radiation doses were 45 Gy to the pleural surface, but the dose to "most of the lung" was kept below 20 Gy by combining electron and photon fields. As in the Helsinki report, substantial toxicity was noted including 25% grade-3 to grade-4 toxicity, 10% severe pulmonary symptoms and two treatment-related mortalities within 1 month of treatment. Median survival time was 13.5 months, with 1-year actuarial local control of 42%.

More recently IMRT has been explored in treating mesothelioma. A series from MSKCC reported 36 patients treated from 2005 to 2010,[450] with both lungs intact and a median dose 46.8 Gy (range, 41.1 Gy to 50.4 Gy) to the hemithorax. Twenty (56%) patients underwent a pleurectomy or decortication before radiation, and 32 (89%) patients received chemotherapy before RT. Acutely, 7 (20%) patients developed grade-3 or worse pneumonitis (1 death) and 2 patients had grade-3 fatigue. Long term, 5 of 30 patients had continuing grade-3 pneumonitis. Despite substantial toxicity median survival and 1-year local failure were 26 months and 48%, respectively, in the cohort treated with pleurectomy.

Intraoperative radiation therapy (IORT) has been explored as an adjunct to external radiotherapy though results have not been encouraging. A report from the University of California–San Francisco included 24 patients treated with IORT. Major complications included radiation pneumonitis in 4 patients, pericarditis in 1 patient, and esophageal stricture in 1 patient. Tumor recurrence was "mostly locoregional" at sites of previous gross tumor. Despite the relatively early stage of disease, the outcome was relatively poor, with a median OS time of 18 months and a PFS rate of 12 months. The MSKCC group also reported their experience with high-dose-rate IORT after pleurectomy or EPP. There were serious complications in 3 of 6 patients (50%) of the EPP/IORT group and in 1 of 5 patients (20%) of the PD/IORT group, and they have abandoned IORT after EPP.[451]

Though outcomes of studies using radiotherapy adjuvant to pleurectomy or decortication suggest reduced locoregional failure rates compared with historical controls of surgery alone, local failure remains common and toxicity is substantial. Expected median survival approximates 2 years in most studies, whereas median survival exceeding 4 years in select reports may relate to selection of patients with early-stage disease.[401] Current NCCN guidelines caution against use of radiotherapy after pleurectomy outside of a clinical trial without following strict normal tissue constraints.[452]

Intrapleural Photodynamic Therapy

PDT uses light activation of sensitized tumor cells to achieve sterilization. It can be delivered intraoperatively immediately following pleurectomy or EPP with the goal of sterilizing microscopic disease throughout the thorax.[422,453] One advantage of PDT is direct visualization of regions at risk for recurrence. The depth of penetration of the light is a few millimeters, which may limit potential pulmonary toxicity. A Phase I trial of Foscan-mediated PDT found that the maximum tolerated dose of photosensitizer was 0.1 mg/kg 6 days before surgery.[454] Dose-limiting toxicity at the next dose level consisted of systemic capillary leak syndrome and led to death in two of three patients treated. Other PDT-related toxicities included wound burns and skin photosensitivity. Fourteen patients were treated at the maximum tolerated dose (MTD) without significant complications.

Photodynamic therapy can be used with other adjuvant therapies.[455] One encouraging series out of the University of Pennsylvania treated 38 patients with radical pleurectomy and PDT.[456] Most patients (97%) had stages III/IV disease. Median survival was 31.7 months for all patients, but only 6.8 months for the 7 of 38 patients with nonepithelial histology. Median PFS was only 9.6 months. Further studies are ongoing.

Radiation Therapy after Extrapleural Pneumonectomy

Reports have been conflicting regarding the impact of aggressive adjuvant therapy on patterns of failure after EPP. A study from the Dana Farber Cancer Institute included 49 patients treated with EPP, and 35 patients received radiotherapy, 30.6 Gy to the "hemithorax" followed by a boost to about 50 Gy, following four to six cycles of chemotherapy.[402] The most-common site of first recurrence was local (35% of patients), whereas abdominal and contralateral thorax relapse was also common. It is likely that abdominal recurrences were related to extension of local disease (Figure 46-8). Isolated distant relapses were uncommon. On the other hand, a Phase II study from MSKCC evaluating hemithorax radiotherapy adjuvant to surgical resection reported only 13% locoregional relapse (in the pleura or regions lymph nodes) in the subset of 55 patients treated with EPP.[457] Distant relapse was a frequent site of first recurrence, particularly in stage III disease. The treatment technique involved photon irradiation to a dose of 54 Gy in 30 fractions.[458] The spinal cord was shielded after 41.4 Gy, and the liver, heart, and stomach were appropriately shielded. The chest wall in the shielded regions was irradiated with matched electron fields so that the goal dose of 54 Gy could be more safely achieved. A report of 86 patients treated with EPP followed by IMRT M. D. Anderson Cancer Center also supports the contention that high-dose radiotherapy may limit local tumor relapse.[459] The goal dose was 45 Gy to 50 Gy to the hemithorax, with 13 patients receiving a boost to 55 Gy to 60 Gy. All irradiation was completed in 25 fractions.

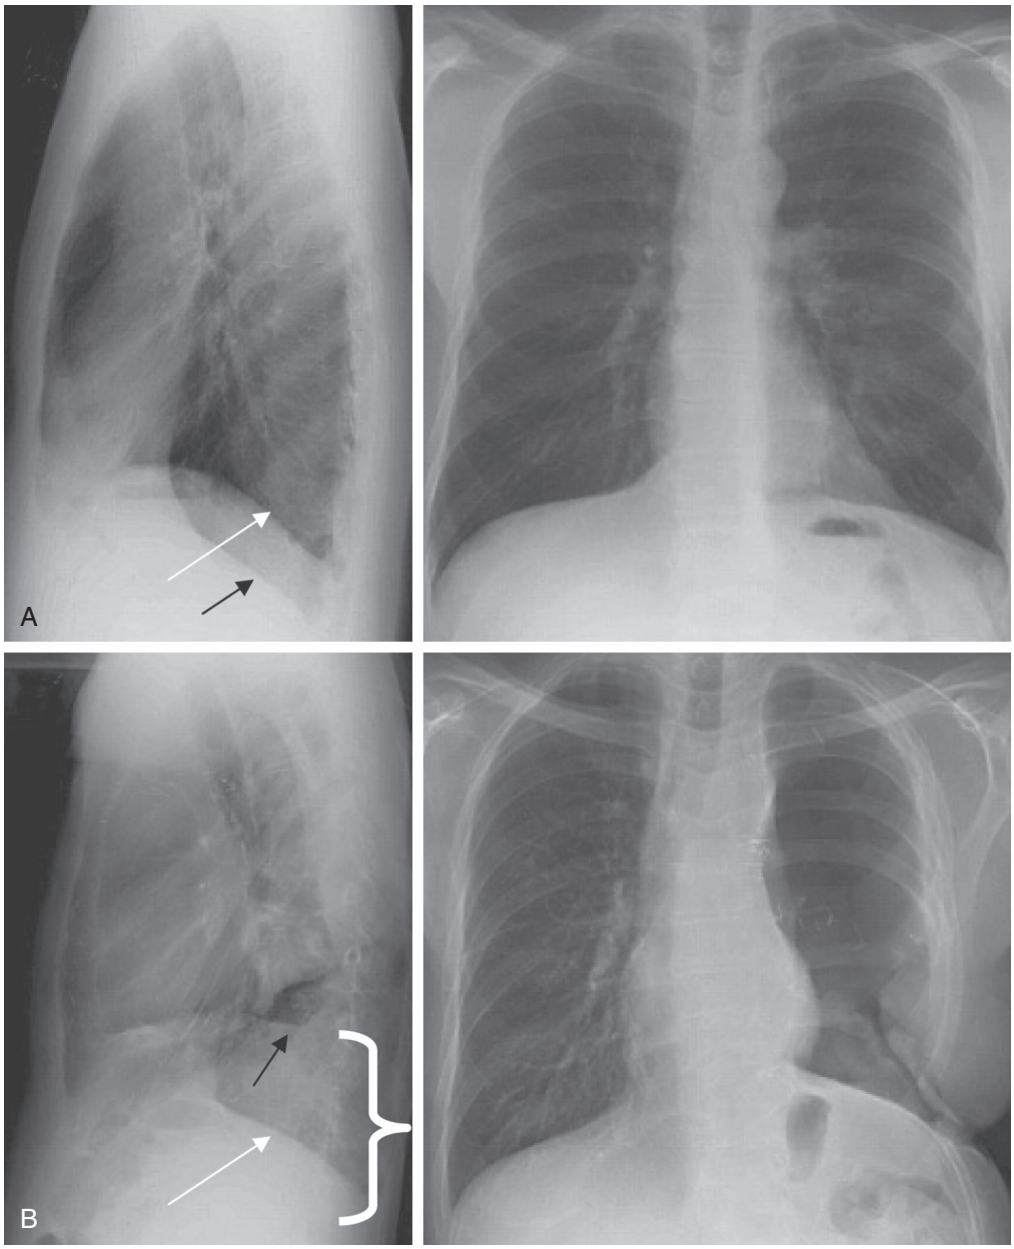

Figure 46-8 Extrapleural pneumonectomy (EPP) can abdominalize portions of the posterior costophrenic recess. **A,** A preoperative radiograph shows that the diaphragm on the contralateral side *(black arrow)* is higher than the ipsilateral hemidiaphragm *(white arrow).* **B,** After EPP, the posterior insertion of the reconstructed hemidiaphragm *(white arrow)* is well above the now flattened, remaining hemidiaphragm *(black arrow).* In this example, the posterior insertion of the diaphragm is about 15 cm higher than before surgery.

Although most patients (77 of 86) had T3 or T4 disease, only 14 (16%) patients experienced a local recurrence while 51 (59%) patients developed distant metastasis.

The results of multimodality EPP studies are difficult to interpret due to patient selection as well as variable interpretation of whether a relapse should be categorized as local or distant. It is critical to distinguish marginal failures, which require better definition of the clinical target volume from in-field failures that may require higher dose. OS appears to correlate well with stage, with much worse outcomes reported for lymph node–positive disease. For example, median survival was 33.8 months for stages I/II disease compared with 10 months for stages III/IV disease in the MSKCC experience. In a recent Canadian series of 60 patients treated with induction chemotherapy, EPP, and hemithoracic RT (≥50 Gy),[460] median survival was a provocative 59 months for N0 disease but dropped to <14 months in the remaining patients.

Multimodality therapy including EPP is reasonably well tolerated in select reports from experienced centers, but treatment is rigorous with potential for substantial toxicity and many patients do not complete planned therapy. The use of IMRT after EPP is controversial given initial reports of fatal radiation pneumonitis.[457] More recent accumulating data suggests that severe pneumonitis may be avoided if stringent dose constraints for the remaining lung are used in IMRT planning.[461]

A summary of large trials for MPM is shown in Table 46-8. Though definitive conclusions can not be reached, it appears that high-dose postoperative irradiation can dramatically reduce ipsilateral thoracic failures in patients undergoing EPP. Local relapse is more common with pleural decortication than after EPP, and the role of radiotherapy after pleural decortications remains unclear. To get a true sense of the benefit of radiotherapy, accurate in-field failure needs to be well documented. Although postoperative irradiation may be well tolerated in experienced hands, the potential for severe toxicity must be considered. The impact of including chemotherapy is difficult to discern and further assessment of systemic therapy is of importance given the benefit in advanced disease.

Palliative Radiation Therapy

Pain Control

Irradiation can provide effective palliation for patients with MPM. A radiation dose-response relationship has been reported after the review of outcomes of 29 courses of palliative external beam radiation therapy delivered to 17 patients with MPM.[398] Four of six patients treated with more than 40 Gy achieved significant relief of symptoms. Only one patient treated with lower doses achieved significant palliation of any symptom, and this was for a painful chest wall mass.

In another study,[464] 26 radiation therapy courses were reviewed for symptomatic improvement. Pain was improved in 13 of 18 cases, and the response was similar regardless of dose or fractionation (i.e., 20 Gy in 5 fractions or 30 Gy in 10 fractions). Although the sample size is small, palliation was achieved in about half of the cases in this mixed patient group. The duration of response was not assessed in either study. These data demonstrate that symptoms from mesothelioma can usually be palliated effectively with brief courses of irradiation.

Therapy for Drain Sites

Unlike most malignant tumors, MPM has a tendency to recur along tracks of previous chest wall instrumentation.[465,466] There is randomized evidence both in support of and against use of local irradiation to drain and biopsy sites.[467] One group took 40 consecutive patients with pathologically proven MPM and randomized them to immediate irradiation to each site of instrumentation or to observation. Elective treatment was 21 Gy in three fractions delivered using en face electron fields. There were no local failures in the irradiated patients

TABLE 46-8 Large Studies Combining Surgery with Postoperative Radiotherapy

Study	Year	Surgery	No. Patients	RT Dose	Local Failure	Survival Time
Maasilta[446]	1991	Pleurectomy	34	55 Gy-70 Gy	33% progression, but remainder with "stable" disease	12 mo median
Lee et al[462]	2002	Pleurectomy	24	41.4 Gy (median) 5-15 Gy IORT	"Most"	18 mo median
Gupta et al[449]	2005	Pleurectomy	123	42.5 Gy (median) 54 of 123 patients IORT	69 of 123	13.5 mo median
Rosenzweig et al[450]	2012	Pleurectomy	20	46.8 Gy (median)	48% local failure at 1-year	26 mo median
Friedberg et al[456]	2012	Pleurectomy + PDT	38		25 of 38	31.7 mo median
Baldini et al[402]	1997	EPP	49	30.6 Gy ≈ 20 Gy boost	21 of 49	22 mo median
Ahamad et al[463]	2003	EPP	28	45-50 Gy	0 2 marginal misses	Not yet reached (2-year OS 62%)
Yajnik et al[458]	2003	EPP	35	54 Gy	13/35	Not reported
Gomez et al[459]	2013	EPP	86	45 Gy-50 Gy, 13 of 86 boosted to 55 Gy-60 Gy	14/86	14.7 mo median
Weder et al[459a]	2004	Chemotherapy + EPP	19	Selected volumes	8 of 13 (13 patients completed all therapy)	16.5 mo median

compared with eight failures (40%) in the untreated patients.[465] A slightly larger randomized trial found no reduction in the incidence of tumor seeding in the irradiated patients.[453] Because such recurrences typically are painful, elective irradiation is a reasonable means of maintaining the patients' quality of life.

Irradiation Techniques

Patient Immobilization and Setup

Two basic techniques have been described for thoracic irradiation following EPP.[458,468] A description of the IMRT techniques for the postoperative treatment of MPM has been described.[459,468] This level of detail is required to ensure that the complex target volumes can be identified and reproducibly treated for 5 weeks.

Computed Tomography Simulation

MPM tends to recur at sites of previous instrumentation, and all incision and drain sites should be included in the CTV. Laparoscopy or mediastinoscopy sites have not been included within the CTV as long as the mediastinoscopy was pathologically negative. Radiopaque wires mark the surgical incisions, and the tissue equivalent bolus extends to 4 cm around the wires. Patients are immobilized supine on the CT simulator using a combination of a vacuum bag and an "extended wing board with T-bar handgrip" immobilization device used in conjunction with a headrest. The patient should be scanned from the middle neck to the anterior superior iliac spine. This low inferior border allows complete definition of both kidneys so that accurate dose-volume histograms can be constructed. Four-dimensional simulation with assessment of respiratory motion should ideally be performed.

Target Volume Delineation

The ipsilateral mediastinum should be included in the target volume,[463,467] even for patients who are node-negative. The superior border should be placed at the thoracic inlet. The medial border includes the ipsilateral nodal regions, the trachea and subcarinal regions, or the vertebral body.[458,468] The posterior mediastinal structures behind the heart need not be included, because no failures in this region have been recorded (unpublished data) despite their omission from the CTV.[463]

The anteromedial pleural reflection is a potential problem for target volume delineation. As shown in Figure 46-9, *A*, the medial pleural space sometimes can cross the midline. This anatomic relationship can be lost after surgery (see Figure 46-9, *B*). When possible, this region should be marked intraoperatively with radiopaque clips. Alternatively, the medial extent of the pleura could be identified on preoperative CT scans and then estimated on the treatment-planning CT scan. This has been the site of a marginal miss in our series (see Figure 46-9, *C*, *arrow*).

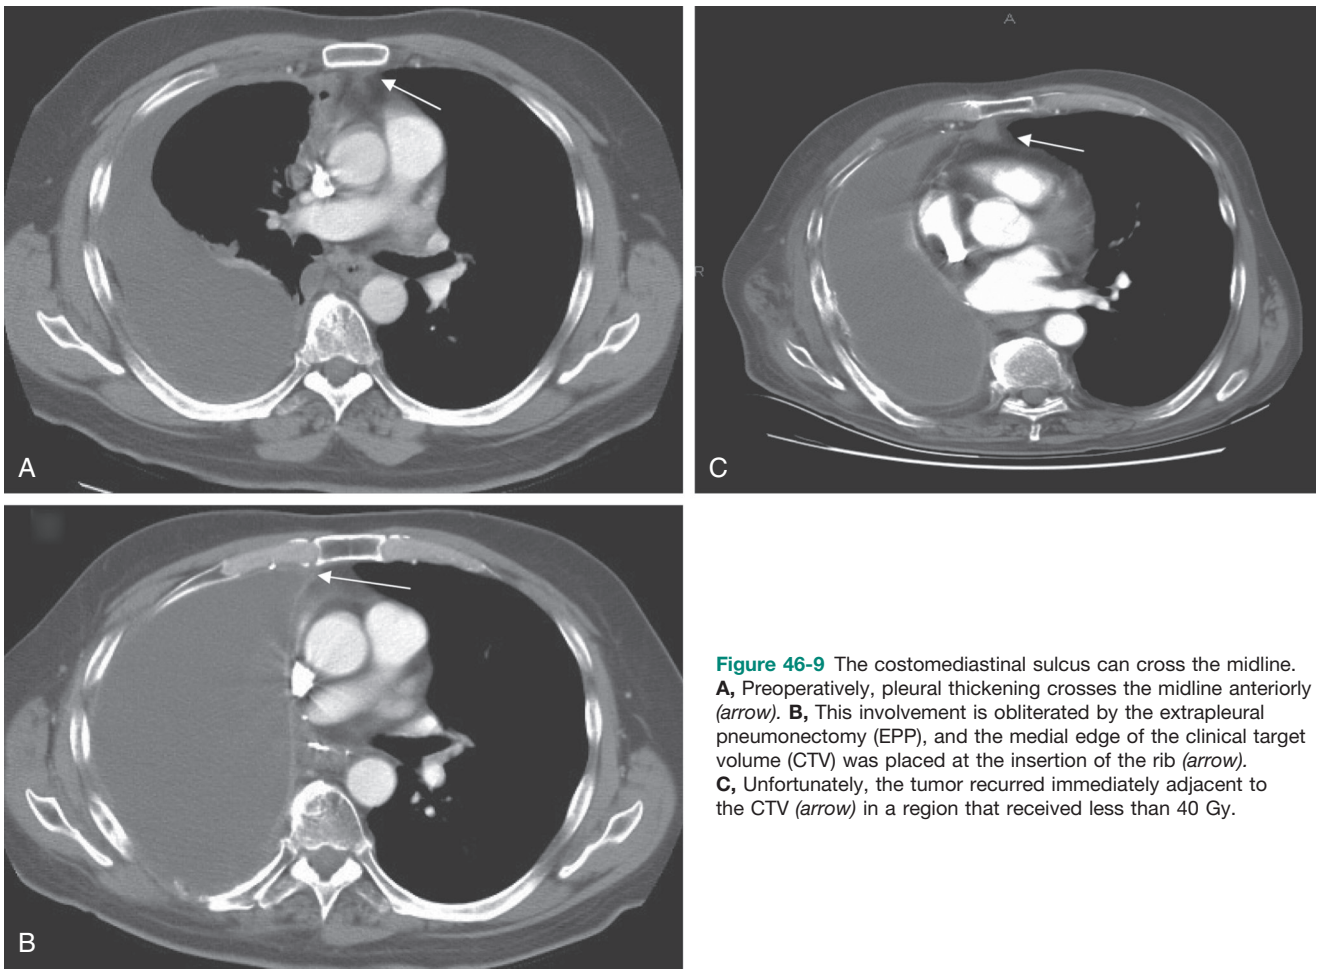

Figure 46-9 The costomediastinal sulcus can cross the midline. **A,** Preoperatively, pleural thickening crosses the midline anteriorly *(arrow).* **B,** This involvement is obliterated by the extrapleural pneumonectomy (EPP), and the medial edge of the clinical target volume (CTV) was placed at the insertion of the rib *(arrow).* **C,** Unfortunately, the tumor recurred immediately adjacent to the CTV *(arrow)* in a region that received less than 40 Gy.

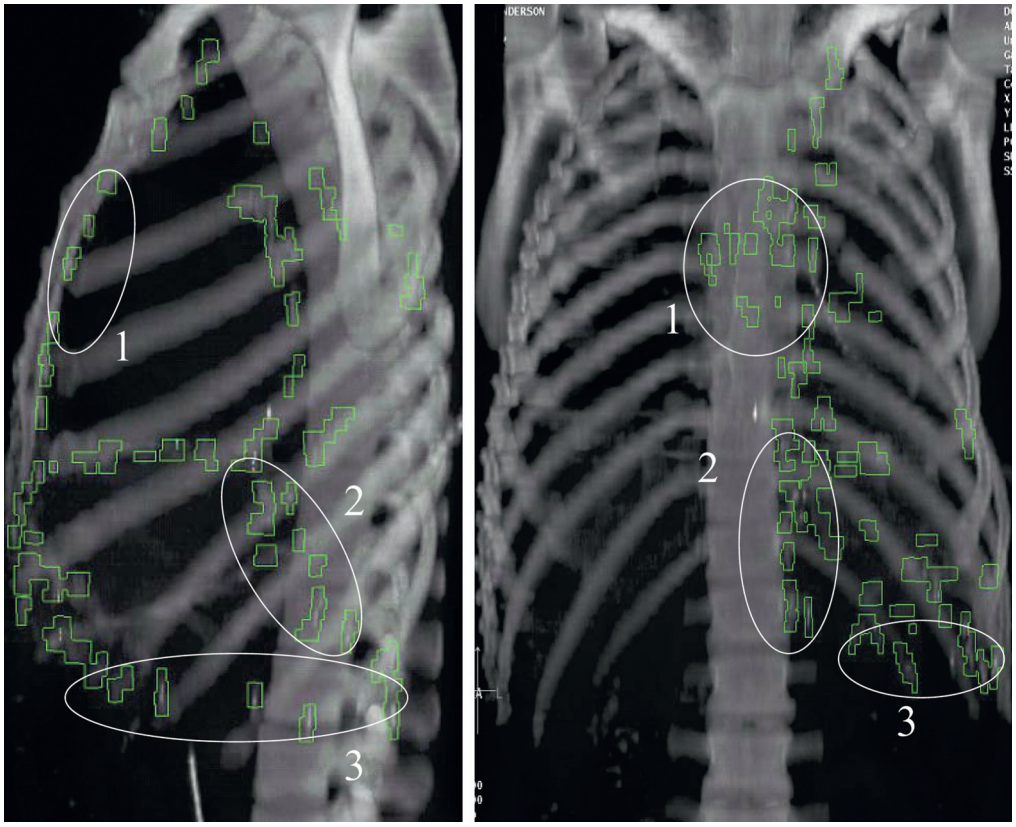

Figure 46-10 Potential problem areas for clinical target volume (CTV) determination. Three parts of the CTV are potentially difficult to discern without great care: the anteromedial pleural reflection of the sternopericardial recess (1), the inferior and medial extents of the crus of the diaphragm (2), and the inferior insertion of the diaphragm (3).

The inferior border should be the insertion of the diaphragm. The location of this is quite variable, ranging from vertebrae L1 to L4. Because of this variability, the diaphragm insertion should be marked by intraoperative placement of radiopaque clips[469] or by suturing the neodiaphragm in this location.[458] When the border of the intrathoracic contents and the abdominal contents is well marked, the radiation therapy margins can be maximally reduced. Because there can be great difficulty in differentiating liver from thoracic fluid, the use of radiopaque Gore-Tex patches for diaphragm reconstructions is helpful.

Another potential source of contouring error is the medial extent of the crus of the diaphragm, especially at its most inferior extent. The ipsilateral crus is usually difficult to identify after surgery without clips. The best way to individualize the inferior edge of the target volume is with intraoperative placement of radiopaque clips, with particular attention to the crus.

When the entire region is extensively clipped, a pattern such as that seen in Figure 46-10 emerges, with regions of potential pitfall highlighted. These potential problem areas include the anterior medial pleural reflection, the crus of the diaphragm, and the inferior aspect of the diaphragmatic insertion.

Treatment Planning

Three-Dimensional Conformal Radiation Therapy

The 3DCRT therapy approach has been described best in two reports from the MSKCC.[457,458] The technique applies anteroposterior-posteroanterior beam geometry to the hemithorax using the volumes described previously as the CTV. For right-sided cases, an abdominal block is present throughout treatment, and the region is boosted with electrons at 1.53 Gy per day, which accounts for scatter under the block. For left-sided cases, the kidney and heart are blocked. The kidney block is present throughout treatment, and the heart block is added after 19.8 Gy. The spinal cord is shielded after 41.4 Gy in all cases. The goal dose to the target volume is 54 Gy in 30 fractions, with the dose calculated at the midplane with equally weighted beams. Patients were treated with arms akimbo.

Treatment by this approach results in good coverage of most volumes at risk to the target dose of 54 Gy. Doses are homogeneous within the regions at risk, although regions such as the crus, the pericardium, and the neodiaphragm may be difficult to treat. Radiosensitive structures such as the liver and heart can be spared well. Protection of the ipsilateral kidney is better than with IMRT.

Intensity-Modulated Radiation Therapy

The target doses and the dose-volume limits for the critical structures are listed in Table 46-9. Treatment is delivered with 13 to 27 intensity-modulated fields using 8 to 11 gantry angles, typically with 100 segments per intensity-modulated field. Because patients have only one lung after EPP, the Duke group recommends contralateral lung irradiation limited to a mean lung dose of less than 9.5 Gy.[470] This is consistent with the results of whole-lung irradiation.[471] The University of Pennsylvania dose constraints are slightly more conservative, with a

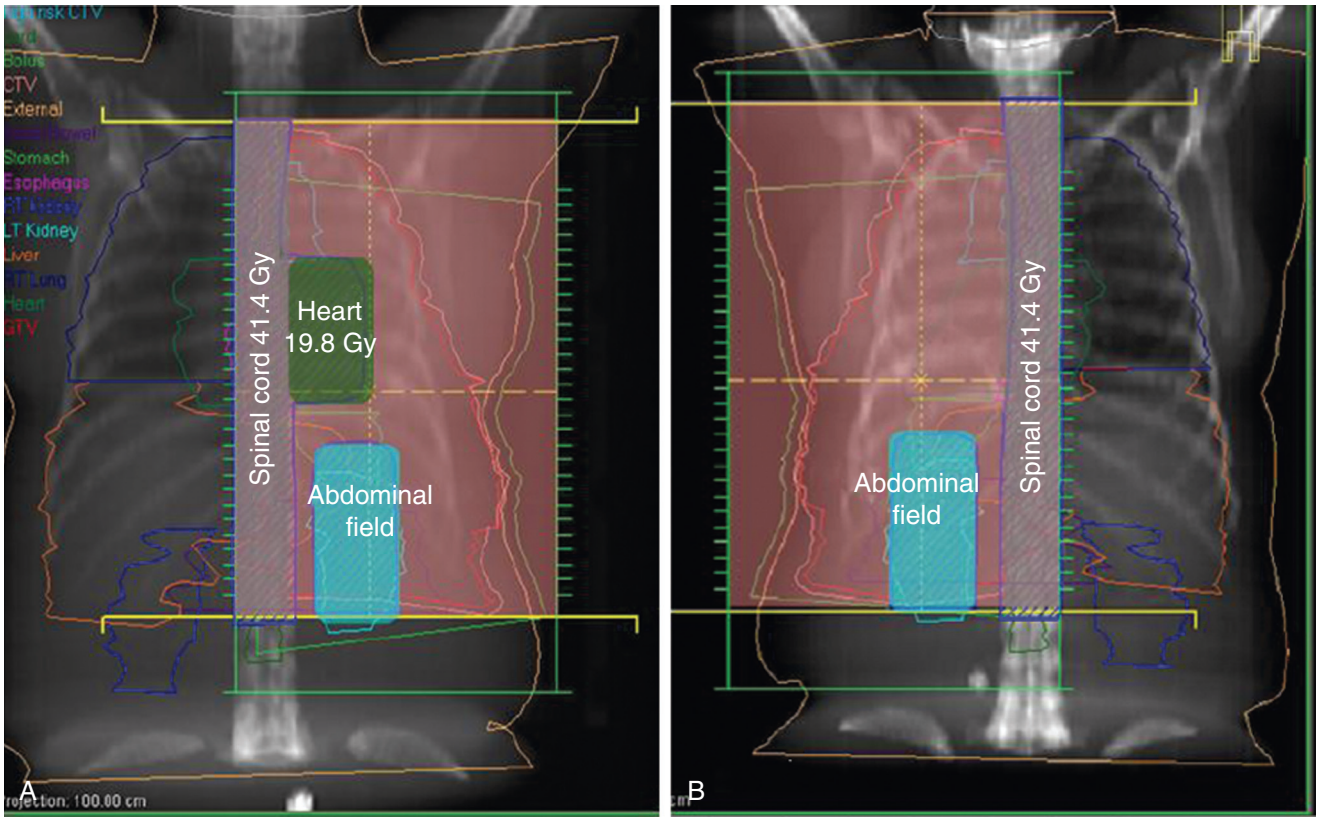

Figure 46-11 The total prescribed dose from the anteroposterior **(A)** and posteroanterior **(B)** photon fields and supplemental electron fields was 54 Gy in 1.8-Gy fractions. At the start of treatment, blocks were placed in the region of the abdomen. During treatment of the left hemithorax, an anterior heart block was placed at 19.8 Gy. Blocked areas were subsequently delivered 1.53 Gy daily through an en face electron field. At 41.4 Gy, anterior and posterior blocks were placed over the spinal cord.

TABLE 46-9 Goal Dose or Constraint Dose of the Target or Organ

Target or Organ	Goal Dose or Constraint Dose
CTV	50 Gy in 25 fractions
bCTV	60 Gy in 25 fractions
Lung	<20% to receive >20 Gy and mean <9.5 Gy
Liver	<30% to receive >30 Gy
Contralateral kidney	<20% to receive >15 Gy
Heart	<50% to receive >45 Gy
Spinal cord	<10% to receive >45 Gy No portion to receive >50 Gy
Esophagus	<30% to receive >55 Gy

bCTV, *Boost clinical target volume;* CTV, *clinical target volume;* Gy, *gray.*

mean lung dose of less than 9 Gy, a V5 of less than 60%, and a V20 of less than 20%.[461] With experience, the mean lung dose can be kept to well under 8 Gy.[461,471]

IMRT is more complicated and takes longer to deliver than 3DCRT, but good coverage of the target can be achieved. IMRT has dosimetric advantages over 3DCRT because of to improved coverage and homogeneity, but there is more dose spillage into the contralateral lung and an increase in the mean lung dose.[472,473] A combined electron and 3DCRT to a dose of 54 Gy had significant reduction to the contralateral lung, contralateral kidney, and heart when compared with IMRT to a dose of 45 Gy.[473] Figure 46-11 shows field and block arrangements employed with the use of a combined electron-photon technique. The IMRT plan of 50 Gy to the isodose line in Figure 46-12 encompasses most of the CTV. Review of the dose-volume histogram for this case (Figure 46-13) demonstrates that the target volume is well covered and the normal tissue constraints are met. The liver and contralateral lung are spared with this technique. In this patient, it was possible to spare the ipsilateral kidney because the organ was particularly low. The ipsilateral kidney usually receives a high dose because the CTV typically abuts its posterior edge. Adequate contralateral renal function is confirmed by pretreatment renal scans. For left-sided lesions, the spleen is likely to receive a high radiation dose and pneumococcal prophylaxis is recommended.

There has been increasing interest in the use of IMRT to treat mesothelioma in patients who have not had pneumonectomy. Rosenzweig et al describe the technique used at MSKCC for treating patients with mesothelioma who have not undergone pneumonectomy.[450] Essentially, a rind of tissue around 15 mm in diameter is treated, including the pleura and chest wall of the entire hemithorax, from thoracic inlet down to the insertion of the diaphragm. Dose constraints are similar to treatment of patients with locally advanced non–small cell lung cancer, with mean lung dose less than 20 Gy. Figure 46-14

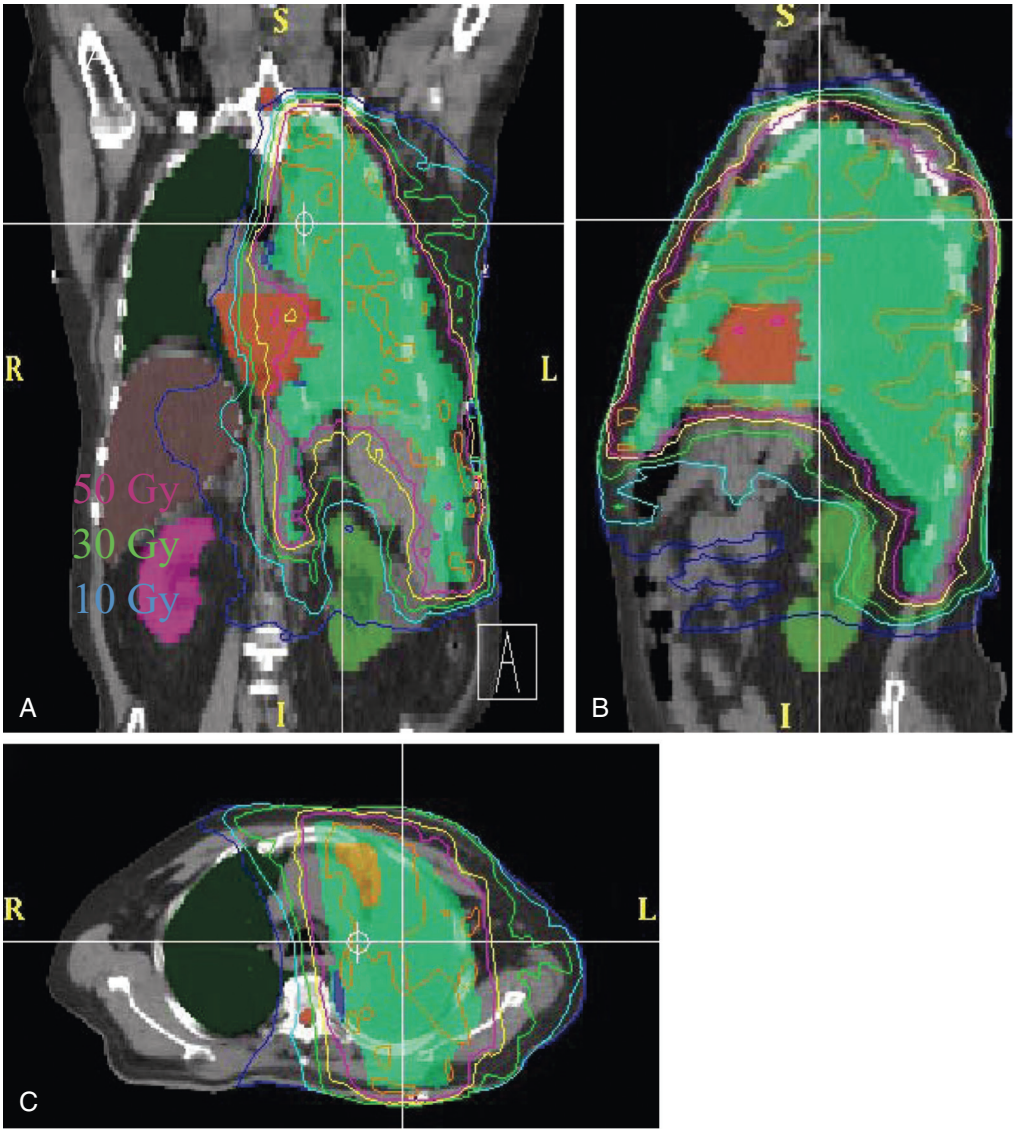

Figure 46-12 **A** to **C,** The dose distributions for intensity-modulated radiation therapy (IMRT) demonstrate good coverage of the clinical target volume (CTV) and the high-dose gradients achievable with this technique. The goal was 50 Gy to the CTV. The 50-Gy, 40-Gy, 30-Gy, and 10-Gy isodose lines are shown in *magenta, orange, green,* and *blue,* respectively.

shows isodose lines and dose-volume histogram (DVH) for a patient postpartial pleurectomy with mesothelioma treated with IMRT to 45 Gy.

SUMMARY

A review of the limited patient studies (see Table 46-8) in MPM suggests that EPP followed by irradiation gives better local control than pleurectomy followed by irradiation in selected patients. The addition of PDT to pleurectomy may improve local control rates, but randomized data are lacking. Postoperative irradiation should include the entire volume immediately adjacent to the pleural space that is at highest risk for microscopic residual disease. This volume should include all sites of pleural reflection, the ipsilateral mediastinum, and the insertion of the diaphragm. The technique by which irradiation is delivered (traditional technique or IMRT) is probably not as important as the target volume delineation and coverage. Integrating systemic therapy with EPP and postoperative irradiation has become standard practice and additional prospective trimodality studies are being conducted.

ACKNOWLEDGMENTS

We wish to thank the following people for their suggestions and contributions:

Laura Bonner, MD (Radiation Oncology Department, EVMS Medical Group); Clifton Fuller, MD (Radiation Oncology Department, University of Texas Health Science Center at San Antonio); David Hussey, MD (Radiation Oncology Department, University of Texas Health Science Center at San Antonio); Jaishree Jagirdar, MD (Pathology Department, University of Texas Health Science Center at San Antonio); and Cindy Scharfen, MD (Redwood Regional Radiation Oncology Center, Santa Rosa, California).

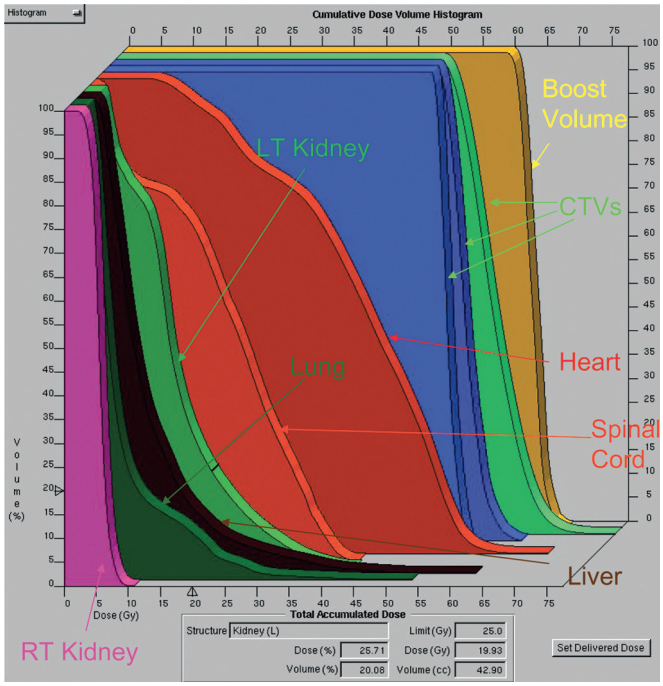

Figure 46-13 The dose-volume histogram demonstrates that coverage of the target volumes is adequate. The contralateral kidney was well below the goal dose, as was about 25% of the ipsilateral kidney. The mean lung dose was about 9.5 Gy. In this left-sided case, the heart dose was slightly higher than the goal dose (60% to 45 Gy, rather than 50%).

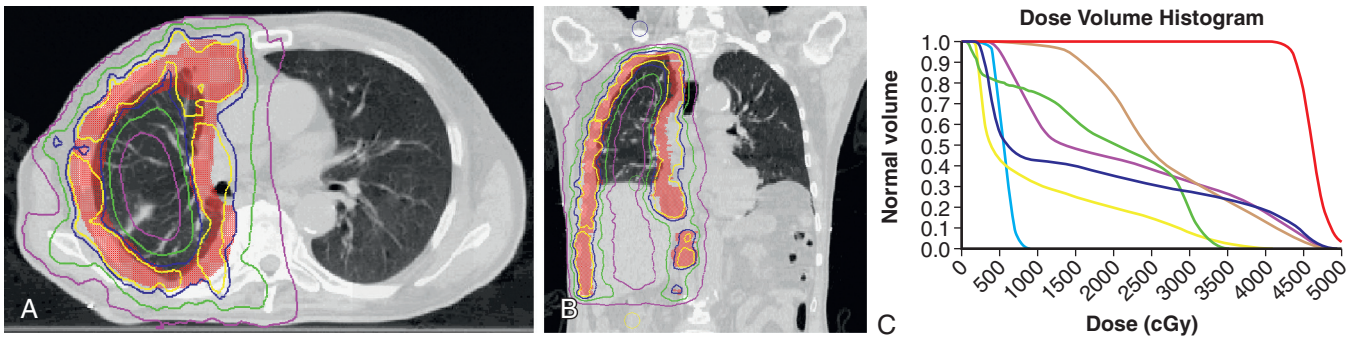

Figure 46-14 Axial **(A)** and coronal **(B)** views for intensity-modulated radiation therapy (IMRT) in mesothelioma with two intact lungs. Isodose lines are closely conformal to the shape of planned target volume *(red)*. Goal was 45 Gy to the PTV. The 45-Gy, 42.75-Gy, 36-Gy, and 22.5-Gy isodose lines are shown in *yellow*, *blue*, *green*, and *purple*, respectively. **(C)** The dose-volume histogram demonstrates that coverage of the target volumes and sparing of normal tissue (PTV = red). The mean lung dose was 17 Gy with V20Gy of 36% *(dark blue)*. Contralateral kidney received little dose *(light blue)* and ipsilateral kidney dose was also acceptable *(yellow)*. Cord max was 37 Gy *(green)*. Mean heart dose was 21 Gy *(pink)*, and mean liver dose was 27 Gy *(brown)*.

Overview

Joel E. Tepper and Leonard L. Gunderson

Gastrointestinal (GI) cancer continues to be a common health problem. Approximately 290,200 new cases of GI malignant disease were estimated to occur in the United States in 2013.[1] Although colorectal tumors account for almost 50% of the cases in the United States (142,720), cancers of the esophagus, stomach, liver, and pancreas continue to occur with regularity and have high mortality rates, and the incidence of hepatoma is increasing rapidly. Although the death rate from colon and rectal cancer is gradually decreasing, and that from gastric cancer has been decreasing for a century, there has been a marked increase in the incidence of tumors arising at the gastroesophageal junction and of primary liver cancers. Pancreatic cancer also continues to gradually increase in incidence and there has been little improvement in overall survival rates. Gastric and hepatic cancers are two of the most common causes of cancer incidence and death worldwide. Hereditary factors play a role in the etiology of GI cancer, and environmental toxins are causative agents in certain diseases. Because these are a diverse group of tumors, the etiology, epidemiology, diagnosis, and treatment vary enormously between diseases and are discussed in the respective chapters.

A significant problem with many GI cancers relates to a delay in clinical presentation. Signs that give early warning of other types of cancer (e.g., pain or palpation of a mass) do not occur early in most patients with GI cancers. For example, the severe back pain that can occur with pancreatic cancer is usually a manifestation of unresectability because of posterior tumor extension. Patients with alimentary tract GI cancers often present with symptoms of bleeding and occasionally bowel obstruction that may be associated with a large primary tumor, a high risk of metastasis, and a low chance of cure.

Physicians should be aware of the early signs and symptoms of GI cancer and educate their patients to be aware of certain symptoms to make earlier diagnoses, and to perform screening procedures (especially for colorectal cancer), as indicated. In general, the early warning signs include vague abdominal discomfort, evidence of GI bleeding, unexplained weight loss, change in bowel habits, or new onset of anemia. Routine colonoscopy or sigmoidoscopy and stool testing for occult blood are recommended screening procedures for colorectal cancer, and virtual colonoscopy may be a viable alternative. With these procedures, survival rates are affected because cancers are found at an early stage and benign polyps are removed before they have had a chance to progress to invasive cancers. Colorectal cancer is one of the few cancer types that can often be prevented, in this case by removing benign polyps before progression to malignancy. Other tests such as routine contrast radiography, upper endoscopy, or cytologic analysis have yet to demonstrate cost effectiveness in the United States as general screening procedures for upper GI malignant diseases, but they may be appropriate for select high-risk populations. There is a major controversy regarding aggressive screening procedures for patients with Barrett's esophagus because although these patients have a significant risk of neoplastic progression, the annual progression rate is quite low. There is substantial interest in innovative approaches of screening, such as molecular analyses of stool or bile for changes such as *RAS* mutations, that could be important in the future. There is also hope that advances in proteomics may lead to development of a blood assay for identifying patients with early cancers; but at the present time this is more a hope than reality.

This overview discusses conceptual issues pertinent to a variety of GI cancers, with site-specific details covered in the disease site chapters. Topics covered here include epidemiology and prevention, biology, anatomy and pathway of tumor spread, staging, prognostic factors and patterns of relapse, treatment issues of surgery alone versus primary chemoradiation or trimodality treatment (surgery, radiation therapy, and chemotherapy), and tolerance of organs and structures that limit the radiation dose in the treatment of abdominopelvic GI cancers.

EPIDEMIOLOGY AND PREVENTION

It has long been known that colon and rectal cancers are related to dietary factors, and these tumors have therefore been used as a model for cancer epidemiology. There is a strong association of colorectal tumors with high-fat and low-fiber diets.[2] It has been argued as to whether high fat or low fiber is most important in the process of cancer development, or whether there are other nutrients associated with these diets that are most important. However, data now suggest that neither high fat nor low fiber is critical but rather that high-fat/low-fiber diets tend to be low in nutrients such as folate.[3,4] Confirmation of this is critical in designing prevention strategies because dietary supplementation is far easier to implement than is a major change in the eating habits of the population. Other environmental factors, specifically exercise, are important in colorectal carcinogenesis, perhaps related to alterations in insulin-like growth factors. It is fortunate that a lifestyle that is healthy for the heart is also beneficial in decreasing colorectal cancer incidence. The same strong dietary correlate with cancer formation is unfortunately not present for most other GI tract tumors. Smoking is a major risk factor primarily for esophageal cancer and, to a lesser extent, for pancreatic cancer.

Along with the dietary factors just described, there have been major epidemiologic changes in geographic location and histopathologic findings for tumors of the esophagus, stomach, colon, and rectum over the last half-century, although the

reason for these changes is largely unknown. The primary histopathologic type of esophageal cancer has changed rapidly from squamous cell carcinoma of the proximal and midesophagus to adenocarcinomas of the distal esophagus, gastroesophageal junction, and proximal stomach. At many U.S. institutions, three fourths of all patients with esophageal cancer have distal esophageal/gastroesophageal junction adenocarcinomas, although this was a relatively rare entity only 20 to 30 years ago. The reasons for these changes are uncertain but are likely related to the increased incidence of Barrett's esophagus and esophageal reflux.[5] One theory is that the increased use of H_2-receptor blockers has relieved the symptoms of reflux but has not decreased the inflammatory response in the distal esophageal mucosa, so that Barrett's lesions continue to form and undergo metaplastic changes to become esophageal cancers. The concomitant substantial increase in the incidence of proximal (cardia) gastric cancers suggests that a similar etiology is present for both cardia and gastroesophageal junction carcinomas and that the increased incidence of esophageal cancers is not simply a misclassification of proximal gastric cancers as esophageal adenocarcinomas.[6]

At the same time that there has been an increased incidence of proximal gastric adenocarcinomas, the overall incidence of gastric cancers is decreasing. At the beginning of the 20th century, gastric cancer was the most common malignant disease in the United States. Although gastric cancer is still a common cause of death, it has decreased in incidence so much that it is now only the 11th-most common cause of death from cancer in the United States.[1] The change has been attributed to dietary modifications, although the exact cause is unknown. The incidence of gastric cancer worldwide is much higher than in the United States.

In the large bowel, there has been a more gradual epidemiologic change. Previously, the majority of colorectal cancers were located in the rectum, but now most are located in the right colon. Although screening for, and removal of, precancerous polyps in the rectum and sigmoid colon with sigmoidoscopy could be producing some of these changes, it is unlikely to be a major factor. Dietary changes are suspected, but unproved, as a cause.

There has also been a major increase in the incidence of hepatocellular carcinoma (HCC) in the United States, although it is not nearly as high as the incidence worldwide. Some of the reasons for this are known, such as the strong association of HCC with hepatitis B and C virus infection. Improved prevention and treatment of hepatitis B and C infections should decrease the incidence of these diseases over the long term.

A major emphasis in the future will be to determine ways to prevent tumor formation or to find tumors early enough so that the risk of tumor mortality is minimized. Data strongly suggest that prevention strategies can be used to decrease the incidence of colorectal cancers. Screening for and removal of polyps before they become malignant interferes with the polyp-to-cancer sequence that occurs in the majority of colon and rectal cancers. Studies of patients screened with flexible sigmoidoscopy have demonstrated a markedly decreased incidence of cancers in areas within reach of the sigmoidoscope but no decrease in areas that could not be effectively screened.[7,8] Convincing data demonstrate the value of regular screening and stool guaiac studies in decreasing colorectal cancer mortality rates.[9,10] However, neither of these interventions is used widely enough to decrease markedly the overall incidence of these diseases. Virtual colonoscopy, a computed tomography (CT)-based radiographic examination, has generated a great deal of interest as a screening tool. However, the data do not yet support its widespread use and patients currently still need to do what many consider to be the worst part of an endoscopic procedure, the bowel preparation. Controlled studies are being performed to determine whether the bowel preparation is necessary or whether electronic deletion techniques can be used to exclude stool from the images.

Screening approaches have also been considered for tumors of other sites in the GI tract, but cost-effective strategies have not been defined. The incidence of gastric cancer in the United States and many Western countries is not high enough to justify the cost and morbidity of screening endoscopy for gastric or esophageal cancer, and radiographic studies such as CT scans are not sensitive. If it were possible to define a high-risk group of patients, then perhaps screening could be used successfully. Although controversial, the one other situation in the upper GI tract in which screening may be useful at the present time is in patients with Barrett's esophagus, where the incidence of esophageal cancer is high and regular endoscopy or elective surgery may be justified, at least for high-grade dysplastic lesions.

Prevention strategies have been studied extensively, especially for colon and rectal cancers. There are a variety of agents that have substantial potential as preventive agents for people at high risk. These include aspirin[11,12] and other nonsteroidal anti-inflammatory drugs (NSAIDs) and calcium.[13,14] The data are now quite convincing that the incidence of polyps can be decreased with the use of NSAIDs, presumably reflecting their activity as inhibitors of cyclo-oxygenase-2 (COX-2).[15] The finding of increased cardiovascular events in patients taking selective COX-2 inhibitors will have a major impact on the use of these agents for cancer prevention, but aspirin use is advocated by some.

BIOLOGY OF GASTROINTESTINAL CANCERS

Over the past decade, an enormous amount of information has been gathered regarding the molecular correlates of GI carcinomas. As is true for other anatomic sites, there are a large number of molecular changes in most of these tumors, but most of the changes occur in only a relatively small subset of tumors. A wide spectrum of molecular abnormalities has been found that likely define the genetic characteristics of the tumor. The specific molecular abnormalities probably have a major effect on both the pace of disease progression and the response of the tumor to therapy, but the relationship is clearly complex. Colorectal cancer is one of the best-studied adult solid tumors in this regard and illustrates the type of information that we are likely to obtain about other solid tumors. The detailed molecular changes associated with GI tumors and the general issues related to carcinogenesis are beyond the scope of this introduction but are covered elsewhere in this book, as well as in multiple reviews.[16]

Although there are a large number of molecular changes observed in colorectal cancer, a few are most common. These include altered promoter methylation, mutations of the *RAS* oncogene, mutations in the *TP53* tumor suppressor gene, mutations of a gene on the short arm of chromosome 18 (in an area referred to as the *DCC* gene [deleted in colon cancer]), and mutations in chromosome 5 in a region associated with the familial polyposis syndrome (FAP). Although there is clearly no orderly progression from one molecular change to another, there is a tendency for certain of these changes to occur early in the oncogenesis pathway. For example, changes in the *FAP* gene and altered methylation tend to occur early, whereas *TP53* mutations tend to occur late.[17]

As one probes deeply into the genome, a large number of abnormalities are being found, but many of these may be secondary to a generalized chromosomal instability. The significance of some types of molecular abnormalities is now

better understood. For example, microsatellite instability in colon cancer is associated with right-sided colon tumors but with an improved prognosis compared with those with no microsatellite instability. These tumors may also have altered (i.e., less) chemosensitivity, especially to 5-FU, compared with tumors without microsatellite instability. There is also awareness that changes in miRNA (and other nonprotein-coding RNAs) can have major importance in defining outcomes and perhaps response to therapy. Some investigators now classify colorectal cancer into three categories: those that have microsatellite instability (MIS), characterized clinically as right colon lesions with a relatively good prognosis (10% to 20% of tumors); those of the CpG island methylator phenotype (CIMP), which have a poor prognosis and relatively poor responsiveness to standard chemotherapy (10% to 30% of tumors); and those with chromosomal instability (CIN; 50% to 70% of tumors). This classification may help in the understanding, subclassification, and management of these diseases. More recently work of the The Cancer Genome Atlas (TCGA), sponsored by the National Cancer Institute (NCI), has compiled a comprehensive analysis of molecular changes in these tumors,[18] including not only mutational analysis, but also methylation, copy number variation, and miRNA changes.

An area of interest is the correlation of the known epidemiologic factors for cancer formation and the molecular abnormalities. For example, it is unknown how dietary changes are related to observed molecular alterations. Determining which dietary factors are of true importance and which dietary factors produce which molecular changes, and the mechanisms by which they do so, may be critical in designing effective prevention strategies.

For other tumors of the GI tract, the molecular correlates are not nearly as well established. Pancreatic cancer is unusual because approximately 90% of these tumors have a mutation in the *K-RAS* oncogene,[18] and mutations in the *P16, TP53*, and *MADH4* genes are common. This has been emphasized by the results of sequencing of pancreatic cancers, where a relatively small number of common mutational events were found, and most of the findings were unexpected from previous data. The finding of abnormalities that are present in most cancers of a certain type produces exciting possibilities for detection, prevention, and therapy because it suggests that these mutational events may be required for cancer formation. In addition, even when a specific mutation is not present, an abnormality in the same pathway may be present and produce the cancer of interest. However, the abnormality may be produced by one of many mutational events or even by gene silencing through altered methylation.

There is a major effort to develop pharmaceuticals that will block the function of critical pathways and thereby either inhibit tumor growth or kill the tumor. Many of the drugs that have been developed as pure molecular inhibitors for primary therapy do not seem to be effective when used alone. However, most of these agents (e.g., endothelial growth factor receptor [EGFR] or vascular endothelial growth factor [VEGF] inhibitors) have substantial radiation sensitization properties and may be useful adjuncts to standard radiation therapy (see Chapter 5).

A great deal of interest exists in using molecular analysis techniques to improve prognostication and to better define which tumors would be best treated with which modalities. These include whole genome sequencing, sequencing of the transcriptome, expression array analyses, epigenetic analyses (such as methylation), and so on. These studies are still in their early phases and require much additional work before routine clinical application. The further work of TCGA may provide additional information on the molecular characteristics of these tumors.

ANATOMY AND PATHWAYS OF TUMOR SPREAD

Upper GI (i.e., stomach, pancreas, and biliary tract) and colorectal cancers have anatomic similarities that lead to common patterns or pathways of tumor spread. The four common mechanisms of tumor spread for these sites include direct extension, lymphatic spread, blood-borne hematogenous metastases, and peritoneal seeding. Esophageal and anal cancers have no risk for peritoneal seeding because of their anatomic location, unless they extend to involve organs with access to the peritoneal cavity (e.g., stomach or upper rectum).

Direct extension of tumor that may lead to surgical unresectability because of fixation to or involvement of surrounding organs or structures is more common with upper GI cancers than with lower GI cancers. Within the triad of upper GI cancers, gastric cancers are most likely to be resectable at the time of diagnosis.

Lymphatic spread and nodal involvement are common at all GI sites. For the alimentary sites (i.e., esophagus, stomach, colorectum, and anus), the risk is minimal for lesions limited to the mucosa. The risk increases with direct extension into the submucosa in view of the presence of submucosal lymphatics, which are especially prominent in the stomach and esophagus. The mechanism of tumor spread within submucosal and subserosal lymphatics can also lead to subclinical tumor spread 5 cm to 10 cm or more from the margin of the gross tumor for both esophageal and gastric cancers. For colorectal cancers, it is unusual to have subclinical tumor extension in the bowel wall for more than 1 cm to 1.5 cm beyond the gross tumor, but nodal spread can occur at more distant locations.

Hematogenous dissemination from GI cancers is usually to the liver or lungs. With esophageal, anal, and rectal cancers, both sites are at risk. Gastric, colon, or pancreas cancers that do not extend beyond the wall or organ to involve other organs or structures have venous drainage via the portal circulation, placing the liver at primary risk for blood-borne metastases.

Peritoneal seeding can theoretically occur when a tumor extends to a free peritoneal surface. The finding of peritoneal seeding at initial surgical exploration is highest for gallbladder and pancreatic cancers, is rare with low rectal cancers, and can sometimes be found with gastric, colon, bile duct, and upper (with or without mid) rectal cancers.

STAGING

The current TNM (tumor, lymph nodes, metastasis) staging system of the American Joint Committee on Cancer (AJCC) is the accepted staging system for GI cancers.[19] However, because of either lesser nodal dissections or incomplete pathology, the pathologic examination of 10 to 15 nodes in gastric cancer does not always occur, and this can decrease the value of the N classification (N1, metastases in 1 to 2 regional lymph nodes; N2, metastases in 3 to 6 regional nodes; and N3, metastases in 7 or more regional nodes [N3a, 7 to 15 regional nodes; N3b, 16 or more regional nodes]). However, for both gastric and colorectal tumors, the aggressiveness of lymph node staging is of enormous prognostic importance. The prognosis is much inferior for "N0" tumors when few lymph nodes have been evaluated compared with these tumors when large numbers of nodes have been studied.[20] The ratio of positive lymph nodes to the total number of lymph nodes in a specimen is also becoming a more widely used measure because it partially compensates for inadequate nodal sampling. These variations in nodal count result in both understaging and stage migration, which make it difficult to compare results by

series. Some individuals have used the lymph node ratio (percentage of nodes that are involved with tumor) as an alternative to lessen the problem of poor nodal sampling.

Colorectal Cancers

The TNM system applies to both clinical and pathologic staging, defines the degree of primary tumor extension for lesions confined to and extending beyond the bowel wall, and defines node involvement by the number of nodes involved (N1, three or fewer nodes; N2, four or more nodes). The updated 2010 AJCC/UICC (Union for International Cancer Control) TNM classification should be used as the standard staging system (see Table D-1).

Considerable improvements in TNM staging for colon and rectal cancer have been achieved as a result of both the sixth and seventh editions of the AJCC staging manual.[21,22] Through the fifth edition of the manual, substaging was not used despite marked differences in outcomes by TN category of disease for patients with stages II and III disease. In both the sixth and seventh editions of the manual, substaging, based on available outcomes data, has been used to account for those differences in survival.[20-28]

Before making substantive changes in the AJCC seventh edition for colon and rectal cancer, the AJCC hindgut task force sought population-based validation that depth of invasion and nodal status interact to affect survival rates. Surveillance Epidemiology and End Results (SEER) survival data were obtained for patients with invasive colon and rectal cancer and evaluable TN category of disease (35,829 patients with rectal cancer and 109,953 patients with colon cancer).[27,28] T4N0 category cancers were stratified by "tumors that perforate visceral peritoneum" (T4a) versus "tumors that invade or are adherent to adjacent organs or structures" (T4b). N1 and N2 categories were stratified according to the number of involved nodes (N+): N1a and N1b (one node versus two to three nodes), and N2a and N2b (four to six nodes versus seven or more nodes). The 5-year observed and relative survival data were obtained for each TN category. The analyses indicated the following information: Survival times are better for patients with T1-2N0 cancers than for those with T3N0 cancers; survival times are better for patients with T3N0 tumors than for those with T4N0 tumors; and survival times are better for patients with T1-2N2 tumors than for those with T3-4N2 tumors. Survival times for patients with T4bN1 tumors are similar to those for T4N2 tumors.

In addition, patients with T4a lesions have better survival times than patients with T4b tumors by N category, and the number of positive nodes affects survival times for each T category. The SEER population-based colon and rectal cancer analyses supported subdividing T4 into T4a and T4b, N1 into N1a and N1b, and N2 into N2a and N2b, and supported revised substaging of II and III (shift of T1-2N2 lesions from IIIC to IIIA or IIIB and T4bN1 lesions from IIIB to IIIC).

Other Gastrointestinal Cancers

Staging of pancreatic, biliary, and esophageal cancers is less useful. The major factors defining therapy are whether the tumor is resectable, borderline resectable, or locally unresectable and whether distant metastatic disease is present. As therapy becomes more sophisticated and treatment outcomes improve, we will likely be better able to use more precise staging information. The ability to evaluate stage more effectively preoperatively through positron emission tomography (PET) scans (especially in esophageal and anal cancer but also in colorectal cancers) and endoscopic ultrasound (in esophageal and gastric cancers) should be of benefit over the long term with regard to choice of treatment (single-modality versus bimodality or trimodality treatment) and sequencing of various modalities (preoperative or postoperative, or both). HCC is generally not staged in the usual manner, but both patient and tumor factors are important in determining therapy and outcome.

TABLE D-1 Comparison of Staging Systems for Colorectal Adenocarcinoma

AJCC TNM Stage*	T	N	M	Dukes Stage	Modified Astler-Coller Stage
0	Tis	N0	M0	—	—
I	T1	N0	M0	A	A
	T2	N0	M0	A	B1
IIA	T3	N0	M0	B	B2
IIB	T4a	N0	M0	B	B2
IIC	T4b	N0	M0	B	B3
IIIA	T1-2	N1/N1c	M0	C	C1
	T1	N2a	M0	C	C1
IIIB	T3-4a	N1/N1c	M0	C	C2
	T2-3	N2a	M0	C	C1/C2
	T1-2	N2b	M0	C	C1
IIIC	T4a	N2a	M0	C	C2
	T3-4a	N2b	M0	C	C2
	T4b	N1-2	M0	C	C3

From Edge SB, Byrd DR, Compton CC, et al, editors: AJCC cancer staging handbook, ed 7, New York, 2010, Springer.

*Tis, *Carcinoma in situ;* T1, *tumor invades submucosa;* T2, *tumor invades muscularis propria;* T3, *tumor invades through the muscularis propria into pericolorectal tissues;* T4a, *tumor penetrates to the surface of the visceral peritoneum; T4b, tumor directly invades or is adherent to other organs or structures (surgical/pathologic definition).*

N0, *no regional lymph node metastases;* N1, *metastasis in one to three regional lymph nodes; (*N1a, *one regional node; N1b, two to three regional nodes);* N2, *metastasis in more than four regional lymph nodes; (*N2a, *four to six regional nodes;* N2b, *seven or more regional nodes);* M0, *no distant metastasis;* M1, *distant metastasis;*

Lymph nodes beyond those encompassed by standard resection of the primary tumor and regional lymphatics (e.g., retroperitoneal nodes) are considered distant metastases.

PROGNOSTIC FACTORS AND PATTERNS OF RELAPSE

Adjuvant Colorectal Cancer

Survival and disease relapse after surgery with or without adjuvant treatment for colon and rectal cancer are a function of both degree of bowel wall penetration of the primary lesion and nodal status. Nodal involvement is not the only important pathologic factor determining survival and relapse.

Impact of TN Category on Relapse and Survival

In the sixth edition of the AJCC staging manual, stage II was subdivided into IIA (T3N0) and IIB (T4N0) and stage III was subdivided into IIIA (T1-2N1M0), IIIB (T3-4N1M0), and IIIC (any TN2M0), based on improved outcomes for patients with stage IIA versus IIB disease and for those with stage IIIA versus IIIB cancers.[21] The placement of all patients in the TN2 category into stage IIIC, however, was not based on in-depth outcomes analyses because the prognostic impact of the depth of bowel wall invasion (T category) in N2 patients had not been evaluated in detail.

TABLE D-2 Pooled Rectal Analyses: Impact of NT Category on Survival

NT Category	Overall Survival (5-year)* No. Patients	%	*p* Value	Disease-Free Survival (5-year)* No. Patients	%	*p* Value
N0T3	668	74	0.046	664	66	0.05

Rectal Cancer Pooled Analyses

Rectal cancer pooled analyses subsequently demonstrated the independent prognostic significance of each TN and NT category of resected rectal cancer with regard to both disease relapse and survival rates[23,24] (Tables D-2 to D-4). Patients with T1-2N1-2 disease had a more favorable prognosis than previously thought, and those with T4N1 lesions (stage IIIB in the AJCC sixth edition, along with T3N1 lesions) had a prognosis more akin to that of patients with T3-4N2 lesions (stage IIIC in the sixth edition). For patients with N2 disease, data from the rectal cancer pooled analyses showed that N2 disease does not by itself confer a poor prognosis (see Tables D-2 and D-3). Substaging by T category influenced both the 5-year overall survival (N2T1-2, 67%; N2T3, 44%; and N2T4, 37%; $p < 0.001$) and the 5-year disease-free survival (58% versus 36% and 30%; $p < 0.001$). Placement of all N2 patients within AJCC substage IIIC in the sixth edition did not reflect the markedly different prognosis of patients who were N2 found in the two rectal cancer pooled analyses.[23,24] Outcomes data from the pooled analyses supported revised substaging of stage III because of improved survival rates for patients with T1-2N2 cancers versus T3-4N2 cancers, and survival rates for those with T4N1 lesions were more similar to those of T3-4N2 tumors than T3N1 tumors.

SEER Colon and Rectal Analyses

As shown in Table D-5, data in the large SEER population-based colon and rectal cancer analyses were highly consistent with those of the rectal cancer pooled analyses with regard to the more favorable prognosis of patients with T1-2N1-2 category lesions (stage IIIC, AJCC sixth edition) and the less favorable prognosis of patients with T4N1 category cancers (IIIB, sixth edition).[27,28] Data from the SEER colon and rectal analyses and the rectal pooled analyses supported shifting T1-2N2 lesions from IIIC to an earlier stage of disease (stage IIIA or IIIB) and shifting T4N1 lesions from stage IIIB to IIIC (see Table D-5).

SEER colon and rectal cancer outcomes data (see Table D-5) supported the substaging of T4, N1, and N2 tumors.[27,28] Patients with T4a cancers (penetration to the surface of the visceral peritoneum [revised definition in the AJCC seventh edition]) have a better prognosis than those with T4b cancers (direct invasion of or adherent to other organs or structures) for each N category of disease (N0, N1, N2). For patients with N0T4a versus T4b lesions, there is a 15% to 20% improvement in absolute 5-year relative and overall survival rates, and for N1T4a versus T4b and N2T4a versus T4b disease, there is a 15% to 25% improvement in 5-year survival rates. Earlier analyses with much smaller data sets had suggested that patients with perforated T4 lesions may have a worse prognosis than those with invasion of or adherence to other organs or structures. However, as has been shown in the large SEER colon and rectal cancer datasets, patients with T4 lesions that penetrate to the surface of the visceral peritoneum have a more favorable prognosis than those with lesions that invade or adhere to other organs or structures.[27,28]

As shown in the SEER colon and rectal cancer analyses and prior series, both the number of positive nodes and the number of nodes examined had prognostic significance.[20,27,28] In the large SEER colon and rectal cancer analyses, patients with one positive node (N1a) have a 5% to 13% better 5-year survival rate than those with two to three positive nodes (N1b) by T category, with improved survival rates for all TN categories. Patients with four to five positive nodes (N2a) have a 5-year survival that is 5% to 19% better than those with more than seven positive nodes (N2b) by T category, with improved survival rates for all TN categories except T1N1a versus T1N1b.

These data in total suggest that both the extent of the primary tumor and the extent of the nodal disease are independent prognostic factors for patients with colorectal cancer. Both must be taken into consideration in designing appropriate therapy.

TABLE D-4 Rectal Cancer Pooled Analyses: Survival and Relapse Rates by Stage or TN Category of Disease

Risk for Relapse*	Stage: TN Category	Stage: Modified Astler-Coller	Survival Rate (5 year)†: Overall (%)	Survival Rate (5 year)†: Disease-Free (%)	Relapse Rate: Local (%)	Relapse Rate: Distant (%)	Stage: Dukes	Stage: TNM (6th ed)

Adjuvant Gastric Cancer

As with other alimentary tract cancers, the two most important prognostic features are depth of invasion and extent of lymph node involvement. Nodal involvement reduces survival times, and the number of positive nodes is of prognostic importance. However, if the primary lesion is confined to the gastric wall (T1 or T2) when nodes are involved, the prognosis at 5 years (40% survival rate) is similar to that of patients with T2N0 or T3N0 lesions (~50% 5-year survival rate; see Chapter 45).

SINGLE-MODALITY VERSUS COMBINED-MODALITY TREATMENT

Radiation therapy has a role as a component of primary therapy in most cancers of the GI tract. It is used as part of the

initial management for patients with locally advanced cancers of the esophagus, stomach, pancreas, colon, rectum, and anus in most U.S. institutions and for hepatobiliary cancer in some institutions.

Chemoradiation: 5-Fluorouracil–Based

Although combined-modality therapy with chemotherapy and external beam radiation therapy (EBRT) is of great importance in many adult solid tumors, its use in the treatment of GI tumors is substantial and of long duration. 5-fluorouracil (5-FU) has been used as an anticancer therapy since the 1950s, and since the late 1960s, it has been used in combination with radiation therapy for GI tumors (concomitant with or without maintenance) (Figure D-1). Early studies of the combination were reported from the Mayo Clinic in the treatment of locally advanced pancreatic, gastric, and large bowel cancers.[29] Although modifications of this therapy have been developed, the use of concomitant 5-FU–based chemotherapy plus radiotherapy has remained a standard therapy for treatment of selected patients with tumors at almost all sites in the GI tract.

Although drugs such as cisplatin or mitomycin C are used in combination with 5-FU in a number of these anatomic sites (especially, the esophagus and anus), they have not replaced 5-FU but are used in conjunction with 5-FU and irradiation. There is now routine use of oral 5-FU analogs (e.g., capecitabine), with the hope that the oral formulation will make this treatment more acceptable to patients while maintaining similar efficacy; however, it has not markedly changed the toxicity profile although tumor efficacy appears as good as 5-FU infusional approaches.

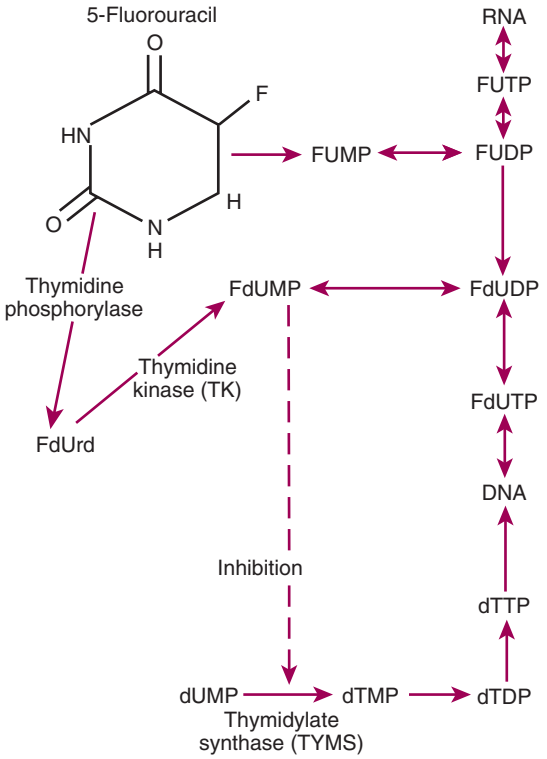

Figure D-1 The agent 5-fluorouracil (5-FU) has, as its primary mode of action, conversion into fluorodeoxyuridine monophosphate (F-dUMP), which acts to inhibit the enzyme thymidylate synthase, which is necessary for production of DNA. 5-FU can also be converted into fluorouracil triphosphate (FUTP) and incorporated into RNA or into fluorodeoxyuridine triphosphate (FdUTP) and incorporated into DNA. *FUMP*, Fluorouridine monophosphate.

For decades, 5-FU was essentially the only drug useful in colorectal and pancreatic cancer. Gemcitabine has now displaced 5-FU as the primary adjuvant drug treatment for pancreatic cancer, but other more aggressive combinations are being used for fit patients with metastatic disease. The combination of 5-FU or capecitabine and oxaliplatin or irinotecan is routinely used in the chemotherapeutic management of colorectal cancer. All of these agents have substantial radiation-sensitizing properties, and their use in rectal cancer has been extensively explored. The Phase III studies of oxaliplatin plus EBRT and 5-FU in rectal cancer have caused increased toxicity with no improvements in disease outcomes,[30] and irinotecan has not been as well studied because of additive toxicity (diarrhea) with radiation plus fluoropyrimidine. As mentioned, the use of EGFR or VEGF inhibitors as radiation sensitizers in a variety of sites in the GI tract, especially rectum, has generated substantial interest, but have not yet produced encouraging results beyond demonstration of tolerability.

Although surgery remains the primary mode of curative treatment for gastric, pancreatic, and large bowel cancers, combined chemotherapy plus irradiation has become the primary treatment for anal cancer and may offer an equivalent option to surgery alone for some patients with esophageal cancer. Although surgical techniques have continued to evolve, most prominently with the use of total mesorectal excision for rectal cancer, therapy with surgery alone is unlikely to significantly improve the survival rates for gastric, pancreatic, esophageal, and large bowel cancers. Adjuvant and neoadjuvant radiation therapy or chemotherapy, or both, offer the best prospect for improving cure rates.

A large number of studies have been performed using the aforementioned strategies. With unresected esophageal cancers, combined chemotherapy plus irradiation has clearly improved rates of disease control and 5-year survival over irradiation alone in Phase III randomized trials.[31] In an important Phase III trial from the Netherlands preoperative chemoradiation, using carboplatin and paclitaxel as the chemotherapy, improved survival rates compared with surgery alone in patients with resectable esophageal/gastroesophageal junction cancer.[32] For resected high-risk rectal cancers, postoperative chemoradiation has improved rates of local and distant disease control, disease-free survival, and overall survival compared with surgery alone or adjuvant irradiation.[33,34] Preoperative irradiation has demonstrated improved local control and survival when compared with surgery alone for resectable rectal cancer in a large randomized trial in Sweden,[35] and a large German trial[36] has shown the superiority of preoperative chemoradiation over the same therapy delivered postoperatively. Adjuvant postoperative chemoradiation has resulted in improved local control and survival in some Phase II and Phase III trials for resected pancreatic cancer.[37-40] Postoperative chemoradiation has also improved local control and survival rates when compared with surgery alone in patients with resected high-risk gastric cancers in a Phase III U.S. GI intergroup trial.[41]

For resected node-positive colon cancers, adjuvant chemotherapy has produced improved disease-free survival and overall survival compared with surgery alone. Postoperative chemoradiation has been evaluated in patients with resected high-risk colon cancers,[42] and although it has not been shown to be of value for the typical patient, it may be of value in selected clinical situations, as when microscopic residual disease remains (although this is not truly an adjuvant setting). A preferred approach would be to use imaging to identify patients who would likely have marginal resection if surgery were the initial component of treatment (e.g., a T4 lesion with adherence to a surgically unresectable structure). In such patients, preoperative chemoradiation would preferably

precede surgical resection. Finally, chemoradiation has replaced surgical resection as the primary treatment for anal carcinomas, with surgical resection being reserved for salvage therapy. Although these positive trials are exciting and encouraging, refinements in multimodality therapy will necessitate continued enrollment of patients in clinical trials to help develop the most effective combined-modality treatment strategies for the future.

Chemoradiation: New Chemotherapy Drugs

For the first time in many years, there are a variety of new drugs that may supplement or supplant 5-FU when used in combination with radiation therapy in the treatment of GI cancers. These new cytotoxic drugs include gemcitabine, irinotecan, oxaliplatin, and oral 5-FU compounds.

Gemcitabine is the first drug developed in many years with single-drug activity against pancreatic cancer.[43] Reliable data demonstrate that gemcitabine has substantial radiation-sensitizing properties,[44] and clinical studies are continuing with this drug used in combination with radiation therapy for patients with both locally advanced and resected pancreatic cancer.[45] Because gemcitabine is a potent radiation sensitizer, it needs to be used cautiously. In view of positive survival outcomes for gemcitabine plus nab-paxitaxal (Abraxane) versus gemcitabine alone for patients with metastatic pancreas cancer[46] it may be of interest to determine if both drugs can be given during concurrent EBRT. Although the combination of gemcitabine and irradiation may be effective in other sites in the GI tract, the fact that gemcitabine lacks substantial activity when it is used alone in colon and rectal cancer makes its use for these diseases unlikely.

A number of other drugs have substantial activity in colon and rectal cancer, including the topoisomerase inhibitor irinotecan (CPT-11) and the platinum compound oxaliplatin. Data exist to demonstrate radiation sensitization with irinotecan[45] and oxaliplatin.[47] Both of these drugs have been tested in combination with radiation therapy for patients with rectal cancer. Although preliminary Phase II data suggested that they appeared to increase the rates of pathologic complete response when used with 5-FU and irradiation in the preoperative setting, subsequent larger studies have suggested that this may not be true.[48-50]

Another group of important drugs are oral analogs of 5-FU, although they may behave slightly differently than the infusional approaches. Some of these agents are 5-FU prodrugs, and some act to inhibit the degradation of 5-FU, either by direct or indirect inhibition of the degradation pathway. Others attempt to increase tumor selectivity, and yet others act as specific inhibitors of thymidylate synthase (in contrast to the nonspecific action of 5-FU).[51] The major potential advantages of these compounds are the convenience for patients and the elimination of the continuous infusion pumps needed for 5-FU. The toxicity spectrum of these agents does not differ substantially from that of 5-FU given by conventional infusion.

Capecitabine is an agent that has entered routine clinical use both as a single-modality chemotherapeutic agent and used in combination with irradiation.[52] Capecitabine is delivered twice daily, and although serum levels are much flatter than after a 5-FU bolus, major variations in serum levels do exist. Therefore, the timing of irradiation and capecitabine may still be important. The recommendation is to take capecitabine approximately 1 hour before the delivery of radiation therapy to maximize radiation sensitization. Capecitabine doses used with concurrent radiation are less than doses of the drug used alone (typically, 1650 mg/m^2/day delivered in two doses) and investigators vary on whether the drug should be delivered 7 days per week or Monday to Friday with EBRT.

IRRADIATION TECHNIQUE AND TOLERANCE

Irradiation Field Definition

Because treatment tolerance to irradiation is usually a function of both dose and volume, proper definition of tumor and target volumes is of utmost importance. If patients are referred for primary or preoperative EBRT, the radiation oncologist can obtain the necessary imaging studies to define both the primary tumor and the nodal areas at risk. If the patient is referred after complete resection, however, the radiation oncologist is dependent on the availability of pertinent preoperative imaging studies or placement of surgical clips at sites of tumor adherence or microscopic residual disease.

For unresected alimentary tract cancers (e.g., esophageal, stomach, colorectal, anal cancers), the primary lesions and nodal areas at risk are best defined with CT scanning. The chest plus the abdomen are imaged for esophageal cancers, the abdomen and generally the chest for gastric cancers, and the chest, abdomen, and pelvis for colorectal and anal cancers. PET/CT scans are preferable for esophageal and anal cancers because these tumors are usually PET avid and the primary tumors are often not well seen on conventional CT scan. Endoscopic ultrasound (EUS) can also be used in esophageal, gastric, and rectal tumors to determine both the depth of invasion in the wall and the presence of nodal involvement. The ability to biopsy suspicious areas is an advantage for endoscopic evaluation. None of these tests adequately define longitudinal disease extension in esophageal cancer, however. EUS is the best widely used imaging technique for determining the T category of disease for esophageal, gastric, and rectal cancers before resection, but it is most useful in rectal cancer for defining the patients who need preoperative therapy. MRI is considered by many to be superior to EUS in rectal cancer because of its ability to assess the adequacy of the surgical mesorectal excision. The use of endoscopy to both define lesions and obtain biopsies has essentially eliminated the use of preoperative contrast radiographs, so the preoperative CT, PET, or MRI imaging is essential to construct proper irradiation fields if patients are referred after resection. However, some important structures (such as the anal verge) are not well defined with cross-sectional imaging unless markers are placed at the site of interest.

For unresected biliary tract cancers, endoscopic retrograde cholangiopancreatography (ERCP), percutaneous transhepatic cholangiography (PTHC), and MRI or magnetic resonance cholangiopancreatography (MRCP) demonstrate the distal and proximal extent of disease most precisely. If transhepatic catheters have been placed at the time of PTHC imaging, the radiation oncologist can reinject the catheter with contrast medium to reconstruct the ductal system and define target volumes. If stents have been placed at ERCP, the relationship of the stent to ductal involvement as demonstrated on ERCP imaging can be used to define tumor and target volumes. MRI can also effectively reveal these tumors and is commonly used. The medial and lateral disease extent is best distinguished with MRI/MRCP or PET/CT imaging.

With unresected pancreatic cancers, abdominal CT or MRI best demonstrates tumor and nodal target volumes, and PET/CT is used by some to better define the primary lesion and rule out early metastatic disease. If the tumor has been resected, postoperative CT or MRI scans of the abdomen can help rule out liver metastases and define postoperative nodal volumes, and the preoperative CT scan and surgical clips can be used to define the tumor bed.

Conformal three-dimensional radiation therapy with CT-based treatment planning is recommended for the

treatment of most, if not all, patients with GI cancer, and intensity-modulated radiation therapy (IMRT) is appropriate for some GI cancer sites, especially anal canal cancers. For patients with esophageal and gastroesophageal junction cancers, CT-based planning is useful in defining the medial-lateral and anteroposterior extent of tumor, but it should be combined with contrast radiographs, endoscopic information, and PET/CT imaging to determine the proximal and distal extent of the primary lesion. In patients with gastric cancer, the proximal stomach or gastric remnant is best defined by oral contrast images plus CT scanning because CT imaging alone may underestimate the anatomic location. With CT scanning for rectal cancer treatment planning, the precise location of the anal sphincter should be defined by placing BB markers or another type of metal marker at the anal verge. The anorectal margin is not visualized on a CT scan without contrast medium in the rectum. Fusion of PET/CT images may be helpful in defining the gross tumor extent for both rectal and anal lesions.

Definition of irradiation fields can be difficult in hepatic irradiation. It is critical to use high-quality CT or MR imaging and to have control over the liver position during the breathing cycle. Diagnostic images often need to be fused with treatment planning scans, and placement of fiducial markers can be useful for some radiation techniques, including stereotactic body irradiation (SBRT). Typically, these tumors do not have a large degree of extension into the hepatic parenchyma, but margins for uncertainty and breathing are critical.

Normal Tissue Tolerance

When irradiating the abdomen and pelvis, there are numerous normal structures that can be dose limiting and must be considered in treatment planning. These include the stomach, small intestine, spinal cord, large intestine, liver, and kidneys, in addition to the soft tissue in the abdomen. A full discussion of the tolerance of these structures is beyond the scope of this overview, but a brief review is given here.

Upper Gastrointestinal and Extrapelvic Colon Cancers

The tolerance of the liver is dose limiting when a substantial portion of the liver is included in the radiation field. The hepatic parenchyma is relatively sensitive to radiation, with total organ tolerance doses in the range of 30 Gy, using conventional fractionation (1.5 Gy to 2.0 Gy), being near tolerance. The ability to tolerate higher doses to portions of the liver is primarily dependent on the volume of liver receiving high doses because recovery of the hepatic parenchyma is dependent on hypertrophy of the unirradiated liver. In an individual with normal baseline hepatic function, it is possible to irradiate approximately 50% to 60% of the liver to high doses without undue problems if the remainder of the liver remains untreated (see Chapter 49). If hepatic function is compromised, less parenchyma can be safely treated, although an exact determination of the safe amount is not defined. Because it is possible to totally irradiate and destroy a portion of the liver without danger to the patient, there is essentially no limit to the dose that can be given to small portions of the liver, although biliary obstruction may be produced after high doses to the major biliary radicals. Dawson et al[53] have conducted a series of elegant clinical trials that define hepatic tolerance better than has been done for most other organs.

Hepatic tolerance is becoming a major issue with the increased interest in irradiating hepatocellular carcinomas and liver metastases. Although radiation oncologists have historically not had a major role in treatment of hepatocellular cancers, improvements in technology has allowed for better radiation dose delivery and a greater use of radiation in selected clinical situations, especially for localized but unresectable hepatocellular carcinomas. Preliminary data suggest that radiosurgical or fractionated SBRT approaches will be effective complements to surgical resection and radiofrequency ablative approaches.

The tolerance of the kidney is conceptually similar to that of the liver in that irradiation of a portion of the kidney to a high dose is well tolerated if the baseline renal function is good and if a significant portion of the remaining kidney is unirradiated to allow for hypertrophy (e.g., only 20% to 30% of the kidney receives more than 20 Gy). It is important to be certain that the baseline renal function is adequate (by measuring creatinine clearance or by estimating the clearance based on the creatinine level, age, gender, and weight of the patient, using the Cockcroft formula) and that the contralateral kidney is functioning properly so that it can take over the renal function. The latter is best done with a functional renal scan (such as a dimercaptosuccinic acid [DMSA] scan) that can provide the percentage of function from each kidney. Although the data on renal tolerance are fairly old, even moderate doses (in the range of 25 Gy) can produce substantial renal injury. Doses higher than 30 Gy are likely to produce major renal parenchymal injury. Studies suggest that clinically significant sequelae are unlikely after conventional abdominal irradiation if the preceding factors are taken into consideration.[54] Although it is possible to produce severe kidney injury with secondary renovascular hypertension, this is an uncommon event.

The stomach has generally been considered to be a radiation-sensitive structure, with ulcer formation occurring after doses greater than 45 Gy to 50 Gy (1.8-Gy to 2-Gy fractions), but precise gastric tolerance has not been well established. Although a large number of patients have received moderate to high doses of radiation therapy to the upper abdomen, this has usually been done for tumors that have a poor cure rate and for patients where survival of longer than 2 years is relatively unusual. The experience in the treatment of Hodgkin's disease clearly demonstrates gastric tolerance to doses of 45 Gy. When irradiating a portion of the stomach in the treatment of upper GI cancers, one must minimize both the volume and the dose to the stomach. It is of interest, however, that there are few recent data describing gastric ulceration, suggesting that some of the old tolerance data may not be reliable. Mayo Clinic data on the treatment of bile duct cancers suggest that gastroduodenal tolerance is best if doses of 54 Gy or less (in 1.8-Gy fractions) are used. With EBRT plus 5-FU, the rate of grade-3 or higher GI intolerance is 10% with doses of 54 Gy or less and 30% to 40% with doses of more than 54 Gy.[55]

Tolerance of the pancreas to radiation therapy is not often discussed, but there is anecdotal evidence that both exocrine and endocrine dysfunction can result, although analyses are complicated by the effects of the tumor and of surgery. It is appropriate for the radiation oncologist to consider the possibility of pancreatic dysfunction during patient follow-up. Pancreatic enzymes are commonly needed during and after therapy, and insulin is required at times.

Pelvic Gastrointestinal Cancers

The small bowel is the organ that has produced the most clinical problems after conventional radiation therapy in the pelvis. Moderate doses to the small bowel (50 Gy in 1.8-Gy to 2-Gy fractions) will begin to cause clinically significant problems. It has been suggested that risk factors for injury include diabetes and hypertension as well as prior surgery, but this finding has not been well substantiated. It is clear that the volume of irradiated small bowel is also important, but it has not been well quantified as to how much bowel can be treated safely. When

larger volumes are treated, small bowel obstruction is the most likely complication.[56] The obstructive episodes can be recurrent, and 50% or more of patients may require laparotomy for resolution. At surgery, it is often not possible to resect the damaged small bowel, which is usually enveloped in a fibrotic mass, and a surgical bypass may be the treatment of choice. However, if the damaged bowel can be resected with low morbidity, that approach is optimal. Dissection of irradiated bowel in an attempt to free up all adhesions may result in enterotomy and subsequent fistula. Small bowel complications are most common with irradiation of the pelvis, an area that has commonly been exposed to extensive surgery with associated adhesions and small bowel fixation. Although complications are less likely in the upper abdomen, they can still occur, and efforts should be made to minimize the volume of irradiated small bowel.

There are a number of manipulations that the radiation oncologist can use to minimize the amount of small bowel in a pelvic irradiation field, including the use of IMRT or three-dimensional conformal irradiation techniques. The first action is to determine the location of the small bowel. This can be done by giving oral small bowel contrast medium at least 45 minutes before a radiographic imaging study, either by conventional simulation or CT scanning. With this information, the radiation oncologist can design fields that will minimize the volume of small bowel irradiated. It is also helpful to work with a surgeon who can perform surgical manipulations to move the small bowel out of the pelvis. A number of techniques have been tried, including reperitonealization of the pelvic floor after abdominoperineal resection, using a vascularized omental sling or pedicle to displace small bowel out of the pelvis, retroverting the uterus to act as a space-occupying device, and putting mesentery or a foreign body into the pelvis for the same purpose. In addition, during simulation, one can use bladder distention or displacement devices to shift small bowel out of the pelvis. Having the patient lay in the prone position on a false tabletop located at or superior to the radiation field (9-cm × 12-cm opening) is one technique that has been effective for many patients. These techniques work to a varying extent on individual patients.[57] Small bowel being fixed in the pelvis is much less of a problem when patients are receiving preoperative radiation therapy for rectal cancer, the standard of care at this time. Whichever approach is taken, the treating physician must pay attention to the location of the small bowel and dose to the organ or risk significant complications.

There is less information on the tolerance of the large bowel (colon and rectum) to high radiation doses, and much of the information available comes from irradiation of non-GI tumors, especially those of the prostate and cervix. There is little information on the tolerance of the colon, partially because there has been little high-dose irradiation of the intraperitoneal or retroperitoneal colon. Rarely is the colon a dose-limiting structure. The rectum or portions of it have been treated to doses of 65 Gy to 70 Gy or higher for cervical, prostate, and anal cancers and for localized treatment of rectal cancers. It is clear that portions of the rectum can be treated to high doses with minimal late effects. The most obvious example of this is in the use of endocavitary radiation therapy of small rectal cancers. In this technique, doses of approximately 90 Gy to 120 Gy have been delivered in four fractions. Although the rectal muscular wall receives a low dose from the first two fractions because of rapid dose fall-off, it receives a full dose for the last one to two fractions. Late complications such as bleeding and ulceration occur in 10% to 15% of patients, and only an occasional temporary diverting colostomy is needed, likely because the rectal mucosa can be repopulated from surrounding normal tissue and because the area of scarring is not large enough to cause stricture formation.

However, when high doses of radiation are given to a substantial portion of the rectal circumference (i.e., more than half), the tolerance is much less. With circumferential irradiation, the dose to a 10-cm length of rectum is preferably limited to 60 Gy or less in 2-Gy fractions to prevent problems with bleeding, ulceration, and narrowing of the rectum. Even with partial organ radiation therapy, there have been significant problems with bleeding (10% to 15% incidence) reported at doses of approximately 72 Gy. Although conservative treatment with bulk agents and steroid preparations can alleviate most situations, laser therapy at the time of endoscopy may be necessary to control bleeding. Difficult management problems are rare but at the extreme can require surgical correction, usually a temporary diverting colostomy.

There is even less information available on anal tolerance. However, it is generally thought that doses higher than 55 Gy to 60 Gy to the whole anal canal in conjunction with chemotherapy, as used in the treatment of anal cancer, have a risk of stricture formation or poor anal sphincter function. In the treatment of rectal cancer, one should try to minimize the amount of anus in the radiation field because anal irradiation produces a large amount of acute morbidity, occasional stricture formation, or poor late functioning of the anus. There is clearly a significant risk of late morbidity in anorectal function that can cause clustering and frequency of bowel movements with suboptimal control and intolerance to certain foods.[58] These effects are likely the result, at least partially, of anal dysfunction as well as poor rectal capacity from surgery or irradiation. Minimizing the radiation dose and volume and careful surgical techniques need to be used to minimize the risk of late complications.

Irradiation Boost Techniques

For completely resected, margin-negative GI cancers, adjuvant doses of irradiation (50 Gy to 54 Gy) plus concomitant 5-FU–based chemotherapy are adequate to achieve local control in 85% to 90% of patients. For margin-positive or unresected GI cancers, the dose of irradiation required to achieve adequate local control would usually exceed the normal tissue tolerance (e.g., >70 Gy in 1.8-Gy to 2-Gy fractions). Therefore, the use of brachytherapy or intraoperative electron irradiation (IOERT) as a supplement to EBRT and chemotherapy after resection may improve local control rates in the treatment of locally advanced GI cancers.

The use of IOERT as a component of treatment for a variety of disease sites is discussed in Chapter 17 and for GI malignant diseases in Chapters 47, 48, 50, and 51. IOERT plus EBRT (with or without 5-FU) and maximal resection appear to improve rates of both local control and survival for locally unresectable and locally recurrent colorectal cancers.[59-61] With unresectable pancreatic cancers, the addition of IOERT to EBRT with or without 5-FU improves local control rates but has no apparent impact on survival rates in view of the high rates of relapse in the liver and peritoneal cavity.[62-64]

Brachytherapy has been used as a supplement to EBRT with biliary tract cancers.[65,66] There is a suggestion of improved survival rates in patients treated with both EBRT and brachytherapy compared with either alone (see Chapter 49), but Phase III trials are unlikely in view of small patient numbers.

SUMMARY

Radiation therapy is now a part of the therapeutic approach for many patients with cancers of the GI tract, although mostly for patients with moderately advanced locoregional disease. In most of these sites, the combination of radiation therapy

and 5-FU–based chemotherapy is standard therapy, although cisplatin or mitomycin is used with 5-FU in tumors of the esophagus and anus. In many GI cancer sites, chemoradiation is used as an adjuvant to surgical resection because of the propensity of GI rumors to recur locally and the difficulty in obtaining a wide resection margin, usually relating to the anatomic site. Careful attention to radiation therapy technique and respect for normal tissue tolerance are essential if local control is to be obtained without producing unacceptable normal tissue morbidity.

CHAPTER

47 Gastric/GE Junction Cancer

Leonard L. Gunderson, Joel E. Tepper, Felipe A. Calvo, and Jonathan B. Ashman

INCIDENCE

For 2015, the predicted incidence of stomach cancer in the United States was 24,590 cases, and the predicted number of deaths was 10,270.

The site of origin within the stomach is shifting in the United States as more proximal lesions are diagnosed.

BIOLOGIC CHARACTERISTICS

The main prognostic factors relate to locoregional tumor extent and include both nodal involvement and direct tumor extension beyond the gastric wall.

STAGING EVALUATION

Initial evaluation should include history and physical examination, complete blood count, liver chemistries, endoscopy with biopsy and ultrasonography (determine degree of direct tumor extension), and computed tomography (CT) of the abdomen (define extragastric disease) and chest (especially for gastroesophageal junction [GEJ] lesions).

Additional studies that may help define extent of disease include laparoscopy (rule out peritoneal seeding or early liver metastasis) and positron emission tomography (PET), especially for for GE junction tumors.

PRIMARY THERAPY

Surgical resection is the primary therapy for resectable gastric cancers. Cure rates of 80% or higher are achieved with early lesions (nodes negative, confined to mucosa or submucosa), which are uncommon in the United States.

Extended D2 node dissection has not improved survival in randomized trials.

ADJUVANT THERAPY (RADIATION, CHEMOTHERAPY)

Adjuvant therapy is indicated on the basis of patterns of relapse and survival results with surgery alone (high incidence of locoregional relapse and distant metastases).

A U.S. Intergroup Phase III trial of 556 patients (pts) demonstrated a survival benefit for combined modality postoperative chemoradiation (postop CRT) versus a surgery alone control arm (3-year relapse-free survival [RFS] 48 versus 31%, $p = 0.001$; 3-year overall survival [OS] 50 versus 41%, $p = 0.005$).

The Phase III ARTIST trial (458 pts) compared postop chemo to postop CRT after D2 resection. In a subset analysis of pts with positive nodes (396 pts), 3-year disease-free survival (DFS) was improved with CRT (77.5% versus 72%, $p = 0.0365$).

Preoperative irradiation improved locoregional control and OS in a Beijing Phase III trial of 370 patients (5-year OS 30% versus 20%, $p = 0.009$).

Preoperative chemoradiation improved survival in a CROSS Phase III trial comparing surgery alone with preop CRT for 366 analyzable patients with adenocarcinoma (ACA) of the esophagus or GE junction. Median OS was 49.4 versus 24 months, 3-year OS 58 versus 44%, and 5-year OS 47% versus 34% ($p = 0.003$).

The POET trial of 120 pts with GEJ lesions tested preoperative (preop) chemotherapy versus CRT; outcomes trends favored preop CRT over chemo alone for both OS ($p = 0.07$) and local control ($p = 0.06$).

Although most Western trials of postoperative chemotherapy alone are negative for both single and multiple drugs, a British Phase III trial of 503 patients demonstrated a survival advantage for perioperative epirubicin, cisplatin, 5-fluourouracil ([5-FU]; ECF) chemotherapy (when compared with surgery alone (5-year OS 36% versus 23%, $p = 0.009$). In addition, a French Phase III trial of 224 patients found a survival advantage for perioperative cisplatin and 5-FU (CF) compared with surgery alone (5-year OS 38% versus 24%, $p = 0.02$).

Postoperative and preop CRT and perioperative ECF or CF are all appropriate appropriate standards of care.

LOCALLY ADVANCED DISEASE

Both external beam radiation plus chemotherapy and intraoperative radiation result in long-term survival in 10% to 20% of patients in randomized and nonrandomized trials.

Neoadjuvant chemotherapy may increase resection rates, but the incidence of locoregional relapse is still high. Pathologic complete response specimens are uncommon (0% to 9%).

PALLIATION

Multidrug chemotherapy regimens have response rates of 30% to 50%, but survival improvements are modest.

The ECF regimen produced improved response rates and survival when compared with the combination of 5-fluorouracil, doxorubicin (Adriamycin), and high-dose methotrexate (FAMTx) in a British Phase III trial.

A recent study of vascular endothelial growth factor (VEGF) inhibition with the monoclonal antibody refucirumab has shown a survival advantage, and HER2 blockade in tumors with HER2 overexpression produces a survival benefit.

European Phase III trials demonstrate improvement in quality and duration of life with palliative chemotherapy versus supportive care.

The primary therapy for resectable gastric cancer for patients who can tolerate the procedure is surgical resection. At the time of diagnosis, gastric cancers are localized and surgically resectable in approximately 50% of patients; however, regional nodal metastases or direct invasion of surrounding organs or structures is frequently encountered and precludes cure by surgery alone in many patients. For patients with lower risk lesions (confined to gastric wall, nodes negative; T1-2N0M0) adjuvant treatment is usually not recommended. Because both local and systemic relapses are common after resection of

high-risk gastric cancers (beyond wall, nodes positive, or both; T3-4N0, Tany N1-3), adjuvant treatment is indicated for these patients. The results of Phase III trials that demonstrate a survival benefit for postoperative chemoradiation, preoperative external beam irradiation (EBRT), preoperative chemoradiation, and perioperative ECF or CF versus surgery alone will be summarized and future trial designs will be discussed. Results of Surveillance, Epidemiology and End Results (SEER) analyses and meta-analyses that support the role of adjuvant irradiation or chemoradiation will be summarized.

For patients with locally advanced disease that appears unresectable for cure, several treatment options appear to favorably impact disease control and survival. These include EBRT plus concurrent chemotherapy, maximal resection plus intraoperative irradiation (IORT), and preoperative chemotherapy or chemoradiation.

In the setting of metastatic disease, there are many active chemotherapy agents that can produce meaningful response alone or in combination with other agents, but the duration of response is usually limited. Phase III trials demonstrate both a survival and quality of life benefit for multidrug chemotherapy versus best supportive care for patients with metastatic cancers.

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

In the United States, gastric cancer now ranks 14th in incidence among the major types of malignancy. Over the past 60 years, there has been a significant decline in the incidence of gastric cancer among both sexes in Western countries[1] (eFigure 47-1). In the United States, from 1930 to 1980, the incidence decreased from 38 to 10 (per 100,000) for men and from 30 to 5 (per 100,000) for women. In 2015, it was estimated that 24,590 new cases and approximately 10,270 deaths would occur.[2] The disease rarely occurs before the age of 40 years, but its incidence increases steadily thereafter and peaks in the seventh decade. African Americans, Hispanic Americans, and American Indians are twice as likely to develop gastric cancer as are whites.[3] There has been a slight improvement in overall 5-year survival among U.S. patients: 11% (1900 to 1963), 15% (1974 to 1976), 18% (1980 to 1982), and 21% (1989 to 1994).[3]

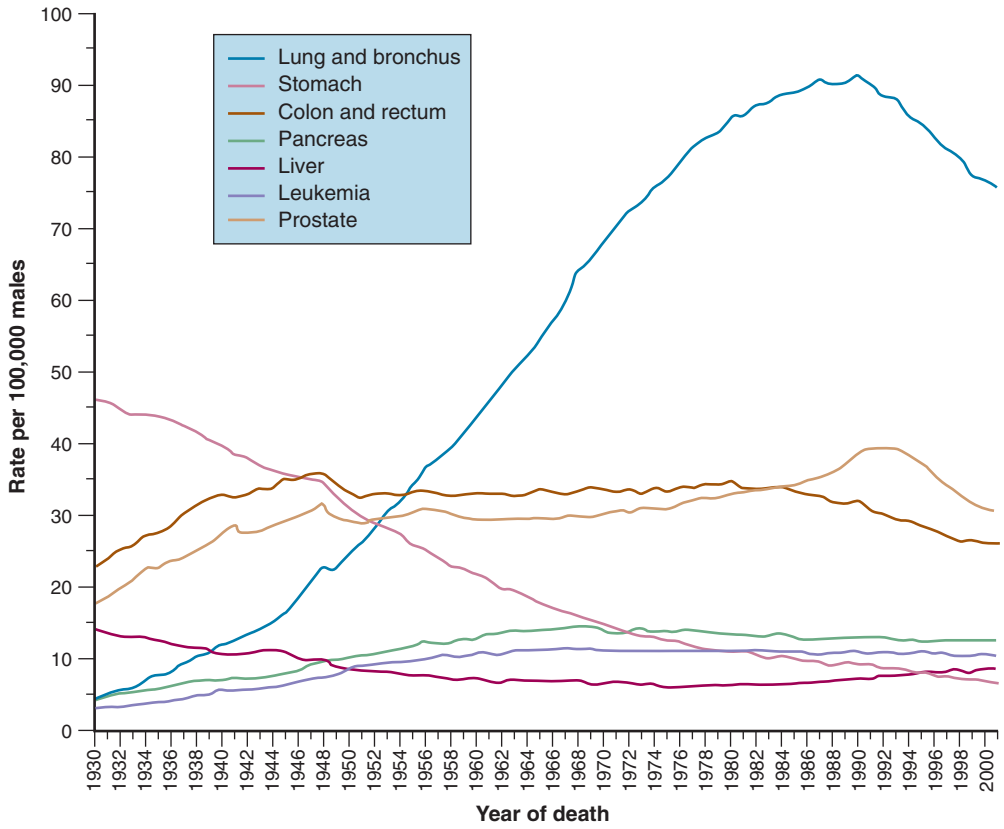
Although gastric cancer incidence has decreased significantly in the United States, on a worldwide scale, gastric cancer has a high incidence rate and is still a leading cause of cancer death.[2,4] Of the 45 countries in which age-adjusted death rates for gastric cancer were compared for 2000 (eFigure 47-2), the United States ranked 45th for both males and females.[2] Kyrgyzstan ranked first for both males (47.0 in 100,000) and females (18.9 in 100,000).

The site of origin within the stomach has changed in frequency in the United States over recent decades, with proximal lesions now being diagnosed and treated much more commonly than previously. The largest percentage of gastric cancers still arise within the antrum or distal stomach (≈ 40%), are least common in the body of the stomach (≈ 25%), and are of intermediate frequency in the fundus, cardia, and gastroesophageal (GE) junction (≈ 35%). In 1930, most cases of gastric carcinoma originated in the distal stomach (body and antrum). The reduction in incidence of gastric cancer from 1930 to 1980 primarily is attributable to a decline in distal lesions.[5]

Since the 1970s, there has been a steady rise in the incidence of adenocarcinoma of the GE junction and proximal stomach. For both sites, the rate of increase during the 1970s and 1980s surpasses that of any other cancer, including melanoma, lung cancer, and non-Hodgkin's lymphoma.[6] Similar trends in the increased incidence of gastric cardia cancer have also been reported in Denmark, where rates were much higher in men, and in the United Kingdom, where rates were highest among those in higher socioeconomic classes.[7]

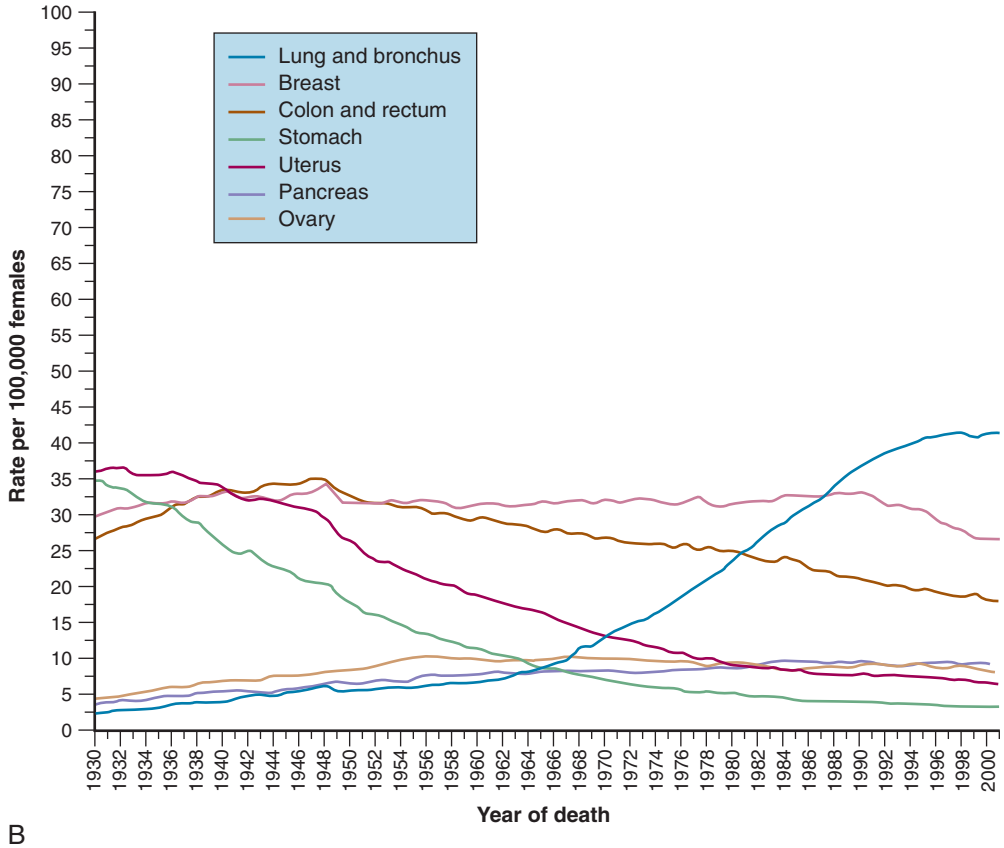
Etiology

Although the precise etiology is unknown, environmental factors are likely to be important. The incidence of gastric cancer in first- and second-generation Japanese who have moved to the United States is much lower than in native Japanese citizens.[8] Studies of immigrant populations from Japan and Eastern Europe show that the risk of the disease declines markedly in the second and third generations.[9] The excess risk of first-generation immigrants is largely restricted to the intestinal type.[10] The risk of gastric cancer is inversely associated with socioeconomic status throughout the world,[11] and the marked decline in the incidence of gastric cancer in industrialized countries, including the United States, suggests that environmental factors play an important role. These may be related to poor nutrition, inadequate sanitation facilities, and substandard quality of food preservation.



Diets rich in fruits or vegetables are associated with a reduced risk of gastric cancer,[12] whereas diets containing abundant quantities of smoked, heavily salted, or poorly preserved foods are associated with an increased risk of this disease.[12,13] Excessive dietary salt has been associated with atrophic changes in the gastric mucosa.[14] Chronic atrophic gastritis and the associated abnormality, intestinal metaplasia, are most closely linked to the intestinal type of gastric adenocarcinoma. These lesions can progress to dysplasia and carcinoma.[15] The prevalence of atrophic gastritis and intestinal metaplasia is highest in regions of the world that have the highest rates of gastric cancer.[16]

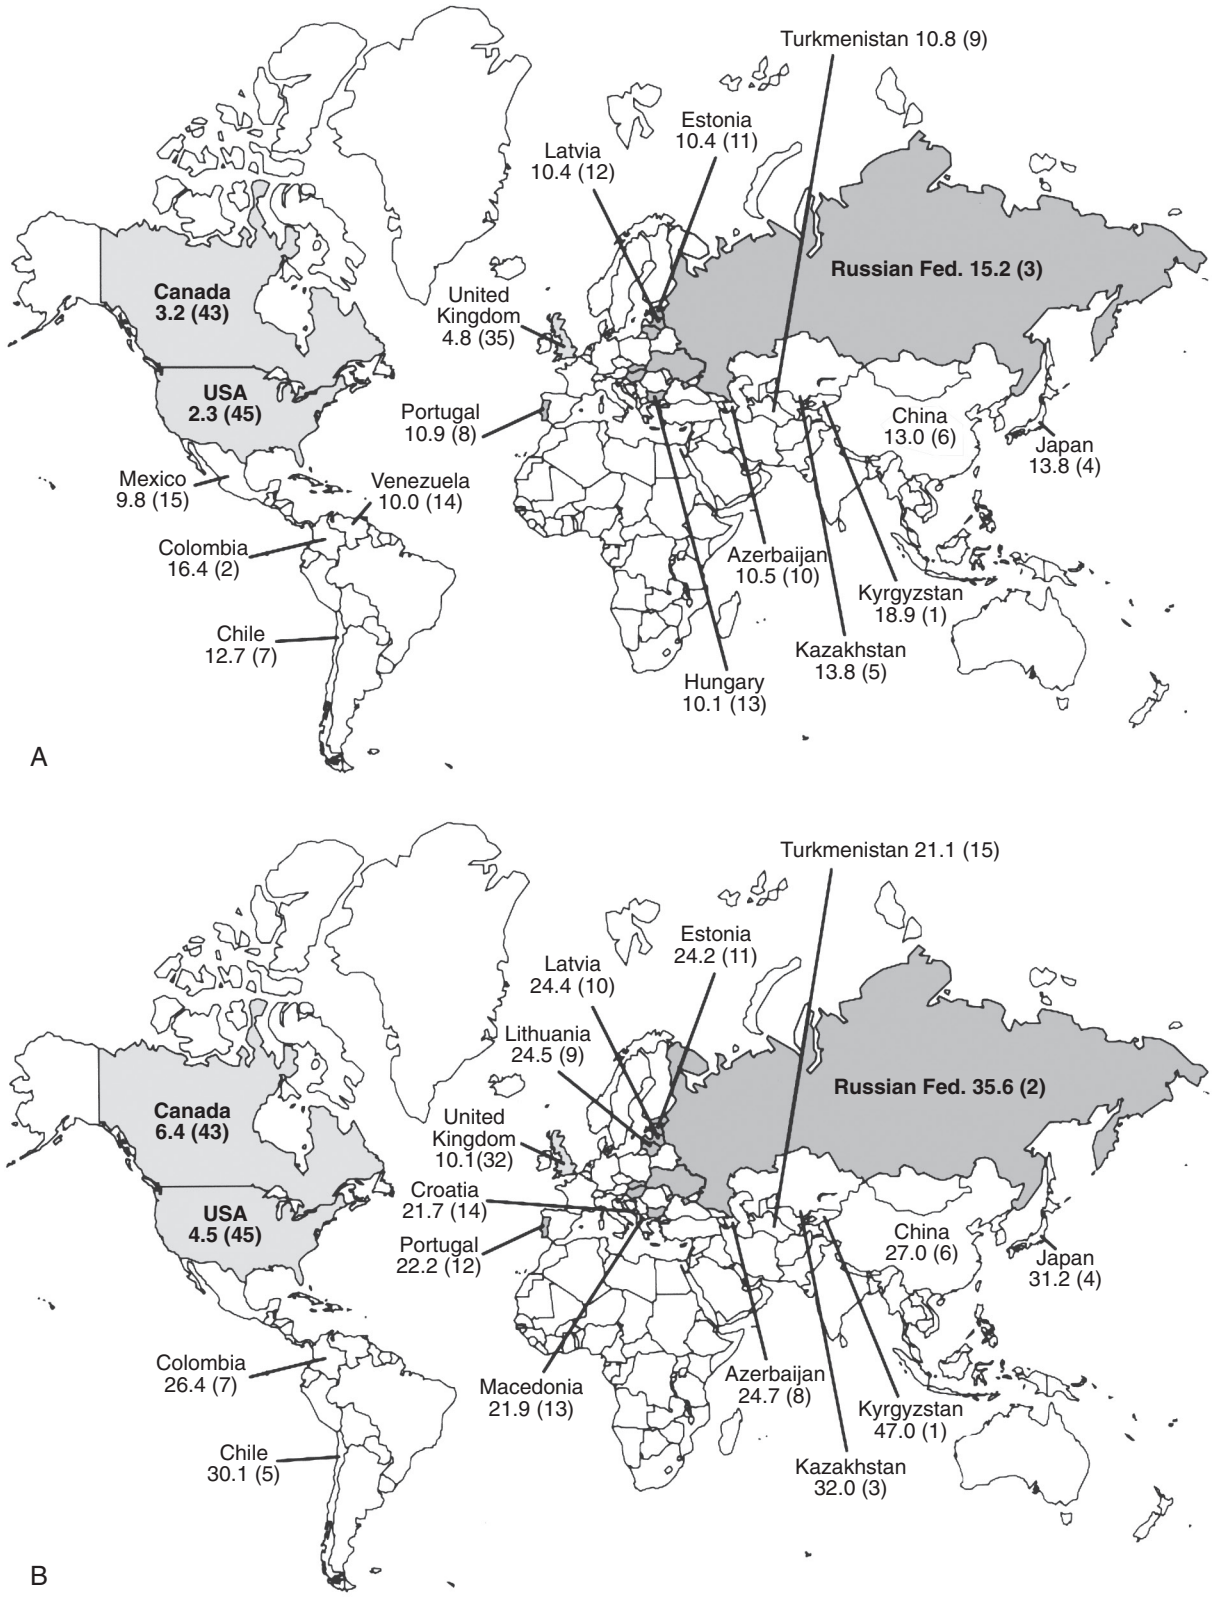
It has been postulated that endogenous formation of *N*-nitroso compounds (amine or amides) can occur in the stomach when both an amino compound and a nitrating agent such as nitrate are present.[13] Anaerobic bacteria that colonize stomachs in which achlorhydria occurs can convert nitrates and nitrites to potentially carcinogenic nitroso compounds.[12]



Epidemiologic studies have demonstrated an association between *Helicobacter pylori* infection and risk of gastric cancer.[17] Serologic studies have reported that persons with *H. pylori* infection have a threefold to sixfold higher risk of distal gastric cancer than those without infection.[18,19] The exact role of *H. pylori* in gastric carcinogenesis is still to be determined, although infection is associated with the development of chronic atrophic gastritis and decreased acid production.[12] However, only a minority of infected patients develops gastric cancer, and data do not yet exist on the effect of treatment of the *H. pylori* infection on subsequent malignancy. Proximal gastric cancers (GE junction, cardia) do not appear to be related to either *H. pylori* infection, atrophic gastritis, or decreased acid production; it is possible that an inverse relationship exists.

There has been a dramatic increase in the incidence of GEJ and gastric cardia carcinoma over the past few decades, similar to the increase in distal esophagus adenocarcinomas, suggesting that they may have similar etiologies.[20,21] Although the reasons for these changes are unknown, they may be related to the increased incidence of gastric reflux and Barrett's esophagus.

In summary, the worldwide decline in distal, predominantly intestinal-type gastric adenocarcinoma may be the result of improved food handling (refrigeration and storage). In contrast, proximal (mostly diffuse-type) gastric cancer, which is equally prevalent in both high-risk and low-risk regions, is probably attributable to other, as yet unrecognized, factors.[20] The exact role of *H. pylori* in gastric carcinogenesis remains to be defined.[14]



A

B

eFigure 47-1 Age-adjusted (to U.S. 1970 standard population) cancer death rates in the United States from 1930 to 2001 in selected sites for males **(A)** and females **(B)**. In females there is a steady decrease in death rates for stomach, breast, and colorectal cancers. From 1960 to 1998, a marked increase in death rates has occurred for lung cancer in females. For males, a similar decrease in death rates has occurred with gastric cancer. An increase in death rates for lung cancer existed in males from 1930 to 1990 with a continual decrease during the 1990's.

PREVENTION AND EARLY DETECTION

Early detection would markedly improve prognosis of gastric cancer because surgical resection has a high cure rate with lesions limited to the mucosa or submucosa. In the United States, however, the incidence of early gastric cancer is less than 5% in most series. In Japan, whereas the incidence of carcinoma confined to the mucosa or submucosa was only 3.8% in the 1955 to 1956 period, by 1966 the incidence of early lesions had increased to 34.5% because of vigorous screening procedures (5-year survival rates of 90.9% in this cohort of patients). The value of screening is evidenced by the 5-year survival rate of 53% for all gastric cancers in Japan versus 21% for the world.[4]

Although mass screening has been useful in Japan to detect early cancers, defined high-risk populations do not exist in the United States to justify the expense of widespread screening. Individual practitioners could use endoscopy to screen patients who have occupational or precursor risk factors or patients with persistent dyspepsia or GE symptoms, but it is not clear that this strategy is appropriate for populations as the conversion rate to cancer per year is low. It is not yet known whether screening of patients with *H. pylori* infection will be of value in achieving diagnosis of early gastric cancer, although treating *H. pylori* infection could reduce incidence.

Germline mutations in the *CDH-1* gene, which encodes the E-cadherin protein, have been recognized in families with hereditary diffuse gastric adenocarcinoma. Carriers of these mutations have a 70% lifetime risk of developing gastric cancer. Several reports of prophylactic gastrectomy have demonstrated the routine presence of microscopic intraepithelial carcinomas for patients having regular endoscopic surveillance with multiple random biopsies.[22-24] Early total gastrectomy has been recommended for this small patient population because of the lack of effective early tumor detection. Microscopic evaluation of the proximal and distal resection margins for complete removal of the gastric mucosa is necessary because residual gastric mucosa can degenerate and result in a gastric cancer.[24]

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

Prognostic Factors

The most valuable prognostic indicators relate to tumor extent. With either blood-borne metastasis or peritoneal seeding, cure is rare to nonexistent. Survival decreases with progressive direct tumor extension both within and beyond the wall of the stomach.[25-29] Lymph node involvement, per se, is not as important as the number and location of nodes.[26,30] Minimal lymph node involvement adjacent to the primary lesion is the most favorable.[31] The solitary finding of either involved lymph nodes or extension beyond the gastric wall is not as ominous as the presence of both.[26-30]

Tumor grade and gross and microscopic pathologic appearance of the primary malignancy appear to provide some prognostic information, but none of these factors is an independent prognostic variable relative to tumor stage. Prognosis is generally worse with higher-grade and diffuse-type carcinomas, which usually present with a higher stage of disease. Borrmann's types I and II carcinomas have a relatively favorable 5-year survival rate, whereas patients with type IV tumors (linitis plastica) have a poor prognosis.[31,32]

Prognostic factors evaluated in a British Study Group Trial included tumor size, macroscopic aspect, number of sites involved, wall invasion (pT), involvement of surgical resection limits, nodal stage, and histologic grade. Multivariate analyses established as prognostic features the depth of pT, nodal involvement, and surgical resection margins involvement.[33]

Some investigators have suggested that tumors of the gastric cardia may have different epidemiologic factors than cancers of the distal stomach[34,35] and may exhibit different tumor biology.[36] Prognosis appears worse for cardia lesions.[37,38]

Molecular Biology

The molecular biology of gastric cancer reflects the heterogeneity of its causes and its histologic subtypes. Identification of the genetic and phenotypic variables existing among gastric cancers may lead to more directed therapeutic approaches and a more accurate prediction of clinical outcome. There are rare genetic mutations that produce a hereditary predisposition to diffuse gastric cancer, and these are dominated by mutations in E-cadherin (CDH1).[39] CDH1 mutations (nongerm line) are also one of the most common mutational events in gastric cancer. Investigators have found a number of pathways critical to cell function that have aberrant regulation in gastric cancer and these often relate to genetic abnormalities seen in multiple types of tumors. Most gastric cancers have a large degree of genomic instability, as is also true for colon cancer. These are then associated with aberrations in a number of specific genes and pathways, often caused by copy number variations with both gains and loss of function.

Loss of tumor-suppressor gene function, especially inactivation of the *p53* gene, plays a critical role and is one of the most common alterations found in gastric cancer. The *p53* gene is located on the short arm of chromosome 17 and plays a key role in tumor suppression and cell-cycle regulation.[40] The *p53* gene puts a brake on DNA replication and triggers programmed cell death in response to DNA damage.[41] Loss of *p53* function is associated with the development of malignancy, impacts the effectiveness of chemotherapy and irradiation,[42,43] and predisposes cells to genetic instability. The latter is particularly important because *p53* mutations typically occur early in carcinogenesis.

Another dominant mutation occurs in SMAD4 that affects cell signaling and modulates the TGFβ protein that is involved in many areas of cellular function. Alterations in Wnt pathway result in a loss of pathway regulation.[44,45] ARID1A, PIK3CA, and CDKN2A have also been found to be significantly mutated in GE junction adenocarcinomas.[46] MET gene overexpression or signaling are common in gastric cancer, and aberrations can occur in multiple sites along the Wnt pathway.[47] However Dulak[46] found only 9% of esophageal adenocarcinomas with mutations. Loss of TTF1 (a trefoil peptide) occurs in perhaps 50% of gastric cancers and likely reflects amplification occurs in more than 50% of gastric cancers, is a poor prognostic factor, and is being explored as a therapeutic target.[48]

Another major aberration affecting gastric epithelial cells is the impact of alterations in mismatch repair genes. Similar to colorectal tumors, there is a substantial subset of patients who demonstrate microsatellite instability, with many of these tumors exhibiting loss of function of the mismatch repair genes MLH1 or MSH2. In gastric cancer these changes appear to be almost entirely as a result of epigenetic, rather than germ line alterations. Hypermethylation of CpG island promoter regions of the mismatch repair gene appear to produce the abnormality. The MSI high phenotype appears to be related to primary tumors located distally in the stomach and to the intestinal variety and with a relatively improved prognosis.[49] Mutations in these genes are implicated in cancer family syndromes and hereditary nonpolyposis colorectal cancer (HNPCC), a syndrome associated with an increased tendency

for the development of colorectal and gastric tumors.[50] Mutations in these genes generate genetic instability and have the potential to lead to further alterations in oncogenes.

Several peptides including estrogen receptor[51] and epidermal growth factor receptor[52] appear to affect prognosis adversely. The expression of epidermal growth factor receptor and high levels of epidermal growth factor correlate with a higher incidence of primary tumor infiltration, poor histologic differentiation, and linitis plastica. The pathophysiologic relationship between these peptide receptors and poor patient prognosis is not clear.

HER2 (ERBB2) overexpression has been shown to occur in approximately 20% of patients with gastric cancer and is associated with a poorer prognosis.[53] Perhaps more importantly, the use of the anti-HER2 antibody trastuzumab has been demonstrated to improve survival by approximately 2.5 months in patients with metastatic disease.[54]

Modern molecular biology observations confirm the heterogeneity of human gastric cancer. Genetic alterations potentially associated with worse prognosis, included CD44 expression; telomerase reactivation; *p53* gene inactivation; dysfunction of repair genes; overexpression of proto-oncogenes like *erb-B2, bcl-2, c-met*; estrogenic receptor expression; and presence of viral genome.[55] Gastric cancers with class II major histocompatibility complex antigen expression (HLA-DR) have a better prognosis, but the loss of expression is not an independent prognostic factor.[56]

Dulak et al[57] have done an extensive survey of genome instability and oncogenesis in esophageal, gastric and colon cancer adenocarcinomas and have found substantial similarities and differences. Focal amplifications were more prevalent in gastric and esophageal cancers than in colon with amplification in 37% of tumors including those that are potential drug targets (ERBB2, FGFR1 and 2, EGFR, and MET).

PATHOLOGY AND PATHWAYS OF SPREAD

Pathology

ACA histology accounts for 90% to 95% of all gastric malignancies, and the terms *gastric* and *stomach cancer* usually refer to such. Other histologies include lymphoma, leiomyosarcoma, carcinoid, adenoacanthoma, and squamous cell carcinomas.[58]

Gastrointestinal stromal tumors (GISTs) were previously classified as leiomyosarcomas but commonly arise in the stomach. GISTs need to be recognized because their management (surgery alone or plus imatinib) is distinctly different from ACA (surgery plus postoperative chemoradiation).

Gastric carcinomas have been categorized with regard to both microscopic and gross pathologic features. The Lauren classification system includes an intestinal type with improved prognosis (predominates in regions with high prevalence of gastric cancer) and a diffuse histologic type with poor prognosis (occurs more commonly in countries with low prevalence).[59] Diffuse carcinomas occur more often in young patients and develop throughout the stomach but especially in the cardia. Intestinal-type lesions are frequently ulcerative and occur in the distal stomach more commonly than the diffuse type. Grossly, gastric cancers can be categorized according to Borrmann's five types: I, polypoid or fungating; II, ulcerating lesions surrounded by elevated borders; III, ulceration with invasion of the gastric wall; IV, diffusely infiltrating (linitis plastica); and V, not classifiable.[60] The Japanese Research Society for Gastric Cancer has a classification system that divides lesions into protruded (I), superficial (II) (with elevated [IIa], flat [IIb], and depressed [IIc] subtypes), and excavated (III) types.[58]

Pathways of Spread

Direct Extension

The stomach is surrounded by organs and structures that can be involved by direct tumor extension when a lesion has spread beyond the gastric wall. These include the omenta, pancreas, diaphragm, transverse colon or mesocolon, duodenum, jejunum, spleen, liver, superior mesenteric and celiac vessels, abdominal wall, left adrenal gland, and kidney. Although adherence from inflammatory conditions can mimic direct extension of tumor, all adhesions between a gastric carcinoma and adjacent structures should be regarded as malignant, and en bloc resection of involved structures is preferred, if feasible.

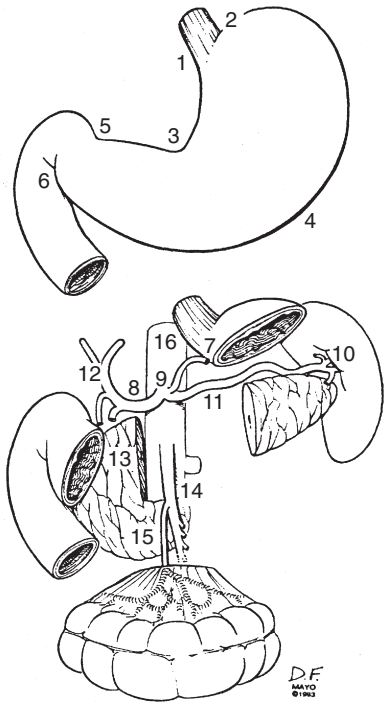
Lymphatics

Abundant lymphatic channels are present within the submucosal and subserosal layers of the gastric wall. Microscopic or subclinical spread beyond the visible gross lesions (intramural spread) occurs commonly via the lymphatic channels. Frozen sections of the gastric resection margins should therefore be obtained intraoperatively to ensure that margins of resection are uninvolved microscopically. The submucosal lymphatic plexus is also prominent in the esophagus and the subserosal plexus in the duodenum, allowing both proximal and distal intramural tumor spread.

Because of the numerous pathways of lymphatic drainage in the stomach, it is difficult to perform a complete nodal dissection (eFigure 47-3). Although initial drainage is usually to lymph nodes along the lesser and greater curvatures (perigastric or N1 nodes using the Japanese Research Society for Gastric Cancer designation), primary nodal drainage includes nodes along all three branches of the celiac (left gastric, common hepatic, splenic) and the celiac itself (Japanese N2 nodes).[58] Node groups that are more distal include hepatoduodenal, peripancreatic, root of mesentery (Japan N3), periaortic, and middle colic (N4). When proximal gastric lesions extend into the distal esophagus, that nodal system is at risk.

Hematogenous Spread

For cancers that are limited to the gastric wall, venous drainage is primarily to the liver via the portal system, although spread can occur to virtually any organ. At initial exploration, liver involvement is found in up to 30% of patients, predominantly resulting from hematogenous metastases but sometimes because of direct tumor extension. When cancers extend proximally to involve the esophagus or extend posteriorly, the lung may be at increased risk for metastasis.



Peritoneal Involvement

Because the stomach is an intraperitoneal organ, peritoneal spread is possible when a lesion extends beyond the gastric wall to a free peritoneal (serosal) surface. Peritoneal involvement may initially be a localized process limited by surrounding organs and ligaments (gastrohepatic, gastrosplenic, and gastrocolic), but is most often a diffuse process.

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Clinical Manifestations

Neither patient symptoms nor routine physical examination leads to an early diagnosis of gastric cancer. The most common presenting symptoms and signs are loss of appetite, abdominal discomfort, weight loss, weakness (as a result of anemia), nausea and vomiting, and melena. The duration of symptoms

eFigure 47-3 Classification and anatomic location of lymph node groups. 1, right paracardial; 2, left paracardial; 3, lesser curvature; 4, greater curvature; 5, suprapyloric; 6, infrapyloric; 7, left gastric artery; 8, common hepatic artery; 9, celiac artery; 10, splenic hilus; 11, splenic artery; 12, hepatic pedicle; 13, retropancreatic; 14, mesenteric root; 15, middle colic artery; 16, paraaortic.
(By permission of Mayo Foundation for Medical Education and Research.)

is less than 3 months in nearly 40% of the patients and longer than 1 year in only 20%.

Patient Evaluation

Positive physical examination findings are those of advanced disease. These may include an abdominal mass (representing the primary tumor, hepatic metastasis, or ovarian metastasis [Krukenberg tumor]); remote nodal metastasis (left supraclavicular [Virchow's node]; periumbilical [Sister Mary Joseph node]; or left axillary [Irish's node]), ascites, or a rectal shelf (peritoneal seeding).

The diagnosis of gastric cancer is usually confirmed by upper gastrointestinal (UGI) endoscopy or radiographs (Table 47-1). Endoscopy is the preferred diagnostic study because it allows direct tumor visualization, cytology, and histologic biopsy that yield the diagnosis in 90% or more of patients with exophytic lesions. Ulcerated cancers and linitis plastica lesions may be harder to diagnose endoscopically, but multiple deep biopsies and washings enhance the probability of accurate diagnosis. Endoscopic ultrasonography (EUS) has a high degree of accuracy in determining depth of tumor invasion before resection (i.e., whether the lesion extends beyond the muscularis propria) but is less accurate in detecting regional nodal metastasis.[61,62] Needle biopsies of suspicious nodes can be performed at the time of endoscopy with EUS. Although EUS may not affect therapy decisions with most current management approaches, the use of EUS may lead to selective management strategies based on tumor stage.

TABLE 47-1 Diagnostic Algorithm: Gastric/Gastroesophageal Junction Cancer

Diagnostic Procedure	Diagnosis and Staging Capability	Recommend Routine Use
PRIMARY TUMOR/REGIONAL NODES*		
Gastroscopy	Accurate modality to detect and define primary lesion, ≈ 90% confirmation rate	Yes; use to screen patients who are symptomatic or are high risk
Ultrasound-endoscopy	Most accurate method of determining extension within and beyond gastric wall	Yes; biopsy node(s), if feasible
CT: abdomen + chest	Most valuable modality to determine degree of extragastric extension and distant metastases	Yes
METASTATIC TUMORS		
Chest films	Good for detecting metastases	Yes
Laparoscopy	May allow visualization of small serosal implants or liver metastases	Optional; recommended if plan preoperative chemotherapy or chemoradiation
Positron emission tomography	Excellent for detecting unsuspected metastases	Optional; recommended if plan preop chemo/chemoradiation

**Laboratory studies: CBC, creatinine, liver function studies (alkaline phosphate, bilirubin, SGOT, LDH), albumin.*

The abdominal extent of disease at laparoscopy or exploration is usually more extensive than is suggested on radiographs or endoscopy. Abdominal computed tomography (CT) is valuable in determining the abdominal extent of disease with regard to liver metastasis, involvement of celiac or periaortic nodes, or extragastric extension (may help determine which lesions extend to surgically unresectable structures) but is of little value in ruling out peritoneal seeding. Diagnostic laparoscopy, often done immediately before resection, allows visualization and biopsy of small peritoneal implants or surface liver metastases.

The value of laparoscopy in the staging of gastric cancer is still being defined. In 71 patients with CT criteria of resectable disease, 69 completed a laparoscopic evaluation.[63] Laparoscopy confirmed disease in 16 of the 17 patients with peritoneal metastasis (avoiding 12 laparotomies) and 1 of 3 patients with small liver metastases and negative CT scan. The combination of CT scan and laparoscopy staging information yielded a resectability rate of 93% for patients defined as potential candidates for curative gastric cancer surgery.

Distant (hematogenous) metastases should be ruled out with a chest and abdominal CT. CT scans also provide valuable tumor localization information should irradiation be indicated. If a proximal gastric cancer extends to involve the esophagus, CT of the chest helps to rule out involvement of mediastinal nodes. Positron emission tomography fused with CT (PET/CT) is an imaging tool that can help to both rule out occult metastatic disease and determine response to treatment although it is less sensitive in gastric than in esophageal cancer.

Treatment planning in patients with gastric cancer could be improved by accurate preoperative classifications of depth of invasion (T category) and lymph node involvement (N category). A prospective study in 108 consecutive patients evaluated EUS, CT scan, and intraoperative surgical assessment for T and N classification.[64] Staging of the T category was correct with CT scan in 43% of the cases, 86% with EUS, and in 56% with intraoperative assessment. Staging of N1 and N2 lymph nodes was correct with CT in 51% of the cases, with EUS in 74%, and with intraoperative assessment in 54%. Advanced gastric tumors tended to be more accurately staged with CT; CT in general overstaged the T category and understaged the N category. Endoscopic ultrasound showed high and similar accuracy for all the T categories, although it also tended to under-stage N categories. Finally, intraoperative assessment was equally accurate for all N categories, but tended to overstage early T stages and to understage N categories.

Staging

The current TNM (tumor, lymph nodes, metastasis) staging system (American Joint Committee of Cancer, seventh edition) is depicted in Table 47-2.[65] The TNM system is the standard system for reporting outcomes in this disease.

Follow-up

Patients who are treated for gastric cancer should be followed for nutritional problems as well as disease relapse. Generally, patients are seen at 3- to 6-month intervals for the first 2 to 3 years and then less frequently. There are no agreed on follow-up strategies, as curative salvage therapy for recurrent gastric cancer after trimodality therapy is unusual. However, it is reasonable to have endoscopy performed one or two times and to use periodic CT scans to detect intraabdominal relapse. There are little data to suggest that early treatment of systemic metastases improves outcomes.

TABLE 47-2 TNM Staging for Carcinoma of the Stomach, AJCC, 7th Edition

Stage	T	N	M
O	Tis	0	0
IA	1	0	0
IB	2	0	0
	1	1	0
IIA	3	0	0
	2	1	0
	1	2	0
IIB	4	0	0
	3	1	0
	2	2	0
	1	3	0
IIIA	4a	1	0
	3	2	0
	2	3	0
IIIB	4b	0-1	0
	4a	2	0
	3	3	0
IIIC	4b	2	0
	4a-b	3	0
IV	Any	Any	0

TNM definitions are as follows:

Tis: carcinoma in situ; intraepithelial tumor without invasion of the lamina propria.

T1: Tumor invades lamina propria, muscularis mucosa or submucosa.
- T1a: tumor invades lamina propria or muscularis mucosa
- T1b: tumor invades submucosa

T2: Tumor invades the muscularis propria

T3: Tumor penetrates subserosal connective tissue without invasion of visceral peritoneum or adjacent structures.

T4: Tumor invades serosa (visceral peritoneum) or adjacent structures.
- T4a: tumor invades serosa (visceral peritoneum)
- T4b: tumor invades adjacent structures†

N0: No regional lymph node metastasis.
N1: Metastasis in 1-6 regional nodes.
N2: Metastasis in 7-15 regional nodes.
N3: Metastasis in more than 15 regional nodes.
M0: no distant metastasis.
M1: distant metastasis.

†*Adjacent structures include the spleen, transverse colon, liver, diaphragm, pancreas, abdominal wall, adrenal gland, kidney, small intestine, and retroperitoneum.*

PRIMARY THERAPY

Surgical Method

Surgical excision of the gastric and nodal components of disease remains the primary therapy for all potentially curable gastric carcinomas. Most cancers can be removed with adequate margins by subtotal gastrectomy, and total gastrectomy is used only when mandated by proximal cancer location or disease extent. Routine total gastrectomy does not improve survival by providing wider margins and eliminating multicentric disease but does increase morbidity and mortality. Surgical resection alone is an excellent treatment for carcinomas limited to the mucosa or submucosa without nodal involvement (Tis or T1N0M0). Although these early gastric cancers occur with an incidence of more than 30% in Japan, the incidence is less than 5% in the United States and other Western countries. For the more invasive gastric carcinomas, surgical resection is indicated for 50% to 60% of patients at the time of disease presentation, but only 25% to 40% of patients will have potentially curative procedures.

Although only one small prospective randomized trial has been performed with regard to extent of the gastric resection,[66] extensive experience exists with various surgical procedures, and appropriate generalizations can be made. The preferred treatment for lesions arising in the body or antrum of the stomach is a radical distal subtotal resection. This removes approximately 80% of the stomach along with the first portion of the duodenum, the gastrohepatic and gastrocolic omenta, and the nodal tissue adjacent to the three branches of the celiac axis. Extensive or proximal cancers will require a total gastrectomy to achieve an adequate proximal gastric margin. However, total gastrectomy is not necessary when subtotal gastrectomy will provide a 5-cm clearance of the gross tumor.[67,68] The propensity for gastric carcinoma to spread via submucosal and subserosal lymphatics dictates the need for a 5-cm surgical resection margin of normal stomach beyond the visible lesion. It may be necessary to extend the resection to include some (or additional) esophagus or duodenum if frozen section pathologic evaluation of the surgical margins fails to confirm the adequacy of proximal and distal resection margins. If total gastrectomy is necessary, a splenectomy is sometimes performed particularly in gastric cancers of the proximal third of the stomach, and tumors of the body near the greater curvature. Cancers in these locations are more apt to metastasize to lymph nodes in the splenic hilum that cannot be completely excised without a splenectomy. Although the value of routine splenectomy has not been addressed in prospective randomized trials, retrospective Japanese and American data do not provide evidence of a survival benefit with the routine use of this procedure and this may increase morbidity.[69,70]

Direct extension beyond the gastric wall should be treated with en bloc extended resection to achieve negative margins if a curative resection is contemplated. Common examples of local tumor extension include involvement of the body or tail of the pancreas (treated by distal pancreatectomy and splenectomy), invasion of the transverse mesocolon (often requires transverse colectomy), and involvement of the spleen (splenectomy) or left lobe of the liver (usually requires wedge resection with a 1-cm or wider clearance).

The optimal extent of lymph node dissection for gastric cancer remains controversial. Several studies have shown that the presence and extent of lymph node metastasis correlate with the depth of primary tumor invasion.[71-73] Although several nonrandomized clinical trials have suggested that extended lymphadenectomies may improve survival,[70,74-78] other nonrandomized[79,80] and randomized trials[81-87] have not demonstrated an advantage. A large multicenter Phase III study in the Netherlands accrued 996 evaluable patients and provides additional objective data on the lack of value of extended lymphadenectomy in gastric carcinoma.[82] Among the 711 patients having curative resections, both morbidity and mortality were significantly higher with the more extensive nodal dissection.[83-85] A randomized study of 400 patients conducted by the Medical Research Council (MRC) in the United Kingdom has also demonstrated higher morbidity and mortality in the extended lymphadenectomy cohort.[86,87] No benefit in DFS or OS was found in either the Dutch or British trials (Table 47-3). Any apparent survival benefit seen with the extended node dissection performed in Japan may be a result of the phenomenon of a shift in stage rather than superior surgery. Although most patients with five or more lymph node metastases or node metastasis not adjacent to the primary tumor have a poor outcome, extended node dissection seems

reasonable when it can be performed by experienced surgeons without significant additional surgical morbidity or mortality. Recent systematic review and meta-analysis demonstrate the safety and feasibility of D2 resection with or without paraaortic nodal dissection but fail to show a benefit in OS.[88,89]

Endoscopic laser surgery has been used in selected patients with early gastric cancer.[90] Small lesions (≤3 cm) that are pedunculated, do not invade the submucosa, and are well differentiated infrequently have lymph node metastasis (<5%). Nearly 75% of these select tumors can be completely removed endoscopically. Advanced techniques such as endoscopic submucosal dissection may further expand the indications for endoscopic therapy as more widespread technical expertise is obtained and long-term data is reported. Although early gastric cancer may have a long natural history before progression, standard surgical resection rather than endoscopic removal is still preferable.[91] Irradiation plus chemotherapy should be considered as adjuvant therapy when the tumor is endoscopically treated.

Quality of life (QOL) after gastrectomy is being analyzed.[92,93] In a University of Heidelberg report of 104 patients, 12 months after gastrectomy, postoperative symptoms of heartburn or dumping in the group undergoing total gastrectomy with pouch reconstruction did not differ significantly from the group having only distal gastric resection.[94] In a recent prospective trial of 120 patients requiring total gastrectomy plus pouch who were randomized to two different types of reconstruction (jejunal interposition versus Roux-en-Y), there were no differences in food passage, body weight, or QOL parameters.[95] However, for all patients there are significant QOL issues related to decreased absorption of fats, iron, and calcium, as well as the loss of intrinsic factor, and thus B12 deficiency. These losses need to be addressed with dietary supplements (iron, calcium), monitoring for osteoporosis, and possible monthly B12 injections.

Surgery Alone Survival Results

OS with surgery alone remains poor, despite improved perioperative care that has resulted in a substantial decline in postoperative mortality.[96] A large review from Europe reported excellent 5-year survival for early gastric cancer patients (83%) but a marked diminution in survival for more invasive cancers (31% for tumors of the antrum, 24% for the midstomach, and 16% for the cardia).[97] Survival in excess of 90% has been achieved throughout the world with resection of lesions confined to the mucosa or submucosa.[98-102] In reports with lower 5-year survivals for the early lesions, most of the mortality is from noncancer causes.[99,103] For gastric cancers with deeper invasion or nodal involvement, survival decreases proportional to the degree of invasion or nodal involvement. When N1 or N2 nodes are involved, Western reports continue to show 5-year OS of 10 to 30%,[104,105] whereas Japanese authors report 5-year OS of 25% to 60% (versus less than 10% with N3 or N4 involvement) (eTable 47-1).[70,105a–d] Although pathologic staging differences, different tumor biology, and more radical surgical extirpation have been proposed as explanations, the cause of the difference in U.S. and Japanese results with N1 or N2 disease remains uncertain. Even in the Orient, half of all patients with more invasive gastric cancer do not survive their disease, a fact that underlies the need for new nonsurgical therapies. Results of Phase III trials, to be discussed subsequently, demonstrate improvements in survival with the addition of adjuvant chemoradiation or neoadjuvant chemotherapy to surgical resection.

TABLE 47-3 Extent of Surgery: Randomized Trials of D1 Versus D2 Dissection

Series	No. of Patients	5-year Survival		Operative Mortality		*p* Value
		D1	D2	D1	D2	
Dutch[84,85]	711	45%	47%	4%	10%	<0.05

**Defined D1 dissection as resection of AJCC nodes (those within 3 cm of primary tumor).*
Both trials showed significantly increased morbidity and mortality with more extensive dissections.

Relapse Patterns after "Curative Resection"

Local relapse or failure (LF) in the tumor bed and regional lymph nodes (RF) or distant failures (DF) via hematogenous (DM) or peritoneal (PS) routes are all common mechanisms of relapse after "curative resection" in clinical, reoperative, and autopsy series.[28,29,106-114] For lesions of the GE junction, both the liver and lungs are common sites of DM. With gastric lesions that do not extend to the esophagus, the initial site of DM is usually the liver, and many relapses could be prevented if an effective "abdominal" or liver therapy could be combined with treatment of the primary tumor and regional lymph nodes.

Locoregional failures occur commonly within the region of the gastric bed and nearby lymph nodes (Table 47-4 and Figure 47-1). Tumor relapse in anastomoses, the gastric remnant, or the duodenal stump is also frequent. In a University of Minnesota reoperative analysis,[28,29] locoregional failure occurred as the only evidence of relapse in 29% of the 86 patients with relapse (23% of the 105 evaluable patients at risk) and as any component of failure in 88%. More extensive operative procedures including routine splenectomy, omentectomy, and radical lymph node dissection neither improved survival[112] nor decreased the incidence of LF-RF[28,29] in the reoperative analysis. Subsequent relapse within the scope of the initial node dissection occurred in a high percentage of the patients even when radical node dissections were performed (removal of N1 and N2 with or without N3 nodes)[29] (eTable 47-2). These data indicate the difficulty of performing a complete lymph node and lymphatic resection in this anatomic location and

provide a partial explanation for the lack of survival benefit with a D2 compared to D1 node dissection in Phase III surgical trials discussed previously. In a more recent clinical analysis of patterns of relapse from Memorial Sloan Kettering Cancer Center, 50% of patients with relapse had a locoregional component.[114]

Patterns of relapse by stage were analyzed in detail in a series of 130 patients who underwent resection with curative intent at the Massachusetts General Hospital (MGH).[108] Locoregional relapse occurred as any component of failure in 49 patients (38%) and as the sole failure in 21 (16% of 130 patients at risk and 24% of the 88 with disease progression). The incidence of locoregional relapse by stage was in excess of 35% for modified Astler-Coller stages B2 (T3 N0), B3 (T4 N0), C2 (T3 N1-3), and C3 (T4N1-3). The sites at higher risk for locoregional relapse included the gastric bed (27 of 130 patients, 21%) and the anastomosis or gastric remnant (33 of 130 patients, 25%). The true incidence of gastric bed, regional lymph node, and peritoneal failures may be higher because this was neither a reoperative nor an autopsy series (see comparative findings in Table 44-4). Additional information on patterns of relapse by stage exists in both the University of Minnesota reoperation analysis[28,29] and the University of Washington autopsy analysis.[111] Although patterns of relapse data are more accurate in such analyses, patient selection is biased.

All of these data suggest that the development of an effective therapy for locoregional disease as an adjuvant to surgery could potentially benefit at least 20% of patients. Effective systemic therapy is also essential to improve the outcome for patients who have resected high-risk gastric cancer s in view of the risks of both intraabdominal (liver and peritoneal) and extraabdominal metastasis (lung, other).

Adjuvant Chemotherapy

The role of adjuvant chemotherapy in gastric cancer has been extensively studied over the past decades, being the first attempt to improve the prognosis of resected gastric cancer.[115-137] Results of randomized clinical trials of adjuvant single-agent chemotherapy, following curative resection in gastric cancer have generally not shown any survival benefit when compared with surgical resection alone.

A Spanish trial compared high-dose mitomycin C following surgical resection (33 patients) versus surgery alone (37 patients).[117] This small trial showed a significant 5-year OS advantage (p = 0.001) in the group receiving chemotherapy (76% versus 30%), and a low rate of relapse in the treated arm (7 of 33 or 21% of the patients) versus the control arm (23 of 37 patients or 62%). This trial was extended to 134 patients with median follow-up of 8.75 years and still showed a survival advantage for postoperative mitomycin (p = 0.025). A subsequent randomized Spanish trial observed a significantly better 5-year survival for mitomycin plus Ftorafur (67%) versus mitomycin alone (44%) in resected high-risk gastric cancer, suggesting a strong benefit in patients with node-negative and early stage disease.[118]

Neri et al treated patients who were surgically resected, node-positive with the addition of adjuvant epirubicin, 5-FU, and leucovorin (68 patients) and compared them to 69 patients who were surgery-alone control.[119] The authors noted an

Two Phase III clinical trials evaluated the impact of 5FU, Adriamycin, Mitomycin-C (FAM) combination chemotherapy after curative surgery in resected high-risk gastric cancer.[115,116] Coombs et al[115] included 315 patients, and no difference was observed in either OS (FAM 45% versus control 35%) or relapse rates (FAM 56% versus control 56%). In a Southwest Oncology Group (SWOG) study, no advantage to adjuvant treatment with FAM was reported, either.[116]

improvement in 5-year OS from 13% to 30% for those receiving adjuvant chemotherapy.

In view of the success of the oral fluoropyrimidine S-1 in metastatic gastric cancer, a Phase III trial was done in Japan of surgery alone compared with surgery plus adjuvant S-1 for 1049 patients with resected Stages II/III disease.[120] Five-year OS was improved with adjuvant S-1 (5-year hazard ratio, 0.669; 95% confidence interval [CI], 0.540 to 0.793).

Perioperative Chemotherapy

In the British MAGIC trial, 503 patients with resectable ACA of the stomach (372 patients), GE junction (58 patients) or lower esophagus (73 patients) were randomized to receive either surgery alone or surgery plus three cycles of preoperative ECF and three cycles of postoperative ECF.[124] The use of perioperative chemotherapy was associated with significant improvement in survival compared with surgery alone (median survival 24 versus 20 months, 5-year OS 36% versus 23%, $p = 0.009$). Overall 103 patients completed all six cycles of chemotherapy.

A separate Phase III French trial of 224 patients with potentially resectable ACA of the lower esophagus, GE junction, or stomach evaluated perioperative CF ($n = 113$ patients; cisplatin plus infusion 5-FU for two to three cycles before and three to four cycles after surgery) compared to surgery alone ($n = 111$).[125] A survival advantage was found for perioperative CF (5-year OS, 38% versus 24%, $p = 0.02$; 5-year DFS 34% versus 19%, $p = 0.03$). Grade-3 or grade-4 toxicity was found in 38% of patients receiving chemotherapy, primarily neutropenia.

Meta-Analysis of Adjuvant Trials

Because many of the trials conducted to date have been underpowered to adequately assess potential differences between the control and treatment arms in regard to OS, seven meta-analyses have been performed since 1990 to better assess the use of adjuvant chemotherapy.[126-132] Three meta-analyses showed a significant survival advantage to the use of chemotherapy following surgical resection of gastric cancer. Seventeen randomized clinical trials, involving 3118 patients, were included in the meta-analysis by Panzini et al.[126] The pooled odds ratio was 0.72 (95% CI, 0.62 to 0.84). The meta-analysis by Janunger et al included 21 randomized clinical trials, involving 3962 patients, a slightly larger and somewhat different group of studies.[127] The pooled odds ratio from this study was 0.84 (95% CI, 0.74 to 0.96). In a subanalysis, Western and Asian studies were assessed separately. The meta-analysis of the Western studies did not show a benefit to adjuvant therapy (pooled odds ratio of 0.96; 95% CI, 0.83 to 1.12), whereas the Asian studies did show evidence of benefit (pooled odds ratio of 0.58; 95% CI, 0.44 to 0.76). In 2010, a meta-analysis by Paoletti et al identified 17 trials with individual patient data availability (3838 patients) and a median follow-up exceeding 7 years. There were 1000 deaths in the 1924 patients assigned to chemotherapy and 1067 deaths in 1857 patients assigned to surgery only. Adjuvant chemotherapy achieved a significant benefit in 5-year OS (55.3% versus 49.6%, $p = 0.001$).[132]

Adjuvant Irradiation

Irradiation has only been minimally evaluated as the sole adjuvant treatment following complete surgical resection in randomized Phase III trials. Adjuvant EBRT reduced locoregional failures when compared with the surgery-alone control arm in the British adjuvant trial noted later, but no survival benefits were found.[135,138] Although Phase III trials from Japan[139,140] and China[141] suggest some survival benefit for IORT versus a surgery-alone control arm, the advantage was found only in subset analyses.

Postoperative EBRT

The British Stomach Cancer Group (BSCG) completed a prospectively randomized trial of surgery alone versus postoperative FAM or EBRT (45 Gy in 25 fractions with or without 5-Gy boost).[135,138] A total of 436 patients were randomized and followed for a minimum of 12 months; arms were well balanced with regard to prognostic factors. No survival differences by treatment arm were seen (median, 15 months). However, locoregional failure was documented in only 15 of 153 patients (10%) in the adjuvant irradiation arm versus 39 of 145 (27%) in the surgery-alone arm, and 26 of 138 (19%) in the FAM group. Interpretation of the results is complicated by the inclusion of 93 patients with resection but gross residual disease and 78 patients (18%) with gross total resection but microscopically positive resection margins. Neither group of patients would be candidates for current gastric surgical adjuvant trials in the United States. In addition, nearly one third of the patients randomized to receive adjuvant treatment did not receive the assigned therapy. Of 153 patients randomized to the irradiation arm, only 104 (68%) received a dose of 40.5 Gy or more. Only 62% of the patients received six or more cycles of chemotherapy. The results of this study are similar to results seen in the adjuvant treatment of rectal cancer, in which adjuvant pre- and postoperative irradiation improve local control but did not increase patient survival unless combined with chemotherapy.

Preoperative EBRT

Randomized trials testing preoperative irradiation have been performed in both Russia and China. All have reported a positive survival benefit when compared with surgery-alone control arms.

Three prospective randomized Russian trials have evaluated preoperative irradiation in potentially resectable gastric cancer.[142-144] The first trial randomly assigned 293 patients to receive either surgery alone, surgery after preoperative EBRT (20 Gy in four fractions), or surgery after the same EBRT plus daily hyperthermia. The survival rates at 3 and 5 years were improved in both irradiation arms compared with surgery alone, and the improvement with combined EBRT and hyperthermia was statistically significant at both 3 and 5 years.[142] The second trial compared preoperative EBRT (20 Gy) versus surgery alone in 279 patients. Three- and 5-year survival rates were increased, and no increase in operative morbidity was observed.[143] The third trial compared surgery alone versus preoperative EBRT (32 Gy with concomitant inhalation of oxygen) plus surgery. A survival advantage was observed with preoperative treatment, and the resection rate was increased by 17%.[144] There are methodologic uncertainties with all three of these trials, and their applicability to Western gastric carcinoma is not clear.

A randomized trial from Beijing, conducted from 1978 to 1989, compared a surgery-alone control arm ($n = 199$) with preoperative EBRT plus surgery ($n = 171$) for patients with ACA of the gastric cardia.[145] Irradiation was given with 8-MV photons or cobalt with anteroposterior and posterior-anterior fields to a dose of 40 Gy in 20 fractions of 2 Gy over 4 weeks. Surgery was performed 2 to 4 weeks after completion of irradiation. The addition of preoperative EBRT produced downstaging of disease and improvements in radical resection rates (radical resection rates of 80% versus 62% with preoperative EBRT versus surgery alone).

Survival and locoregional disease control were improved in the patients assigned to preoperative EBRT versus surgery alone.[145] The 5- and 10-year OS were 30 versus 20% and 20% versus 13%, respectively (Figure 47-2; $p = 0.009$ Kaplan-Meier log rank). The divergence in survival curves began in the first

Adjuvant chemotherapy with FAM2, seven cycles, was compared with surgery alone in a European Organization for Research and Treatment of Cancer (EORTC) randomized Phase II trial that included 314 patients with stages II and III gastric ACA.[121] Five-year OS was 70% for patients who were stage II, and 32% for patients who were stage III with no significant differences between groups. Toxicity was high with FAM2 but time to disease progression was significantly longer in this group. DFS increased to a borderline significant value. Similarly, an adjuvant FAM randomized trial done by the SWOG, failed to show improved survival results.[122]

EORTC and the International Collaborative Cancer Group (ICCG) conducted independent randomized Phase III studies of either adjuvant 5FU, Adriamycin, Methotrexate (FAMTX) or 5FU, Epirubicin, Methotrexate (FEMTX) compared to surgery alone.[123] Both studies were closed when they failed to reach accrual after being open for 7 years. A pooled analysis of the two studies demonstrated that they both caused substantial toxicity but had no significant effect on OS, the primary endpoint of each study.

The use of ECF was generally well tolerated in the preoperative setting. The incidence of overall postoperative complications was similar (45.7% versus 45.3%) as well as 30-day mortality rates (5.6% versus 5.9%). Of the 237 patients who started chemotherapy, 215 completed the planned three cycles of preoperative therapy. Of the 209 patients who went to surgery, 137 started postoperative chemotherapy. The most common reasons for not starting included disease progression, early death, postoperative complications, and patient choice.

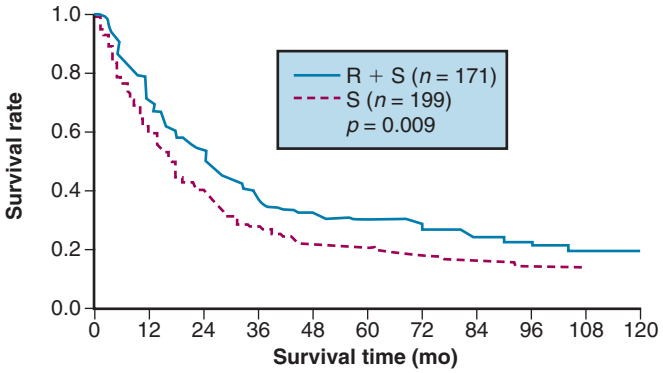

Figure 47-2 Overall survival rates in Beijing Phase III randomized trial of surgery alone or plus preoperative external beam irradiation for adenocarcinoma of the gastric cardia.
(From Zhang ZX, Gu XZ, Yin WB, et al: Randomized clinical trial combination on the preoperative irradiation and surgery in the treatment of adenocarcinoma of the gastric cardia [AGC]: Report on 370 patients. Int J Radiat Oncol Biol Phys 42:931, 1998. Copyright 1998.)

year of follow-up and persisted through 9 years. Local and regional disease control were also improved with combined modality treatment with local relapse rates of 39% versus 52% ($p < 0.025$) and regional node relapse rates of 39% versus 54% ($p < 0.005$). The rates of distant metastases were the same at 24% versus 25%. The improvements in survival and disease control (locoregional) were accomplished with no increase in treatment-related morbidity or mortality (operative mortality 0.6% versus 2.5% with or without preoperative EBRT; intrathoracic leak rates were 1.8% and 4.2%, respectively).

Adjuvant Irradiation Plus Chemotherapy

Postoperative EBRT Plus Chemotherapy

Phase II Trials

Phase II single-institution gastric cancer trials that showed promise for postoperative adjuvant chemoradiation included series from MGH,[146] Israel (Hadassah),[147] Thomas Jefferson University Hospital (TJUH),[148,149] the University of Pennsylvania,[150] and Mayo Clinic.[151] Information on the Phase II trials is provided on the Expert Consult website (eTable 47-3).

Phase III Trials: Mayo Clinic, U.S. GI Intergroup 0116

A prospective randomized trial was conducted at the Mayo Clinic and included 62 patients with poor prognosis completely resected gastric cancers (Table 47-5).[164] Patients were randomized to either surgery alone or surgery followed by EBRT plus concomitant 5-FU (37.5 Gy in 24 fractions over 4 to 5 weeks; 5-FU, 15 mg/kg/day 1-3 by IV bolus). A nonstratified, prerandomization scheme was used with a 2:3 ratio favoring treatment. Informed consent was requested only of the 39 patients randomized to treatment. Ten of the 39 refused further therapy and were observed. When analyzed by intent to treat, the adjuvant arm had statistically significant improvement in both relapse-free and OS (5-year OS 23% versus 4%; $p < 0.05$).

Because of conflicting results in prior small Phase III studies, a U.S. GI Intergroup trial (INT 0116) was initiated to evaluate postoperative combined 5-FU–based chemotherapy and irradiation to the gastric bed and regional nodes versus surgery only in patients who were resected but were high risk.[169] Patients eligible had completely resected ACA of the stomach or GE junction with complete penetration of the muscularis propria (T2-4N0) or involved nodes (T1-4N1-3). After an en-bloc resection, 556 patients were randomized to either surgery alone or postoperative combined modality therapy. This consisted of one 5-day cycle of 5-FU and leucovorin followed by concurrent chemoradiation (45 Gy in 25 fractions plus concurrent 5-FU and leucovorin, 4 days/week 1, 3 days/week 5) followed by two additional 5-day cycles of 5-FU and leucovorin given at 1-month intervals. Nodal metastases were present in 85% of patients. With median follow-up of 5 years, RFS at 3 years is 48% for adjuvant treatment and 31% for observation ($p = 0.001$); 3-year OS is 50% for treatment and 41% for observation ($p = 0.005$) (see Table 47-5). The median OS in the surgery-only group was 27 months, as compared with 36 months in the chemoradiation group. The median duration of RFS was 30 months in the chemoradiation group and 19 months in the surgery-only group (Figure 47-3).

Patterns of relapse were based on the site of first relapse only and were categorized as local, regional, or distant.[169] Local recurrence occurred in 29% of the patients who relapsed in the surgery-only group and 19% of those who relapsed in patients who had chemoradiation. Regional relapse—typically abdominal carcinomatosis—was reported in 72% of those who relapsed in the surgery-only group and 65% of patients who relapsed in the chemoradiation group. Extraabdominal distant metastases were diagnosed in 18% of patients who relapsed in the surgery-only arm and 33% of patients who relapsed in the chemoradiation arm. Treatment was tolerable, with three toxic deaths (1%). Grade-3 and grade-4 toxicity occurred in 41% and 32% of cases, respectively.

The results of this large randomized Phase III U.S. GI Intergroup trial demonstrate a clear survival advantage to the use of postoperative chemoradiation in patients who are resected and are high risk.[169] Furthermore, the results strongly support the integration of postoperative chemoradiation into the routine care of patients with curatively resected high-risk carcinoma of the stomach and GE junction. This approach is viewed as an appropriate standard of care in the United States.

Quality control (QC) of irradiation field design in INT 0116 was conducted during the cycle of chemotherapy given before the start of concurrent chemoirradiation.[170] The upfront QC provided the mechanism to correct most of the major or minor deviations (35% incidence) in field design before the start of treatment and resulted in only a 6.5% final major deviation rate. Utilization of up-front QC may have been a key factor in achieving a positive survival advantage for adjuvant chemoradiation.

An updated long-term analysis of INT 0116 was done with over 10-year median follow-up. Continued strong benefit from adjuvant postoperative chemoradiation was found with regard to both OS and RFS (OS: HR 1.32, $p = 0.0046$; RFS: HR 1.51, $p < 0.0001$).[171]

The successor US GI Intergroup phase III trial (CALGB 80101) was designed to build on the positive results of INT 0116 by testing infusion 5-FU compared to bolus 5-FU+leucovorin as concurrent chemotherapy during EBRT, and ECF compared to 5FU+leucovorin as maintenance chemotherapy.[156] Preliminary analyses have not found a survival benefit for the nonstandard treatment arm. Irradiation fields were based on idealized field design by site of the primary lesion and TN category of disease.[165]

Postoperative Chemoradiation Plus D2 Resection

The final results of the Phase III British and Dutch multicenter trials evaluating the value of extended lymphadenectomy (D1 versus D2 resection) demonstrated that D2 resection produced greater morbidity with no impact on survival.[84-87] Despite these negative results because D2 resections were not

Gunderson et al reported a median survival of 24 months and 4-year survival of 43% in 14 patients from MGH who had complete resection of tumors with extension beyond the wall, nodal involvement, or both.[146] Patients received postoperative EBRT (45 Gy to 52 Gy, 1.8 Gy/day) plus concurrent 5-FU–based chemotherapy. Subsequent locoregional relapse was documented in 2 of 14 patients (14%) in contrast to a 42% incidence in patients who were similarly high risk treated with surgery alone at MGH.[108]

In a gastric series from TJUH, 120 patients had surgical resection but were at high risk for relapse because of extension beyond the gastric wall, nodal metastases, or positive margins of resection.[148] Seventy patients had surgery alone and 50 received adjuvant therapy. Apparent improvements in local control as well as median and 5-year survival were noted with additional therapy. For patients with negative resection margins, 2-year local control with surgery alone was 55% versus 93% with adjuvant irradiation with or without chemotherapy ($p = 0.03$). For patients with T3 and T4 tumors and lymph node involvement, median survival was 9 months versus 13 months (surgery alone or plus adjuvant treatment), and 5-year survival was 4% versus 22% ($p = 0.03$). In a separate TJUH analysis of 55 patients with cancers of the GE junction, local relapse with surgery alone was 74% versus 36% in patients with adjuvant EBRT with or without chemotherapy ($p = 0.0014$).[149] Survival trends for patients who were node positive appeared better in patients who received adjuvant treatment (5-year survival 15% versus 0%, $p > 0.01$).

In a University of Pennsylvania analysis, treatment intensification appeared to improve both disease control and survival. The incidence of local relapse with surgery alone was 75% (31 of 40) versus 24% with adjuvant irradiation (4 of 17) and 15% with adjuvant irradiation plus chemotherapy (4 of 27).[150] Five-year survival trends favored adjuvant chemoradiation over surgery alone at 55% versus 31%.

In a retrospective Mayo analysis, 63 patients received postoperative EBRT with or without 5-FU after resection of carcinoma of the stomach or GE junction.[151] Twenty-five of the 63 patients had complete resection with no residual disease but had high-risk factors for disease relapse (extension beyond gastric wall, 92% of the patients; involved nodes, 92%; both high-risk factors, 84%). Concurrent 5-FU with or without leucovorin was given with EBRT in 84% of the 25 patients who were treated adjuvantly, but maintenance chemotherapy was given in only 20%. Locoregional control was achieved in 20 of the 25 (80%) with median survival of 19 months. Four-year survival was 31% despite the poor prognostic factors in these 25 patients.

When patient outcome was compared by actual treatment received (29 adjuvant treatment, 33 surgery alone), 5-year survival still favored the adjuvant group (20% versus 12%), but the differences were not statistically significant. The 10 patients who refused assignment to adjuvant treatment had more favorable prognostic findings than the other two groups of patients. When the two groups with equally poor prognostic factors were compared, 5-year OS was 20% versus 4%, with an advantage to those receiving adjuvant treatment. When analyzed by treatment delivered, locoregional relapse was decreased with adjuvant treatment (54% incidence with surgery alone versus 39% with irradiation plus 5-FU).

commonly performed as a component of surgery in the U.S. GI Intergroup Phase III gastric adjuvant trial, some have questioned whether chemoradiation would give added benefit following a D2 resection.

The potential role of postoperative chemoradiation in patients who were D2 resected was evaluated in a series of 990 patients treated in Seoul, South Korea (eTable 47-3, Table 47-6).[152] Surgery alone was used in 446 patients, and postoperative chemoradiation was given to 544 patients (disease and patient characteristics and method of chemoradiation paralleled the US GI INT 0116 trial). Both disease control and survival were improved in patients who received trimodality treatment (median OS 95.3 versus 62.6 months, 5-year OS 57% versus 51%, $p = 0.02$; 5-year RFS 54.5% versus 47.9%, $p = 0.016$; locoregional relapse 14.9% versus 21.7%, $p = 0.005$). Five-year RFS and OS were consistently better with trimodality treatment for each stage grouping.

A Phase III study (ARTIST trial) was subsequently performed in South Korea to compare postoperative chemotherapy with capecitabine plus cisplatin (XP; $n = 228$ pts) compared with XP plus concurrent chemoradiation ($n = 230$) following D2 resection.[172] Patients on the chemoradiation arm received two cycles of XP followed by 45 Gy in 25 fractions plus concurrent capecitabine 825 mg/m^2 twice daily during EBRT. On univariate analysis, in the subgroup of 396 patients with positive nodes, 3-year DFS was improved in those who received chemoradiation (77.5% versus 72.3%, $p = 0.0365$; see Table 47-5), and the statistical significance was retained on multivariate analysis ($p = 0.0471$).

Preoperative EBRT Plus Chemotherapy

Although no randomized trials testing preoperative EBRT plus chemotherapy for gastric cancer have yet been published, four Phase III trials for patients with esophagus cancer (alone

or combined with GE junction or cardia lesions) included patients with ACA. This includes studies by Walsh et al,[173] Urba et al,[174] the U.S. GI Intergroup trial published by Tepper et al,[166] and the CROSS trial.[167]

In the Dublin trial by Walsh et al[173] patients with ACA of the esophagus and gastric cardia were randomized to either immediate surgery (control arm) or preoperative EBRT plus 5-FU and cisplatin (40 Gy in 15 fractions; 5-FU, 15 mg/kg/day for 5 days weeks 1 and 6 as a continuous infusion or approximately 600 mg/m^2/day for 5 days; XP 75 mg/m^2 on the first day of each 5-FU infusion), followed by surgical resection 8 weeks after completion of EBRT plus chemotherapy. A highly significant difference in survival was observed with combined modality therapy (intent to treat: median survival 16 versus 11 months; 3-year OS, 32% versus 6%; $p = 0.01$; actual treatment: median survival 32 versus 11 months; $p = 0.001$; 3-year OS, 37% versus 7%; $p = 0.006$). Survival rates for the control group of patients were inferior to other historical data.

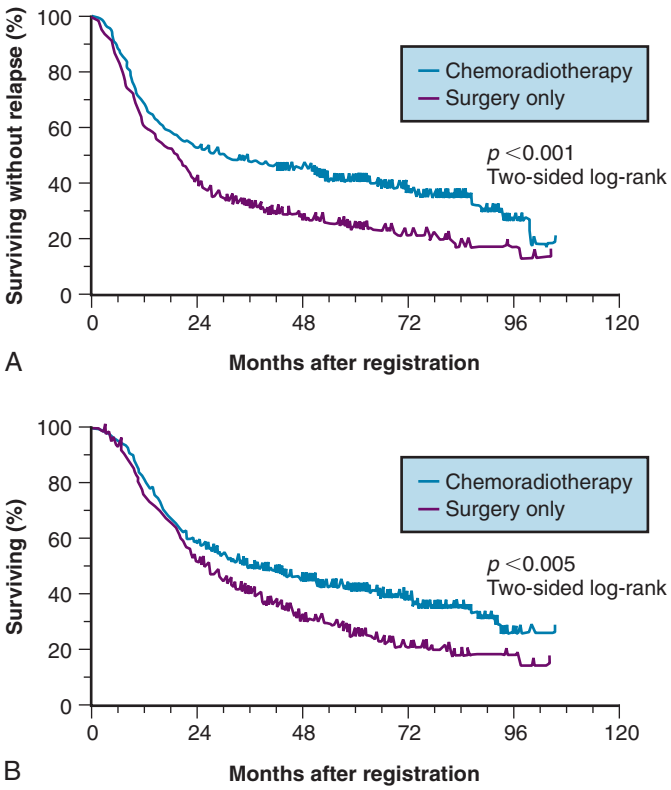

Figure 47-3 Relapse-free survival (RFS) **(A)** and overall survival (OS) **(B)** curves from the U.S. Gastrointestinal (GI) Intergroup Phase III randomized trial (INT 0116) demonstrate a survival benefit for combined modality postoperative chemoradiation versus a surgery alone control arm. Patients had resected high-risk adenocarcinoma of the stomach or GE junction. (3-year RFS 48% versus 31%, $p = 0.001$; 3-year OS 50% versus 41%, $p = 0.005$).
(From MacDonald JS, Smalley SR, Benedetti J, et al: Chemoradiotherapy after surgery compared with surgery alone for adenocarcinoma of the stomach or gastroesophageal junction. N Engl J Med 345:725–730, 2001.)

Urba et al at the University of Michigan found a borderline survival advantage for patients treated with preoperative chemoradiation compared to surgery alone.[174] Preoperative treatment involved 5-FU, XP, and vinblastine given concurrent with EBRT (45 Gy/1.5 Gy twice daily/3 weeks). Patients with either squamous cell (SCC) or ACAs were eligible, but 75 of the 100 randomized patients had ACA. Survival differences favoring trimodality treatment compared with surgery alone did not appear until several years of follow-up (3-year OS, 30% versus 16%; $p = 0.15$ Cox regression; 0.09 log rank multivariate analysis).

A confirmatory US GI Intergroup trial (CALGB 9781) included patients with either esophagus or GE junction cancers (SCC or ACA); this was stopped prematurely because of poor accrual. Despite the low accrual, patients randomized to trimodality treatment had a survival benefit when compared with patients randomized to surgery alone (median survival 54 months versus 21.6 months; 5-year OS 39% versus 16%, $p = 0.008$).[166]

Perhaps most impressive are the results of the Phase III CROSS trial of 366 analyzable patients with ACA ($n = 275$) or SCC ($n = 84$) of the esophagus and GE junction treated with either surgery alone ($n = 188$) or preoperative chemoradiation ($n = 178$; concurrent chemotherapy with carboplatin and taxol).[167] This study found a major increase in OS with the trimodality therapy (Table 47-8; median OS 49.4 months versus 20 months, 3-year OS 58% versus 44%, 5-year OS 47% versus 34%; HR, 0.657, $p = 0.003$). In a subsequent analysis of CROSS I and II trials, preoperative chemoradiation reduced locoregional recurrence from 34% with surgery alone to 14% ($p < 0.001$) and also had a small but significant effect on hematogenous spread (35% versus 29%, $p = 0.025$).[168] These data strongly suggest that radiation therapy was a critical component of the improvement in outcome and may have been the dominant component. Because this is the single-most convincing positive study of neoadjuvant therapy in this disease, many institutions have now adopted this as their standard of care for patients with esophageal and GE junction tumors.

Summary: Adjuvant EBRT Alone or Plus Chemotherapy

In summary, postoperative chemoradiation[169,171] has been demonstrated to be superior to surgery alone for resectable gastric and GE junction cancers in randomized Phase III trials.

Adj CRT, *Adjuvant chemoradiation.*

For GE junction tumors, neoadjuvant chemoradiation has convincing evidence for its local control and survival benefit compared with surgery alone.[166-168,173,174]

GE Junction: Preoperative Chemoradiation versus Chemotherapy (POET Trial)

The POET Phase III trial by Stahl et al included 120 eligible patients with T3-4 ACA of the GE junction treated with either preoperative chemoradiation (CRT; $N = 60$) or chemotherapy alone (N = 60).[175] All patients received two cycles of cisplatin, leucovorin, 5FU, (PLF) chemotherapy weeks 1 to 6 and 7 to 13 (cisplatin 50 mg/m^2 for 1 hour on day 1, 15, 29; leucovorin 500 mg/m^2 for 2 hours, and 5-FU 2 gm/m^2 per 24 hours via infusion on days 1, 8, 15, 22, 29, 36) followed by either PLF alone (weeks 14 to 17) or CRT with 30 Gy EBRT/15 × 2 Gy/3 wk (weeks 14 to 17) plus concurrent PE week 1 of EBRT (cisplatin 50 mg/m^2 for 1 hour on days 2 and 8; etoposide 80 mg/m^2 four 1 hour on days 3 to 5). Outcomes analyses trends favored preoperative CRT over chemo alone with regard to both OS ($p = 0.07$, see Table 47-5) and freedom from local relapse ($p = 0.06$).

SEER Analysis, Gastric Cancer: Adjuvant Irradiation or Chemoradiation

Coburn et al[176] evaluated the impact of postoperative adjuvant EBRT or CRT in 4041 patients who had resection of nonmetastatic gastric ACA from May 2000 to December 2003 (SEER database). Patients treated with postoperative EBRT (alone or plus concurrent chemotherapy) compared with surgery alone had improved median OS for stages III (31 months versus 24 months; $p = 0.005$) and IVM0 (20 months versus 15 months; $p < 0.001$) and the difference approached significance for stage II ($p = 0.0535$). Adjusted analysis using a propensity score suggested that the benefit of adjuvant irradiation was similar for patients in stages II and III (HR of death 0.733 and 0.773, respectively). One must interpret these retrospective analyses with care because biases can inadvertently be introduced.

Meta-Analyses, Gastric/Esophageal Cancer: EBRT, Chemoradiation, and Chemotherapy

A meta-analysis by Fiorica et al[177] evaluated the impact of adjuvant EBRT or CRT in the reduction of all-cause mortality in patients with resectable gastric ACA (nine published Phase III trials: four preoperative EBRT, five postoperative CRT). For patients treated with preoperative EBRT, the HR for all-cause mortality was 0.62 ($p = 0.002$). In patients treated with postoperative CRT, the HR for all cause mortality was 0.45 ($p < 0.00001$).

An Australian meta-analysis published by Gebski et al[178] evaluated the impact of either preoperative CRT or preoperative chemotherapy in patients with resectable esophagus ACA or SCC. For patients treated with preoperative CRT, the HR for all-cause mortality was 0.81 ($p = 0.002$) with similar results for patients with ACA (HR 0.75, $p = 0.02$) and SCC (HR 0.84; $p = 0.04$). In patients treated with preoperative chemotherapy, the HR for all-cause mortality was 0.90 ($p = 0.05$) with significant benefit found for patients with ACA (HR 0.78; $p = 0.014$) but no benefit for those with SCC (HR 0.88; $p = 0.12$).

IORT Alone or Plus EBRT

The pioneering work of Abe at Kyoto University, Japan, in the 1970s, fostered a renewed interest in the old idea of irradiating tumor-bearing areas under direct vision during laparotomy.[139,140] Although Abe's work triggered gastric IORT trials around the world, only a few investigators have favored the use of IORT as the only adjuvant treatment after surgical resection.[157,179-183] Most Western IORT protocols included the delivery of EBRT pre- or postoperatively (45 Gy to 50 Gy in 1.8-Gy to 2.0-Gy fractions) and used IORT doses in the range of 10 Gy to 20 Gy as a boost.[153-155,158-161,184,185] (Figure 47-4).

Survival and Locoregional Relapse Outcomes

Survival results of IORT (with or without EBRT) are reviewed in Table 47-5 and eTable 47-4.

IORT Alone

Takahashi and Abe[140] reported results from a large Japanese trial in which 211 patients were selected, on the basis of day of hospital admission, to receive surgery only or surgery plus IORT (28 Gy to 35 Gy). Five-year OS for Japanese stages II to IV were improved approximately 15% to 25% in the IORT group versus those treated with surgery alone (see Table 47-5; stage II, 84% versus 62%; stage III, 62% versus 37%; stage IV, 15% versus 0%). This magnitude of survival improvement correlates nicely with the approximately 20% of patients who fail only locoregionally after complete surgical resection. However, this method of treatment selection is susceptible to bias, and the trial failed to stratify for important prognostic factors.

In an analysis from Beijing, patients with stage III (serosal involvement or node-positive tumors) or stage IV (unresectable metastasis or adjacent organ involvement) disease were randomized to surgery alone or plus IORT (25 Gy to 40 Gy).[141] In a report of 200 patients, a survival advantage with IORT was demonstrated for patients in stage III (see Table 47-5; 65% versus 30% 5-year OS; 52% versus 22% 8-year OS; $p < 0.01$).

IORT Versus EBRT

At the National Cancer Institute (NCI), Sindelar et al[179] performed a small randomized trial of IORT compared to EBRT following complete surgical resection that demonstrated improved local control with IORT but no survival benefit. The incidence of locoregional recurrence was lower in the IORT versus control group, at 31% versus 80% ($p < 0.01$). The 5-year OS was 10% for 15 patients with resected gastric cancer stages III and IV treated with radical surgery plus IORT.[179] Median survival time for this subset of patients was 25 months. The median survival of the surgery with EBRT arm of 25 patients was 21 months, and the 5-year OS was 20%. No patients in stage III or IV in the control group survived after a median follow-up of 7 years, whereas 3 out of 15 (20%) in the IORT group were alive with no evidence of disease (NED) at the time of the analysis ($p = 0.06$).

IORT Plus EBRT or Chemoradiation

Phase II single or multiinstitution gastric cancer trials that showed promise for IORT plus EBRT or chemoradiation included series from Pamplona, Spain (Calvo et al)[153-155,158]; RTOG/USA (Avizonis et al)[159]; Lyon, France (Gilly et al)[160,161,184]; and China (Zhang et al).[185] Information on the Phase II trials is provided on the Expert Consult website (eTable 47-4).

LOCALLY ADVANCED DISEASE AND PALLIATION

Locally Advanced Disease

The term *locally advanced disease* has different interpretations depending on the author and institution. For the purposes of this chapter, the term refers to cancers that the surgeon would not expect to resect with negative pathologic margins (i.e., unresectable for cure as determined at surgical exploration or as defined preoperatively). Other authors use the term to

Ogata et al reported a study from the Kochi Medical School, Japan, with 178 patients with gastric cancer, Japanese Research Society (JRS) stages II through IV treated with surgery alone (120 patients) or surgery plus IORT (58 patients) from August 1983 to July 1992.[181] The patients were not randomized, but a surgery-alone group served as controls. In general, the patients who had IORT had more unfavorable features. The IORT results by stage (see eTable 47-4) demonstrated a survival advantage in stages III and IV that was not statistically significant; the survival in patients in stage II was surprisingly high but did not reach statistical significance.

Calvo et al described a 5-year OS of 39% and a locoregional failure rate of 10.4% in 48 patients with gastric cancer treated with IORT plus EBRT in Pamplona.[153-155,158] This report included 16 patients with AJCC stages I and II and 8 patients with anastomotic or nodal recurrences. The proportion of patients with serosal involvement was 70% and of nodal involvement 56%. An update by Martinez-Monge et al[154] of the 28 patients with serosal (89%) or lymph node involvement (63%) revealed a 10-year OS of 38% and a locoregional failure rate of 11%.

Avizonis et al reported the RTOG series of 27 patients with gastric cancer treated with surgery plus IORT 12.5 Gy to 16.5 Gy with or without EBRT 45 Gy.[159] Seventy percent of the patients had AJCC stages III and IV tumors. The 2-year OS was 47%, 2-year DFS 27%, and median survival 19.3 months.

Gilly et al reported on 45 patients with gastric cancer treated in Lyon with surgical resection, IORT 15 Gy, and EBRT 44 Gy.[160] The 5-year OS for patients who were node positive (N1/N2) was 51%. In the last update of the Lyon experience with 82 patients,[161] 8-year OS among the 49 patients with pT3 or pN+ treated with surgery plus IORT plus EBRT was 50% compared to 28% in similar stage patients treated with surgery alone during the same time period.

The addition of intraoperative electron irradiation (IOERT) to adjuvant chemoradiation and resection has been evaluated in series from Spain[158] and China.[185] In a series of 53 patients with esophagus or GE junction cancer, Calvo et al found on multivariate analysis that locoregional control was improved with the addition of an IOERT boost (n = 37 patients) after preoperative chemoradiation and resection ($p = 0.01$).[158] Zhang et al found on multivariate analysis that the addition of IOERT to resection and postoperative chemoradiation (n = 46) improved both locoregional control (p = 0.02) and DFS (p = 0.05) when compared to results found in 51 patients treated only with adjuvant postoperative chemoradiation for T3/4 or N+ gastric ACA.[185]

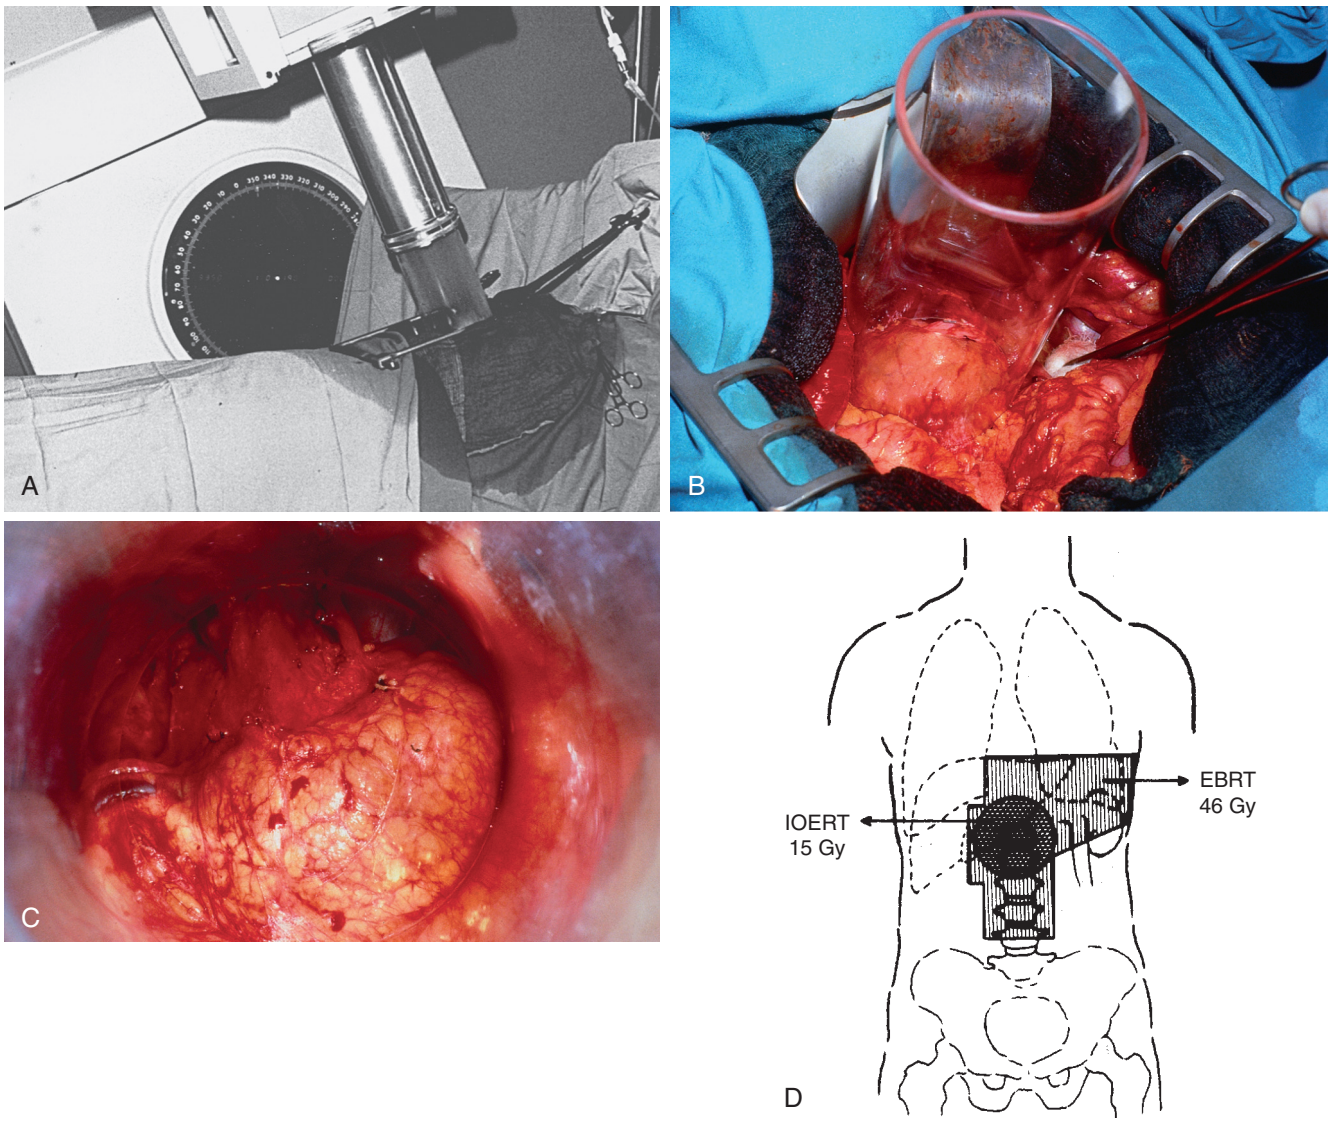

Figure 47-4 Intraoperative electron radiation (IOERT) procedure in a patient with gastric cancer. **A,** View of the linear accelerator and electron beam Lucite applicator. **B,** Applicator (9-cm diameter) positioned for treatment; visceral structures are mobilized from field. **C,** IOERT applicator beam's-eye view of the IOERT target volume: body of pancreas, celiac trunk, and peripancreatic nodal regions. **D,** Idealized artist's depiction of integration of the IOERT and external beam radiation (EBRT) treatment components.

include lesions that are completely resected but have high-risk factors for local recurrence or distant metastasis (nodal involvement, extension beyond the gastric wall, or both).

Surgery

The extent of a surgical procedure must be tempered by the knowledge that cure is at best improbable. Patients with symptomatic obstruction, hemorrhage, and ulceration, and some with perforation, can be successfully relieved of symptoms by even limited gastric resection. Radical subtotal or total gastrectomy may be indicated in some patients whose lesions cannot be completely resected with negative pathologic margins to achieve symptomatic palliation. Results with total gastrectomy in advanced gastric cancer showed good quality of life when this procedure was indicated for bulky or proximal tumors, but symptom relief was less likely for patients with linitis plastica.[162] Although adjacent organ resection can be undertaken if all gross tumors can be removed, it is rarely justified if gross residual tumor (visible or palpable) would remain. Because total (or near-total) gastrectomy has the risk of both acute and long-term morbidity (severe early satiety), it should be used sparingly. If sites of adherence or residual disease are marked with surgical clips, postoperative irradiation plus chemotherapy can be delivered with greater accuracy.

Irradiation with or without Chemotherapy

Although some patients with no resection have long-term survival using irradiation alone or plus chemotherapy, this is not a viable alternative to surgical resection plus adjuvant therapy if that therapy is appropriate. The initial bulk of disease and the limited tolerance of the stomach and surrounding organs prevent a suitable therapeutic ratio between cure and complications. When locally unresectable disease is diagnosed preoperatively, preoperative chemoirradiation would preferably be delivered before an attempt at resection of all gross primary and lymph node disease.

Irradiation

The available literature suggests that ACA of the stomach is radioresponsive. Wieland and Hymmen used 60 Gy when

feasible (1.5 Gy to 2.0 Gy daily) with 11% (9 of 82) 3-year and 7% (5 of 72) 5-year survival.[163] Takahashi compared historical controls with patients whose tumors were unresectable or who had palliative procedures and received postoperative radiation (unknown if chemotherapy was also used).[186] The average survival for irradiated patients was 9 to 10 months longer, with 74% 1-year (32 of 43) and 27% 2.5-year survival (12 of 43).

Abe and Takahashi reported 5-year survival rate of 15% with a single dose of IORT after resection (28 Gy to 33 Gy) in a group of 27 patients with stage IV disease.[140,141] Three of the four long-term survivors had proven residual disease after maximal resection. In the same study, 18 patients in stage IV were randomized to a surgery-alone control arm; the 5-year survival was 0%.

Irradiation Plus Chemotherapy

Most reports of combined irradiation and chemotherapy for gastric cancer involve patients with residual and unresectable disease, and most Phase III trials in this setting show an advantage for combined modality treatment over single-modality treatment. In a randomized series from the Mayo Clinic, 5-FU was used during the first 3 days of EBRT in half of the patients (EBRT, 35 Gy to 37.5 Gy in 4 to 5 weeks; 5-FU 15 mg/kg for 3 days, week 1 of EBRT).[187,188] For the combined treatment group, mean and OS was improved (13 versus 5.9 months and 3 of 25 or 12% versus 0 of 23 for 5-year survival) (Table 47-7). In a randomized study by the GITSG,[189,190] the combination of EBRT and 5-FU followed by maintenance 5-FU plus MeCCNU resulted in statistically superior long-term survival when compared with 5-FU MeCCNU alone (3- and 4-year survivals of 18% versus 6% to 7%; $p < 0.05$). GITSG performed a second trial in which combined irradiation plus chemotherapy did not produce a survival advantage when compared with chemotherapy alone.[191] Because 46% of the patients on the combined arm either did not receive full-course EBRT or had a major deviation in the delivery of the EBRT, the results are difficult to interpret. In a randomized EORTC trial of EBRT with or without 5-FU, residual disease after resection was identified in 22 patients.[192] The three long-term survivors (14%) received EBRT plus 5-FU.

Data from nonrandomized single-institution or group analyses also suggest that the combination of EBRT and chemotherapy may have an impact on disease control and survival. In published series from the Mayo Clinic[194] and MGH,[164] long-term survival of 10% or more was demonstrated in patients who received EBRT plus chemotherapy following subtotal surgical resection with residual disease (MGH) or with unresectable lesions. In a University of Pennsylvania analysis of patients with unresected ACA of the GE junction or esophagus, local control was better with combined- versus single-modality treatment (irradiation, 1 of 23, or 4%; chemotherapy, 0 of 8; irradiation plus chemotherapy, 11 of 21, or 52%). Median survival with the combined modality treatment was 10 months compared with 5 months for irradiation alone. In a Mayo Clinic- North Central Cancer Treatment Group (NCCTG) dose escalation pilot study, EBRT was combined with 5-FU plus low-dose leucovorin (400 mg/m^2 and 20 mg/m^2, respectively, for 3 to 4 days, week 1, or 1 plus 5 of irradiation).[195] Two of six patients with locally advanced gastric cancer were alive and disease free beyond 3 years.

Published analyses from both GITSG and MGH suggest an improvement in survival if partial resection with gross residual disease or gross total resection with microscopic residual can be accomplished. In the GITSG series 3-year survival was about 25% versus 10% in patients who were partially resected compared with unresected.[189,190] In the MGH analysis, median survival for patients with irradiation plus chemotherapy was 24 months for microscopic residual, 15 months with gross residual, and 14 months in unresected.[164] Four-year OS was 0% for patients who were unresected compared to 10% in those patients with residual disease after maximal resection.

TABLE 47-7 Unresectable or Residual Gastric Cancer: Treatment Results

Group or Institution	Treatment Arms	EBRT Dose/ Schedule (Gy)	Chemotherapy	No. of Patients	Results (Failure Patterns) and Survival
RANDOMIZED

†An additional 14 had "curative resection" with high-risk LF: 40% 4-year actuarial SR with EBRT + CT.

In a Mayo Clinic analysis of irradiation with or without chemotherapy for gastric or GE junction cancers, an improvement in median survival was also suggested for patients with gross total resection but microscopic residual when compared with higher-risk subsets of patients.[193] In these analyses, the results of irradiation or chemoradiation were evaluated in 87 patients with either locally advanced primary or locally recurrent ACA of the stomach or GE junction treated from 1980 through 1996 at the Mayo Clinic. Of those with primary lesions, 28 had unresectable disease and 39 had resection but residual disease (R1 resection, 28 pts; R2, 11). An additional 21 presented with a local or regional relapse with no evidence of abdominal (liver, peritoneal) or extraabdominal metastasis (lung, other). Chemotherapy with 5-FU (with or without leucovorin) was given during or following EBRT in 75% of the patients with R1 resection and 92% of the other subgroups (concomitant with EBRT in 84%). IOERT supplement to EBRT was given in 13 patients. Median survival in patients with primary cancer was 16.7 months for patients with R1 resection, 9.6 months with R2 resection, or 12 months with unresectable disease. Patients who presented with local or regional relapse had a median survival of 10 months.

Prognostic factor analyses showed that long-term survival appeared slightly poorer in patients who had resection before irradiation or chemoradiation in the Mayo Clinic analysis.[193] Actual 4-year survival was 0% versus 9% in patients with R2 resection (1 of 11 patients alive NED 2 years after treatment), 9% in those with R1 resection, and 18% in patients with unresectable primary or locally recurrent cancers. The survival trends may be a reflection of both treatment sequence and higher irradiation dose, since 12 of 13 patients with EBRT plus IOERT had unresectable primary or locally recurrent cancers. In the 21 patients with local or regionally recurrent cancers, irradiation dose greater than 54 Gy had a trend for improved survival (median survival 25.6 versus 5.5 months, $p = 0.06$). If patients with R1 resection are excluded, an increase in the number of cycles of chemotherapy appeared to correlate with an improvement in median survival (less than two cycles, median 5.2 months versus 11.5 months with two or three cycles and 14.5 months with four or more cycles, $p = 0.014$).

Although problems with excess toxicity were encountered in the GITSG study,[189,190] such problems were minimal or nonexistent in the MGH series of 46 patients.[146] In the MGH series, shaped radiation portals and single fraction size of 1.8 Gy were used; 43 of 46 patients received both irradiation and chemotherapy.

Neoadjuvant Chemotherapy

The use of adjuvant preoperative (neoadjuvant) chemotherapy has been less well studied in patients with locally advanced disease compared to adjuvant postoperative therapy. Because of the inability of adjuvant (postoperative) systemic therapy to prolong survival in surgically managed gastric cancer, several investigators have pursued the approach of neoadjuvant chemotherapy in an attempt to increase resectability and improve survival. These studies involve a mix of patients including those with clinically operable, "locally advanced" or unresectable lesions. All but one of these studies are Phase II protocols.[196-210] eTable 47-5 summarizes the results of these reports.

One of the few randomized trials to assess the potential benefit of preoperative chemotherapy to surgery alone in potentially resectable patients failed to show any benefit.[209] In this Dutch study, patients were randomized to either FAMTX followed by surgery or surgery alone. The study was closed early because of poor accrual, but analysis of the enrolled patients showed no benefit to rate of curative resectability, rate of relapse, or median survival.

Unresectable

Wilke et al examined the role of etoposide, Adriamycin, and cisplatin (EAP) in a group of 34 patients with laparotomy-determined unresectable stomach cancer.[196] This study was prompted by the promising results with this regimen in advanced disease (21% complete remission and 73% overall response rate).[211] Following exploratory laparotomy, patients were begun on EAP. Twenty patients (59%) who achieved clinical response went on to a second-look operation followed by two additional courses of chemotherapy. Fifteen patients (44%) out of the original cohort were able to have a resection and 5 patients were pathologic complete responders (15% of the original 34). Median survival in this Phase II trial was 18 months for the entire study group. In an update of these data, results were reported in 21 patients who had total resection after EAP chemotherapy for locally unresectable disease.[212] Fourteen of 21 patients had relapsed, and 11 of 14 had a locoregional component of disease (79% of relapses, 52% of group at risk).

Verschueren et al evaluated 17 patients with unresectable gastric cancer.[197] Fifteen of them were defined as unresectable at laparotomy whereas two were deemed unresectable on the basis of CT imaging. After receiving up to four courses of sequential 5-FU and high-dose methotrexate, 13 patients (76%) underwent attempted resection. Although 7 patients had resectable tumors (41%), locoregional relapse occurred in 5 of 7.

Summary

The high response rates achieved with neoadjuvant chemotherapy are of interest in these patients with locally advanced or unresectable tumors, and this form of treatment will undoubtedly be the subject of further investigation. The roles of neoadjuvant systemic treatment in increasing resectability rates and improving survival in localized gastric cancer are unknown. Although resectability rates seem higher than the median rate of 40% from several studies, the patients in the neoadjuvant studies were highly selected. Except for the two trials in which tumors were unresectable on the basis of exploratory laparotomy, the successful resection in these reports may not have been influenced by neoadjuvant chemotherapy. In general, pathologic CR rates are low (≤15%), and no proof exists that primary lesions are made more resectable by such treatment. The impact of preoperative systemic treatment on survival is even less clear. The one randomized trial that has been reported shows a nonsignificant improvement in survival for neoadjuvant chemotherapy in borderline resectable locally advanced disease.[199,200] Newer technologies such as EUS may identify patients who will do poorly with standard therapy alone and would be reasonable candidates for adjuvant studies.[213]

In view of the high incidence of locoregional relapse in several series of patients whose tumors were resected after neoadjuvant chemotherapy for initially unresectable lesions, irradiation should be incorporated into the study design of future trials for patients with high-risk factors. Patients with unresectable lesions who do not respond to neoadjuvant chemotherapy may still respond to preoperative EBRT plus chemotherapy. The favorable outcomes with preoperative chemoradiation compared with surgery alone for patients with potentially resectable cancers have previously been discussed.[152,165-168,172-174]

Palliation for Metastatic Disease

This section is limited to discussion of patients with hematogenous or peritoneal metastasis at time of disease presentation.

Locally Advanced

Two studies have tested the use of preoperative systemic treatment for patients with locally advanced stomach cancer. Ducreux et al treated 30 patients with two or three cycles of cisplatin and 5-FU before surgery.[198] Twenty-eight (93%) patients subsequently underwent laparotomy, and 23 (77%) had their tumor resected; the pathologic response rate was not reported. Median survival was 16 months. Kang et al randomized 107 patients with locally advanced gastric cancer to receive two or three cycles of EFP (etoposide, fluorouracil, Platinol) followed by surgery versus surgery alone.[199,200] Of the 53 patients randomized to preoperative treatment, 47 (89%) were explored, and 37 (70%) had a complete resection. A complete pathologic response rate of 7% was noted. More patients were able to undergo a curative resection in the treated group when compared with surgery alone (70% versus 61%). Median survival was 43 versus 30 months in favor of neoadjuvant treatment, but this did not achieve statistical significance ($p = 0.114$).

Potentially Resectable

Ajani et al reported two Phase II studies of preoperative chemotherapy (EFP, EAP) in patients thought clinically to have potentially resectable disease.[202,203] Patients were treated with two or three cycles of EFP/EAP preoperatively plus an additional two or three cycles postoperatively if a positive response to neoadjuvant treatment could be detected. No pathologic complete responses were seen with either EFP ($n = 25$ patients) or EAP ($n = 48$ patients), and median survival was 15 and 15.5 months, respectively. The impressive results obtained with neoadjuvant EAP in Wilke et al's study could not be reproduced in this group of patients who had potentially smaller tumor burdens.

Other investigators have examined the utility of combining preoperative chemotherapy and postoperative treatment with intraperitoneal chemotherapy in view of the high peritoneal failure rate following resection of gastric cancer.[204-207] Schwartz et al[204,205] delivered three cycles of neoadjuvant FAMTX plus postoperative intraperitoneal (IP) 5-FU and cisplatin along with infusional 5-FU. No complete pathologic responses were observed. Leichman et al[206,207] delivered two cycles of 5-FU, leucovorin, and cisplatin preoperatively, and two cycles of IP 5-fluoro-2′-deoxyuridine (5-FUDR) and cisplatin postoperatively. In the updated report of 59 potentially resectable patients, 96% underwent exploration and 68% had complete resection.[207] The pathologic CR was only 9%, but median survival was about 52 months.

Surgery

Surgical intervention in the patient with metastatic gastric cancer requires sound judgment. The underlying health and function (performance status) of the patient, the estimated duration of patient survival, and the nature of the symptoms must all be taken into account before deciding to proceed with an operation. Resection for palliation is generally better than bypass or intubation in appropriately selected patients, leading to better symptomatic relief and often longer survival.[162] Obstructing lesions may be resected with excellent palliation, but endoluminal stents, endoscopic laser treatments, or gastrostomy tube placement should be considered for poor operative candidates.[214] Although significant hemorrhage from an ulcerating or necrotic polypoid tumor may be temporarily controlled by endoscopic techniques, stabilization and urgent surgical intervention should be undertaken when appropriate. A perforated gastric cancer usually presents as an emergency and may be unrecognized preoperatively. Aggressive treatment with gastric resection should be carried out in the fit patient; pain control and hydration alone are preferable for the moribund or unfit patient.

Laser or Irradiation

If palliative resection is not indicated in symptomatic patients with metastases, laser treatment, stent placement, or a shortened course of EBRT alone or plus 5-FU could be used (37.5 Gy in 15 fractions over 3 weeks, for example), or stereotactic body irradiation (SBRT, see Ch 24), to be followed by systemic treatment. Patients who have proximal lesions with esophageal obstruction may be candidates for laser or esophageal stents instead of irradiation, although stents in the distal esophagus often cause problems with migration. If either method is successful in overcoming obstruction, patients could proceed directly to treatment with chemotherapy.

Chemotherapy

Traditional chemotherapy agents with 20% or more response rates include doxorubicin,[215,216] cisplatin,[217] 5-FU,[218] etoposide,[219] and mitomycin C.[220] More recently a variety of chemotherapy drugs have shown promising response rates in advanced gastric cancer including taxotere (23%), irinotecan (23%), and paclitaxel (17% to 21%).[221-223] Complete remissions with single-agent chemotherapy are exceedingly rare, and remission duration is usually 3 to 5 months. For patients with measurable disease, survival is usually only 3 to 6 months. Single-agent chemotherapy therefore offers little practical benefit to the patient.

Combination chemotherapy regimens, which almost universally incorporate a fluorinated pyrimidine, obtain reliable responses in 25% to 50% of patients.[220-232] Combination chemotherapy regimens that have produced response rates of 30% to 45% include the following: the FAM regimen[220]; 5-FU + BCNU[224]; 5-FU + MeCCNU[225]; 5-FU + mitomycin C[216]; 5-FU + doxorubicin + MeCCNU (FAMe)[215,225]; 5-FU + doxorubicin + BCNU (FAB)[226]; 5-FU + doxorubicin + cisplatin (FAP)[227-229]; EAP[230]; FAMTX[229,231]; and etoposide, leucovorin, and 5-FU (ELF).[232] Most of the combination chemotherapy regimens report median survival of 5 to 7 months, which is similar to the survival of patients receiving single-agent chemotherapy. Many of the combinations that had promising activity in single institution evaluations were less active and more toxic in subsequent Phase II and III trials.

Platinum Regimens

See expert consult website for additional information on platinum regimens.

A regimen combining epirubicin, cisplatin, and infusional 5-FU (ECF) was introduced by investigators at the Royal Marsden Hospital for patients with advanced esophagogastric adenocarcinoma. An overall response rate of 71% was obtained with a CR rate of 12%.[247] A subsequent randomized Phase III trial, which compared FAMTX with ECF, showed that ECF was associated with a superior response rate (45% versus 21%) and OS (median 9 versus 6 months).[248] In view of the promising results of this trial, ECF has become the standard regimen to which other regimens are compared.

A Phase III trial for gastroesophageal cancer was conducted to assess the potential benefit of replacing cisplatin with oxaliplatin and infusional 5-FU with capecitabine using a 2×2 design.[249] This trial enrolled 1002 patients from 61 centers. Using a noninferiority statistical design for the trial, the combination of epirubicin, oxaliplatin, and capecitabine (EOX) was shown to be the most active of the four regimens evaluated. Compared to ECF, patients receiving EOX had both an improved 1-year survival (46.8% versus 37.7%) and a statistically improved median survival (11.2 months versus 9.9 months; HR, 0.80; 95% CI, 0.65 to 0.97).

Taxane Regimens

Several Phase II studies have evaluated non–5-FU-containing combinations. The response to combinations, such as docetaxel and cisplatin, paclitaxel and cisplatin, have been comparable to 5-FU-containing regimens.[250,251]

The combination of docetaxel and cisplatin has been evaluated in a number of clinical trials as either the two-drug combination or in combination with other chemotherapy agents. As a two-drug combination in Phase II trials the reported response rate is 28% to 46% and median survival of 10.4 to 11.5 months.[252-255] Other trials explored the added benefit of 5-FU and reported response rates of 40% to 43% and median survivals of 9.0 to 9.7 months.[256,257] A multicenter randomized Phase II trial, involving 158 patients, assessed docetaxel and cisplatin with or without 5-FU as potential support for a Phase III trial.[257a] In this trial the combination of docetaxel and cisplatin gave a response rate of 26% and a median survival of 10.5 months. The addition of 5-FU increased the response rate to 43%; however, the median survival was only 9.6 months.

The combination of docetaxel, cisplatin, and 5-FU was compared to cisplatin and 5-FU in a Phase III trial.[258] Overall survival was significantly longer with docetaxel, cisplatin, and 5-FU ($p = 0.02$). The response rate was also higher with this combination (69% versus 59%, $p = 0.01$). However, the combination of docetaxel, cisplatin, and 5-FU was also more toxic with 69% of patients developing treatment-related grade-3 or grade-4 adverse events compared to 59% of patients receiving cisplatin and 5-fluorouracil. Neutropenia and neutropenic fever were both significantly higher with the three-drug combination.

As is true in most malignancies, there is an enormous interest in using biologics for the treatment of metastatic gastric cancer. For patients who are HER2-positive, the Trastuzumab for GAstric cancer trial (ToGA) trial demonstrated a survival advantage to the use of trastuzumab, a HER2 inhibitor, when combined with chemotherapy (extension of median survival by 2.7 months compared to chemotherapy alone).[259] An international Phase III trial recently reported a benefit to single agent ramicirumab, a VEGFR2 inhibitor, in therapy of previously treated patients with metastatic gastric cancer (extension of median survival by approximately 1.5 months).[260] How well this, or other VEGF inhibitors, will impact survival when combined with chemotherapy is uncertain. Other biological manipulations have not as yet shown much efficacy.

Supportive Care versus Chemotherapy

Chemotherapy has been shown to be advantageous to best supportive care in both retrospective analyses and Phase III trials. These analyses are reviewed on the Expert Consult Website.

Several trials have compared single-agent 5-FU with combination chemotherapy in advanced gastric cancer. Most of the trials have been unable to demonstrate improved survival for multiagent regimens. The NCCTG reported a prospective randomized Phase III trial comparing 5-FU with 5-FU + doxorubicin to FAM. Overall responses were quite similar, and no differences were seen in survival.[233] A large Korean study randomized 324 patients to 5-FU, 5-FU plus cisplatin, or FAM. Responses were observed more often in the patients treated with 5-FU plus cisplatin, but OS was similar in all three treatment arms.[234] Others have reported similar problems in demonstrating improved survival for multiagent regimens in Phase III trials.[235,236] Several trials have also used pharmacologic manipulation of 5-FU with leucovorin in gastric carcinoma in attempts to follow up on the apparent benefit that this combination achieved with patients who had colorectal carcinoma.[237] Responses varied between 11% and 50%, but median survival rates were almost identical to those of 5-FU alone at 5.5 months.

Many of the combination chemotherapy regimens, which achieved response rates of 30% to 50% in single-institution trials, have often failed to reproduce the initially high response rates when subjected to confirmatory trials. A case in point is the EAP regimen. The initial Phase II trial reported overall response rates of 64% (complete and partial) and 21% (complete) and median survival of 9 months.[211] The studies that followed did not confirm such high response rates, and toxicity was sometimes substantial.[238]

FAMTX Regimens

The combination of 5-FU, doxorubicin, and methotrexate (FAMTX) was a widely used regimen in the 1990s. Klein first reported a 58% response rate for the combination in a Phase II study.[239] The EORTC group performed a randomized Phase II trial of FAM versus FAMTX in 213 patients with advanced measurable or nonmeasurable gastric cancer.[230] FAMTX was found to have a significantly superior response rate (41% versus 9%; $p < 0.0001$) and survival (median 42 versus 29 weeks; $p = 0.004$). The authors considered FAMTX the reference chemotherapy for future advanced gastric trials.

Kelsen et al[231] randomly compared FAMTX and EAP for advanced disease in 60 patients. Response rates were similar, at 33% compared to 20% (advantage to FAMTX; $p = 0.24$), and tolerance was better for FAMTX with a significantly higher toxic death rate for EAP. Accordingly, the trial was stopped.

In 1991, the combination of etoposide, leucovorin, and 5-FU (ELF) was introduced as an alternative to more aggressive regimens for patients with cardiac or poor medical conditions or advanced age.[240] It achieved a response rate of 53%, and a median survival time of 11 months. Multiple clinical trials have now evaluated the activity and tolerability of ELF, and have generally shown OS in the range of 8 to 10 months and response rates of about 30%.[241-243]

FAMTX has been compared to ELF and infusional 5-FU/cisplatin (FUP) in a Phase III EORTC study. No apparent differences in response rates or survival have been demonstrated to date.[244]

The Italian Group for the Study of Digestive Tract Cancer reported an intensive, multiagent regimen including the most active agents in gastric cancer, cisplatin, epirubicin, leucovorin and 5-FU (PELF).[245] Administered weekly with growth factor support, this regimen produced an overall response rate of 62%, CR rate of 17%, and a median survival time of 11 months.

PELF was subsequently compared to FAMTX in a randomized Phase III trial. Although both the overall and CR rates with PELF were significantly higher (overall, 39% versus 22%; complete, 13% versus 2%), only a nonsignificant improvement in OS was seen with PELF.[246]

In 1993 Murad et al published results of a randomized trial where a modified FAMTX regimen was compared to best supportive care.[261] The trial was interrupted after entry of 22 patients because the treated patients were enjoying a significantly better outcome. The next 18 patients were assigned directly to treatment. Median survival for all the treated patients was 10 months versus 3 months for the untreated controls ($p = 0.001$).

Pyrhonen et al reported the results of 41 patients randomized to 5-FU, epirubicin, and methotrexate (FEMTx) plus vitamins A and E versus the same vitamins and best supportive care.[262] In patients treated with FEMTX, 29% had an objective response and 33% had stable disease for greater than 2 months. In control patients, 20% had stable disease. Median time to progression (5.4 versus 1.7 months, $p = 0.0013$) and median survival (12.3 versus 3.1 months, $p = 0.0006$) both favored treatment with FEMTx.

Glimelius et al studied, in a group of 61 patients with inoperable gastric cancer, the cost-effectiveness of palliative therapy by randomly assigning patients to primary chemotherapy with ELF or 5-FU leucovorin versus best supportive care.[263] Improved or prolonged high QOL was documented in patients receiving chemotherapy versus supportive care alone. Patients in the chemotherapy arm had a significantly longer median survival at 8 months versus 5 months ($p = 0.003$, adjusted) and QOL ($p < 0.05$) also favored the treated patients.

Park et al performed a retrospective analysis of 409 patients with incurable gastric cancer in which 202 patients were treated with a modified FAM regimen and 207 were not treated.[264] The 1-year survival was 34.1% for patients treated with FAM versus 22.5% for the control group. Details on how treatment decisions were made were not in the report.

A 2010 meta-analysis reviewed the efficacy of chemotherapy versus best supportive care, combination versus single-agent and different combinations regimens in advanced gastric cancer.[265] A total of 5726 patients from 35 trials were analyzed. Survival benefit was observed in favor of chemotherapy versus supportive care, combination chemotherapy versus single agent (but with an increased toxicity) and cisplatin-containing regimens.

Summary

The response rate of gastric cancers to combination chemotherapy is somewhat higher than some other gastrointestinal malignancies. Patients who respond to therapy with acceptable tolerance have the potential of achieving symptomatic benefit from this palliative treatment. Nevertheless, aggressive combination regimens are costly, toxicity is sometimes formidable, and remissions are of short duration. If possible, all patients with disseminated gastric cancers should be considered for entrance into well-designed clinical trials.

IRRADIATION TECHNIQUE AND TOLERANCE

Irradiation Field Design

For patients who receive postoperative EBRT following surgical resection or exploratory laparotomy, the irradiation field should include unresected or residual tumor or the tumor bed plus major nodal regions (lesser and greater curvature; celiac axis including pancreatico-duodenal; suprapancreatic, splenic, and porta hepatis; paraesophageal with proximal lesions). The pattern of tumor bed and nodal failures in the reoperative series from the University of Minnesota is demonstrated in Figure 47-1, *A*. This represents an idealized, shaped irradiation field that incorporates the areas of locoregional relapse.[28] The tumor bed and nodal volumes are reconstructed with the aid of preoperative and postoperative imaging studies and surgical clip placement. In Figure 47-1, *B*, the idealized field is superimposed on the organs and structures that define irradiation tolerance. For individual patients, the idealized field needs to be modified depending on the surgical or pathologic extent of disease (primary site, TN extent of disease) and the adjacency of tolerance organs or structures[165,170,266] (Figures 47-5 and 47-6; eFigures 47-4 to 47-6).

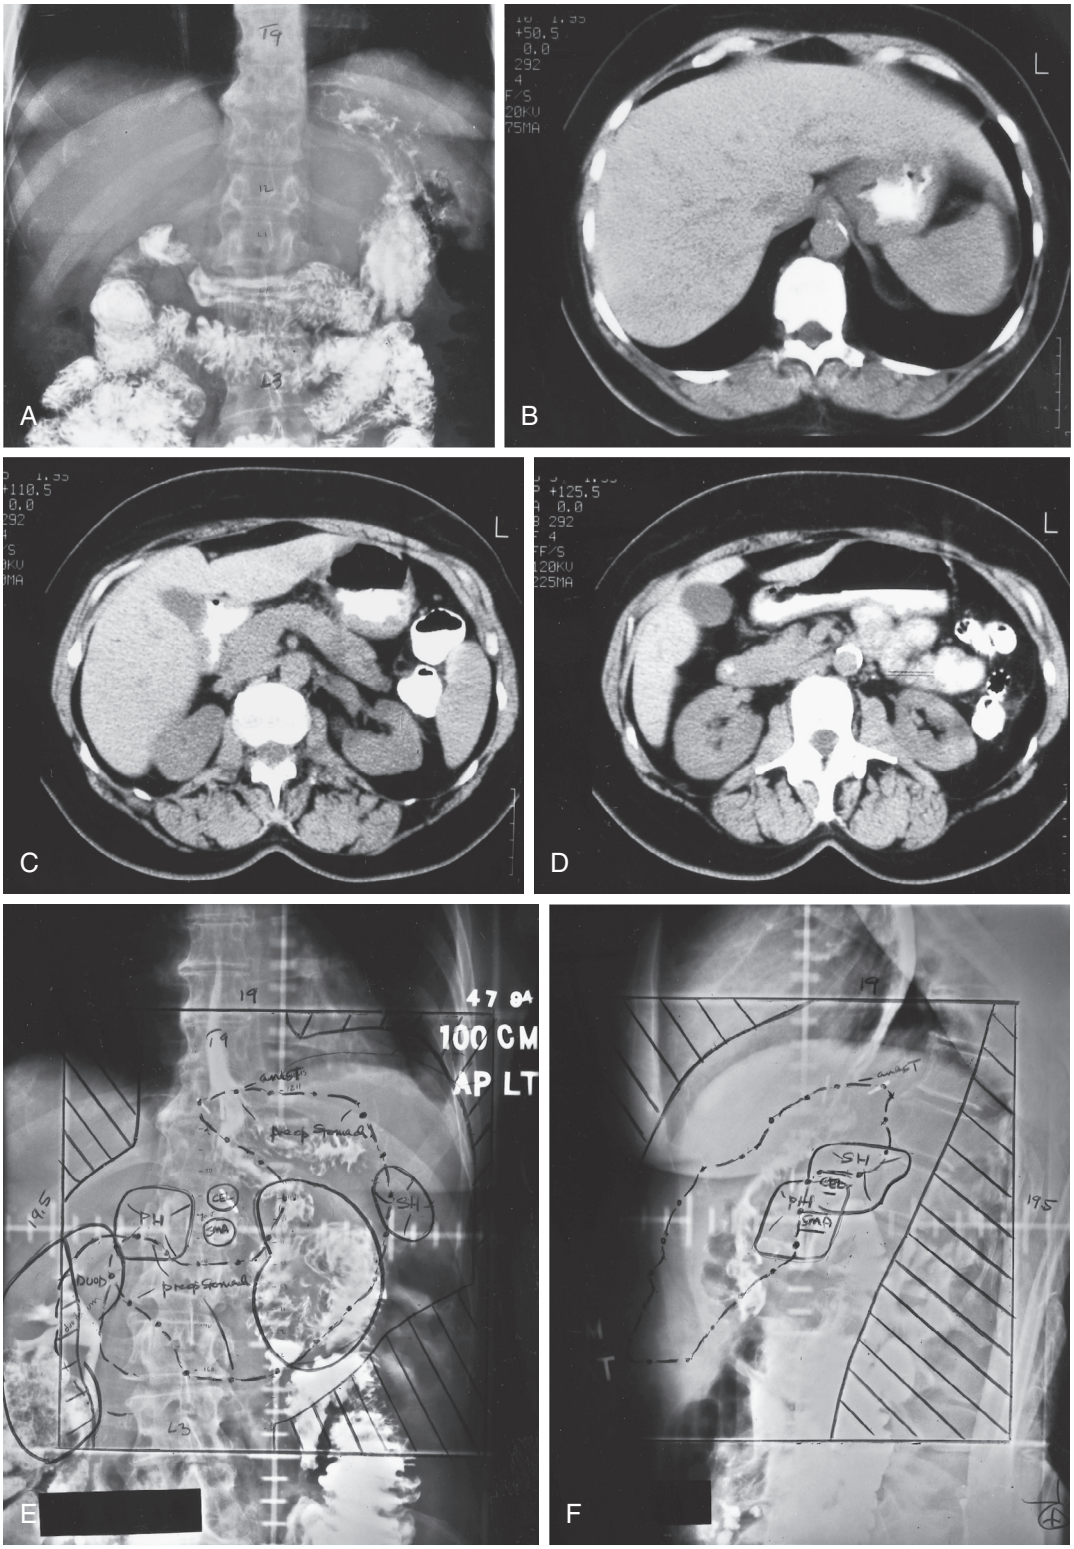
The relative risk of nodal metastases at a specific nodal location is dependent on both the site of origin of the primary tumor and other factors including width and depth of invasion of the gastric wall. Tumors that originate in the proximal portion of the stomach and the GE junction have a higher propensity to spread to nodes in the mediastinum and pericardial region but a lower likelihood of involvement of nodes in the region of the gastric antrum, periduodenal area, and porta hepatis. Tumors that originate in the body of the stomach can spread to all nodal sites, but have the highest likelihood of spreading to nodes along the greater and lesser curvature, near the location of the primary tumor mass. Tumors that originate in the distal stomach have a high likelihood of spread to the periduodenal, peripancreatic, and porta hepatis nodes but a lower likelihood of spread to nodes near the cardia of the stomach, the periesophageal and mediastinal nodes, or splenic hilar nodes.[165] Any tumor originating in the stomach has a high propensity to spread to nodes along the greater and lesser curvature, although they are most likely to spread to those sites in close anatomic proximity to the primary tumor mass.

With preoperative or primary chemoradiation for GE junction or proximal gastric cancers because of the risk of submucosal or subserosal lymphatic spread, a margin of 5 cm or more of uninvolved esophagus/proximal stomach should be included proximally, and the distal/lateral field extent should include a margin of 5 cm or more of uninvolved stomach (Figures 47-7 to 47-9 and eFigure 47-7). If the lesion extends beyond the gastric/GE junction wall, a major portion of the left hemidiaphragm should be included. Cerrobend blocks or multileaf collimators (MLC) should be used to decrease the volume of irradiated heart and lung, when technically feasible (see Figure 47-7 and eFigure 47-7). Preoperative EBRT fields can usually be much more conservative than postoperative fields with regard to both heart and lung volumes, especially for GE junction tumors, and are preferred, if preoperative imaging and EUS demonstrate indications for preoperative adjuvant treatment (compare Figures 47-7 and 47-8 to eFigures 47-5 and 47-6). Intensity-modulated irradiation (IMRT) may reduce dose to normal structures, especially to the heart, when dose-volume histogram (DVH) are compared with three-dimensional (3D) conformal techniques for patients with GE junction cancers and reduce kidney doses for more distal lesions (see Figure 47-9), but there is uncertainty whether this will improve short- or long-term treatment tolerance.

With postoperative irradiation of GE junction cancers (see eFigures 47-5 and 47-6), the irradiation field may include the anastomotic site and some or all of the remaining stomach. Postoperative fields are larger than preoperative fields unless an involved field approach is chosen for select T3N0 patients (eFigure 47-6).

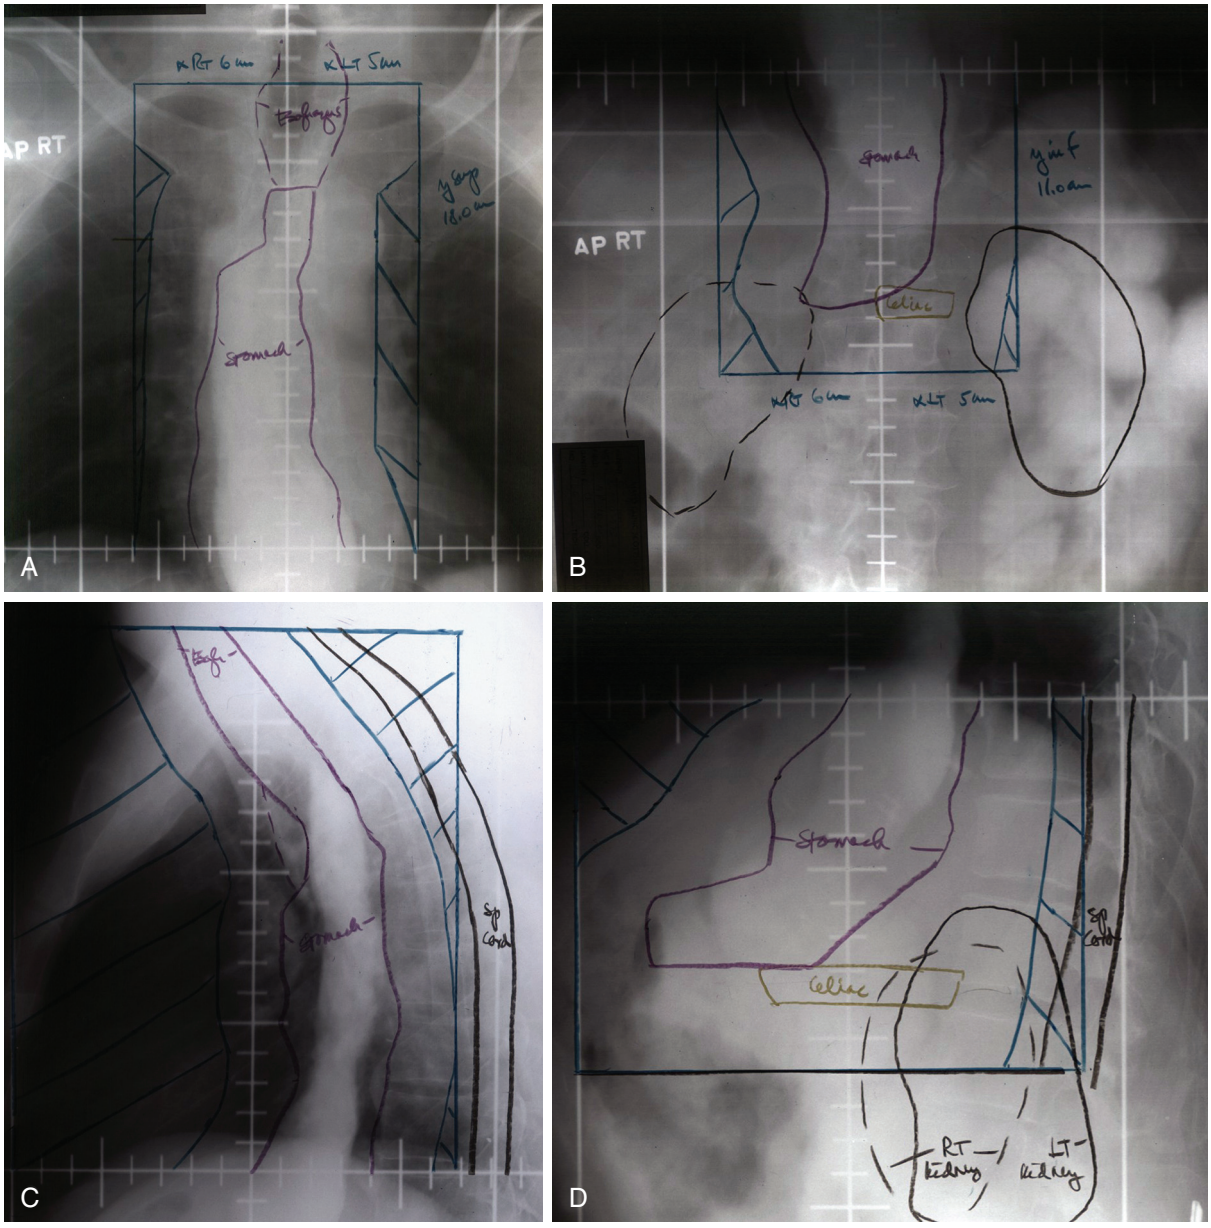
Dose-Limiting Organs and Structures

Dose-limiting organs and structures in the upper abdomen are numerous (stomach, small intestine, liver, kidneys, and spinal cord). With properly shaped fields, doses of 45 Gy to 50.4 Gy in 1.8-Gy to 2.0-Gy fractions can be delivered to the stomach and small intestine with a 5% or less risk of severe toxicity.[165,171,266] In most patients a portion of both kidneys will be within the treatment fields, but at least two thirds or three fourths of one kidney should be excluded (can include entirety of both kidneys to a dose of 20 Gy if necessary).



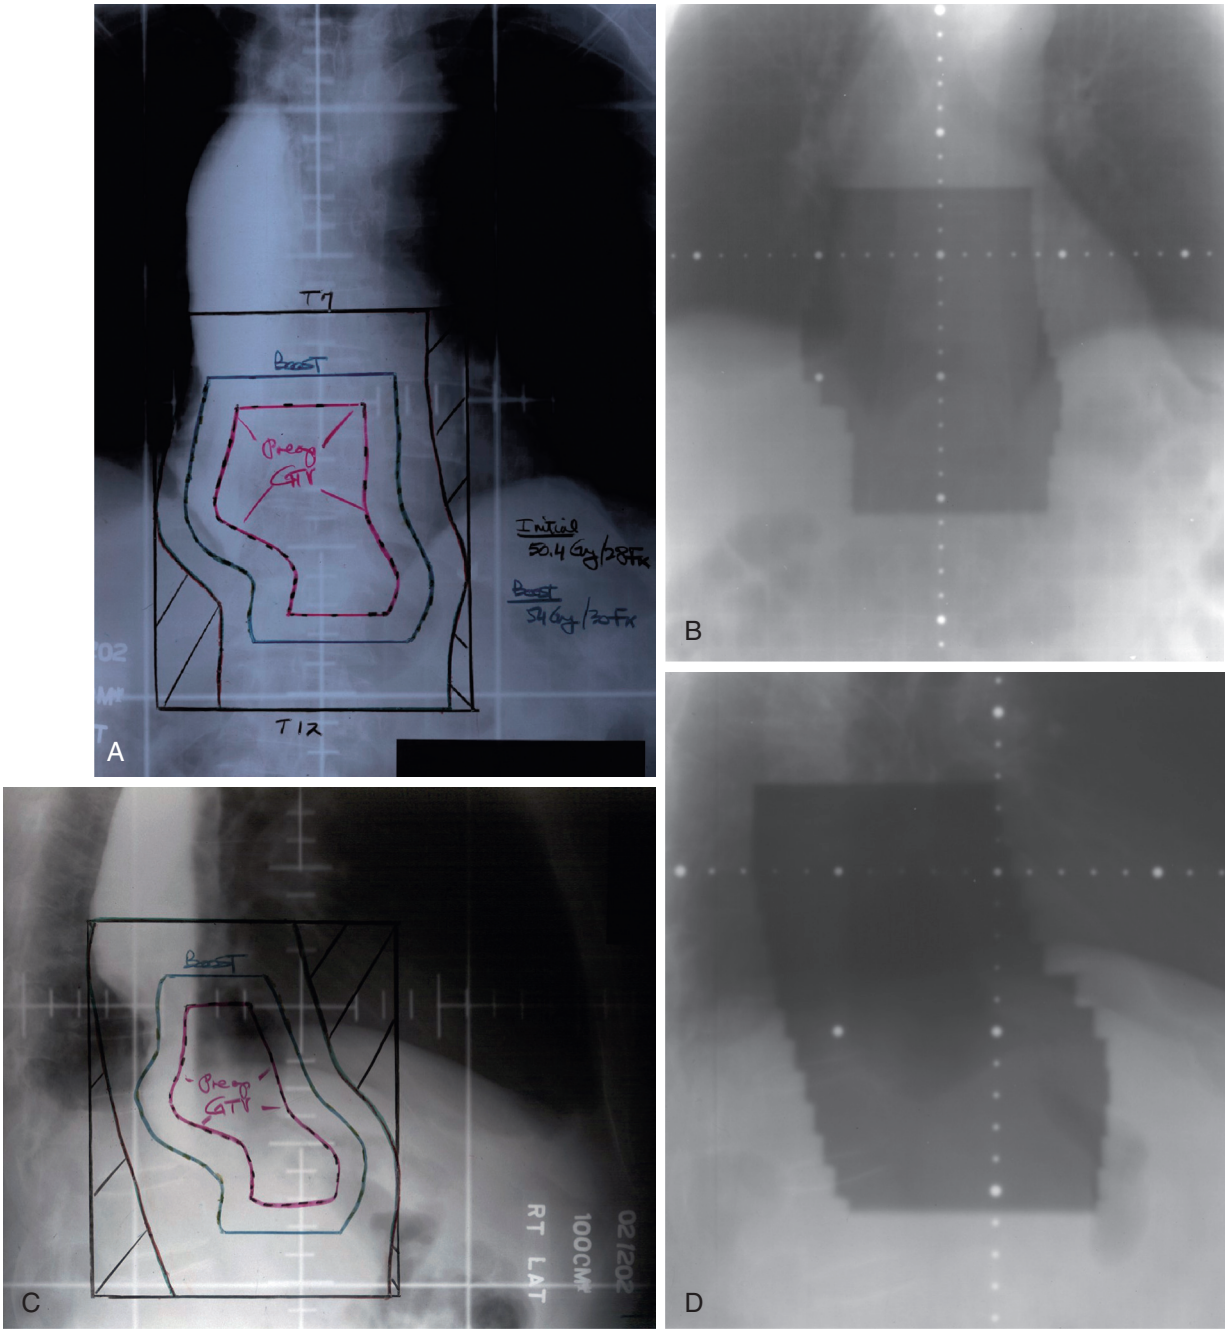
For patients with GE junction, or proximal to midgastric cancers one half to two thirds of the left kidney can often be spared as a result of accurate field definition, which is aided by pre- and postoperative imaging studies and surgical clip placement (see Figures 47-5, 47-7, 47-8 and eFigures 47-4 to 47-7). The pancreatic-duodenal nodes can be included, if indicated, while sparing 75% to 90% of the right kidney.

In patients with distal gastric lesions and narrow or positive duodenal resection margins, the duodenal circumference should be included as target volume (see Figure 47-6). In such instances 50% or more of the right kidney is within the field, and two thirds to three fourths of the left kidney should be spared. Chronic renal problems are infrequent when these techniques are used.[267]

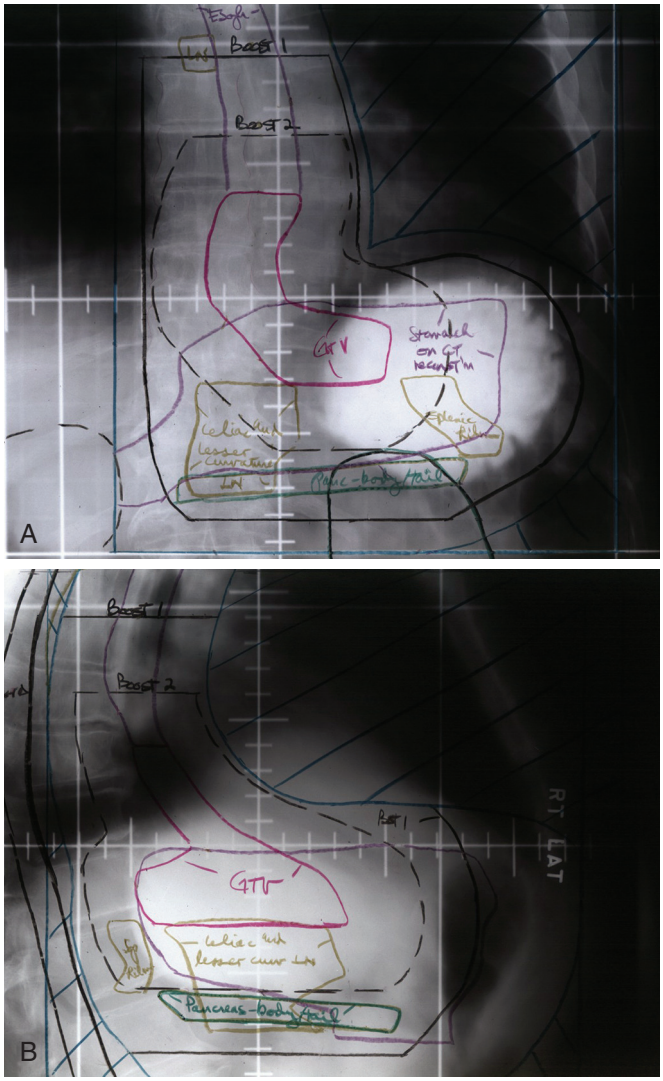


As noted in the GI Tumors Overview, 3D conformal irradiation with CT-based planning is recommended in most patients because of the ability to spare more normal organs/structures (heart, lung, liver, kidneys, and spinal cord). IMRT may optimize sparing of normal organs and structures (see Figures 47-8 and 47-9).[268-274] As noted by Wysoka et al, planning target volume margins need to account for respiratory motion during conformal EBRT for gastric cancer.[275]

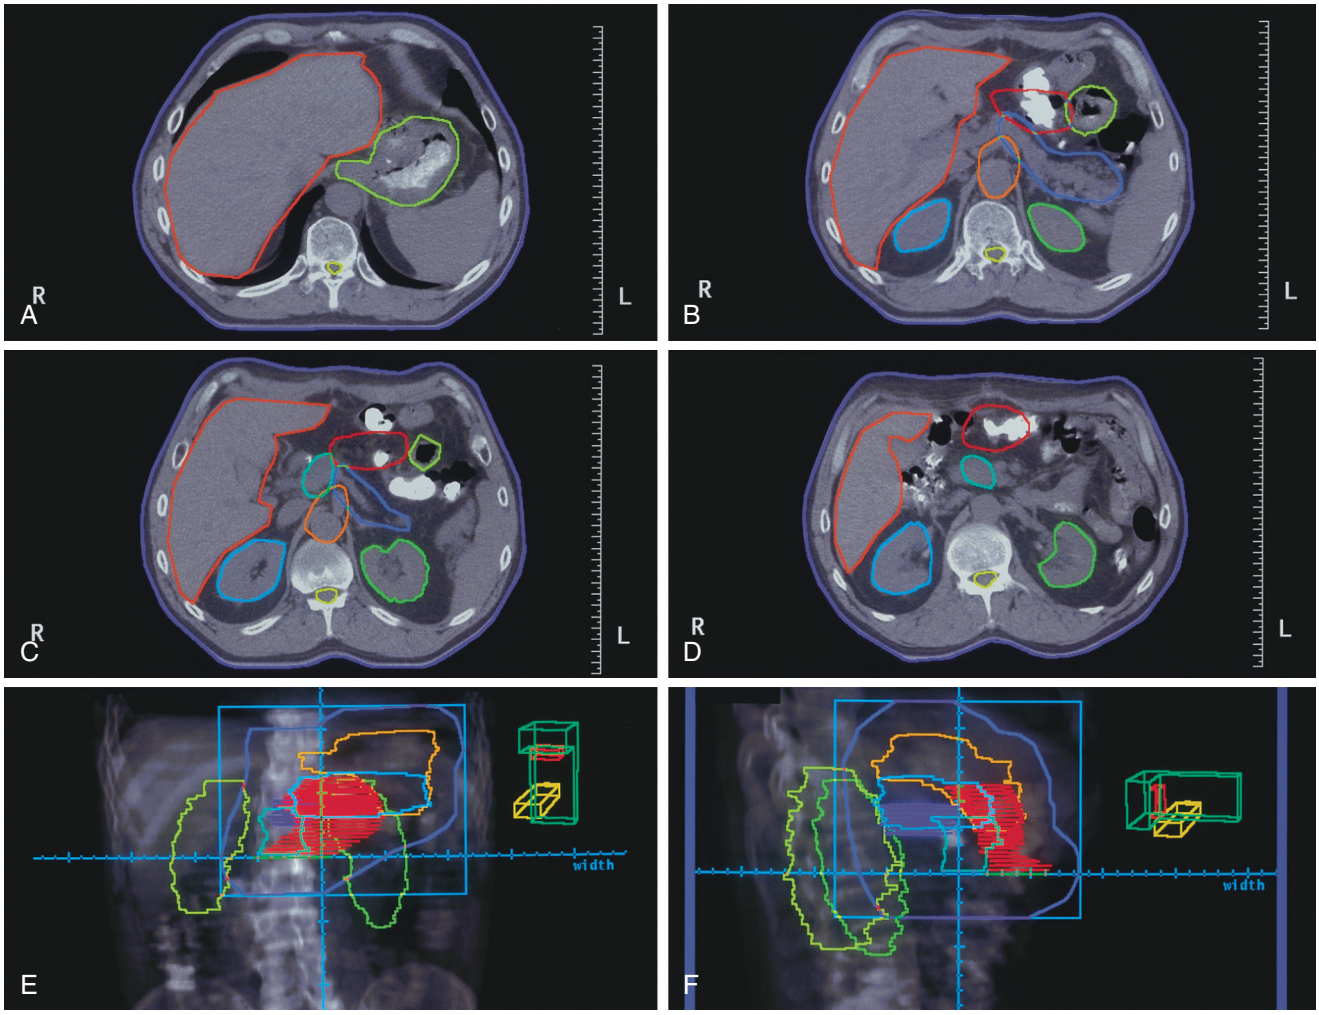
Multiple-Field Techniques



Routine use of multiple field techniques should be considered even for postoperative irradiation, when preoperative imaging exists to allow accurate reconstruction of target volumes (see Figures 47-5 to 47-9) Single-institution data suggest that multiple-field arrangements may produce less toxicity.[151] When patients are treated preoperatively, paired lateral fields can be combined with anteroposterior and posterior-anterior fields to achieve improved dose distributions on normal



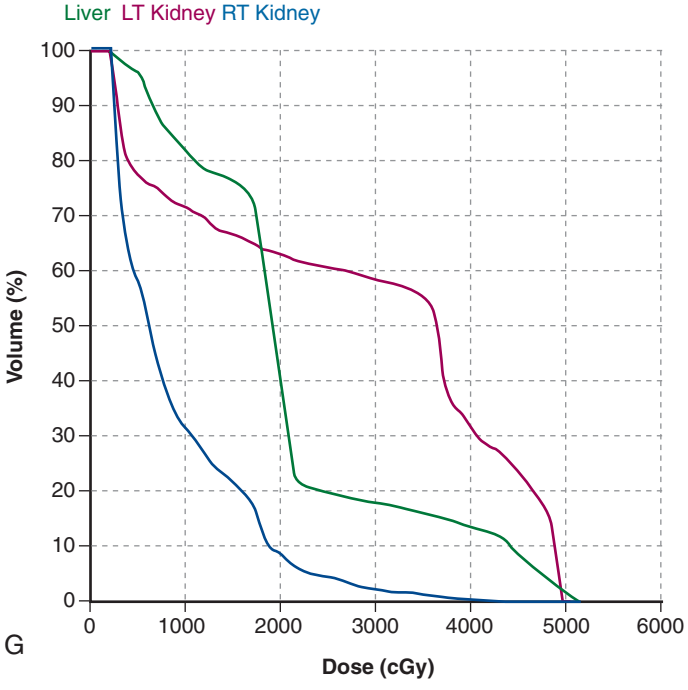
eFigure 47-4 Postoperative radiation fields based on preoperative radiographs following complete resection of a proximal gastric cancer (T3N2M0); the patient was randomized to the irradiation plus chemotherapy arm on the U.S. GI Intergroup 0116 gastric adjuvant study. Tumor bed and target volumes were reconstructed using the preoperative upper GI **(A)** and CT **(B-D)**. Computed tomography cuts demonstrated thickened gastric wall proximally **(B** and **C)** and normal thickness distally **(D)** as well as relationship of the stomach to surrounding organs including liver and spleen **(B)**, liver, body and tail of pancreas, and splenic flexure **(C)**, and head of pancreas **(D)**. Anteroposterior-posteroanterior (AP-PA) irradiation field **(E)** with crosshatched blocks encompasses all of the left kidney but less than 20% of the right. Nodal groups at risk and preoperative gastric duodenal locations (-●-●) are demonstrated on the AP-PA and lateral **(F)** simulation fields. *CEL,* Celiac; *PH,* porta hepatis; *SH,* splenic hilum; *SMA,* superior mesenteric artery.
(From Gunderson LL, Donohue JH, Burch FA: Stomach. In Abeloff MD, Lichter AS, editors: Clinical oncology, ed 2, Philadelphia, 1999, Churchill Livingstone.)



eFigure 47-5 Radiation fields in a patient with a T2N1 adenocarcinoma (ACA) of the gastroesophageal (GE) junction who had a transhiatal esophagectomy with cervical esophagogastrostomy (see Table 47-9). Postoperative chemoradiation was recommended, and the patient was placed on the current Phase III U.S. GI Intergroup trial. At the time of simulation, oral contrast medium was used to define the esophageal (EG) anastomosis at the thoracic inlet **(A** and **C)**, the residual stomach within the mediastinum, and the duodenal sweep inferiorly **(B** and **D)**. A combined treatment planning and diagnostic CT was obtained to define the celiac artery and dose-limiting structures including heart, lungs, spinal cord, kidneys, and liver. Irradiation fields were defined to include the distal cervical esophagus and supraclavicular nodes superiorly, the remaining stomach and perigastric nodes and nodal groups in the mediastinum and celiac axis **(A-D)**. Lateral simulation films **(C** and **D)** demonstrate the ability to spare heart and spinal cord with appropriate use of blocks *(crosshatched blocks)*. The patient received 45 Gy in 25 fractions plus concurrent protracted venous infusion (PVI) 5-FU (200 mg/m^2/24 hours) in addition to systemic multidrug chemotherapy before and after concurrent chemoradiation.

eFigure 47-6 Radiation and port films on a 65-year-old patient with Ivor Lewis esophagogastrectomy (transthoracic plus abdominal approach) for a T3N0 ACA of the gastroesophageal (GE) junction (see Table 47-9). Postoperative chemoradiation, as per INT 0116 was recommended. Simulation films **(A, C)** were obtained with contrast in the remaining stomach, and a treatment planning CT was obtained for purpose of reconstructing tumor bed volumes. The patient was concerned about treatment-related morbidity, so the decision was made to treat with a more involved treatment field approach in view of pathologic findings of 12 negative nodes and adequate proximal and distal resection margins (~5 cm). The involved fields included the tumor bed (preoperative gross tumor volume), as generated from preoperative CT imaging, but excluded the remaining stomach and nodal sites to decrease normal tissue morbidity. The initial anteroposterior and posteroanterior fields **(A, B)** included tumor bed with 3-cm superoinferior and 2-cm lateral margin to block edge (clinical target volume [CTV]/planning target volume PTV]). Lateral fields **(C, D)** were generated with an anterior margin of 2 cm to block edge and demonstrate sparing of heart and spinal cord. Initial fields were treated to 45 Gy in 25 fractions; boost fields **(A, C)** received an additional 9 Gy in 5 fractions to gross tumor volume plus 1-cm margin to block edge (total 54 Gy in 30 fractions). The patient received 5-fluorouracil (5-FU) plus leucovorin before, during, and after external beam radiation therapy (EBRT) as per INT 0116.

eFigure 47-7 Patient is a 73-year-old male with T3N0 ACA of the gastroesophageal (GE) junction (see Table 47-9) who preferred primary chemoradiation treatment with surgery reserved for salvage, as indicated. Baseline positron emission tomography with computed tomography (PET/CT) scan and CT chest were negative for nodal or blood-borne metastases. Radiation fields were generated using treatment planning CT and beam's-eye reconstruction. The patient was treated with a four-field technique of anteroposterior and posterior-anterior **(A)** and paired lateral fields **(B)**. The initial fields included a margin of more than 5 cm of uninvolved esophagus superiorly, a margin of about 5 cm of stomach in all directions and nodal groups including celiac artery and lesser curvature nodes, suprapancreatic (body/tail of pancreas) and splenic hilum. The patient received external beam irradiation (EBRT) plus one cycle of concurrent carboplatin/taxol and infusion 5-fluorouracil (5-FU) during the first week of EBRT but did not receive further concurrent chemotherapy in view of intolerance. The extended fields received 39.6 Gy in 22 fractions of 1.8 Gy; boost 1 received an additional 4.5 Gy in 3 fractions (total 45 Gy in 25 fractions) and boost two received an additional 9 Gy in 5 fractions for a total dose of 54 Gy in 30 fractions over 6 weeks.



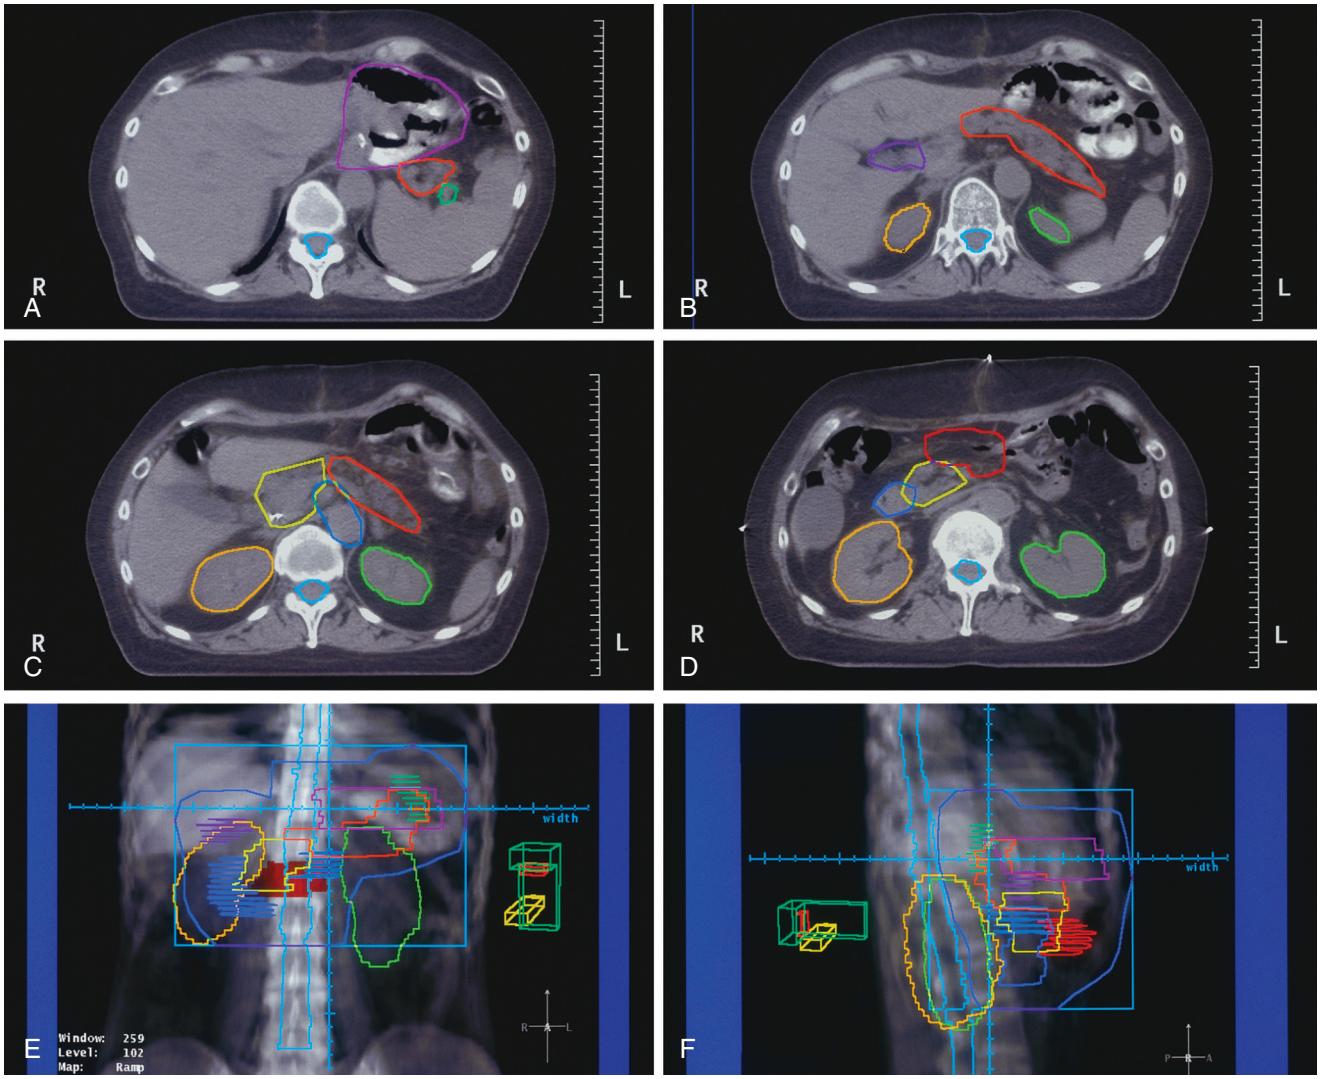


Figure 47-5 Optimized postoperative radiation fields for patient with T4N0 ACA of the posterior wall of the body of the stomach (middle third, see Table 47-10). CT simulation was performed and structures of interest were delineated based on pre- and postoperative CT imaging and operative/pathologic findings (**A-D;** tumor bed; gastric remnant; tolerance organs/structures: kidneys, liver, spinal cord). **A,** Gastric remnant and distal esophagus *(yellow-green)* are adjacent to liver *(red-orange)* and spleen. **B,** CT image demonstrates tumor bed *(red)*, body/tail of pancreas *(blue)*, celiac artery *(orange)*, and kidneys (right—*light blue*; left—*green*). **C,** Head of pancreas *(blue-green)* and splenic artery/body of pancreas are shown at level of mid-kidney. **D,** Tumor bed and head of pancreas on more distal CT image. Radiation fields were designed with the aid of digitally reconstructed radiographs (DRR; **E-F**) and a dose-volume histogram (DVH) was performed with regard to tolerance organs/structures **(G)**. A four-field technique of anteroposterior and posteroanterior and paired lateral fields was selected (field margins in *medium blue*). The fields included the gastric remnant *(yellow-orange)*, tumor bed *(red)*, and nodal regions at risk based on sites of adherence of the primary lesion (celiac [*blue-purple cross-hatched*]), suprapancreatic [body of pancreas, *light blue*], superior mesenteric, pancreatico-duodenal [head of pancreas, *blue-green*]). **E,** The anteroposterior and posteroanterior field includes ~two thirds of the left kidney and a portion of the left lobe of the liver but excludes most of the right kidney and the right lobe of the liver. **F,** The lateral field demonstrates exclusion of the spinal cord and posterior kidneys. **G,** DVH demonstrates a dose of 20 Gy to >60% of the left kidney versus less than 10% of the right kidney.

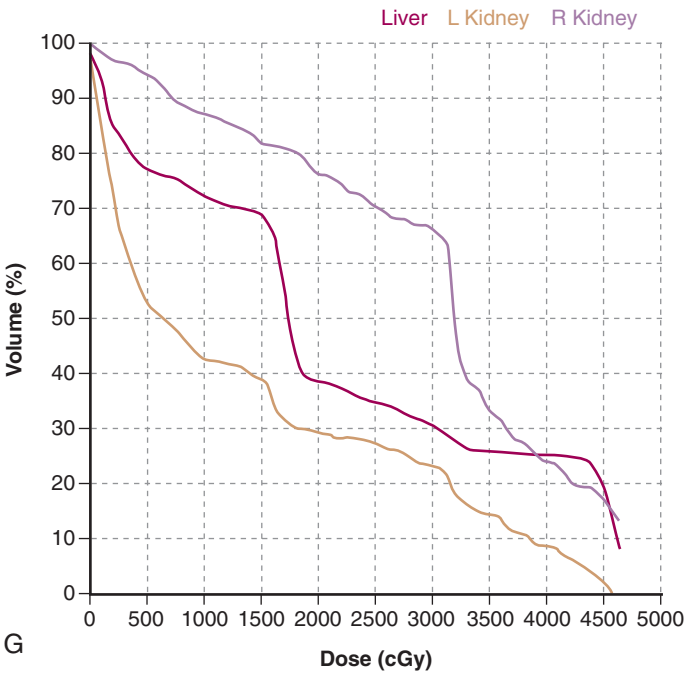

Figure 47-6 Optimized postoperative radiation fields for patient with T3N2 antral primary (distal third, see Table 47-11). Structures of interest were delineated at time of CT simulation **(A-D)**. **A,** Gastric remnant *(lavender)* is demonstrated along with the body/tail of pancreas *(red-orange)*, and splenic hilum *(light green)*. **B,** Porta hepatis *(blue-purple)* and kidneys (left, *yellow green*, right, *yellow orange*) are delineated. **C**, Head of pancreas *(yellow)* and celiac versus superior mesenteric artery *(light blue)* are shown. **D,** Antral tumor bed *(red)* and duodenum *(medium blue)* are delineated. Irradiation fields were designed with the aid of DRR **(E, F)** and a dose-volume histogram (DVH, **G**) was performed with regard to dose-limiting structures (liver, kidneys, spinal cord). A four-field technique of anteroposterior and posteroanterior and paired lateral fields was chosen (field margins shown in *medium blue*). Treatment fields include the gastric remnant, tumor bed, head of pancreas, first and second part of the duodenum (*medium blue cross hatched*), pertinent nodal volumes (perigastric, pancreaticoduodenal [head of pancreas], porta [*blue blue-purple cross hatched*], celiac, suprapancreatic [body/tail pancreas]) and the optional nodal volume of splenic hilum (light green cross hatched). **E,** Anteroposterior and posteroanterior field (field margins exclude ~two thirds of the left kidney and include ~90% of the right kidney). Exclusion of optional splenic hilar nodes would not have allowed additional sparing of the left kidney in view of the adjacency of the gastric remnant and splenic hilum. **F,** Lateral field demonstrates exclusion of the spinal cord *(turquoise)* and substantial portions of both kidneys. **G,** The DVH, combining doses from all four fields, demonstrated that the dose volume of 20 Gy included ~30% of the left kidney versus ~75% of the right kidney. With regard to the liver, ~30% receives a dose of 30 Gy and ~25% receives a dose of 35 Gy to 40 Gy.

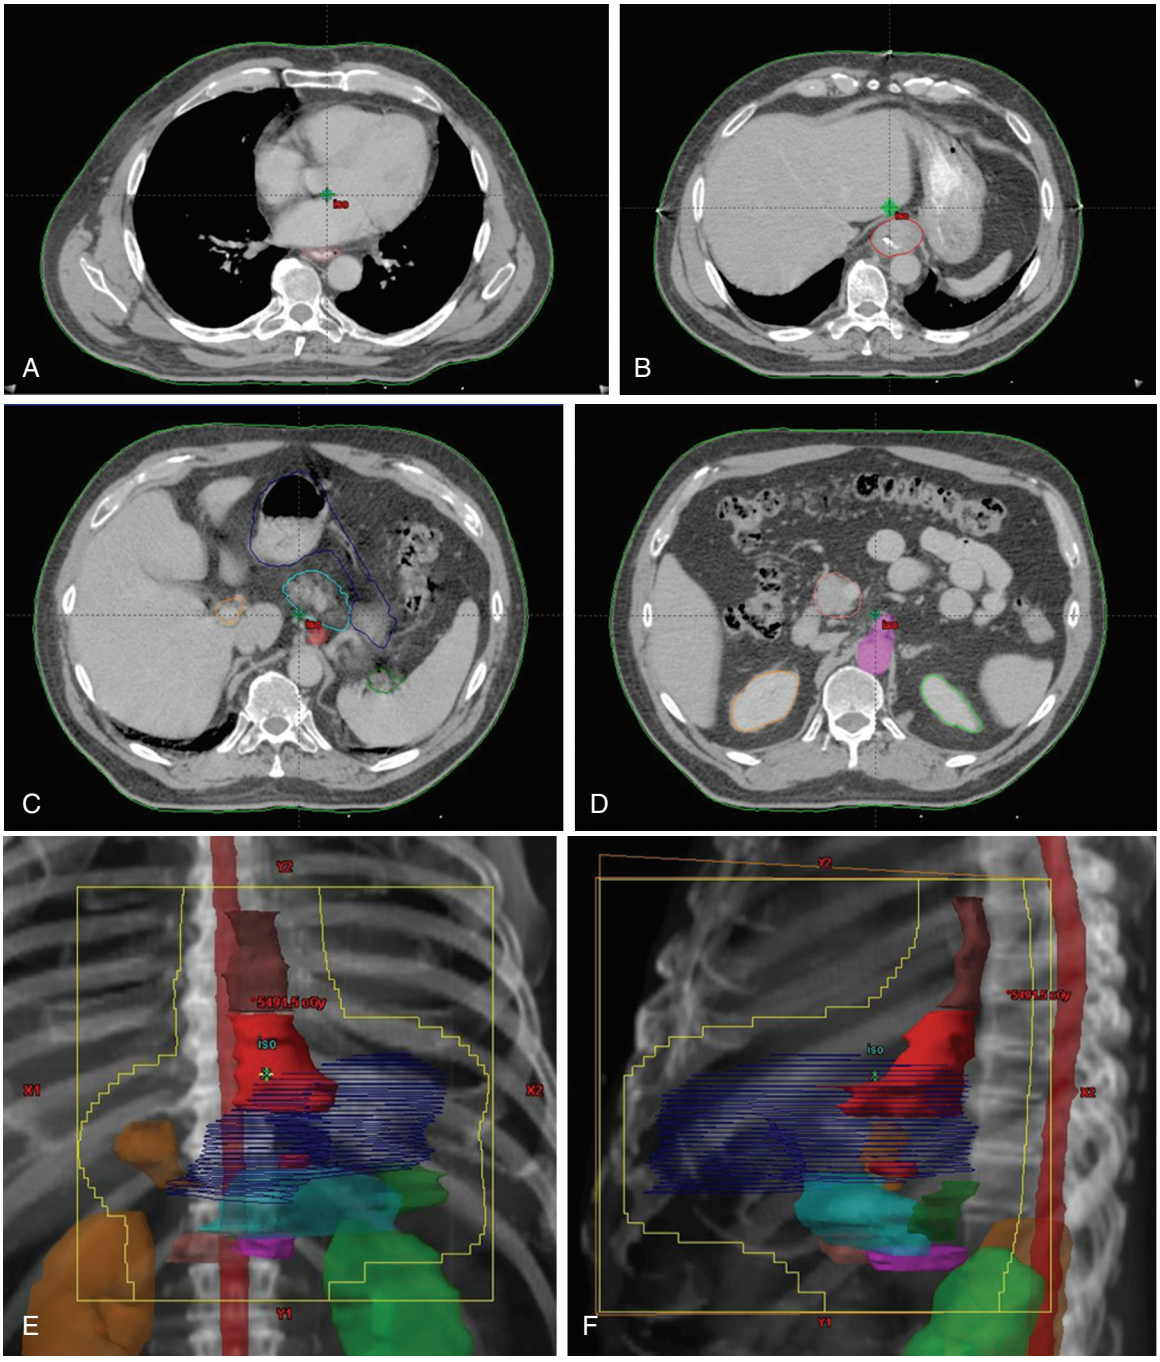

Figure 47-7 Patient is a 54-year old male with a T3N1 adenocarcinoma of the GE junction treated with preoperative chemoradiation at Mayo Clinic in Arizona (45 Gy in 25 fractions over 5 weeks to an extended field and 50.4 Gy/28 fractions within boost field). CT simulation was done with intravenous and oral contrast and organs/structures of interest were delineated **(A-D)**. The normal thickness of the more proximal esophagus wall **(A)** contrasts with the markedly thick distal esophagus wall at the level of the GE junction **(B)**. An enlarged gastrohepatic node **(C)** was biopsy positive for cancer. Other outlined organs/structures include celiac artery, body/head of pancreas, porta hepatis and splenic hilum **(B-D)**. Three-dimensional conformal irradiation fields **(E, F)** were designed to include primary tumor (red) with greater than 5 cm margins of esophagus proximally and stomach distally, plus nodal volumes (periesophageal and celiac, as per Table 47-9; porta hepatis, suprapancreatic, and splenic hilar nodes were also included in view of the documented gastrohepatic nodal disease [also shown in *red*]). Lateral fields **(F)** were used as a component of treatment to spare heart and spinal cord. The patient subsequently had a laparoscopic esophagogastrectomy, mediastinal and celiac node dissection, pyloroplasty and neck anastomosis (esophagogastrostomy) at Mayo Hospital in Arizona. Pathologic examination revealed a 3.5- × 2.5- × 1.5-cm ulcerated mass at the GE junction that consisted microscopically of pauci-cellular and acellular mucin and rare tumor cells floating in muscle with 0 of 20 positive nodes.
(From Gunderson et al in Abeloff Ed 4, with permission.)

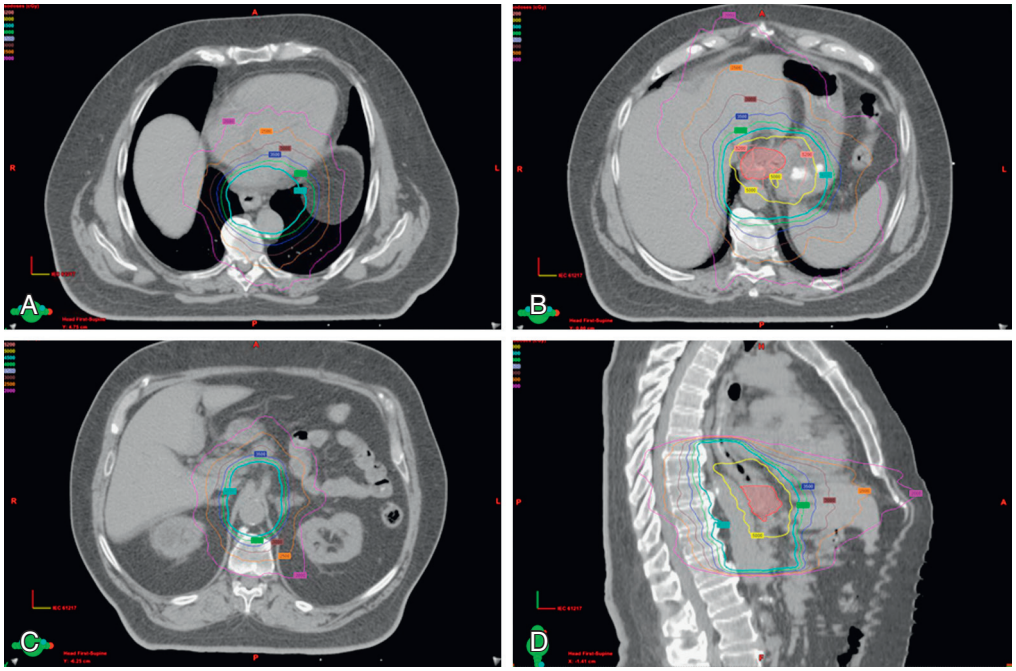

Figure 47-8 Intensity modulated radiation (IMRT) fields for patient with T3N1M0 adenocarcinoma of the gastroesophageal junction on endoscopic ultrasonography (EUS) was treated with preoperative concurrent chemoradiation at Mayo Clinic in Arizona. A volumetric modulated arc therapy (VMAT) technique was used to deliver 45 Gy in 25 fractions (Fx) of 1.8 Gy in 5 weeks to an extended volume (*yellow* isodose curves), which extends superiorly to include ~5-cm margin on the gross tumor volume (GTV, *red*) and inferiorly to include the celiac axis. A simultaneous integrated boost field received 50 Gy in 25 fractions of 2 Gy in 5 weeks (GTV plus ~2-cm margin plus margin for organ motion; *light blue* isodose curves). Isodose curves are shown in the axial plane at the superior portion of the field **(A),** limiting dose to the heart, at the isocenter **(B)** including the proximal stomach, and at the inferior portion of the field **(C)** including the celiac axis and limiting dose to the kidneys. Isodose curves are shown in the sagittal plane **(D)** demonstrating the borders of high- and low-dose volumes and limiting dose to the spinal cord posteriorly and the heart anteriorly.

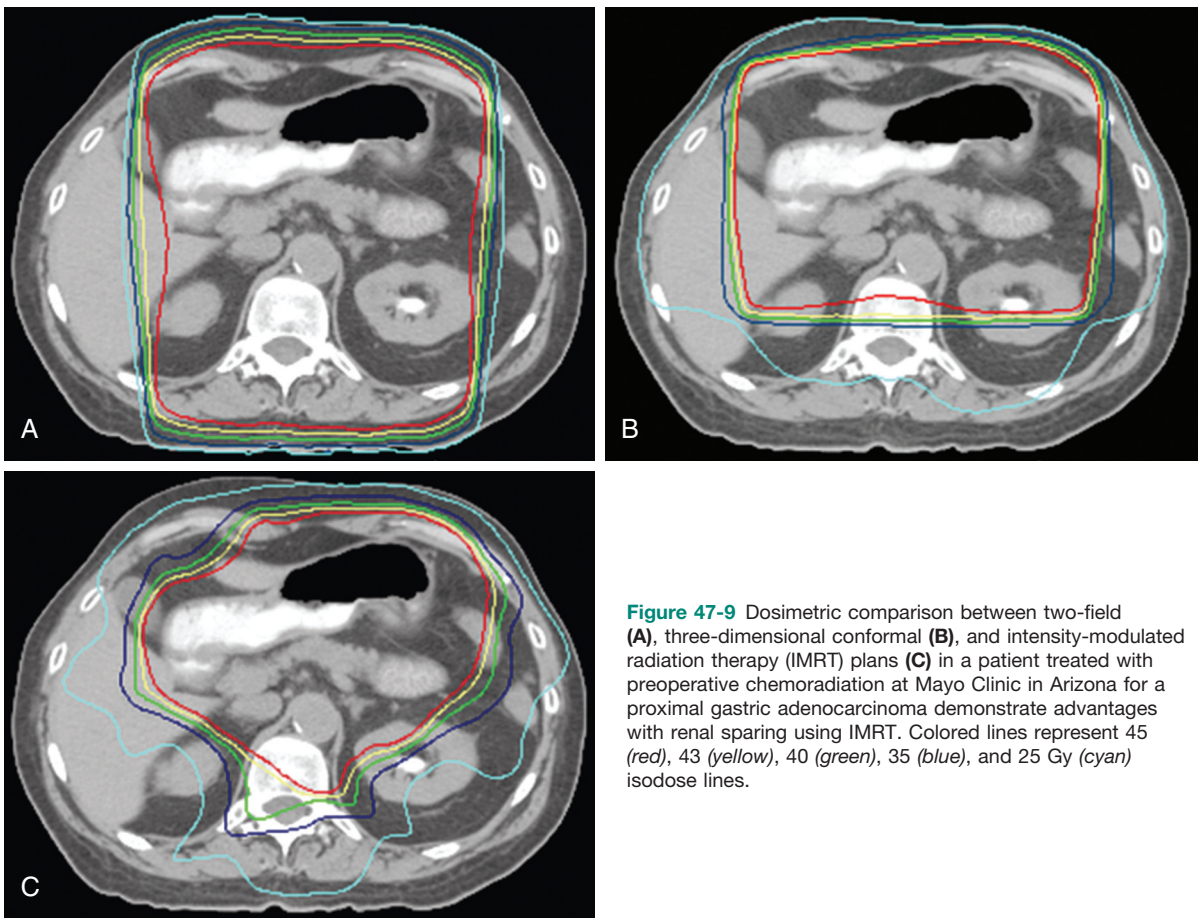

Figure 47-9 Dosimetric comparison between two-field **(A)**, three-dimensional conformal **(B)**, and intensity-modulated radiation therapy (IMRT) plans **(C)** in a patient treated with preoperative chemoradiation at Mayo Clinic in Arizona for a proximal gastric adenocarcinoma demonstrate advantages with renal sparing using IMRT. Colored lines represent 45 *(red)*, 43 *(yellow)*, 40 *(green)*, 35 *(blue)*, and 25 Gy *(cyan)* isodose lines.

tissue. Depending on the posterior extent of the gastric fundus, either obliqued or lateral fields can be used to deliver a 10-Gy to 20-Gy component of radiation to spare spinal cord and kidney. Liver and kidney tolerance limits the use of lateral fields to 20 Gy or less for patients with gastric cancer; for patients with GE junction cancers, the contribution from lateral fields is generally limited to 10 Gy to 15 Gy because of lung tolerance issues.

With the wide availability of 3D conformal treatment-planning systems, it may be possible to target more accurately the high-risk volume and to use unconventional 3D conformal field arrangements or IMRT to produce superior dose distributions (Figures 47-8 and 47-9). To accomplish this without marginal misses it is necessary to both carefully define and encompass the various target volumes because target volumes that would be included in anteroposterior and posterior-anterior fields may be missed with other field arrangements (oblique, lateral, non-coplanar). Extent of disease on EUS and PET/CT should be incorporated into target definition and field design.

When treating patients with GE junction cancers, irradiation dose to the heart and lung is of particular concern in the neoadjuvant setting, because of potential perioperative morbidity.[276-279] The volume of lung spared from doses of 5 Gy or more (V5) was the only independent predictor of perioperative pulmonary complications in an analysis by Wang et al.[276] Because IMRT may result in increased lung volumes exposed to low doses, it has not gained widespread acceptance over 3D conformal approaches. However, a Mayo Clinic Arizona analysis found a decrease in lung and heart doses in patients treated with IMRT compared with 3D conformal techniques with no compromise in early clinical outcomes (disease control, treatment tolerance including perioperative complication).[277,278] At a median follow up of 24 months, 2-year OS was 58%.[279] With regard to the heart, longer follow-up will be required to see if dosimetric improvements of IMRT will reduce long-term cardiac toxicity. Hybrid IMRT and conformal plans may also be used to improve target conformality while minimizing dose to the lungs and heart.[280] Acceptable treatment plans can be achieved with either 3D conformal or IMRT planning techniques.

Idealized Treatment Field Guidelines

Guidelines for defining the clinical target volume for postoperative radiation fields have been developed by Tepper and Gunderson based on location and extent of the primary tumor (T-category) and location and extent of known nodal involvement (N category).[165] Table 47-8 presents general guidelines on the impact of T and N category on inclusion of the remaining stomach (gastric remnant), tumor bed, and nodal sites, whereas Tables 47-9 to 47-11 and eTable 47-6 present treatment guidelines based on TN category for each of the four primary sites (GE junction, proximal, mid, and distal stomach). In general, for patients with node-positive disease, there should be wide coverage of tumor bed, remaining stomach, resection margins, and nodal drainage regions. For node-negative disease, if

TABLE 47-8 General Guidelines of Impact of T and N Category on Inclusion of Remaining Stomach, Tumor Bed, and Nodal Sites within Radiation Fields

TN Category	Remaining Stomach†	Tumor Bed	Nodes
T1-2 N0 (not into subserosa)	No	No	No
T2 N0 (into subserosa)*	Variable	Yes	No
T3 N0	Variable	Yes	No
T4 N0	Variable	Yes	Variable
T1-2 N+	Yes	No	Yes
T3-4 N+	Yes	No	Yes

**Tolerance organs or structures: kidneys, liver, and spinal cord.*

†For tumors with wide (>5 cm) surgical margins confirmed pathologically, treatment of residual stomach is optional if this would result in substantial increase in normal tissue morbidity.

‡Use preoperative imaging (CT, barium swallow), surgical clips, and postoperative imaging (CT, barium swallow).

§Optional node inclusion for T2-3N0 lesions if adequate surgical node dissection (D2 dissection) and at least 10-15 nodes examined pathologically.

there is a good surgical resection with pathologic evaluation of at least 10 to 15 nodes, and there are wide surgical margins on the primary tumor (at least 5 cm), treatment of the nodal beds is optional. Treatment of the remaining stomach should depend on a balance of the likely normal tissue morbidity and the perceived risk of local relapse in the residual stomach. Calvo et al have discussed guidelines for idealized IORT field design for institutions with IORT availability.[281]

Nutritional Support (before, during, and after Chemoradiation)

Patients who have surgical resection for gastric cancer can have significant management problems. Postoperatively, especially after removal of more than three fourths of the stomach, maintaining adequate nutrition can be a major clinical problem. Placement of a feeding jejunostomy tube during surgery can be critical in getting the patient past the first 2 months postoperatively. Problems of early satiety are extremely common, and it is usually not feasible to start postoperative adjuvant therapy until the patient has stabilized their weight.

During the course of postoperative chemoradiation, strict attention must also be paid to nutritional support. It is rare that a patient will manage with three meals per day; most need to eat five or six planned meals, often with nutritional supplements. Postoperative problems of dumping syndrome are fairly common but are often not recognized by the

treating physician. Dumping is expressed by the enhanced gastrocolic reflex with clustered bowel movements in association with meals. What is not as well recognized is the reactive hypoglycemia that can occur in these patients, related to the rapid transit of the gastric contents into the small bowel, rapid absorption of glucose into the circulation, and the associated insulin secretion. As there is no residual food in the stomach (as would normally occur), a reactive hypoglycemia occurs, typically 1.5 to 2 hours after meals. Proper patient awareness of this problem can alleviate many of the associated difficulties.

Many patients who receive preoperative chemoradiation (with plans to proceed to surgical resection) or primary chemoradiation may also require parenteral or enteral hyperalimentation during treatment. Improvement in nutritional status may require stent placement during endoscopy or feeding jejunostomy. Feeding jejunostomy is strongly preferred to percutaneous endoscopic gastrostomy (PEG) tube placement to preserve use of the stomach for reconstruction.

Nutritional problems can exist long-term in these patients. The lack of acid production results in poor absorption of a number of minerals but most importantly iron and calcium. The iron loss is usually noted because of the associated anemia, but the calcium malabsorption is not usually appreciated until many years later. Calcium supplementation (with calcium citrate, not calcium carbonate) will usually need to be lifelong, but iron requirements can be assessed during follow-up. Periodic bone densitometry is appropriate. Malabsorption of fat and other nutrients should also be observed. Loss of vitamin B12 absorptive capacity is well known after a total gastrectomy secondary to loss of intrinsic factor. However, the body typically has vitamin B12 stores to last for up to 3 years, so it is possible to observe the patient carefully to assess whether the patient will require lifelong monthly vitamin B12 injections.

TREATMENT ALGORITHM, CHALLENGES, AND FUTURE POSSIBILITIES

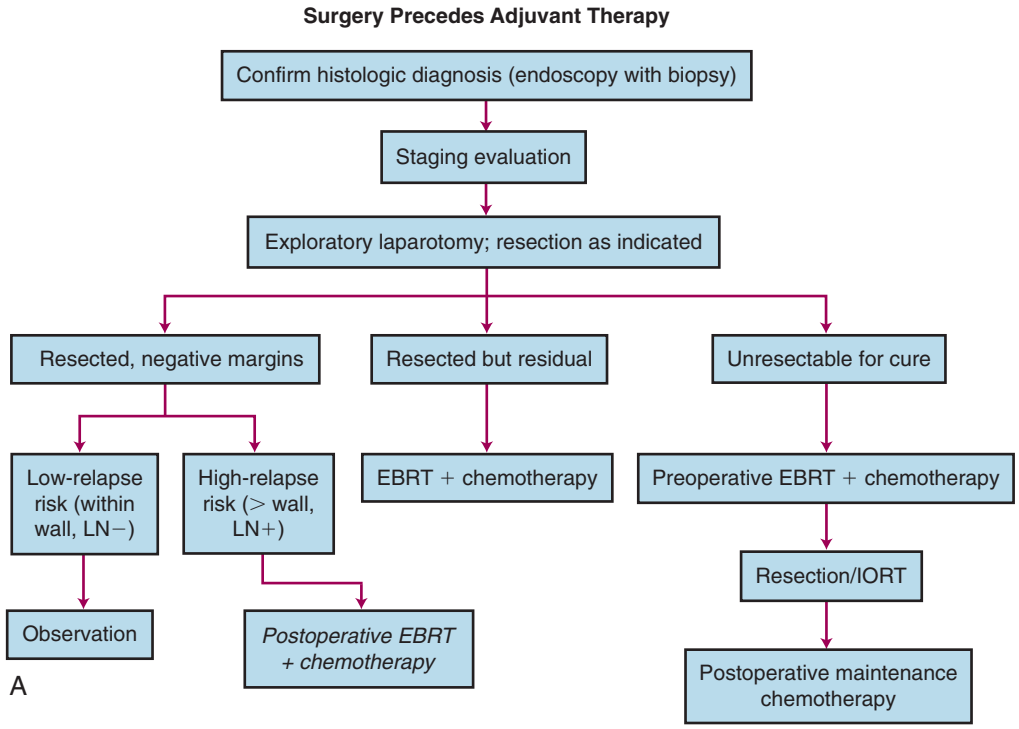
Primary and Adjuvant Therapy

Although the Dutch and British Phase III multicenter trials evaluating extended lymphadenectomy found increased morbidity but no benefit in survival because experienced surgeons can perform extended node dissection without significant additional surgical morbidity or mortality, use of D2 nodal dissection is reasonable in patients felt to be node-positive. Patients with extended resection are still at high risk for locoregional and systemic relapse,[113] however, and should receive postoperative chemoradiation (see treatment algorithm by TNM extent, Figure 47-10 and Table 47-12). The nonrandomized Samsung Medical Center analysis by Kim et al appeared to demonstrate an advantage in disease control and survival in the 544 patients who received postoperative chemoradiation following D2 resection compared to the 446 surgery-alone patients (5-year OS 57 versus 51%, $p = 0.02$; 5-year RFS 54.4 versus 47.9%, $p = 0.016$).[152] In the subsequent Phase III trial by Lee et al, the subset analysis of 396 patients with D2 resection and positive nodes found improved 3-year DFS with postoperative chemoradiation compared to chemotherapy only (3-year DFS 77.5% versus 72%, $p = 0.0365$).[172]

The most recent U.S. GI Intergroup Phase III randomized postoperative chemoradiation trial (CALGB 80101) tested ECF versus 5-FU leucovorin as both initial and maintenance chemotherapy (control arm was from the Phase III GI Intergroup Trial 0116). Preliminary analyses did not demonstrate a survival benefit for ECF chemotherapy.[156] Accordingly, the postoperative chemoradiation arm of US GI INT 0116 (with concurrent and maintenance bolus 5 FU-leucovorin) remains an appropriate standard of care for patients who are resected and are high risk with gastric or GE junction cancers.

Preoperative chemoradiation (preop chemoRT)[166-168,173] and perioperative chemotherapy (periop chemo)[124,125] have also become appropriate standards of care in view of positive Phase III trials testing those approaches versus surgery-alone control arms. A survival advantage was found for periop ECF or CF compared to surgery alone for resectable gastric/distal esophageal cancers in the MAGIC and French trials (MAGIC trial: 5-year OS 36% versus 23%, $p = 0.009$; French trial: 5-year OS 38% versus 24%, $p = 0.02$).[124,125] Preop chemoRT improved survival in a large CROSS Phase III trial comparing surgery alone with preop chemoRT for 366 analyzable patients with ACA of the esophagus or GE junction (median OS 49.4 versus 24 months, 5-year OS 47% versus 34%, $p = 0.003$).[167,168] In addition, the POET Phase III trial of 120 pts with GEJ lesions tested preop chemo compared to chemoRT; outcomes trends favored preop chemoRT over chemo alone for both OS ($p = 0.07$) and local control ($p = 0.06$).

Current and Future Trials



In summary, for patients with potentially resectable high-risk gastric cancer, appropriate treatment approaches include postop chemoRT and periop chemo (ECF or CF). Although

TABLE 47-12 Treatment Algorithm: Gastric or GE Junction Cancer

TNM Extent	Surgery	Irradiation (Alone or with Chemotherapy)	Chemotherapy
T1-2N0M0	Radical subtotal gastrectomy and regional nodes	Not routinely recommended; exception: posterior wall T2N0M0	Evaluate in view of distant metastasis rates of ~30% with T1-2N0 lesions
T1-2N1-3M0; T3N0-3M0	Radical subtotal and regional nodes	Postop chemo EBRT, 45 Gy-50 Gy; evaluate preop EBRT-CT, gastric; prefer preop EBRT-CT, GE junction*	5-FU/leucovorin bolus wk 1, 5: CCRT and maintenance
T4N0-3M0	Radical subtotal and regional nodes; attempt en bloc resection, involved organ(s)	Preop EBRT-CT, 45 Gy-50 Gy; attempt resection and IOERT	5-FU-leucovorin, bolus wk 1, 5; eval alternate CCRT (i.e., infusion 5-FU); eval other maint CT (ECF, EOX, other)
T any N any M1	Palliative if feasible	Palliative CCRT if indicated	MACT; ICT Phase I, II, or III

CCRT, *Concurrent chemoradiation;* EBRT, *external beam irradiation;* EBRT-CT, *external beam irradiation + chemotherapy;* eval, *evaluate;* GE, *gastroesophageal;* ICT, *investigational chemotherapy clinical trials;* IOERT, *intraoperative electron irradiation;* MACT, *multiagent chemotherapy;* maint, *maintenance;* NR, *not recommended;* postop, *postoperative;* preop, *preoperative.*

**Prefer preoperative CRT for gastroesophageal junction cancers found to be T1-2 N1-3 M0 or T3 N0-3 M0 on EUS, as can usually design safer EBRT fields with preoperative CRT rather than postoperative CRT. If transhiatal resection is performed, keeping the reconstructed stomach in the mediastinal midline, postoperative CRT can be given more safely than if Ivor-Lewis resection is performed.*

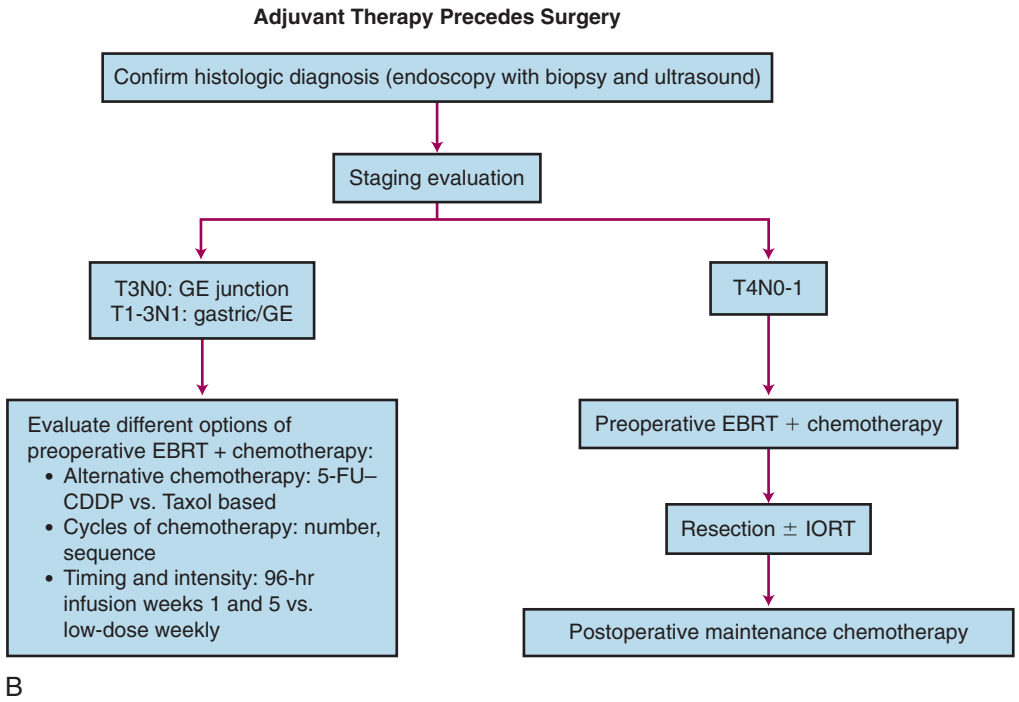


Figure 47-10 Treatment algorithms for patients with newly diagnosed gastric or gastroesophageal junction cancer. *5-FU,* 5-fluorouracil; *EBRT,* external beam radiation; *GE,* gastroesophageal; *IORT,* intraoperative irradiation; *LN–,* lymph nodes negative; *LN+,* lymph nodes positive.

some investigators and institutions may prefer to simply replace postop chemoRT with periop ECF or CF in these patients, it would seem advantageous to attempt to combine the advances in disease control and survival found with both approaches because neither approach by itself resulted in optimal relapse or survival outcomes.[282] In patients with potentially resectable high-risk GE junction cancer, however, the preferred treatment option is preop chemoRT in view of positive Phase III trials and the advantage of treating more conservative EBRT fields with less associated morbidity.

Current and future trial designs are attempting to build on or further define preop chemoRT and periop chemo (alone or followed by postop chemoRT). A Phase III AGITG/ESTRO study is testing periop multidrug chemotherapy (three cycles ECF or ECX [xeloda/capecitabine] before and after surgery) compared to preop chemoRT and postop chemo (preop: two

cycles ECF/ECX plus 45 Gy in 25 fractions for 5 weeks with concurrent PVI 5 FU; postop: three cycles ECF/ECX) for patients with gastric or GEJ cancers. The European CRITICS Phase III trial is testing periop chemo (three cycles ECC [etoposide/capecitabine/cisplatin] before and after surgery) compared with three cycles preop ECC plus postop chemoRT (45 Gy for 5 weeks plus concurrent capecitabine/cisplatin). A U.S. GI Intergroup Phase IIR trial is randomizing patients with esophagus or GEJ cancers to one of two preop chemo regimens (FOLFOX6 versus carboplatin plus paclitaxel) and using PET response to determine the type of chemo to be given concurrent with preop RT (PET responders continue same chemo with RT, nonresponders crossover to alternative chemo with RT; 50.4 Gy in 28 fractions for 5.5 weeks).

Locally Unresectable and Borderline Resectable Disease

For patients with locally unresectable or borderline resectable disease, it seems reasonable to build on existing positive treatment data (primary chemoRT, IORT, preop chemoRT, postop chemoRT, preop chemo) plus patterns of relapse information (see Figure 47-10; Table 47-12).

For patients with gastric cancer whose treatment is initiated with preop chemo, those with marginal gross total or subtotal resection with residual disease or complete resection but high-risk factors for relapse (beyond the gastric wall, nodes positive, or both) should be placed on studies that evaluate IORT, postop chemoRT, or both in conjunction with concurrent and maintenance chemotherapy. For patients whose tumors are unresectable after preop chemo but who still have localized tumor on the basis of preoperative staging (including laparoscopy) or exploratory laparotomy, preop chemoRT should be given. Decisions regarding attempts at later resection with or without IORT could be individualized.

With locally unresectable GE junction cancers, our preferred approach is to initiate treatment with preop chemoRT followed by restaging, resection (with or without IORT), and postoperative maintenance chemotherapy. Questions to be addressed with this approach include whether to give several cycles of multiagent chemotherapy before initiating concurrent chemoRT, how many cycles of chemo to deliver, and which agents to give both with EBRT and in the systemic component of treatment.

Combinations of EBRT and new drugs should continue to be evaluated. This is best accomplished in the setting of locally advanced primary or locally recurrent cancers.

Metastatic Disease

Although newer combination chemotherapy regimens have produced better response rates than single agents, survival has not been dramatically enhanced. Clearly new drug regimens need to be tested in advanced gastric cancer. The topoisomerase I inhibitors and taxanes are presently being evaluated. Alternative approaches such as biologicals, gene therapy, angiogenesis inhibitors, and metastasis inhibitors will also be evaluated in clinical trials. Given the limitations of available chemotherapy, continued evaluation of novel agents, either alone or in combination with chemotherapy, is indicated.

Treatment Algorithm by TNM Disease Extent

T1-2N0M0

Total surgical resection of the adenocarcinoma with a radical subtotal gastrectomy and reconstruction with gastrojejunostomy is recommended as standard treatment (see Table 47-12 and Figure 47-10). Patients with posterior wall T2N0M0 lesions should be evaluated for postoperative chemoradiation (chemoRT; see T1-2 N1-3 M0; T3 N0-3 M0).

T1-2N1-3M0; T3 N0-3 M0

Postoperative chemoradiation or perioperative chemotherapy is the preferred adjuvant treatment for patients with gastric cancer. If transhiatal resection is performed, keeping the reconstructed stomach in the mediastinal midline, postop chemoRT is facilitated. For GE junction cancers found to be T1-2 N1-3 M0 or T3 N0-3 M0 on EUS, preop chemoRT is preferable because safer EBRT fields can be designed for preop chemoRT rather than postop chemoRT.[21,277]

T4 N0-3 M0

Preoperative chemoradiation followed by restaging, gross total resection (may include en bloc resection of adjacent organs), and IOERT is recommended for potentially resectable T4N0-3 lesions in institutions with that capability. Postop chemoRT has also been used for completely resected lesions. For locally unresectable cancers, preop or primary chemoRT or multidrug chemotherapy can be used, preferably in the setting of controlled prospective clinical trials.

T any N any M1

Multidrug chemotherapy combinations are the preferred treatment for patients with metastatic cancers. Patients should be placed on controlled trials if available.

CHAPTER

48 Pancreatic Cancer

Joseph M. Herman, Christopher H. Crane, Christine Iacobuzio-Donahue, and Ross A. Abrams

INCIDENCE AND EPIDEMIOLOGY

In the United States in 2015, an estimated 48,960 patients will be diagnosed with pancreatic cancer (PCA) and 40,560 will die of the disease. PCA is the 12th-most commonly diagnosed cancer and the 4th-leading cause of cancer-related death in men and women in the United States. Incidence rates are highest in Western and developed countries. Cigarette smoking, high dietary fat intake, obesity, diabetes mellitus, and chronic pancreatitis are associated with a higher risk of PCA.

BIOLOGIC CHARACTERISTICS AND MOLECULAR MECHANISMS

The most frequently activated oncogene in pancreatic adenocarcinoma is *KRAS* (>95%). The *CDKN2A, TP53,* and *SMAD4* tumor suppressor genes are inactivated in about 90%, 80%, and 55% of PCA, respectively. Molecular abnormalities may be used to define precursor lesions that may lead to invasive malignancies, facilitate characterization of histologically ambiguous lesions, develop novel screening modalities, and advance personalized, targeted therapies.

STAGING EVALUATION

The baseline evaluation for a patient who presents with a pancreatic mass includes a history and physical examination, complete blood count, serum chemistries, and a carbohydrate antigen 19-9 (CA 19-9). Either pancreatic sequence computed tomography (CT) or magnetic resonance imaging (MRI) of the abdomen may be used for diagnostic and staging evaluation. The role of fludeoxyglucose positron emission tomography (FDG-PET)/CT imaging remains unclear, although it may be useful for assessing response and detecting metastases that could be missed with CT alone. Management decisions would preferably be based on multidisciplinary consultation at a high-volume center with high-quality imaging to evaluate the extent of disease.

Although preoperative biopsy is not required for resectable tumors, biopsy to confirm histologic diagnosis is necessary before neoadjuvant or definitive therapy for patients with borderline resectable, unresectable, or metastatic PCA. A variety of biopsy techniques are acceptable, but endoscopic ultrasound-guided fine needle or core biopsy is preferred.

PRIMARY THERAPY

For patients with resectable PCA (15% to 20%), immediate surgery with a pancreaticoduodenectomy (Whipple procedure) or distal pancreatectomy remains the standard of care. Laparoscopic or robotic-assisted surgeries may decrease surgical morbidity. Resections should preferably be done at institutions that perform at least 15 to 20 pancreatic resections annually. Following resection, median overall survival (OS) ranges from 15 to 23 months and the 5-year OS is ~20%. Tumor grade, differentiation, size, margin status (R0), and extent of lymph node involvement are the strongest prognostic factors for long-term survival following curative-intent resection. The most common sites of postoperative relapse are the abdomen (liver, peritoneum, or regional nodes) and lung.

ADJUVANT THERAPY

The standard adjuvant regimen for patients with resected PCA continues to evolve. In both prospective and retrospective studies, adjuvant chemotherapy (CTX) or chemoradiation (CRT) with gemcitabine (GEM) or 5-fluorouracil (5-FU) has demonstrated a survival advantage over observation after surgical resection in both prospective and retrospective studies. However, it is unclear whether CRT improves survival compared with CTX alone. The results of the Radiation Therapy Oncology Group (RTOG) 0848 trial should provide needed insight into the role of modern adjuvant RT.

Neoadjuvant therapy offers some theoretical advantages, but in patients with truly resectable disease only a few cancer centers use this approach routinely. In patients with borderline resectable disease, neoadjuvant CTX followed by CRT is being prospectively evaluated.

UNRESECTABLE AND LOCALLY ADVANCED DISEASE

In patients with locally unresectable and borderline resectable pancreas cancer (LUPC, BRPC), treatment decisions are based on performance status (PS), patient preferences, and tumor relationship with arterial structures. Patients with excellent PS typically receive aggressive combination CTX and dose-escalated RT. Patients with poor PS may receive single-agent CTX single-agent CTS; RT is reserved for patients with pain or other symptoms of local progression.

Since about 20% of patient with LUPC and BRPC develop early metastatic disease, an appropriate standard of care is 2 to 3 months of CTX followed by restaging. Concurrent CRT should be considered if patients have achieved maximal response from or can no longer tolerate CTX and in patients who have local progression on CTX or have pancreas-related pain. Standard treatment includes 5-FU- or GEM-based RT for 50 Gy to 63 Gy in 1.8-Gy to 2-Gy fractions. Stereotactic body radiation therapy (SBRT) and proton therapy are being evaluated.

METASTATIC DISEASE, PALLIATION, AND SYSTEMIC THERAPY

Nearly 60% of patients present with metastatic disease, with a median survival of 6 months from diagnosis. Specific palliative interventions to relieve biliary or bowel obstruction (e.g., stent placement) and cancer-related pain (e.g., celiac block) can provide excellent symptomatic relief. Systemic and local therapies can palliate symptoms and, in select cases, improve survival.

PCA is almost invariably fatal and is projected to become the second-leading cause of cancer death by 2020.[1] Despite tremendous clinical and laboratory research efforts, mortality rates have remained nearly unchanged over the past 30 years. PCA is rarely detected at an early stage and the patient population is predominantly elderly. The biologic aggressiveness, decreased vascular density, and immune suppression associated with PCA further enhance its therapeutic resistance.[2] Nevertheless, advances in systemic therapy (e.g., combination CTX, targeted therapy), interventional procedures, radiation therapy, and supportive care (e.g., antinausea medication, pain control, pancreatic enzyme supplementation) can improve the quality and quantity of life in patients with PCA.

Managing PCA is a challenging endeavor for physicians, patients, and their families. Multidisciplinary care (MDC) involving radiation oncology, surgical oncology, medical oncology, interventional radiology, pathology, and palliative care are imperative for optimal management of patients with PCA. MDC ensures consensus regarding treatment plans and improved communication among the care team. At specialized, high-volume PCA treatment centers, MDC changes the initial management plan (from referring providers) in nearly 25% of patients and results in more accurate staging and diagnosis.[3,4]

Surgical resection remains the only potentially curative option for patients with PCA. However, few (~15% to 20%) patients present with resectable disease, and 5-year postoperative survival rarely exceeds 20%, even for patients with histologically negative (R0) margins.[5,6] The remaining 80% to 85% of patients with PCA present as follows: ~10% borderline resectable (BRPC), ~30% locally unresectable (LUPC), and ~50% metastatic.[7] Unfortunately, 5-year survival for locally unresectable and metastatic PCA is less than 5%, even with aggressive treatment.[8]

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

Between 1973 and 2002, the incidence rate for pancreatic adenocarcinoma of the head of the pancreas remained stable (5.6 per 100,000), whereas the rate for body/tail tumors increased by 46% (to 1.6 per 100,000).[9] Higher survival rates are observed among patients with pancreatic head tumors in comparison with body/tail tumors.[10,11]

In 2015, it is estimated that there will be 48,960 cases of PCA and 40,560 PCA-attributable deaths in the United States.[12] Although it is the 12th-most common malignancy in terms of incidence, PCA is the 4th-leading cause of cancer death. Incidence rates of PCA are highest in Western and industrialized countries. Most patients with PCA present with advanced disease. The median age of diagnosis in the United States is 72, and more than 66% of patients are older than 65.[13]

Etiology

PCA has historically been associated with cigarette smoking, high dietary fat intake, obesity, diabetes mellitus, and chronic pancreatitis. Cigarette smoking is the most consistent risk factor associated with PCA, with smokers having a twofold increased risk.[14] Obesity and chronic diabetes mellitus increase PCA risk by 20% and 50%, respectively.[15] Additional risk factors for PCA include advanced age, non-O blood group, African American origin, high alcohol consumption, occupational exposure to chlorinated hydrocarbon solvents or nickel, hepatitis B or C, history of cholecystectomy, and cystic fibrosis.[7,16-19] Although dietary factors such as increased consumption of red or processed meat, dairy products, and vitamin D have been suggested to be associated with an elevated PCA risk, the published data on these risk factors are inconclusive.[15]

A family history of PCA has become increasingly recognized as a risk factor for PCA. Approximately 10% of PCA is caused by hereditary factors that are associated with an increased risk of both pancreatic and nonpancreatic cancers including breast, ovarian, and bile duct cancers.[20] First-degree relatives of patients with PCA have an 18-fold increased risk of PCA, whereas individuals with three or more affected family members have a 57-fold increased risk of PCA.[21]

Known associations exist between PCA and hereditary breast and ovarian cancer (HBOC) syndrome, which involves *BRCA1* and *BRCA2* gene mutations. Inherited *BRCA2* mutations increase the risk of PCA 3- to 10-fold.[20,22] Furthermore, germline mutations in *CDKN2A/p16* (familial atypical melanoma mole syndrome), *STK11* (Peutz-Jeghers syndrome),[23] *MLH1* or *MSH2* (hereditary nonpolyposis colorectal cancer),[24] *APC* (familial adenomatous polyposis),[23] and *PRSS1* (hereditary pancreatitis)[25] have been associated with familial PCA. Establishing factors that are associated with a genetic predisposition for PCA improves our understanding of PCA signaling pathways and advances the development of personalized therapies. The current understanding of familial PCA is regularly updated on the Johns Hopkins National Familial Pancreatic Tumor Registry (NFPTR) webpage (pathology.jhu.edu/pancreas/PartNFPTR.php).

PREVENTION AND EARLY DETECTION

Given the poor outcomes in PCA, risk reduction and early detection are crucial. Smoking cessation, avoiding excessive alcohol consumption, dietary improvements, and increased exercise may help to reduce the risk of PCA.[26] Unfortunately, many serious risk factors for PCA are related to hereditary factors and acquired genetic changes that currently cannot be prevented or modified.

Anatomical and functional imaging has improved the ability to detect, diagnose, and stage PCA although detection at early stages remains uncommon. Multidetector computed tomography (MDCT) scans with thin slices (≤3 mm) and three-dimensional (3D) reconstruction are now considered the gold standard for PCA and have an overall sensitivity for PCA of 95% to 100%.[27-30] MDCT can capture an image of the entire body in one breath-hold and create multiplanar reconstructions and isotropic volume rendering, making it the preferred option for preoperative staging and treatment planning.[31] A recent study demonstrated a good correlation between tumor size on 3D MDCT and at pathologic analysis after resection.[32] Detection of small tumors (<2 cm) or peritoneal metastases with MDCT remains a challenge.

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

The molecular characteristics of PCA can influence the natural history of disease, patterns of failure, and sensitivity to targeted therapies that may consequently guide therapeutic management. Pancreatic carcinogenesis is a complex process that includes somatic alterations affecting a combination of oncogenes, tumor suppressor genes, and proteins that alter cell behavior or the tumor microenvironment. In some instances, these proteins limit the immune system's ability to control the tumor while simultaneously enhancing resistance to standard therapies such as CTX and RT.

Mutated oncogenes cause uncontrolled cell proliferation by inhibiting apoptosis and promoting cell growth (eTable 48-1). *KRAS* is the most frequent oncogene mutation in PCA and is mutated in more than 95% of PCA tumors. Activating mutations in *KRAS* causes chronic activation of downstream proliferative and survival signaling pathways (e.g., *PI3K, MAPK,* and *RAF*), which leads to inhibition of apoptosis, migration angiogenesis, cytoskeleton alteration, and proliferation despite the presence of inhibitory growth signals.[23,26,33-35] Activation of the *AKT* oncogene through phosphorylation in the *PTEN/PI3K/AKT* pathway allows cancer cells to overcome cell cycle arrest, block apoptosis, and promote angiogenesis.[26] Additional oncogenes that are activated by mutation or gene amplification in PCAs include *BRAF* (in *KRAS* wild-type tumors specifically), *C-MYC, MYB,* and *AKT2*.[23,34,36,37]

Tumor suppressor genes act in the opposite manner than that of oncogenes; when tumor suppressor genes are inactivated by mutations, deletions, or methylation, uncontrolled cellular proliferation can occur. *CDKN2A/TP16* is the most commonly inactivated tumor suppressor gene in PCA (95% of cases); loss of *CDKN2A* promotes cell cycle progression through the G2/M checkpoint.[23,26,33] *TP53* is also frequently inactivated in PCAs, with inactivated mutations observed in 80% of cancers.[38] In normal cells that suffer DNA damage, *TP53* stops the cell cycle to allow for DNA repair or the initiation of apoptosis. *TP53* inactivation results in the loss of this important checkpoint, thereby permitting accumulation of DNA damage and additional genetic alterations.[33,35]

A third significant tumor suppressor gene in PCA is *SMAD4 (DPC4)*. *SMAD4* encodes a protein, Smad4, which is a central mediator of the canonical transforming growth factor-beta (TGF-β) signaling pathway, which, in turn, regulates diverse cellular processes including proliferation, differentiation, apoptosis, and migration.[38] TGF-β also leads to a decrease in activity of helper T cells, and subsequently suppresses the body's immune system reaction against abnormal cancer cells.[33] *SMAD4* is inactivated in approximately 55% of pancreatic tumors (Figure 48-1). Several studies have suggested that immunolabeling to detect Smad4 protein expression or determining the genetic mutation or deletion status of *SMAD4* can aid in predicting OS following PCA resection.[39,40] In an autopsy series of patients with advanced PCA, Smad4 status was highly correlated with the pattern of relapse.[41] Patients whose cancers expressed Smad4 tended to have a limited metastatic burden and more often died of localized disease, whereas patients whose PCA did not express Smad4 (indicating a deleted or mutated *SMAD4* gene) more often died of widely disseminated metastatic disease.[36]

In addition to the aforementioned genetic alterations, several other proteins are abnormally expressed in PCA, including insulin-like growth factor (IGF), p21 and p27, and epidermal growth factor receptor (EGFR). Overexpression of IGF leads to the abnormal activation of many downstream pathways, whereas p21 and p27 mutations cause loss of regulation at the G1 checkpoint. EGFR overexpression induces activation of the mitogen-activated protein kinase (MAPK) pathway, which influences cell proliferation, differentiation, and survival.[35,42]

Epigenetic modification is the alteration of gene expression by mechanisms other than changes in the actual DNA sequence and plays a role in PCA tumor development and progression. The primary epigenetic mechanisms associated with PCA include DNA methylation, histone modification, and changes in microRNA expression.[7,23] A variety of proteins that play critical roles in embryonic development pathways are also aberrantly expressed; these include members of the Hedgehog (Hh), Notch, and Wnt signaling pathways. The Hh signaling pathway plays an important role in embryogenesis, and

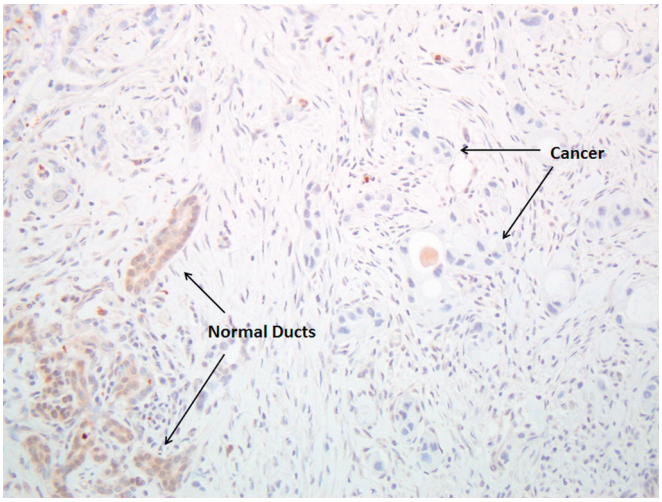

Figure 48-1 Example of Smad4 immunolabeling in resected pancreatic cancer. Normal ducts show intact labeling for Smad4 protein, whereas the infiltrating carcinoma cells are negative indicating a mutation or deletion of the SMAD4 gene in this patient's tumor.

overexpression of Hh ligands has been shown to promote tumor progression in mouse models of PCA. Whereas Hh expression is largely confined to the cancer cells during carcinogenesis, it is predominantly produced by the tumor-associated stroma in infiltrating PCAs and has paracrine activity on the tumor cells.[34,42] Similarly, the Notch pathway is primarily active during normal embryogenesis, where it is an important factor in cell differentiation.[34,42,43] Aberrant activation of the Notch pathway in PCA allows cells to remain in an undifferentiated state, thereby contributing to tumor growth and the oncogenic phenotype. The Wnt signaling pathway also plays a role in stem cell maintenance in normal cells and is hyperactivated in some PCAs as a result of reduced expression of Wnt inhibitors (e.g., *Dkk1*).[26,44]

The PCA microenvironment is comprised of stromal cells (fibroblasts), inflammatory cells, and endothelial cells. Cancer cell secretion of the growth factors IGF-1, TGF-β, fibroblast (FGF), vascular endothelial (VEGF), and platelet-derived (PDGF) have been shown to stimulate the pancreatic stellate cells within the stroma (also called myofibroblasts) to secrete excess amounts of extracellular matrix. The matrix and its stromal cells, in turn, secrete cytokines and growth factors that promote cancer cell growth, invasion, and dissemination. This tumor stromal environment is associated with the development of abnormal vasculature that inhibits the delivery of chemotherapeutic drugs to the pancreatic cells; therefore, targeting the stroma may enhance the efficacy of CTX and RT in PCA.

Secreted protein acidic and rich in cysteine (SPARC), or osteonectin, comprises a family of proteins that is typically overexpressed in the pancreatic stroma. The role of SPARC is complex, cell type-specific, and displays both anti- and pro-oncogenic functions. Overexpression of SPARC has been shown to promote tumor invasion through deregulation of inflammatory response and immune surveillance, and induction of epithelial-to-mesenchymal transition (EMT), cell-adhesion, invasion and metastasis.[45] Nab-paclitaxel (NP) may target SPARC overexpression in PCA, enhancing intratumoral drug penetration and stromal collapse.[46] Identification of tumor-specific biomarkers predictive for local and distant recurrence based on these molecular mechanisms could guide future targeted therapy in patients with PCA.

eTABLE 48-1 Genetic Mutations in Pancreatic Cancer

Gene	Chromosome	Prevalence (%)	Function	Significance
ONCOGENES				
KRAS	12p	95	Growth-factor initiated signaling	*KRAS* mutations occur early, may be a target for early detection
TUMOR SUPPRESSOR GENES				
p16/CDKN2A	9p	95	Regulation	
TP53	17p	80	Cell cycle apoptosis	
SMAD4 (DPC4)	18q	55	TGF-β signaling	*SMAD4* loss associated with poor prognosis and widespread disease

PATHOLOGY AND PATHWAYS OF SPREAD

Pathology

Recent work has shed some light on the mechanisms underlying the malignant transformation of pancreatic lesions. Potentially curable, noninvasive precursor lesions that give rise to PCA called *pancreatic intraepithelial neoplasia* (PanIN) have become a subject of increasing interest. However, the small size of most PanIN tumors makes direct observation difficult, and the best estimates of the timeline for progression of PanIN lesions to invasive carcinoma come from genetic sequencing studies.[47] Iacobuzio-Donahue et al sequenced a series of primary invasive PCAs and multiple matched metastases from the same patients. Evolutionary modeling was applied to the patterns of genetic alterations present in multiple lesions from the same patient. It was estimated that it takes at least a decade for a cell with an initiating mutation in the pancreas to progress to what was designated as the "parental, nonmetastatic founder cell" (a cell likely to present in an advanced PanIN lesion, before the onset of the invasion required to define the lesion as an adenocarcinoma). This study estimated that it takes at least another 5 years for the neoplastic clone to develop the ability to metastasize.

Classification

Pancreatic neoplasms may be broadly classified as either solid or cystic tumors. This classification facilitates diagnosis, influences prognosis, and affects decisions about patient management.

Solid Neoplasms

The most common solid pancreatic tumors are the infiltrating ductal adenocarcinomas and are the tumors most often referred to as *pancreatic cancer*. These malignant epithelial neoplasms arise from cells that give rise to the ductal epithelium and consequently often have glandular or ductal differentiation. Infiltrating ductal adenocarcinoma is typically poorly defined, infiltrating, firm, and solid; vascular and perineural invasion, as well as invasion of peripancreatic tissues, is common.[48] These tumors elicit an intense desmoplastic reaction, which causes significantly elevated interstitial fluid pressure that may act as a barrier to imaging and therapy.[49] Treatments incorporating NP (targeting SPARC) or Hh inhibitors show promise for targeting the desmoplastic stroma.[50]

A number of other variants of ductal adenocarcinoma of the pancreas have been described. Pancreatic neuroendocrine tumors (PanNETs) are the second most common type of pancreatic solid tumors, and arise from endocrine cells of the pancreas located within the islets of Langerhans. PanNETs are less aggressive than invasive ductal adenocarcinomas, with a 10-year survival rate of 45%.[52] Prognosis is indicated by tumor grade, size, and stage.[53] Adenosquamous carcinoma is a rare histological variant with squamous differentiation in addition to ductal differentiation.[151] These cancers disseminate aggressively and are associated with a particularly poor prognosis. Anaplastic carcinoma is another rare variant of ductal adenocarcinoma that tends to present as a large tumor involving the pancreatic body and tail.[51] This is an aggressive cancer with poor OS and no reported 5-year survivors. Anaplastic carcinomas with associated giant cells resembling bony osteoclasts, known as undifferentiated carcinoma with osteoclast-like giant cells, have a slower rate of metastasis and a somewhat better prognosis.[52] Acinar cell carcinomas are a rare type of carcinoma that arises from acinar cells of the pancreas. Survival and patterns of spread are parallel to that of standard adenocarcinoma of the pancreas.

Cystic Neoplasms

With advanced cross-sectional imaging, cystic pancreatic lesions are increasingly identified. Only 5% to 15% of pancreatic cystic lesions are actually neoplastic; most are nonneoplastic lesions such as pseudocysts, congenital cysts, and retention cysts.

The cystic neoplasms of the pancreas are either serous or mucinous neoplasms. Most serous cystic neoplasms are serous cystadenomas, also known as microcystic adenomas and glycogen-rich cystadenomas. Serous cystic neoplasms of the pancreas are typically benign, whereas mucinous cystic neoplasms are more frequently malignant. Mucinous cystic neoplasms are usually in the body/tail, without communication with the main pancreatic ductal system.[54] Interestingly, mucinous cystadenocarcinomas are associated with a better prognosis than typical adenocarcinoma of the pancreas, with approximately 50% of patients surviving 5 years.

Intraductal papillary mucinous neoplasms (IPMNs) are cystic tumors that arise in the larger pancreatic ducts. They are detectable and curable noninvasive precursors to invasive PCA and are associated with a better prognosis than invasive pancreatic malignancies.[48] A more aggressive variant is papillary mucinous carcinoma, which has significant cytologic and architectural atypia or overt invasion. IPMNs with a colloid component tend to have a better prognosis than those with a tubular component.[156]

Solid-pseudopapillary neoplasms, or Hamoudi tumors, are low-grade malignant neoplasms that primarily occur in women in the third decade of life. Patients present with abdominal distention, discomfort, or pain. These tumors are often large, typically ranging from 5 cm to 15 cm in diameter. Other rare pancreatic neoplasms include pancreatoblastoma, acinar cyst adenocarcinoma, and primary mesenteric mesenchymal tumors.

Pathways of Spread

The anatomy of the pancreas also plays an important role in tumor spread and associated symptomatology. The pancreas is a retroperitoneal organ with rich lymphatic drainage that lies in close relationship to the stomach, duodenum, jejunum, kidneys, spleen, celiac trunk, superior mesenteric artery (SMA), superior mesenteric vein (SMV), common bile duct, liver, and portal vein (PV) (Figure 48-2). At the time of diagnosis, more than 85% of PCAs extend into adjacent organs, lymph nodes, fat, or soft tissue, allowing for early metastasis to regional and distant lymph nodes.

Lymphatic invasion, and specifically nodal involvement, is the strongest predictor for survival in nonmetastatic tumors. Tumor cells enter the lymphatic system by migration through the interendothelial valves or by destroying the vessel walls. Entrance into the smaller intralobular lymphatic vessels located within the pancreas are followed by drainage into the four main lymphatic branches of the pancreas: the anterior, posterior, inferior, and superior pancreaticoduodenal lymphatic vessels. These branches then drain into regional lymph nodes, which are typically located around larger blood vessels (most commonly around the celiac artery, common hepatic artery, SMA, and aorta for head/neck tumors and around the splenic artery for body/tail tumors). Frequently involved nodal sites include the posterior pancreaticoduodenal, superior pancreatic head, inferior pancreatic head, superior pancreatic body, and porta hepatis nodes.[55] There is also a relationship between paraaortic lymph node involvement and involvement of posterior pancreaticoduodenal nodes by direct interlymphatic communication (Figure 48-3). Finally, there is direct lymphatic drainage from the pancreas to the liver via

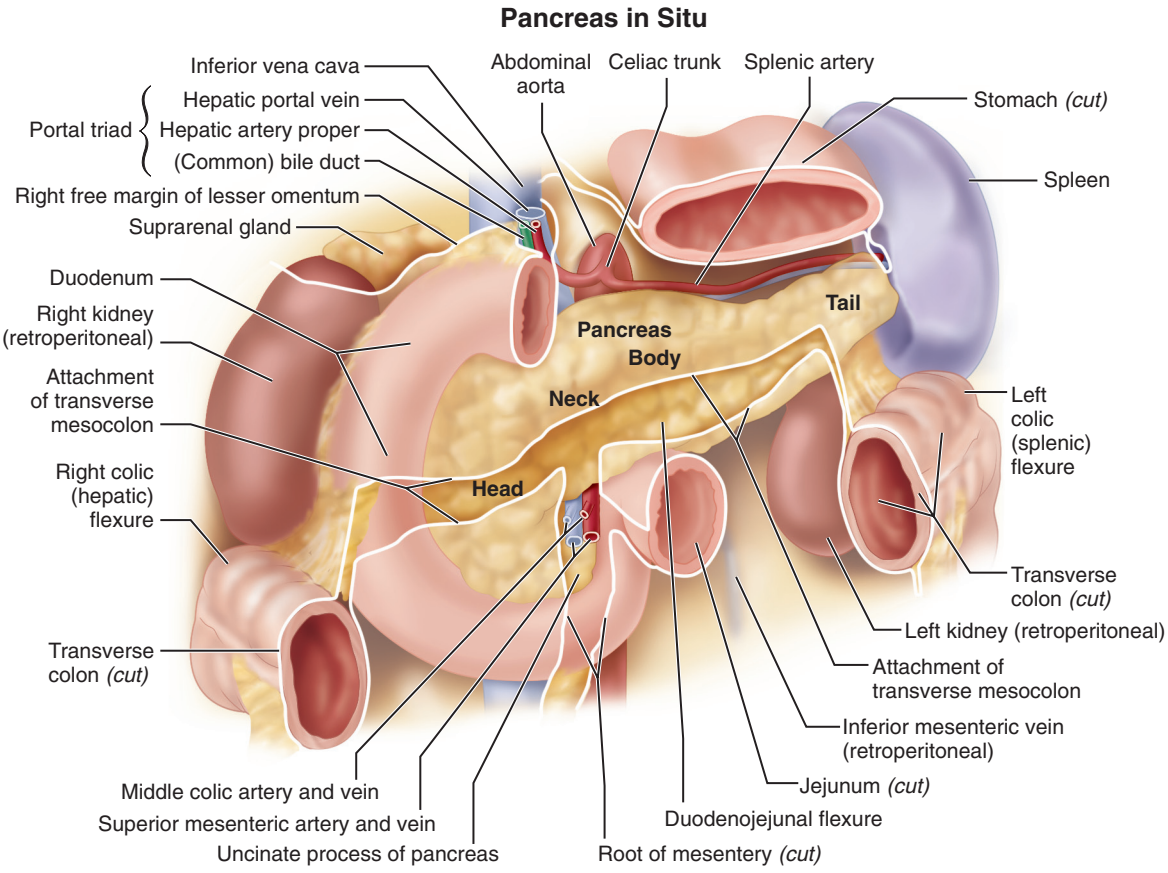

Figure 48-2 Anatomy of the pancreas.

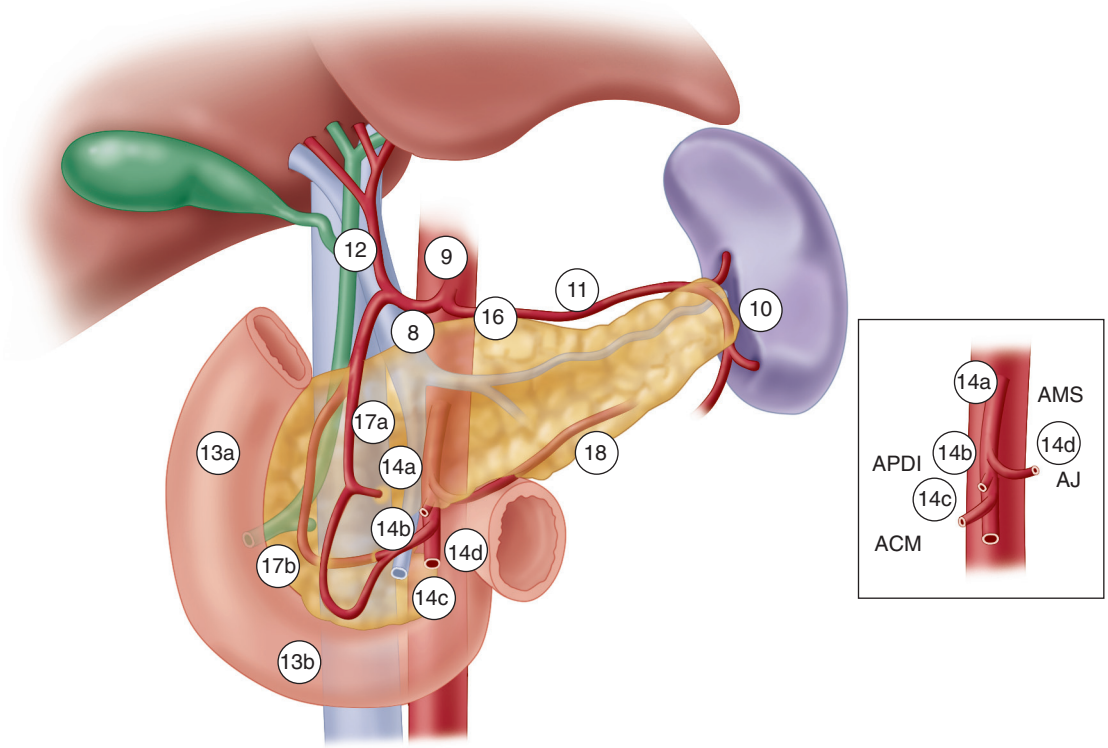

Figure 48-3 Classification of regional lymph nodes of the pancreas. *Inset,* Subdivision of area 14 described: *8,* Hepatic arterial; *9,* celiac axis; *10,* splenic hilum; *11,* distal splenic artery; *12,* portacaval; *13a,* superior pancreaticoduodenal; *13b,* interior pancreaticoduodenal; *14a,* superior mesenteric artery (AMS); *14b,* inferior pancreaticoduodenal artery (APDI); *14c,* medial colic artery (ACM); *14d,* jejunal artery (AJ); *16,* proximal splenic artery; *17a,* proximal gastroduodenal artery; *17b,* lymph node along the posterior surface of pancreatic head; *18,* inferior margin. *From Cubilla AL, Forter J, Fitzgerald PJ: Lymph node involvement in carcinoma of the head of the pancreas area. Cancer 41:880, 1978.*

the hepatoduodenal ligament,[56] whereas venous drainage of the pancreas to the liver proceeds through the PV. At least 75% of all resected tumors also have positive lymph nodes.[57]

The head of the pancreas is innervated by the superior mesenteric ganglion and the pancreaticus capitalis I and II plexi (branches of the celiac plexus); these are the main routes for malignant perineural invasion in pancreatic head tumors. Cancers of the body and tail primarily spread through the celiac plexus and the splenic plexus. Intrapancreatic or extrapancreatic neural invasion is seen in virtually all advanced stage tumors and in greater than 70% to 75% of stage I tumors, implying that this is an early event in the tumor's progression. The head and neck of the pancreas are supplied by the superior pancreaticoduodenal arteries, which arise from the celiac trunk, and the inferior pancreaticoduodenal arteries, which arise from the SMA. These areas drain into the SMV, inferior vena cava (IVC), PV, and inferior mesenteric vein. The pancreatic body and tail, which are supplied by the splenic artery (arising from the celiac trunk) and pancreatic branches off the SMA, mostly drain into the splenic vein. Given their proximity to the pancreas, the SMV and SMA are the most commonly involved arteries and veins in PCA, especially in pancreatic head tumors. The celiac artery, splenic artery, hepatic artery, PV, and, more rarely, the IVC and aorta may also be involved.[58]

Haeno et al investigated progression of pancreatic tumors in more than 300 patients with PCA by using a mathematical framework of metastasis formation.[59] Initially, PCA growth was determined to be exponential. After estimating the rates of PCA growth and dissemination, the authors determined that patients likely harbor metastases at diagnosis and predicted the number and size distribution of metastases as well as patient survival. It was concluded that therapies that efficiently reduce the growth rate of cells earlier in the course of treatment (neoadjuvant therapy) appear to be superior to immediate tumor resection. These findings are being evaluated in additional datasets.

Tumor cells travel along nerves, lymphatics, or vessels to form distant metastases. The liver is the most common site of metastasis, and the peritoneal cavity is the next most common site of distant spread. Recent reports emphasize the influence of the retroperitoneal margin, poor differentiation, and lymph node involvement in determining relapse risk, especially locally.[60,61] In addition, rapid autopsy results from Johns Hopkins Hospital (JHH) indicate that local recurrence may be associated with alterations in *SMAD4* and that local recurrence may be the cause of death in up to 30% of patients with overt metastatic disease.[41] Determination of *SMAD4* status (among other biomarkers) at diagnosis (fine-needle aspiration or core biopsy) may be helpful to design personalized treatment regimens that target individual risks for local versus systemic disease progression.[62]

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Patients with PCA typically present with locally unresectable or metastatic disease. The presenting symptoms depend on the location of the pancreatic tumor. Most tumors occur in the periampullary region of the pancreas (head, neck, uncinate process), and tumors in this area often cause obstructive jaundice with pruritus, choluria, hypocholia, and steatorrhea. They may also cause pain or gastric outlet obstruction through celiac plexus involvement and duodenal compression or invasion, respectively. Nearly 25% of patients present with new-onset diabetes. In fact, a recent study revealed that baseline hemoglobin-A1c values at presentation can correlate with clinical stage and be associated with OS.[63] Recent-onset depression and anxiety, as well as pancreatitis and cholangitis, may antedate the diagnosis of PCA.[64]

In contrast to cancers of the pancreatic head, tumors in the body or tail are usually more advanced at presentation. For these tumors, jaundice is a late manifestation; however, severe back pain is quite common (often indicating posterior extension into the celiac plexus). Patients with tumors in the tail of the pancreas may have evidence of "left-sided" portal hypertension, gastrointestinal bleeding, or splenomegaly from splenic vein obstruction or thrombosis.

Initial laboratory results may show elevated levels of serum bilirubin, alkaline phosphatase, gamma glutamyl transpeptidase, and hepatic aminotransferase. Historically, serum carbohydrate antigen 19-9 (CA 19-9) has been useful for the detection of PCA. A preoperative CA 19-9 level of more than 100 U/mL to 200 U/mL may predict unresectability and poor survival for patients with PCA[65]; however, it is not an entirely reliable diagnostic marker. CA 19-9 levels may be elevated as a result of cholangitis, pancreatitis, poorly controlled diabetes, and obstruction of the pancreaticobiliary tree. Additionally, CA 19-9 may be undetectable in patients lacking Lewis antigens.[66] Nonetheless, when it is elevated as a result of PCA, CA 19-9 is widely used to monitor the course of disease and response to therapy. In the Radiation Therapy Oncology Group (RTOG) 9704 trial, a postoperative CA 19-9 level (>90 U/mL) was a highly significant predictor of OS in pancreatic head tumors.[67]

Patient Evaluation

Patients are initially evaluated based on presenting symptoms, physical examination, PS, imaging, and laboratory tests (Figure 48-4). Following detection of disease, resectability should be determined, ideally in a multidisciplinary setting at a high-volume center with high-quality imaging available to stage the patient and evaluate the extent of disease.

The accuracy of radiologic diagnosis and staging of PCA has increased substantially with improvements in CT and MRI. Patients with body or tail lesions are often diagnosed incidentally (e.g., on imaging) or when symptomatic local or systemic progression occurs. If a pancreatic mass appears suspicious for malignancy and subsequent imaging deems it resectable, then immediate surgery is standard. However, a biopsy is required if the mass is not clearly malignant or if the plan is to proceed with neoadjuvant CTX or CRT. Endoscopic ultrasound (EUS) can be used to guide fine-needle or core biopsies of the pancreatic tumor to confirm the diagnosis. EUS guidance can also be used to place biliary or duodenal stents in cases where the tumor obstructs the bile duct or duodenum.[68] Endoscopic retrograde cholangiopancreatography (ERCP) is another endoscopic approach for biopsy, decompression of the biliary tree, and identification of the source of obstruction. Biliary obstruction can also be relieved by percutaneous and transhepatic cholangiography; however, EUS is the preferred modality because of the higher complication rate (particularly pancreatitis) associated with ERCP and percutaneous approaches.

Multi-detector CT (MDCT) remains the standard imaging modality for PCA detection and staging although MRI provides improved tumor resolution and better visualization of tissue planes for surgical assessment and radiation planning. The accuracy of MRI is comparable to that of CT and should be considered if intravenous (IV) contrast MDCT cannot be performed (e.g., in patients who are allergic to iodine-containing contrast) or if findings require clarification. In addition to biopsy, EUS can be used to evaluate whether the tumor invades the duodenum or stomach and to determine the extent of venous/arterial involvement (PV, SMV, SMA, celiac artery) and nodal status. In fact, one study suggested that MRI and

EUS are actually superior to CT in detecting pancreas lesions.[69] However, EUS is operator-dependent and is often not as accurate as MDCT in determining PV or arterial involvement.[70]

The role of FDG-PET in pancreatic imaging is evolving.[71,72] FDG-PET imaging is particularly useful when combined with the detailed anatomic technique of MDCT to depict the tumor and adjacent normal structures. FDG-PET/CT can also be used to analyze tumor response to therapy and detect occult distant metastases that could be missed with CT alone. A retrospective study demonstrated that the use of FDG-PET/CT after a standard CT protocol increased sensitivity for the detection of metastatic disease when compared with the standard CT protocol or PET/CT alone.[73] The sensitivity for metastatic disease for standard CT alone, FDG-PET/CT alone, and the combination of FDG-PET/CT and standard CT were 57%, 61%, and 87%, respectively. The clinical management of 11% of patients with invasive PCA was changed as a result of the PET/CT findings. Recently, baseline PET/CT parameters, including metabolic tumor volume and total lesion glycolysis, have been demonstrated to be associated with survival outcomes in patients with LUPC receiving SBRT.[74]

Diagnostic laparoscopy may also be useful for detecting metastatic PCA before surgery or CRT. Laparoscopy may identify occult disease in up to 30% of patients that may otherwise have been missed with other modalities.[75,76] The use of laparoscopy has become less common, although it may be beneficial in patients with a high CA 19-9 level, cancer in the body or tail of the pancreas, a large tumor, before the delivery of RT, or if imaging is suggestive of metastatic disease.[77,78]

The quality and interpretation of imaging studies are operator-dependent. Therefore, predictive and prognostic biomarkers may be useful predictors of tumor differentiation, treatment sensitivity, and progression risk and could ultimately aid in making individualized treatment decisions. Advances in endoscopic techniques now permit multiple fine-needle aspiration passes or core biopsies that can be made into cell blocks. Such cell blocks and core biopsies may help improve staging evaluations through immunohistochemistry and next generation sequencing. Moreover, plasma may be used as a "liquid biomarker" to assess changes prior to and following treatment. For example, proximal ligation assay technology has been used to create multiplexed, PCA-specific serological biomarker panels.[79,80]

Staging

The American Joint Committee on Cancer (AJCC) is the standard staging system for PCA (Box 48-1). Although the AJCC system is useful in stratifying patients by outcome, differentiation by the categories of resectable, borderline resectable, locally unresectable, and metastatic disease more accurately depicts features likely to influence management decisions. Therefore, a number of institutional panels including the National Comprehensive Cancer Network (NCCN)

BOX 48-1 American Joint Committee on Cancer (AJCC) TNM Staging and Definitions for Pancreatic Cancer

PRIMARY TUMOR (T)

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor limited to the pancreas ≤2 cm in greatest dimension
T2	Tumor limited to the pancreas >2 cm in greatest dimension
T3	Tumor extends beyond the pancreas but without involvement of the celiac axis or the superior mesenteric artery
T4	Tumor involves the celiac axis or the superior mesenteric artery (unresectable primary tumor)

REGIONAL LYMPH NODES (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis

DISTANT METASTASIS (M)

MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

have proposed a staging system to stratify patients based on resectability.[81] More recently, a PCA consensus guideline was recommended by the Americas Hepato-Pancreato-Biliary Association (AHPBA).[82] Borderline resectable disease is a relatively new category and Katz et al recently published a summary of the definition of BRPC that has been adopted by the NCCN (eTable 48-4).[83]

The resectability of PCA depends on the presence or absence of metastatic disease and on the degree of involvement of major vessels. The assessment of vascular involvement is made separately for the arterial axes and the portovenous system. With regard to the latter, any degree of involvement of the PV or SMV is still considered resectable as long as the vessel can be reconstructed following en bloc resection. Pancreatic tumors staged as T1, T2, or T3 using the AJCC TNM system are generally considered to be resectable. The extent of resection also carries prognostic significance; a patient who underwent a complete (R0) resection has a better prognosis than a patient who underwent a resection with microscopically (R1) or grossly (R2) positive margins. Margin clearance greater than 1.5 mm is needed to optimize locoregional control, and the extent of clear margins in R0 resections may be used to estimate the risk of locoregional failure.[84]

In contrast, involvement of the major arteries is frequently based on the degree of encasement identified on the axial plane of cross-sectional imaging. The arteries of interest include the superior mesenteric, celiac, and hepatic arteries. Greater than 180 degrees encasement of any of these vessels is considered locally unresectable.[81] Rare exceptions are made in which a short segment of an encased hepatic artery is resected en bloc and can be reconstructed. Less than 180 degrees of involvement is considered borderline resectable (eTable 48-4).

PRIMARY THERAPY

Surgery

A margin-negative (R0) resection is the primary goal of surgical resection and is achieved in 60% to 80% of cases. However, the poor long-term survival rates suggest that microscopic disease may frequently be left behind.[57] Even after an R0 resection, the 5-year OS is 25%, whereas 10-year survival is less than 10%.[85] Resections should be done at high-volume institutions that perform a large number (at least 15 to 20) of pancreatic resections annually as this has been shown to correlate with short- and long-term outcomes.[3]

The classic operation for carcinoma of the head of the pancreas is a pancreaticoduodenectomy (PD), or Whipple procedure. This operation includes resection of the head of the pancreas, distal common bile duct, gallbladder, part of the duodenum, and regional lymph nodes. In a classic PD, the stomach is divided proximal to the antrum, whereas the first portion of the duodenum is transected distal to the pylorus in a pylorus-preserving PD (Figure 48-5). Studies comparing the efficacy of these procedures reported no significant differences in outcomes.[86,87]

It is important that radiation oncologists understand the changes in upper abdominal anatomy that occur as a result of PD. As illustrated (Figure 48-5), gastrointestinal reconstruction after PD requires enteric (stomach to jejunum), biliary-enteric, and pancreatic-enteric anastomoses. Although postoperative mortality is less than 2%,[57] the morbidity rate of PD remains high at 30% to 45%.[88] Pancreatic leaks and infections, delayed gastric emptying, and pancreatic fistula are among the most common postoperative complications.[57]

For body and tail tumors, surgery includes a distal pancreatectomy with an en bloc splenectomy. Carcinoma of the body of the pancreas tends to extend superiorly beyond the pancreas and often involves the celiac trunk, common hepatic artery, and base of the splenic artery at its take-off from the celiac trunk; therefore, the determination of resectability is based on the extent of involvement of the celiac axis.[48] A select subset of patients can undergo an Appleby procedure, which involves an en bloc resection of the body and tail of the pancreas along with the celiac artery, proximal common hepatic artery, and splenic artery as well as a total gastrectomy.

Minimally invasive surgery is an alternative to traditional pancreatectomy and includes laparoscopic or robotic surgery. These techniques are believed to have similar oncological outcomes—including margin status and lymph node counts—to the standard approach.[89,90] Furthermore, minimally invasive surgery may lower the risk of postoperative complications in comparison with an open approach, although additional investigation is warranted.

Selection of Surgical Candidates

A number of factors should be considered when evaluating resectability in a patient with PCA; therefore, a multidisciplinary approach to patient evaluation is highly recommended.[3] Preexisting comorbidities (e.g., cardiac disease, chronic obstructive pulmonary disease, dementia) and certain biological characteristics of the tumor (e.g., size, differentiation) may preclude surgical resection of PCA.

An Early Mortality Risk Score (EMRS) was created to identify patients most likely to benefit from surgery.[91] Records of 740 patients who underwent upfront curative resection were analyzed to identify predictors of early mortality, defined as death at 9 and 12 months. EMRS factors were age >75 years, tumor size greater than 3 cm, poor differentiation, and comorbid diseases. Patients with these factors may be less likely to benefit from upfront surgery because of the high risk of postoperative complications, although prospective validation is needed.

Prognostic Factors Associated with Results of Surgical Resection

The most significant independent prognostic factor for survival in PCA has historically been extent of lymph node

involvement.[92,93] After extensive review of periampullary malignancies, Yeo et al reported that lymph node involvement, tumor differentiation, and resection margin status are significant prognostic factors following resection.[93-95] Patients with lymph node metastases had a shorter median OS (16.5 months) compared with patients who were node-negative (25.3 months; $p = 0.001$). Rather than the total number of lymph node metastases or the number of nodes examined, lymph node ratio (LNR) was the most significant predictor of survival. As the LNR increased, median OS decreased. After adjusting for other factors associated with survival, LNR remained an independent predictor of OS ($p < 0.001$). A high number of metastatic lymph nodes (>5) and LNR >0.4 have also been associated with a high risk of local failure.[61]

Tumor size is also an important prognostic factor for PCA. Large surgical series report that 5-year and median OS were significantly improved in tumors smaller than 2 cm (23 to 30 months) in comparison with tumors larger than 2 cm (10 to 15 months).[96,97] The 5-year and median OS in patients with tumors 1.5 cm or less were 75% and 62 months, respectively, significantly better than that of tumors between 2.1 cm and 4.0 cm ($p = 0.02$). Of note, although size has prognostic importance in PCA, small size does not always confer a good prognosis.[98]

Tumor differentiation has also been associated with survival and progression of PCA. In a Japanese study, tumors less than or equal to 2 cm were more likely to be well-differentiated than tumors larger than 2 cm (44% versus 15%, $p = 0.001$).[99] This suggests that small tumors may represent a more indolent subset of disease rather than a precursor to large tumors. Furthermore, patients with poorly differentiated large tumors had 5-year OS of 0% and a median OS of 13 months. Poor tumor differentiation was also correlated with local recurrence ($p = 0.01$).

Resection margin status is an additional predictor of survival following surgery for PCA. A close (2 mm to 3 mm) margin appears to be equivalent to having an R1 resection, whereas a R2 resection is essentially equivalent to having LUPC. Therefore, resection should only be attempted when it is likely that a R0 resection can be achieved. Winter et al reported on the prognostic value of resection margin status in addition to tumor size, lymph node status, and histologic grade as pathological factors that significantly impact survival of pancreatic patients.[57]

Patterns of Failure Following Surgical Resection

Despite curative-intent resection in PCA, more than 60% of patients develop relapse within 2 years of PD. The most commonly reported sites of relapse are within the abdominal cavity and include the SMA margin, liver, lung, and peritoneum. A retrospective analysis of 145 consecutive resections for PCA between 1998 and 2005 sought to define patterns of failure of patients with PCA.[60] The most common distant sites were liver ($n = 57$), peritoneum ($n = 35$), and lung ($n = 15$). Isolated locoregional or extrapancreatic relapse was observed in 9 and 60 patients, respectively, whereas 41 patients developed combined locoregional and extrapancreatic recurrence. More than 50% of all liver metastases developed in the first 6 months following surgery, even in patients with early-stage tumors. The majority of peritoneal relapses developed between the 4th and 15th postoperative month, and lung metastases developed less frequently and more gradually over the postoperative course.

Patterns of local recurrence in patients with resected PCA were recently mapped to inform adjuvant RT planning (Figure 48-6).[100] Of 202 patients that underwent a PD, 40 (20%), 34 (17%), and 128 (63%) received no adjuvant therapy, adjuvant CTX, and adjuvant CRT, respectively. Local recurrence

occurred in 90 of 202 patients overall (45%), with 48% ($n = 19$), 65% ($n = 22$), and 38% ($n = 49$) in the no adjuvant therapy, adjuvant CTX, and adjuvant CRT groups, respectively. Ninety percent of the recurrences were within a few centimeters of the celiac axis and SMA. Mapping guidelines outlined 80% to 90% of locoregional recurrences.

Adjuvant Therapy

The observed patterns of failure in the preceding analyses indicate the need for adjuvant interventions to address both local and systemic relapses. Although a clear benefit of adjuvant CTX has been demonstrated, the optimal adjuvant regimen remains unclear. Theoretically, adjuvant CRT would be a preferred option for patients with PCA who are at risk of local recurrence (margin-positive resection) or concurrent risk of locoregional and distant failure. A summary of adjuvant CTX and CRT studies in PCA can be found in Table 48-1.

Adjuvant Chemoradiation

Extensive evaluation of concurrent 5-FU–based CTX with external beam radiation therapy (EBRT) pioneered the acceptance of adjuvant CRT in resected PCA. A well-designed prospective, randomized trial ($n = 42$) conducted by the Gastrointestinal Tumor Study Group (GITSG) was the first to demonstrate the benefit of this regimen.[101] EBRT was delivered as two courses of 20 Gy in 10 fractions, each with a planned 2-week rest, and 5-FU CTX was given on the first 3 days of each half of RT at a dose of 500 mg/m^2 (intravenous bolus). Superior survival was observed in the patients treated with combined CRT (20 months) as opposed to the patients treated with surgery alone (11 months; $p = 0.03$). Two-year OS was 42% versus 15% in the CRT versus observation group, whereas 5-year OS was 19% versus 5%, respectively.

Investigators at JHH retrospectively reviewed 616 patients treated between 1993 and 2005.[107] Adjuvant CRT and maintenance CTX improved median, 2-year, and 5-year OS (21.2 months, 44%, 32%, respectively) when compared to surgery alone (14.4 months, 20%, 15%, respectively; $p < 0.001$). This survival advantage persisted even after controlling for age, medical comorbidities, and surgical complications.

Mayo Clinic investigators also demonstrated a survival advantage with adjuvant CRT over surgery alone in a retrospective analysis of 472 patients with R0 resections.[108] Despite the significantly increased number of adverse prognostic factors ($p = 0.001$) in the CRT group ($n = 274$), median, 2-year, and 5-year OS were superior in patients with adjuvant CRT (25.2 months, 50% and 28%) in comparison with surgery alone ($n = 180$; 19.2 months, 39% and 17%; $p = 0.001$).

Furthermore, collaboration between JHH and Mayo Clinic Rochester resulted in an analysis of 1092 patients (JHH, $n = 618$; Mayo, $n = 474$) who underwent PD with curative intent.[109] Five hundred and eighty-three patients received adjuvant 5-FU–based CRT (median RT dose of 50.4 Gy). Propensity scores and matched-pair analyses were performed to account for biases associated with nonrandom allocation of patients to adjuvant CRT or surgery alone. OS was significantly longer among patients who received adjuvant CRT compared with PD alone (median 21.1 versus 15.5 months, 2-year OS 44.7% versus 34.6%, 5-year OS 22.3% versus 16.1%, $p < 0.001$). In propensity score analysis, adjuvant CRT improved survival compared with surgery alone for all patients (relative risk [RR] = 0.67, $p < 0.001$) after adjusting for covariates. Matched-pair analysis demonstrated that OS was longer with adjuvant CRT versus PD alone ($p < 0.001$).

A subsequent multiinstitutional, randomized trial performed by the European Organization for Research and Treatment of Cancer (EORTC) demonstrated similar results to those of the GITSG randomized trial and the Johns Hopkins-Mayo Clinic nonrandomized cohorts although small patient numbers hindered the ability to produce a statistical advantage. The trial evaluated surgery alone versus adjuvant 5-FU–based CRT in 218 patients with periampullary cancers including PCA.[102] The radiation dose and fractionation were the same as in the GITSG trial (40 Gy in split-course fashion over 6 weeks) although continuous infusion (CI) 5-FU was administered rather than bolus 5-FU and no maintenance 5-FU was given. In a subset of 114 patients with PCA, patients in the CRT arm ($n = 60$) had a median OS of 17.1 months versus 12.6 months in the surgery alone arm ($n = 54$). The 2-year OS for the two trial arms were 37% versus 23%, whereas 5-year OS was 20% versus 10%, respectively ($p = 0.099$). There were no differences

in locoregional recurrence rates, which were high among the CRT (34 of 104, 33% of patients at risk) and surgery alone (37 of 103, 36% of patients at risk) arms.

The randomized Phase III European Study Group for Pancreatic Cancer (ESPAC)-1 study evaluated the independent effects of adjuvant CTX and CRT in 541 patients with grossly resected PCA.[103] A subset of 285 patients underwent randomization (2 × 2 factorial design) to essentially three separate but concurrent trials with the following regimens: (A) observation; (B) concurrent CRT alone (20 Gy in 10 fractions over 2 weeks with 500 mg/m^2 5-FU intravenous bolus during the first 3 days of RT and then repeated after a planned 2-week break) followed by no additional CTX; (C) CTX alone (leucovorin 20 mg/m^2 bolus followed by 5-FU 425 mg/m^2 administered for 5 consecutive days repeated every 28 days for six cycles); and (D) CRT followed by six cycles of adjuvant 5-FU/leucovorin. Patients were randomized to two separate but concurrent trials testing one of the main treatment comparisons (adjuvant CTX versus none, n = 188; adjuvant concurrent CRT versus none, n = 68). Background therapy was allowed before enrollment into the latter two trials, and RT was performed according to the standard of the individual institutions in all three trials. Interestingly, adjuvant CTX was associated with superior survival, whereas adjuvant CRT resulted in inferior survival. Initial analysis demonstrated a survival advantage for adjuvant CTX only by merging data from the three separate randomized trials; median OS was 19.7 months in the 238 patients randomized to receive adjuvant CTX and 14 months in the 235 patients randomized to no adjuvant CTX (p = 0.005).[112] However, the latest analysis of the ESPAC-1 trial analyzed only the patients randomized to the 2 × 2 factorial design (no background therapy allowed). Patients randomized to receive adjuvant CTX (two of the four arms, n = 147) had a survival advantage (2-year 40% versus 30% and 5-year 21% versus 8%; p = 0.009).[103] Local recurrence was a component of relapse in 99 patients (34%). Major concerns regarding the design and execution of this trial, however, warrant attention.[113] More than one randomization scheme, optional background therapy in two of the three trials, no restaging before adjuvant therapy, heterogeneity among patient populations, and lack of quality assurance guidelines for the delivery of radiation (i.e., no section in the protocol on appropriate field design, no central audit of radiation fields) are study limitations. These results must therefore be interpreted with caution.

Newer Chemoradiation Regimens

Although 5-FU–based CRT is traditionally administered in the adjuvant setting, new systemic agents have been coupled with RT over the past decade. Many feasibility studies have shown that these regimens can be safely administered although further randomized trials are necessary to assess treatment efficacy.

Interferon-Based Chemoradiation

In 2000, the Virginia Mason Medical Center published their experience of 33 patients with resected PCA who received concurrent CRT.[114] EBRT was given to a dose of 45 Gy to 54 Gy with CI 5-FU 200 mg/m^2/day, weekly cisplatin 30 mg/m^2 IV bolus, and interferon-alpha 3 million units subcutaneously every other day. After CRT, CTX alone was administered (CI 5-FU 200 mg/m^2/day) in two 6-week courses during weeks 9 to 14 and 17 to 22. The median and 2-year OS were statistically

The conclusion of the EORTC trial was that there was no discernible benefit from adjuvant CRT, although survival trends favored adjuvant CRT for the 114 patients with PCA. Matters of concern include exclusion of patients with T3 lesions, lack of clear pathologic criteria to distinguish between pancreatic and nonpancreatic periampullary lesions, and inadequate assessment of the retroperitoneal margin. Moreover, 20% of patients assigned to the CRT arm never received treatment but were analyzed by intent-to-treat principles. Many have criticized the use of a two-sided log-rank test, and it has been suggested that if a one-sided test had been used, the survival benefit of CRT would have reached significance.[110] The lack of statistical survival advantage persisted in an update of the trial in 2007 after a median follow-up of 11.7 years.[111] Although this trial is used as evidence against CRT, it undoubtedly has several methodological flaws.

superior in the patients treated with interferon-based CRT than those treated with the GITSG regimen (24 versus 18.5 months and 84% versus 54%, $p = 0.04$). Significant grade-3 to grade-4 gastrointestinal toxicity occurred in the interferon-based group, requiring hospitalization in 35% of patients; however, the majority of patients were still able to receive more than 80% of the planned therapy. A follow-up study included 53 patients with resected PCA treated with similar interferon-based CRT.[115] The clinical efficacy of this regimen was encouraging, with median OS of 46 months and 2-year OS of 53%.

The American College of Surgeons Oncology Group (ACOSOG) conducted a multiinstitutional Phase II study further evaluating the interferon-based CRT regimen in patients with resected PCA. Patients received adjuvant RT to 50.4 Gy with 1.8-Gy fractions given concomitantly with 5-FU (175 mg/m^2 CI, days 1 to 38), cisplatin (30 mg/m^2 intravenously weekly), and interferon-alpha (3 million units subcutaneously every other day). This was followed by CI 5-FU for two cycles. The radiation fields in this study were designed to include the regions at highest risk for local recurrence (surgical margins, celiac axis, and SMA/uncinate regions). Initial results demonstrated promising 2-year and median OS (55% and 27.1 months) although the study was closed early due unexpected high acute toxicity rates (only slightly higher than that observed in the GEM arm of RTOG 9704).[116] Similar results were confirmed at Barnes Hospital and Washington University in St. Louis (2-year OS, 56%; median OS, 25 months).[117]

Gemcitabine-Based Chemoradiation

With the success of GEM alone in the adjuvant setting, researchers have explored GEM-based CRT. The optimal method of combining RT with GEM is still being studied, with investigators publishing the use of full-dose, twice-weekly low-dose, and reduced-dose weekly GEM. Researchers from the University of Michigan performed a Phase I dose escalation study with full-dose GEM (1000 mg/m^2) after curative intent surgery.[118] To give full doses of GEM with RT, treatment volumes were constrained by avoiding elective nodal areas. They found a maximal tolerated dose of 39 Gy given with 2.6-Gy fractions. Blackstock et al used twice-weekly low-dose GEM concurrent with upper abdominal RT including elective nodes to 50.4 Gy after resection.[119] This regimen was well tolerated and shows promising results in comparison with historic controls. Other series have demonstrated the feasibility of reduced-dose weekly GEM (around 300 mg/m^2) concurrent with RT in the adjuvant setting.[120]

A Phase II prospective European Intergroup study evaluated concurrent CRT versus GEM alone (EORTC-40013-22012/FFCD-9203/GERCOR).[106] Patients with PCA of the pancreatic head ($n = 90$) were randomized to either four cycles of GEM alone (1000 mg/m^2 by 30-minute infusion during 3 consecutive weeks followed by 1 week of rest) or two cycles of GEM followed by weekly GEM (300 mg/m^2) with concurrent RT (50.4 Gy in 28 fractions). Median disease-free survival (DFS) was similar (12 versus 11 months) among patients receiving CRT versus CTX alone, whereas median and 2-year OS were equivalent at 24 months and 50%, respectively. Rates of distant progression were similar between the two arms although significantly fewer first local recurrences occurred in the CRT arm (11 versus 24%, $p = 0.16$). Therefore, the investigators concluded that adjuvant GEM-based CRT is a feasible, well-tolerated regimen that should be evaluated in larger Phase III trials.

The goal of RTOG 9704 ($n = 451$) was to explore the outcomes of CTX in addition to the standard CRT arm following gross total resection (R0 resection, 66% of patients; R1, 34%).[104] There were no exclusion criterion relative to postoperative CA 19-9 levels. Patients were randomized to receive either one cycle of GEM (1000 mg/m^2 weekly for 3 weeks on/1 week off) or 5-FU (250 mg/m^2 per day for 3 weeks) before CRT. RT was delivered in a continuous fashion to a total dose of 50.4 Gy along with CI 5-FU (250 mg/m^2). Three to five weeks following CRT, additional CTX was delivered, either as 3 months of CI 5-FU (4 weeks at 250 mg/m^2 followed by 2 weeks off for 2 cycles) or 3 months of GEM (3 cycles of 1000 mg/m^2 weekly given for 3 weeks before a 1-week break). The initial report showed a nonstatistically significant trend for patients with pancreatic head tumors with adjuvant GEM as opposed to 5-FU. The updated 5-year report failed to show a survival difference between the two arms; median OS was 20.5 months versus 17.1 months and 5-year OS was 22% versus 18% in the GEM and 5-FU arms, respectively.[121] RTOG 9704 was the first trial to evaluate whether radiation field design influenced outcomes.[122] Failure to adhere to specified RT guidelines was associated with reduced survival and, for patients receiving GEM, a trend toward increased nonhematologic toxicity. In fact, nearly 50% of the RT plans deviated from protocol guidelines. There are now consensus panel guidelines to delineate the clinical target volume.[123]

RTOG, in cooperation with the Southwest Oncology Group (SWOG) and EORTC, opened the RTOG 0848 trial (NCT01013649) in 2009. This two-step randomized Phase III trial aims to 1) determine whether GEM plus erlotinib produces superior survival results to GEM alone and 2) evaluate the role of RT (50.4 Gy) added to 5-FU– or capecitabine-based CTX. The trial stratifies for known prognostic variables, includes a surgical quality assurance component as well as real-time online quality assurance to ensure RT guideline adherence and requires the enrollment of more than 900 patients over 4 years. This study is the only Phase III trial currently open that will address the role of adjuvant fractionated CRT.

Chemoradiation Using IMRT or SBRT

Acute toxicity with conformal CRT can be substantial as shown in RTOG 9704. In this study, 70.5% patients had any grade-3 or greater toxicity and 59% had grade-3 or greater nonhematologic toxicity. Yovino et al reported significantly reduced toxicity when comparing a cohort of 46 patients treated with adjuvant capecitabine-based CRT (per the RTOG 9704 schema) to a dose of 50.4 Gy with intensity-modulated radiation therapy (IMRT) compared to a cohort treated per RTOG 9704 with conventional CRT.[124] The investigators found an 8% rate of acute nonhematologic grade-3 or greater toxicity with a 21% local regional failure rate, consistent with the rates seen in the larger randomized trials discussed previously. Given the high local recurrence rate even with adjuvant CRT, IMRT allows for dose escalation which may lead to improved local control, especially in patients with R1 resections. Furthermore, Abelson et al reported an 8% rate of acute nonhematologic grade-3 or greater than toxicity in 47 patients treated with up to 56 Gy with IMRT, and, similarly, Ben-Josef et al reported a 7% rate of acute nonhematologic grade-3 or greater toxicity in 15 patients treated with up to 55 Gy with IMRT.[125,126]

IMRT also allows for the addition of more aggressive concurrent CTX (e.g., full-dose GEM) or targeted therapies such as erlotinib. A Phase I adjuvant trial of the EGFR inhibitor gefitinib with capecitabine and three-dimensional conformal radiation therapy (3D-CRT) resectable and locally unresectable PCA produced significant dose-limiting diarrhea that precluded determination of a recommended Phase II gefitinib dose.[127] Another adjuvant study included a similar targeted therapy (erlotinib) with capecitabine-based IMRT. The fact that 83% these patients were able to complete CRT with erlotinib suggests that IMRT may have reduced toxicity; however,

no definitive conclusions can be drawn in this single-arm study. Rates of severe (grade-3 to grade-4) toxicity observed in this study were similar to those reported for other adjuvant therapies (see Table 48-1) and suggest that erlotinib can be safely combined with CRT and CTX in the adjuvant setting. The large magnitude of improvement in toxicity strongly argues for further prospective investigation of IMRT.

SBRT has typically been used in the treatment of unresectable PCA and high rates of tumor control have been reported.[128-130] In the adjuvant setting, SBRT theoretically would have the greatest advantage in the treatment of patients with close or positive margins, where increased dose to the tumor bed may improve outcomes. A limited series examining SBRT to 24 Gy to 30 Gy (over one to three fractions) in 24 patients that had undergone resection with close or positive surgical margins reported a 1-year local control rate of 66%.[131] Ongoing studies are evaluating the potential efficacy of adjuvant SBRT with more aggressive CTX and immunotherapy.

Adjuvant Chemotherapy

Following the ESPAC-1 trial,[103] European studies have focused on CTX regimens in the adjuvant setting. The Charité Onkologie (CONKO)-001 trial enrolled patients with PCA who had undergone curative-intent resection, excluding patients with a postoperative CA 19-9 value ≥2.5 times the upper limit of normal. Patients were randomized to six cycles of GEM (1000 mg/m^2 weekly, 3 of every 4 weeks) versus observation. At first publication, the use of GEM significantly improved DFS from 6.9 to 13.9 months ($p < 0.001$), and there was a trend toward an improvement in OS.[6] An update with longer follow-up showed that patients in the GEM arm had a significant improvement in median OS (22.8 versus 20.2 months, $p = 0.005$), as well as improvements in 5-year OS (21.0% versus 9.0%).[132] The significance of these results has established GEM as an important component of adjuvant therapy for PCA.

Subsequently, the ESPAC-3 trial evaluated the survival benefit of bolus 5-FU versus GEM in the adjuvant setting.[105] This trial randomized patients with R0 or R1 resections (n = 1088) to either 5-FU/leucovorin or GEM for 6 months. There was no difference in median survival between the 5-FU/leucovorin (23.0 months) and GEM groups (23.6 months; p = 0.39). Furthermore, there was no significant difference in the effect of treatment across subgroups according to extent of resection (R0 or R1), progression-free survival (PFS), or global quality of life (QOL) scores. Of note, increased high-grade treatment-related toxicity was associated with the bolus 5-FU arm (14% versus 7.5%, p = 0.001). Therefore, GEM was concluded to be the preferred chemotherapeutic agent over bolus 5-FU.

Because of the conflicting results of GEM CTX in the adjuvant setting, further investigation is necessary. The ESPAC-4 trial (ISRCTN96397434) is currently open to enrollment and aims to compare the survival of patients receiving adjuvant GEM versus capecitabine.

Novel Combination Chemotherapy

Treatment regimens with demonstrated survival benefit in advanced and metastatic PCA are now also being tested as adjuvant therapy. These regimens include 5-FU, leucovorin, irinotecan, and oxaliplatin (FOLFIRINOX) as well as gemcitabine/nab-paxitaxel (GEM/NP).[132a]

Vaccination and Immunotherapy Strategies in the Adjuvant Setting

An improved understanding of the complex signaling pathways associated with PCA has contributed to the design of a novel approach to adjuvant therapy with vaccine immunotherapy. Immune-based strategies use tumor-specific antigens and regulators of the antitumor immune response in an effort to destroy malignant cells and prevent progression of disease. To date, peptide, recombinant microorganism, and whole cell vaccines along with anticytotoxic T-lymphocyte antigen 4 blockade and anti-CD40 strategies have been explored.[133]

Multiple studies have investigated the use of vaccines targeting tumor-specific *ras* mutation.[134-136] Other studies are attempting to target the catalytic subunit of telomerase (hTERT), which is expressed in 85% to 90% of PCAs and is an attractive target. A GV1001 peptide vaccine is in use to induce telomerase-specific CD4+ and CD8+ T-cell responses.[137,138] The genetically modified allogeneic whole cell vaccine (GVAX) has also been developed as a promising granulocyte-macrophage colony-stimulating factor (GM-CSF)–based immunotherapy.[139,140] Moreover, a unique technique has been introduced involving a "hyperacute" rejection as used in transplant immunotherapy. This irradiated whole cell vaccine induces complement-mediated cell lysis and activation or recruitment of antigen-presenting cells following acute rejection and immune response.[141] Integration of standard CRT or SBRT in the adjuvant or neoadjuvant setting may enhance immunotherapy.[142] A study at JHH is currently evaluating a combination of adjuvant GVAX vaccine, SBRT, and FOLFIRINOX.[132a]

Present Status of Adjuvant Therapy

Although surgery alone is no longer an appropriate option for patients with PCA, even after R0 resection, the role of adjuvant therapy needs to be more clearly defined. The most convincing level I data currently available are from the CONKO-001 trial, which has clearly established a role for GEM as an effective adjuvant treatment. However, every Phase III trial exploring adjuvant RT to date is subject to serious criticism (e.g., GITSG, EORTC, ESPAC-1) or has not directly addressed the efficacy of adjuvant RT (e.g., RTOG 9704). Current practice and guidelines reflect this unresolved controversy. A consensus has not been reached on the role, timing, dose, or technique of RT, nor has the optimal CTX regimen been established. The NCCN guidelines for adjuvant management of PCA include CTX (GEM, capecitabine, 5-FU) or CTX followed by CRT, although participation in a clinical trial is highly recommended. Future studies will continue to evaluate novel CTX regimens (S-1), targeted agents, and immunotherapy as well as advances in surgery (laparoscopic) and radiotherapy (IMRT/SBRT). There is a clear need for blood and tumor biomarkers to guide personalized management in this patient population.

Neoadjuvant Therapy

There are many unique advantages to the use of neoadjuvant (NAdj) treatment of patients with localized PCA. Most compelling is the ability to treat virtually all patients that present with localized, resectable PCA with therapy that immediately addresses the limitations of curability—micrometastatic disease that is often already present in regional lymph nodes, liver, lung, or peritoneum. A second important advantage is improved patient selection for pancreatic surgery, which is often associated with significant patient morbidity even when performed by an experienced surgical team. Allowing tumors with aggressive biology to declare themselves can spare patients from nontherapeutic surgery. Third, up to half of patients may not be good candidates for adjuvant therapy because of delayed recovery from surgery. The use of NAdj therapy allows nearly all patients to receive some adjuvant therapy. Finally, pancreatectomy appears to be safer following NAdj CRT (with a reduced risk of pancreatic anastomotic leak resulting from the pancreatic fibrosis induced by preoperative therapy) and, based on BRPC data, the R0 and node-negative resection rate is likely to be improved with NAdj therapy.[143]

Numerous small and mostly nonrandomized studies have considered both NAdj CTX and CRT options; however, because of the lack of large randomized trials, NAdj therapy remains controversial.

Neoadjuvant Therapy in Resectable Disease

One of the earliest studies on NAdj therapy in PCA reported on 54 consecutive patients with seemingly resectable disease.[144] Some patients ($n = 31$) went directly to surgery whereas others ($n = 23$) received 50 Gy EBRT to the region of the pancreatic head. No difference in resectability, 3-year OS, or 5-year OS was observed. However, a slight advantage was seen in 1-year OS of the patients treated with NAdj EBRT. Furthermore, there was a decreased incidence of regional relapse among patients who received NAdj therapy. A NAdj GEM-based CRT regimen was also tested in 20 patients with potentially resectable PCA.[145] These patients received three cycles of full-dose (1000 mg/m^2) GEM with concurrent RT (36 Gy in 2.4-Gy fractions) given during the second cycle. Overall, 80% of patients had stable disease, 15% had partial response, and 5% had progressive disease. Seventeen (85%) patients underwent curative resection with a 94% rate of R0 resection and 65% had a node-negative resection. At median follow-up of 18 months, preliminary survival data were promising in resected patients (median OS 26 months, 2-year OS 61%), with 41% of the patients alive with no evidence of disease.

M. D. Anderson Cancer Center (MDACC) enrolled a total of 176 patients on two GEM-based CRT trials for potentially resectable PCA.[146,147] In these trials, the most common reason precluding resection following CRT was metastatic disease. Only 1 out of 176 patients had isolated local progression following surgical resection. Median OS in all (22.7 and 17.4 months) and resected patients (34 and 31 months), were promising and better than historical controls.

A multicenter Phase II trial provided additional data on the use of full-dose GEM (three cycles of 1000 mg/m^2) and 36 Gy RT (2.4 Gy × 15 fractions) in resectable PCA ($n = 13$).[148] The results were promising, with a 94% 1-year survival rate following resection.

More recently, a retrospective review revealed that resectable patients receiving NAdj GEM and S-1 combination therapy had significantly longer median OS (39.4 versus 20.8 months, $p = 0.0009$) and higher R0, "true" R0 (R0 with tumor marker normalization after resection), and N0 rates (85%, 69%, 44% versus 72%, 48%, 24%, respectively) than patients who underwent surgery without prior therapy.[149]

Further evaluation of NAdj GEM-based CRT in resectable PCA was performed in a multiinstitutional Phase II trial.[150] Patients received two cycles of GEM (1000 mg/m^2) and oxaliplatin (85 mg/m^2) concurrently with 30 Gy (2 Gy × 15 fractions) of RT delivered during the first cycle of CTX. Following treatment, patients were evaluated for surgery. Patients who underwent surgery received two additional cycles of adjuvant CTX. For patients who presented with resectable disease ($n = 13$), median survival was 44.7 months in comparison with 26.5 months for patients who did not undergo resection.

Rare Tumors

Optimal treatment of rare tumors of the pancreas (e.g., adenosquamous carcinoma, PanNET, acinar cell carcinoma, pancreatoblastoma, IPMN, solid-pseudopapillary neoplasm) is unclear because of the infrequent presentation of these tumors and limited clinical research available. Little is known about the underlying genetic mechanisms of these rare tumors and further insight into therapeutic strategies is necessary. Current treatment options demonstrated to be effective based mainly on retrospective reports can be found in eTable 48-2.

LOCALLY ADVANCED DISEASE AND PALLIATION

For the purpose of this chapter, the term *locally advanced disease* is intended to include both BRPC and LUPC. The nuances of differentiating BRPC from LUPC and sequencing of treatment will be discussed.

Borderline Resectable Disease

Patients with BRPC have tumors that can technically be resected; however, there is an increased risk of margin-positive resection due to extensive vessel involvement. Because a margin-positive resection is associated with poor survival, NAdj therapy is typically recommended. The most widely recognized definition of BRPC can be found in the NCCN guidelines: having tumor abutment of the SMA involving 180 degrees or less of the arterial circumference, but without distant metastases or tumor extension to the celiac axis. However, other groups such as the MDACC Group[159] and the Americas Hepato-Pancreato-Biliary Association (AHPBA)/Society of Surgical Oncology (SSO)/Society for Surgery of the Alimentary Tract (SSAT)[82] have introduced other anatomic criteria. In an attempt to standardize the definition and treatment for BRPC, Katz et al proposed the first prospective clinical trial with the Alliance for Clinical Trials in Oncology (ACTO) group (Alliance Trial A021101). See eTable 48-3 for a comparison of BRPC definitions.[83]

Nearly 10% of all patients with PCA present with borderline resectable tumors.[83] Because BRPC is one of the most challenging stages of PCA, multidisciplinary review at baseline and subsequent imaging is highly recommended. Collaboration among multiple specialties will allow for more accurate staging to ensure optimal initiation of therapy and coordination of care. Patients with BRPC who undergo upfront surgery have a higher risk for an R1/R2 resection, local recurrence, and distant metastases because they often require a larger, more complex, and high-risk operation to remove their primary tumor.[159] Therefore, upfront CTX followed by CRT is considered a standard approach. In fact, some series suggest that patients with BRPC receiving multimodality therapy (CRT and CTX) before surgical resection can expect equally favorable survival as patients who present with resectable tumors in some series.[160] Numerous studies using NAdj CRT have demonstrated the benefit of NAdj therapy in BRPC (Table 48-2). Despite the common perception that tumors can be downstaged from borderline to resectable disease, there is little evidence that the radiographic stage of BRPC changes after NAdj CTX or RT. However, NAdj CRT is an effective way to sterilize the interface of the tumor and vascular structure. Furthermore, prospective evaluation from 1999 to 2006 demonstrated that patients with BRPC who received NAdj therapy before pancreatic resection had significantly better survival than those who did not undergo pancreatectomy.[159] Patients with BRPC who require vein resections have been suggested to benefit from adjuvant treatment.[161]

Takahashi et al reported their experience with NAdj GEM-based CRT for resectable and BRPC.[168] Of a total of 268 patients, 188 had resectable primary tumors and 80 had borderline resectable tumors. Unsurprisingly, the resection rate of patients with resectable disease was higher than that of patients with BRPC (87% versus 54%, $p < 0.001$) but a high rate of R0 resections was achieved in both groups. The 5-year OS rates of resectable and BRPC cases were 57% and 34%, respectively ($p = 0.029$). Although the 5-year cumulative incidence of local recurrence was comparable in both groups (15% and 13%, respectively; $p = 0.508$), the 5-year cumulative incidence of

eTABLE 48-2 Treatment Recommendations for Rare Tumors of the Pancreas

Rare Tumor	Recommended Course of Therapy*
SOLID TUMORS	
Adenosquamous carcinoma	*Adjuvant*: CRT recommended, the addition of platinum agents (cisplatin or oxaliplatin) to GEM appears to improve outcomes[151,152]
Neuroendocrine tumor (PanNET)	*Adjuvant:* CRT in patients with residual disease or adverse pathologic features (large tumor, node-positive disease) *Definitive:* CTX and targeted agents (e.g., sutinib and everolimus appear to improve PFS) *Metastatic*: liver-directed therapies (e.g., surgical resection, SBRT, transarterial chemoembolization, radioembolization)[153]
Acinar cell carcinoma	*Adjuvant/Definitive*: the role of RT is unclear[154,155]
Pancreatoblastoma	*Adjuvant*: the role of adjuvant therapy is unknown *Definitive/Metastatic*: there are case reports describing palliative benefit of RT[155]
CYSTIC NEOPLASMS	
IPMN with invasive component	*Adjuvant*: CRT appears to be beneficial in patients with high-risk features (tubular versus colloid, node-positive disease)[156-158]
Solid-pseudopapillary (Hamoudi) tumor	*Adjuvant/Definitive*: the role of RT is unclear

peritoneal and distant relapse was significantly higher in the patients with BRPC (43% and 76%) than in the patients with resectable disease (17% and 43%).

Recent data suggests that dose-escalation using SBRT or IMRT with CTX may be an effective NAdj regimen for patients with BRPC. A single-institution retrospective study ($n = 32$) of induction CTX followed by SBRT in BRPC revealed excellent rates of R0 resection (97%) and local control at 1 year (81%) among a group of a patients without arterial involvement.[163] IMRT has been used to safely deliver higher doses of RT to the tumor while limiting the dose to adjacent normal tissue.[169,170] Although the studies of this approach were small ($n = 14$ and 34, respectively), IMRT for NAdj CRT delivery has shown promise in decreasing tumor volume[171] and increasing pathologic complete response rates.[165]

Gemcitabine-based CRT has historically been the first-line of treatment for BRPC. However, the use of more aggressive CTX regimens such as FOLFIRINOX[172] or GEM/NP with CRT may result in better systemic and local control among patients with BRPC. A recent study demonstrated that 55% ($n = 12$) of patients initially presenting with BRPC underwent successful R0 resection following FOLFIRINOX, with or without SBRT.[173] A multiinstitutional, single-arm, pilot Alliance Trial A021101 has been initiated to evaluate the efficacy and toxicity of NAdj FOLFIRNOX followed by capecitabine and EBRT for patients with BRPC.[83] Rigorous standards of clinical trial design are incorporated into this trial, such as centralized review of the radiation plan and mandatory imaging review before enrollment. Because a radiographic response is rarely seen after NAdj therapy, attempted resection is required for all patients with a good PS (ECOG 0-1, KPS 70-100) in the absence of radiographic evidence of cancer progression.

Serum CA 19-9 levels following NAdj therapy for patients with BRPC may be a prognostic factor for survival. In 84 patients with BRPC who underwent resection following NAdj CRT (GEM or 5-FU–based with or without GEM-based induction CTX), a decrease in CA 19-9 levels during NAdj therapy had a positive predictive value of 70% for successful resection, while an 88% negative predictive value for unresectability was achieved when CA 19-9 failed to decrease.[174] Posttreatment CA 19-9 levels were a better predictor of metastases than pretreatment levels. Moreover, normalization of CA 19-9 during NAdj therapy was associated with longer OS both in patients who were resected and unresected.

Locally Unresectable Disease

LUPC involves a tumor that has grown beyond the pancreas to involve >180 degrees of the SMA or celiac axis or where tumor involvement precludes reconstruction of the SMV or PV. For patients who receive treatment, median OS is between 8 and 12 months. Survival benefits are typically limited to patients with adequate PS (ECOG 0-2) who receive CTX or CRT. Palliative care and comfort-directed measures are recommended for patients with poor PS (ECOG 3-4). The timing and optimal regimen of therapy in patients with LUPC remain unclear. Options include CRT followed by CTX, CTX followed by CRT, or single- or multi-agent CTX alone.

Chemoradiation or Chemotherapy

The role of CRT in patients with LUPC has been established for decades. However, the benefit of CRT versus CTX has recently become controversial. The NCCN guidelines currently recommend the use of an initial course of CTX (two to six cycles) followed by CRT for patients with LUPC with stable disease or with an objective response to initial CTX.[81,175] This approach aims to control systemic disease while allowing identification of patients with occult metastatic disease who are not likely to benefit from CRT. However, immediate CRT is sometimes recommended for patients with pain or locally obstructive symptoms.

Results of some Phase III trials have favored the use of CRT for the treatment of this patient population[176-178] while others have yielded conflicting results (Table 48-3).[179,180] A GITSG trial found improved median OS ($p < 0.01$) with 5-FU–based split-course CRT (40 Gy over 6 weeks, median OS 8.3 months;

60 Gy over 10 weeks, 11.3 months) versus EBRT alone (60 Gy over 10 weeks; 5.5 months). A subsequent GITSG trial found that combination chemotherapy with streptozocin, mitomycin E, 5-FU (SMF) was inferior to 5-FU–based CRT (54 Gy, nonsplit-course) followed by SMF (median OS 8 months versus 10.5 months, $p < 0.02$). ECOG 4201 randomized patients with LUPC ($n = 74$) to either GEM alone or GEM-based CRT followed by GEM.[178] Although the study was closed early because of poor accrual, the OS was 11.1 months in the CRT arm as opposed to 9.2 months for those who received GEM alone ($p = 0.017$).

The Francophone de Cancérologie Digestive-Société Francophone de Radiothérapie Oncologique (FFCD-SFRO) trial evaluated patients with LUPC who were randomized to GEM alone or an intensive induction regimen of CRT with 5-FU plus cisplatin followed by GEM.[181] The safety of the CRT regimen had not been evaluated in Phase I or II trials before this study, and large fields treating a large volume of the duodenum to a dose of 60 Gy were used. Therefore, patients receiving CRT experienced high rates of toxicity. GEM alone was associated with increased 1-year OS in comparison with CRT (53% versus 32%, $p = 0.006$). The observed differences in survival were possibly attributable to the toxicity of the CRT regimen.

Preliminary results of the international Phase III Groupe Coopérateur Multidisciplinaire en Oncologie (GERCOR) LAP 07 trial revealed no clear survival benefit with the addition of conventional CRT following four cycles of NAdj CTX.[183] Using a 2 × 2 randomization, patients initially received GEM with or without erlotinib for four months and were subsequently randomized to two additional months of CTX or capecitabine with 54 Gy RT. Nearly 40% of patients progressed before the second random assignment. There was no difference in OS between the CTX and CRT groups (16.5 versus 15.3 months, $p = 0.083$) after a median follow-up of 36 months. Of note, there were several deviations in the delivery of RT, at least 20% of patients in the CTX alone arm received CRT off-study, and a subset of patients randomly assigned to receive CRT did not receive treatment.

In the GERCOR Phase II and III trials, patients with LUPC were given upfront CTX with the option of receiving CI 5-FU–based CRT if no progression occurred. Retrospective analysis demonstrated that the OS of patients receiving CRT was superior (15.0 months versus 11.7 months) to that in patients receiving CTX only.[175]

Multiple studies have also assessed the efficacy of the upfront CRT approach in LUPC. In an Italian study, 28 patients with nonmetastatic PCA received RT (39.6 Gy) plus 5-FU (CI, days 1-4 at 1000 mg/m²/day).[185] After 4 weeks, patients were evaluated for surgical resection. In patients who were resected ($n = 9$), a dose of 10-Gy IOERT was selectively given before reconstruction. Three of 19 patients with unresectable tumors had tumor downstaging (15.8%). Two patients showed partial

response (7.1%) and 4 (14.3%) had minimal tumor response. Median OS was 20.5 months in resected patients. Only one local failure was recorded in 8 patients with an R0 resection. This study suggests that select patients with LUPC may benefit from attempted resection/IOERT after upfront CRT.[185] A Phase II trial ($n = 69$) explored the role of GEM and oxaliplatin followed by CRT (50.4 Gy with capecitabine) in LUPC.[62] Survival rates were encouraging, with a median OS of 19.2 months and 1-year, 2-year, and 4-year OS rates of 66%, 25%, and 11%, respectively. Moreover, *SMAD4* expression in cytology specimens correlated with a local pattern of disease progression ($p = 0.016$).

GEM has been combined with cisplatin and RT in published Phase I trials, following up on promising preclinical data suggesting synergy among these agents. A study based at the Mayo Clinic administered twice-weekly GEM and cisplatin for 3 weeks during EBRT (50.4 Gy in 28 fractions). Dose-limiting toxicities consisted of grade-4 nausea and vomiting. The recommended Phase II dose was GEM 30 mg/m^2 and cisplatin 10 mg/m^2.[186] In this trial, 10 of 30 patients with LUPC underwent curative surgery with promising R0 resection and complete response rates.[184]

Because the ESPAC-3 and RTOG 9704 studies showed no difference in OS or DFS in patients treated with GEM or 5-FU in the adjuvant setting, it is unclear which drug to use concurrently with RT in the definitive setting for patients with LUPC. The MDACC retrospectively examined its database of 114 patients with LUPC treated with combination EBRT (rapid-fractionation 30 Gy in 10 fractions) with either concurrent CI 5-FU 200 mg/m^2 to 300 mg/m^2 (61 patients) or GEM 250 to 500 mg/m^2 weekly for 7 weeks (53 patients).[187] Patients receiving GEM had significantly higher incidences of severe acute toxicity, defined as toxicity requiring a hospital stay of more than 5 days, mucosal ulceration with bleeding, more than three dose deletions of GEM, or toxicity resulting in surgical intervention or death compared with those patients receiving 5-FU (23% versus 2%, $p < 0.0001$). Five of 53 patients treated with GEM-based CRT subsequently underwent surgical resection compared with 1 of 61 patients treated with 5-FU–based CRT. However, with short median follow-up, median OS was similar (11 versus 9 months, $p = 0.19$). The recent randomized Phase II SCALOP trial ($n = 70$) evaluated GEM-based compared with capecitabine-based CRT in LUPC. When compared to GEM, the addition of capecitabine was associated with improved 1-year OS, PFS, and less toxicity.[182] However, the results of this trial should be interpreted with caution because of inconsistent treatment planning and dosing techniques.[188] Additional investigation of these agents and their optimal dosages and treatment sequences is necessary.

Alternate Chemotherapy Regimens

As mentioned in the prior adjuvant section, there has been considerable interest in identifying more effective CTX regimens. Agents that have been tested in the metastatic or locally unresectable setting include 5-FU, cisplatin, oxaliplatin, irinotecan, exatecan, and capecitabine. Unfortunately, these trials have not shown survival advantages, with the exception of the combination of GEM/erlotinib or GEM/NP.

GEM and erlotinib was tested in advanced PCA by Moore et al in a large randomized Phase III trial of 569 patients, of whom about one fourth (24%) had LUPC.[189] Subgroup analysis did not suggest a greater effect in patients with LUPC. With the use of an intent-to-treat analysis, survival was improved with the addition of erlotinib, with a hazard ratio of 0.82 (6.24 versus 5.91 months; $p = 0.038$). PFS and 1-year OS were also significantly improved with the addition of erlotinib. However, the recently reported results of the Phase III LAP 07 trial revealed that erlotinib demonstrated no clear benefit in LUPC.[183] Median OS was 13.6 and 11.9 months for GEM and GEM + erlotinib, respectively (HR 1.19, 95% CI [0.97, 1.45], $p = 0.0930$), with increased grade-3 to -4 toxicity associated with the addition of erlotinib.

Since the Metastatic Pancreatic Adenocarcinoma Clinical Trial (MPACT) trial demonstrated that combination CTX with GEM and NP in PCA is superior to GEM alone for metastatic PCA,[190] its potential role in LUPC should be evaluated. In that regard, a single-center retrospective experience reported a promising 1-year OS of 77% and a 38% conversion of patients from locally unresectable to resectable disease with GEM/NP.[191] Additional studies are under way to evaluate the effect of adding NP to the standard GEM regimen in LUPC.

FOLFIRINOX is another promising regimen for LUPC. A retrospective experience at the Massachusetts General Hospital Cancer Center (MGHCC) demonstrated successful conversion of >20% of initially unresectable patients to surgical candidates using FOLFIRINOX and concurrent CRT, with a median PFS of 11.7 months.[192] Overall, 5 of 22 (23%) resections achieved R0 status although 3 of 5 (60%) patients experienced distant relapse within 5 months.

Alternate Radiation and Chemoradiation Approaches

The chemoradiation studies previously discussed involved standard EBRT. Typical EBRT doses are 45 Gy to 54 Gy in 1.8-Gy to 2.0-Gy fractions for 5-FU–based or low dose GEM-based therapy and 36 Gy in 2.4-Gy fractions for full-dose GEM-based therapy. With recent developments establishing local progression as a contributor to mortality in LUPC, modern studies are focusing efforts toward identifying ways to intensify radiation dose. Alternative RT techniques used to escalate radiation dose such as IMRT, SBRT, and intraoperative radiation therapy (IORT) have been explored in the context of LUPC.

Intensity-Modulated Radiation Therapy and Stereotactic Body Radiation Therapy

In comparison with 3D-CRT, IMRT has demonstrated an ability to significantly increase target volume dose while substantially decreasing the dose to local organs at risk (OARs).[193] Ben-Josef et al demonstrated the use of 55 Gy of IMRT in 1.8-Gy fractions in 50 patients with LUPC.[169] Median and 2-year OS were 14.8 months and 30%, respectively. Furthermore, 12 patients (24%) underwent resection (10 R0, 2 R1) and survived a median of 32 months. Unfortunately, the 2-year freedom from local progression remained at 59%. In an attempt to determine the maximum tolerated dose using IMRT and concurrent full-dose GEM, this study suggests that IMRT can be used to effectively escalate the dose of RT above 55 Gy as long as normal tissue dose constraints are met. However, optimal results will not be observed with IMRT until improved systemic control can be achieved.

SBRT is similar to IMRT in that it uses multiple fields of RT to conformally treat the planning target volume (PTV). However, SBRT is typically delivered in 1 to 5 fractions (versus 25 to 28 fractions) and smaller margins are used around the tumor (2 mm to 5 mm) to limit dose to normal tissues. CTX is generally given before and after SBRT instead of concurrently. Early data on 45 Gy SBRT in 15-Gy fractions reported poor outcomes and unacceptable toxicity.[194] Single-fraction SBRT (25 Gy × 1 dose) demonstrated disease stability but with high rates of duodenal toxicity.[195,196] Compared to conventional CRT, delivery of fractionated SBRT (3 to 5 fractions) demonstrates favorable tumor response rates (~30%) and less acute toxicity.[129,197,198] Most recently, a prospective multicenter Phase II trial evaluating 33 Gy SBRT in 6.6-Gy fractions in patients with LUPC reported more acceptable acute and late toxicity rates than single-fraction SBRT.[199] Median OS was 13.9 months,

A trial conducted by Brunner et al used strictly time-scheduled GEM (dosing on days 2, 5, 26, and 33 after a weekly regimen was too toxic) and cisplatin (days 1 to 5 and 29 to 33) combined with RT, with a recommended Phase II dose of 20 mg/m^2 for cisplatin and 300 mg/m^2 for GEM.[184]

with low rates of grade 2 or greater acute (2%) and late (11%) GI toxicity and stable QOL scores. Additional studies are necessary to evaluate the optimal dose of fractionated SBRT and determine how to best integrate SBRT into NAdj treatment paradigms for BRPC and LUPC.

Intraoperative Irradiation

IORT is another method of RT dose escalation to the operative bed when combined with EBRT/CRT. Initial trials on electron-based IORT (IOERT) combined with EBRT/CRT for patients with LUPC demonstrated improved local control rates in series from Mayo Clinic Rochester and Thomas Jefferson University Hospital (TJUH) (eTable 48-4).[200-206] This did not, however, translate into improvement in median or 2-year survival in view of problems with abdominal relapse. In a Mayo Clinic Rochester analysis of 159 patients by Roldan et al,[202] the local control rate at 1 year was 82% for EBRT plus IOERT (n = 37) versus 48% for EBRT alone (n = 122) and 2-year local control was 66% versus 20% (p = 0.0005). Median and 2-year OS were similar, however, with median survival of 13.4 versus 12.6 months (IOERT versus none) and 2-year OS of 12% versus 16.5%. The lack of survival improvement was related to a high incidence of abdominal relapse in both groups of patients (IOERT: 54% with liver or peritoneal metastases versus 56% in patients undergoing non-IORT).

IOERT Plus EBRT or CRT. Generally, IOERT has been given in combination with EBRT in the range of 45 Gy to 50.4 Gy in 25 to 28 fractions with 5-FU alone or 5-FU–based combination CTX. The dose of IOERT is typically in the range of 10 Gy to 20 Gy (usually 20 Gy for patients with locally unresectable cancers; for those with resection before or after CRT, the IOERT dose varies from 10 Gy to 12.5 Gy).

In experienced hands, IOERT can be given with acceptable morbidity. However, there are occasional reports of high complication rates. RTOG reported on 51 patients with IOERT for locally unresectable PCA.[201] In this multiinstitution Phase II trial, there was a major postoperative complication rate of 12% and 2 patients with major morbidity leading to death. There was no obvious improvement in median survival.

In a 2005 update of the MGH experience, 150 patients with LUPC received IOERT as a component of treatment from 1978 to 2001 in conjunction with EBRT and 5-FU–based CTX.[206] Long-term survival was seen in 8 patients, and 5 were alive at or beyond the 5-year interval. Actuarial 1-, 2-, 3-, and 5-year OS rates for the 150 patients was 54%, 15%, 7%, and 4%, respectively, and median OS was 13 months. Survival was significantly related to the diameter of the IOERT treatment applicator (which is a surrogate for tumor size). In the 26 patients treated with a 5-cm or 6-cm applicator, 2- and 3-year OS were 27% and 17%; none of the 11 patients treated with a 9-cm diameter applicator survived beyond 18 months, and those treated with a 7-cm or 8-cm applicator had intermediate survival ($p < 0.05$). In an updated MGH analysis of 194 IORT patients with LUPC, median OS was 12 months.[209] On multivariate analysis, an IORT applicator diameter ≤8 cm (p = 0.009), a Charlson age-comorbidity index ≤3 (p = 0.001), and receipt of CTX ($p < 0.001$) predicted improved OS. The median OS for patients with all three of these prognostic factors was 21.2 months.

Neoadjuvant CRT Plus IOERT. In an *attempt* to improve patient selection and survival, a number of institutions have altered the sequencing of IORT and EBRT/CRT. Garton et al from the Mayo Clinic Rochester evaluated neoadjuvant EBRT with or without concurrent 5-FU followed by IORT in 27 patients with LUPC.[203] Median survival from diagnosis was 14.9 months with a 2-year OS rate of 27% and 5-year OS of 7% (eTable 48-4). Local control was achieved in 78% of patients, but 52% developed liver or peritoneal relapse.

Investigators from Mayo Clinic Arizona have used only the sequence of preoperative CRT followed by restaging and surgical exploration with resection/IORT for select patients with BRPC or LUPC.[208] NAdj CRT was delivered with concurrent 5-FU– or GEM-based regimens and 45 Gy to 50.4 Gy (25 fractions to 28 fractions) in 27 of 31 patients who were explored after restaging. Twenty-eight patients received IOERT (10 Gy to 20 Gy) and 16 patients had gross total resection (R0, 11 patients; R1, 5 patients). Sixteen patients also received adjuvant CTX. Median survival for the total group was 19 months, with a 2-year OS of 31% and a 3-year OS of 16%. Survival outcomes were improved in patients who underwent R0 or R1 resection after NAdj CRT (n = 16) versus those who had R2 or no resection (n = 15) (median OS 23 versus 10 months; 2-year OS 40% versus 17%; 3-year OS, 40% versus 0%; p = 0.002). Liver or peritoneal relapse was documented in 22 of 31 patients (71%). Local failure in the EBRT field or central failure in the IORT field occurred in 5 of 31 patients (16%).

Neoadjuvant Therapy in Locally Unresectable Disease

In patients with LUPC, NAdj treatment serves to provide local control and prevent disease progression. Infrequently, conversion to resectability can occur.

NAdj combination CTX regimens have been suggested to be more beneficial than single-agent CTX.[214,215] A meta-analysis of NAdj therapy in PCA reported on 4394 patients enrolled on 111 trials.[216] Patients who were nonresectable (BRPC and LUPC) had a disease control rate of 76.6%, including a 4.8% complete response rate, 30.2% partial response, and 41.6% stable disease. Forty-seven percent of the initial patients who were unresectable underwent surgical exploration, with an overall resection rate of 33% and an R0 resection rate of 79%. Median OS among patients who were resected and unresected were 20.5 and 10.2 months, respectively.

Initial CTX is an effective way to select patients who are most likely to benefit from CRT. Two retrospective analyses identified induction CTX as an appropriate tool to identify patients with LUPC who may benefit from subsequent treatment with CRT. After at least 3 months of initial CTX, Huguet et al evaluated whether outcomes could be used to select patients who would benefit from CRT.[175] The patients who received CRT after CTX had a markedly better OS than those patients who continued with CTX alone (15.0 versus 11.7 months, p = 0.0009). Another retrospective analysis analyzed 323 patients with LUPC who were treated with initial CRT (n = 247) or who received induction CTX with GEM for 2.5 months before CRT (n = 76).[217] Induction CTX was associated with significantly improved PFS (6.4 versus 4.2 months, $p < 0.001$) and OS (11.9 versus 8.5 months, $p < 0.001$).

Metastatic Disease and Palliation

Median survival for the vast majority of patients with metastatic PCA is extremely poor (3 to 6 months).[218] Both the NCCN and National Cancer Institute (NCI) treatment guidelines recommend that all patients be referred for CTX or enrollment in clinical trials. Therapy for patients with five or fewer metastases is directed toward improving clinical outcome whereas those with more than five metastases should seek best supportive care.

Chemotherapy

First-line treatment for patients with metastatic PCA with good PS includes FOLFIRINOX or GEM/NP. GEM has been established as an approved regimen for advanced disease since 1997.[219] GEM combinations such as GEM/NP, GEM plus capecitabine, GEM/docetaxel/capecitabine (GTX), and GEM/

In 2009, TJUH published an update of their IOERT experience.[210] Thirty-six patients treated with PD and IOERT were compared with 46 patients who underwent surgery without IOERT using a propensity score analysis. Approximately 75% of the IOERT patients also received EBRT, and almost 90% received CTX. Although IOERT was determined to be safe in resectable PCA without increasing perioperative morbidity, it did not seem to significantly increase OS or locoregional control.

The MDACC experience also showed a nonsignificant increase in locoregional control in patients treated with IOERT (9% versus 4%).[211] It is likely that these rates of recurrence are lower than the TJUH experience because fewer patients had positive margins. The investigators suggest that a local control advantage large enough to cause a survival benefit would only be possible in a group with high risk of locoregional recurrence (e.g., R1 or R2 resections). Improvements in CTX will likely be necessary for the possible local control benefits of IOERT to have survival implications.

A pooled analysis of 270 patients undergoing IOERT from five European institutions was performed.[205] Radical surgery was performed in 247 cases (91.5%; R0 resection, 53.4%; R1, 27.4%; R2, 19.2%) and exploratory laparotomy in 8.5%. Surgery was preceded by EBRT in 63 patients (concurrent CRT in 38%) and 106 received postoperative EBRT (concurrent CRT was given in only 7.5%). Median OS was 19 months for the entire cohort, and 5-year OS was 17.7%. Survival and local control appeared to be superior in patients treated with preoperative EBRT/CRT before IOERT compared with adjuvant EBRT (or CRT) or IOERT alone (median OS: 30 months versus 22 months versus 13 months; local control: median not reached versus median 28 months versus median 8 months, respectively). This may be because the patients destined to fail early systemically would do so during preoperative EBRT, sparing them from the attempt at surgery and IORT. On multivariate analysis, nodal status and timing of EBRT significantly affected survival. In the subset of patients who remained free from local relapse for more than 2 years, the 3- and 5-year OS were 32% and 28% versus 12% and 0% in patients with local relapse within 2 years.[209]

Irreversible Electroporation

Irreversible electroporation (IRE) is a novel, minimally invasive technique that has recently been evaluated in the management of LUPC. IRE uses electrical impulses to alter the cell membrane and disturb homeostasis.[213] This triggers apoptotic cell death without damage to protein-based structures (vascular elastin, collagenous structures). IRE is an alternative to thermal ablation techniques (e.g., radiofrequency ablation, microwave ablation, cryoablation), which often cause damage to adjacent structures and blood vessels. Patients should be selected for IRE following evaluation by a multidisciplinary team. A Phase I trial (NCT01939665) is currently under way to evaluate the efficacy of IRE in palliating symptoms and improving local tumor control in LUPC. At JHH, IRE is typically offered to patients with LUPC who have received optimal systemic and radiation therapy (CRT or SBRT) for greater than 6 months from the date of diagnosis.[216a] Because investigation of IRE is in its early stages, additional study is required to determine its optimal use.

erlotinib plus bevacizumab offer clinical advantages, although only a subset of patients may benefit.[189,220-222] A combination of GEM and cisplatin is recommended for patients with metastatic disease and known hereditary factors (e.g., *BRCA* or *PALB2* mutations).[223] Recently, the MPACT study established the GEM/NP regimen as a new option for the first-line treatment of metastatic PCA.[190,224] A significant improvement in OS, PFS, and response rates was associated with combined GEM/NP over GEM alone in patients with metastatic PCA. GEM/NP also demonstrated promising results in LUPC.[191] NP added to GEM has particular efficacy because of its ability to increase the activity of GEM by depleting the stroma and increasing the concentration of GEM in the tumor. FOLFIRINOX has shown increased treatment response rates (>30%) and improvements in survival and QOL in patients with metastatic PCA.[225-227]

A select number of PCA patients with oligometastatic disease who have been stable on CTX for greater than 6 months may receive concurrent CRT. For patients with oligometastatic or unstable disease or poor PS, palliation is of the utmost importance although the potential for improvement in clinical outcome is unclear. The NCCN currently recommends administration of GEM alone in patients with poor PS although the addition of NP is being evaluated. Patients presenting with poor PS may benefit from GEM; however, comfort-directed measures are given priority.

Symptom Palliation

Setting medically appropriate goals while maintaining open and honest communication with the patient is the best approach to palliative care. Patients with PCA have many physical and emotional challenges; therefore, the goal of palliative medicine is to relieve suffering and to improve QOL by addressing a patient's specific needs. Control of pain and nonpain symptoms, clear and effective communication, and addressing psychosocial needs are essentials of palliative care.[228] Given the poor survival rate and distressing symptom profile of PCA, palliative care should be offered upon diagnosis. Pain management is a particular concern among patients with PCA. Although opioid medications are the backbone of therapy, interventional therapies such as percutaneously or endoscopically placed celiac plexus block are often effective for patients with refractory pain or intolerable side effects of opioid therapy. Palliative CTX or RT may also help to improve symptoms, as will be detailed below. Nausea, gastric outlet obstruction, and obstructive jaundice are other common and distressing symptoms in this patient population; careful attention should be paid to optimizing both medical and interventional therapies for such symptoms.

Palliative Chemotherapy

Single-agent GEM is the standard therapy for poor PS or patients who are elderly with PCA regardless of stage (localized or systemic disease); however, median survival remains a mere 6 months in this group. Hsu et al reported that elderly patients (>75 years) with multiple comorbidities have a high mortality rate 9 months after surgery[229] and are less likely to benefit from adjuvant therapy than younger patients.[230] Therefore, patients who are elderly or have poor PS may benefit from more aggressive NAdj therapy and be spared the morbidities of surgery. In metastatic patients with poor PS (KPS > 70), GEM/NP was superior to GEM alone.[190] In fact, most patients with poor PS receiving GEM/NP did not require a dose reduction, and the addition of NP increased the cumulative GEM dose with no increase in significant toxicity. GEM/NP may also improve outcomes with limited toxicity in patients with nonmetastatic PCA who are not well-suited for aggressive CTX or surgery; however, further study of the regimen is required in this group of patients.

Palliative Radiation Therapy

Radiation therapy may be able to improve symptoms such as pain, biliary obstruction, gastric outlet obstruction, or duodenal obstruction. To date, only one clinical trial in LUPC has specified pain control as a study endpoint.[231] This small randomized study from Taiwan demonstrated higher rates of pain control (39% versus 6%) in patients who received GEM-based CRT (50.4 Gy to 61.2 Gy) compared with 5-FU–based CRT. Interpretation of these results is difficult given the small sample size (n = 34) and the fact that outcomes in the 5-FU group were significantly worse than what would be expected based on historical data. CRT has also been compared to best supportive care (with no antineoplastic therapy) in a small randomized trial from Japan.[232] The study enrolled 31 patients, 16 of whom were randomized to 5-FU–based CRT and 15 of whom received supportive care. Ten patients had pain before the start of treatment; of these, 8 had improvement in pain after treatment. The median duration of pain control was 5.2 months. Although this study is unlikely to be replicated, it does support the use of RT to control tumor-related pain.

In selected patients, salvage reirradiation with SBRT may be an option for palliative care, as suggested by a recent retrospective series.[233] Median RT dose was 25 Gy (in 5-Gy fractions) prescribed to the gross tumor alone (plus a 2-mm to 3-mm margin). Although the number of patients treated was fairly small (n = 18), the rate of pain control among patients with pain at baseline was 57%. Therapy was well-tolerated with no acute grade-3 toxicity and a single episode of late grade-3 late toxicity (small bowel obstruction). Furthermore, a multicenter Phase II trial explored the benefit of 33-Gy SBRT (6.6 Gy × 5 fractions) in combination with GEM in patients with LUPC (median age, 67.9). Patients reported a significant improvement in pain 4 to 6 weeks after SBRT (p = 0.001).[199]

The available, although limited, evidence suggests that RT is an effective option for symptom palliation in patients with PCA. The expected response rate is approximately 40% to 80%. As rates of acute treatment-related toxicity are fairly low with the use of modern radiation techniques including IMRT and SBRT,[124,196] RT should be considered as a palliative option in patients whose pain is not adequately controlled by optimal medical management or interventional procedures such as celiac plexus block. Further studies are needed to better quantify the expected clinical benefit of RT in this setting, particularly in terms of pain control.

Palliative Surgery and Stenting

Surgery has historically been used to alleviate symptoms such as duodenal or biliary obstruction. Surgical palliative procedures may include a surgical bypass such as hepaticojejunostomy or gastrojejunostomy. At the time of a surgical bypass, intraoperative celiac plexus block could be considered if the surgeon is comfortable with the technique.[234] Routine palliative bypass has been advocated for patients with PCA who are explored with curative intent but are found to have inoperable disease at the time of surgery. However, with enhanced imaging techniques and improved patient selection and categorization of disease, fewer surgeries of this type are performed.

With the advent of improved endoscopic techniques, rates of duodenal and biliary duct stent placement have increased while the need for palliative surgical bypasses has declined. There is limited data regarding the performance of a prophylactic gastrojejunostomy versus duodenal stent placement at the time of a later duodenal obstruction. However, a meta-analysis of duodenal stents versus gastrojejunostomy found that the latter were preferable for those with a longer (>3 months) projected survival.[237] If survival is likely to be short, endoscopic stent placement is preferred to surgery.[238] Patients

Patients with poor PS—whether due to comorbidities, cancer-related symptoms, or advanced age—are a PCA population that is often overlooked. Equally important is support of the caregivers and family members who are also affected by a PCA diagnosis. A multidisciplinary clinic or tumor board involving established palliative care programs can help provide the necessary resources for patients and families to gain access to the information needed to better understand their diagnosis, decide on treatment options, control pain, understand nutrition, and cope with the associated social stressors.

A recent JHH experience reported on 1913 patients who were surgically explored for cancers of the head of the pancreas between 1996 and 2010.[235] Interestingly, the rate of palliative bypass procedures decreased over time because of improved patient selection. Of the 1913 patients, 583 (30.5%) underwent a palliative procedure. Most patients who underwent surgical palliation (64.5%) had a double bypass, and a minority had either gastrojejunostomy (28.2%) or hepaticojejunostomy (7.2%) alone. Although the number of PDs remained relatively stable over time, there was a temporal decrease in palliative bypass rates ($p < 0.001$). When considering palliative bypass, one should consider several factors that are predictive of poor outcome: the presence of distant metastatic disease (HR 2.59, $p < 0.0001$), poor tumor differentiation (HR 1.71, $p = 0.009$), severe preoperative nausea and vomiting (HR 1.48, $p = 0.013$), and lack of previous placement of a biliary stent (HR 1.36, $p = 0.048$).[236] Patients with a prognostic score of 0 were significantly more likely to survive past 6 months than those with a prognostic score of 1 (HR 2.71, $p < 0.0001$), 2 (HR 3.70, $p < 0.0001$), or ≥3 (HR 5.63, $p < 0.0001$).

can initiate or resume CTX within a few days of endoscopic stenting, whereas recovery from a palliative bypass may take 3 to 6 weeks, therefore delaying CTX.

IRRADIATION TECHNIQUES AND TOLERANCE

Overview

The standard treatment approach is to use 3D-CRT with concurrent GEM or 5-FU (CI or oral capecitabine). The goal of NAdj RT in potentially resectable PCA patients is to (1) select patients who are likely to benefit from aggressive curative surgical resection and (2) increase the likelihood of a margin- and node-negative resection to prevent subsequent local recurrence. In patients with truly unresectable PCA, the goal is to improve median survival, prevent local progression, palliate pain, and perhaps decrease the risk of subsequent systemic spread.[239] The goal of adjuvant RT is to prevent locoregional progression. Before delivering adjuvant treatment, it is important to 1) thoroughly review the tumor location on preoperative and postoperative imaging, the operative note, and pathology report and 2) assess PS and nutritional status (e.g., the need for pancreatic enzymes). Integration of newer techniques such as IMRT and SBRT/stereotactic ablative radiotherapy (SABR) will be briefly discussed.

Simulation and Treatment Planning

Patients should undergo a CT simulation (thin slices through the pancreas or tumor bed and locoregional nodal basins) with intravenous and oral contrast for improved delineation of the tumor or tumor bed and adjacent normal structures.[81] Patients are simulated supine in an Alpha Cradle (Smithers Medical Products Inc, North Canton, OH) or equivalent immobilization device with arms up. Patients should be scanned from the carina through the top of the pelvis using 2-mm to 3-mm slices. For resected cases, preoperative CT scans and strategically placed clips are used to determine the tumor bed. In the neoadjuvant, borderline resectable and locally unresectable settings, the pancreatic gross tumor volume (GTV) and pathologic nodes (minimum >1 cm) are contoured with assistance from anatomical (CT/MRI) and functional imaging (PET). The planning target volume (PTV), defined per ICRU-62 guidelines, should be constructed using image guidance.[240] A GTV should be defined for intact pancreatic tumors.

Elective nodal irradiation (ENI) is commonly used for adjuvant cases but is controversial for neoadjuvant, borderline resectable, and locally unresectable PCA cases. Standard margin expansions for intact tumors include the gross tumor and any pathologic lymph nodes (gross tumor volume, GTV) plus a 0.5-cm to 1.5-cm margin to target microscopic extension (clinical target volume, CTV) and an additional 0.5-cm to 2.0-cm volume to account for tumor or breathing motion and patient set-up errors (planning target volume, PTV). Breath-hold and gating techniques in conjunction with 3D-CRT or IMRT can result in improved PTV coverage with decreased dose to OARs. With regards to SBRT, smaller margins are used (0.2 cm to 0.5 cm) and the PTV does not cover locoregional nodes (Figure 48-7).

Motion Management

Both interfractional and intrafractional variations are important when considering margin expansions. Interfractional motion is mainly due to setup error, whereas intrafractional variations are typically the result of breathing motion or bowel or stomach distension. Portal imaging does not take into account breathing motion or bowel distension. On average, portal imaging for radiation (PORT) films are associated with a 5-mm to 6-mm difference in each translation whereas cone-beam computed tomography (CBCT) has systematic errors of 2.4 mm left-right (LR), 2 mm anterior-posterior (AP), and 3.2 mm cranio-caudal (CC), as well as random errors of 3.2 mm LR, 1.8 mm AP, and 3.6 mm CC.[241] Based on these data, at least a 1-cm CTV to PTV is recommended when using PORT imaging.

Respiratory motion is a major source of intrafractional motion. Reese et al summarized several studies that described a large range of potential respiratory motion from 5 mm to 43 mm, indicating the need for individualized margins.[242] Four-dimensional (4D) CT may underestimate motion compared to fluoroscopy, ultrasound, and MRI. In fact, studies have shown that both under- and overestimation with 4D CT can occur as a result of technique, patient comfort level, and parameters. In general, regular or real-time verification of patient positioning during treatment is ideal, especially if tight margins are used. When possible, a combination of tumor fiducial placement in or around the tumor, 4D CT simulation, gating or breath-hold, and image-guided radiation therapy (IGRT) can effectively result in "personalization" of nonuniform PTVs (as opposed to uniform PTV expansion).[243] Motion of the pancreatic head, body, and tail appears to be different.[244-246] The SMA, celiac, and other vessels have been found to move less than 5 mm, which is substantially less than the pancreas.[247,248] Given these variations, individual patient assessment of motion is paramount.

If patients have a greater than 3 mm breathing motion on fluoroscopy or 4DCT scan, tumor immobilization techniques should be employed. There are two approaches to motion management: immobilization of the target motion (abdominal compression or breath-hold techniques) or physiologically monitoring tumor motion (tracking or gating). Abdominal compression limits diaphragmatic excursion while breath-hold techniques (active or passive) stabilize the tumor for a short period of time to ensure delivery of RT while the breath is held within a previously established tidal volume. Abdominal compression should be used with caution because it may compress the duodenum or bowel into the pancreas, thus increasing the volume of normal tissue that may be exposed to RT. In general, if breathing motion is less than 3 mm, patients can be treated free-breathing with an internal target volume (ITV) based on the 0% and 50% phases of the breathing cycle or in a gated manner. FDG-PET or MRI simulation may enhance the ability to better delineate the pancreas tumor and adjacent structures and can provide a baseline to assess treatment response.

Tracking often requires fiducial markers to be placed within the tumor such that the radiation beam follows the tumor motion. A recent study showed rates of migration of gold fiducials to be minimal in patients with LUPC receiving SBRT.[249] Before simulation for IG-IMRT or SBRT/SABR, three or more gold fiducials should be implanted into or adjacent to the pancreatic tumor using endoscopic ultrasound (preferred) or percutaneous guidance. Pancreatic stents appear to have potential as a surrogate for pancreatic motion given their proximity.[250] However, the stent motion may be greater than GTV motion creating a larger expansion than necessary.[251] Although the use of the stent for image guidance during daily treatment is attractive as it is easily seen with on-board imaging; however, studies have shown that the mean migration of the stent has been found to be approximately 1 mm over the course of RT, and spontaneous loss of the stent has been reported to occur in 5.8% of patients.[249] As the motion and loss rate may be greater for standard fractionated therapy, stents are not completely reliable markers for daily image guidance.

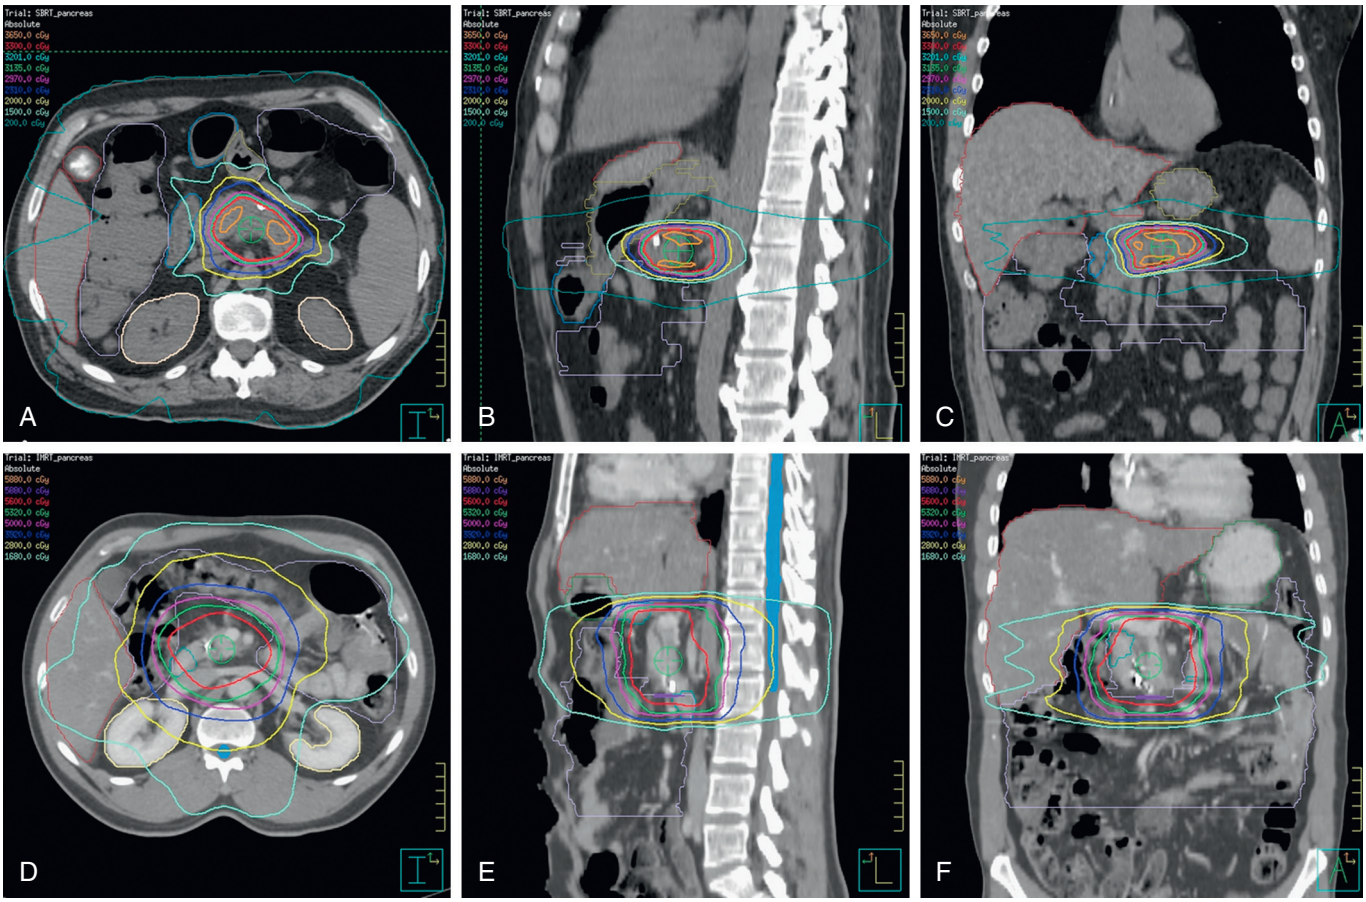

Figure 48-7 Stereotactic body radiation therapy (SBRT) and intensity-modulated radiation therapy (IMRT) treatment plans. Modern conformal radiation techniques allow precise dose delivery to the pancreas and nodal stations at risk. SBRT (panels **A-C**) and IMRT plans (panels **D-F**) are shown in orthogonal cross-section projections. Note the steeper dose fall off and smaller obligate low-dose region with SBRT compared to IMRT.

The pancreas is also affected by motion of the gastrointestinal tract. The stomach is a remarkably distensible adjacent organ and can quadruple in size with oral intake.[252] The pancreas has been shown to move when the stomach is injected with 500 mL to 900 mL of fluid, with the pancreatic tail and SMA having the greatest motion (median motion of 5.3 mm and 5.7 mm, respectively).[253] Gastric distension must therefore be accounted for during simulation and treatment. To ensure a consistent gastric volume, it is recommended that patients take no food or drink for 2 hours before simulation and treatment of any pancreatic target (whether postoperative or intact anatomy is present). Two hundred and forty mL of oral contrast (simulation) or water (treatment) is given to ensure consistent stomach and bowel filling, maximizing the reliability of dose calculations to the stomach and duodenum.

Treatment Planning and Radiation Delivery

Conventional RT or 3D-CRT is generally given using three or four fields whereas IMRT and SBRT/SABR use multiple coplanar isocentric (linac-based) or noncoplanar nonisocentric (CyberKnife) beams. High-energy photons (>10 MeV) are preferred; lower energy megavoltage beams can be used but may result in more gastrointestinal toxicity.

In RTOG 0848 (NCT01013649), the principles utilized in two-dimensional (2D) RT planning from RTOG 9704 have been extended to 3D and IMRT planning. In addition, an atlas of images illustrating these principles has been posted on the RTOG website (RTOG.org). The resulting CTV and PTV are significantly smaller than historical standards that used 2D imaging and planning. This protocol targets the areas of greatest subclinical tumor concentration based on anatomic landmarks not readily apparent in 2D imaging (celiac and SMA, PV, pancreaticojejunostomy, GTV location of the resected tumor) and more precisely specifies suggested tolerance parameters for critical normal organs.

Intensity-Modulated Radiation Therapy

IMRT and intensity-modulated proton beam therapy (IMPT) using IG have become increasingly popular in the management of PCA. Implementation of IMRT requires a high level of precision in treatment planning and dose delivery because multiple beams are used to irradiate the target volume. Compared with 3D-CRT, IMRT improves dose conformality and decreases toxicity, even allowing for the safe delivery of boost doses up to 64.8 Gy while meeting normal tissue constraints.[126,169,254] Furthermore, IMRT effectively reduces the mean dose to the liver, kidneys, stomach, and small bowel, resulting in improved toxicity.[255] A recent dosimetric study conducted by van der Geld et al revealed that 4D IMRT planning significantly reduced the mean volume of right kidney exposed to 20 Gy by more than 11%, while also lowering the mean dose to the stomach, liver, and small bowel.[256] These dosimetric improvements may allow for larger systemic doses of concurrent CTX to be given safely. Small reductions in margin size can result in a substantial reduction in the volume to be irradiated.

Abrams et al emphasize the significance of adherence to standard guidelines and quality assurance with RT delivery.[122] By using prospectively defined guidelines, patients' treatment plans were scored as per protocol, variation acceptable, and variation unacceptable. Of the 416 evaluable patients, 52% were per protocol, whereas 48% were less than per protocol. Survival was increased for all per protocol patients compared with less than per protocol (1.74 years versus 1.47 years, $p = 0.019$). This result persisted on multivariate analysis. The Kaplan-Meier curves comparing per protocol and less than per protocol patients appeared to diverge at approximately 14 months, which the authors thought implied an effect on tumor control.

Proton Beam Radiation Therapy

IMPT has a unique advantage in its ability to deposit energy directly into the tumor while minimizing radiation to normal tissue. A feasibility study reported that NAdj capecitabine and a short course of proton beam therapy is a feasible regimen.[257] IMPT involved 240-MeV protons generated from a cyclotron and delivered using 3D passively scattered protons. The first dose level consisted of 3 GyE delivered daily 5 days per week for 2 weeks for a total of 30 Gy. In levels 2 to 4, patients were treated with 5 GyE per fraction for a total fraction of 25 GyE in progressively shorter schedules. Further research is necessary because high-dose proton plans do not appear to be as conformal as high-dose photon plans.[258] In a dosimetric study conducted at MDACC, investigators virtually translated a 3-cm pancreatic tumor every 5 mm over a 5-cm length extending from the head to tail of the pancreas.[259] For eleven tumor locations, 3D-CRT, IMRT, and IMPT plans were generated. IMRT was the most conformal in higher gradient dose regions, whereas IMPT reduced low doses to gastrointestinal OARs. Thus, IMRT seems to be the more appropriate tool for dose escalation whereas proton therapy would be expected to have a modest impact on low-grade acute toxicities such as nausea and fatigue and is not currently an optimal choice for dose escalation. Multiple clinical trials are currently under way to investigate the role of proton radiation in PCA (clinicaltrials.gov).

Stereotactic Body Radiotherapy

Advances in IGRT and radiation technology have resulted in SBRT, or stereotactic ablative radiotherapy. SBRT delivers high doses of RT to the pancreas tumor or tumor bed plus a small margin (~2 mm to 3 mm) while sparing adjacent normal tissues. To date, Phases I and II trials for lung, liver, spine, pancreas, kidney, and prostate tumors have suggested that SBRT may provide equivalent tumor control to surgical resection, without the typical morbidities associated with an invasive approach.[260,261]

Initially analyzed in LUPC, SBRT also shows promise in the borderline resectable and metastatic setting. Current literature has suggested that fractionated SBRT appears to be an effective and well-tolerated treatment for LUPC because of its ability to improve QOL and increase survival and local control (Table 48-4).[129,130,195-197,262,263] SBRT is a complement to standard RT because local control rates appear comparable, toxicity is favorable, and delay of CTX is limited. However, more data is needed. As the role of pancreatic SBRT has evolved, dosimetric margins, patient positioning, and motion management have proven to be essential for accurate targeting.[263a] Severe gastrointestinal toxicities have been reported as a result of SBRT in past studies[194,195]; however, continuing efforts to establish specific dose constraints have been able to minimize normal tissue toxicity. In cases in which the PTV is in close proximity to critical OARs, the maximum point doses and dose-volume histograms of those structures should be evaluated.[264] The following dose constraints have shown efficacy in minimizing treatment-related toxicity with the delivery of 33 Gy (in 6.6-Gy fractions) SBRT to patients with LUPC based on results of a multicenter study: proximal duodenum and stomach (9 mL <15 Gy; 3 mL <20 Gy; 1 mL <33 Gy), liver (50% <12 Gy), combined kidneys (75% <12 Gy), and spinal cord (1 mL >8 Gy).[199]

Intraoperative Radiation Therapy

Intraoperative RT is used to escalate RT dose to the unresected pancreas cancer or operative tumor bed. High single-fraction doses of 15 Gy to 20 Gy are typically delivered as nearby dose-limiting structures can be physically removed from the radiation field during the procedure. Two techniques may be used: IOERT and high-dose-rate brachytherapy (HDR-IORT). HDR-IORT allows for the delivery of a more concentrated dose at the surface of the target area, whereas IOERT delivers RT more homogenously throughout the unresected tumor or tumor bed.[267,268] The flexible applicators associated with HDR-IORT can be shaped to precisely conform to individual tumor beds.[269] Ideally, IORT is performed in cases in which surgical resection may result in close or positive margins. However, the role of IORT in PCA is still being evaluated, and this procedure should only be performed at specialized centers and in well-selected cases.[81]

Toxicity and Dose Constraints to Normal Tissues

Critical OARs (e.g., kidney, stomach, small bowel, liver, spinal cord) should be contoured and evaluated in the dose-volume histogram to maximize treatment response while minimizing toxicity. Dose-volume recommendations based on the NCCN guidelines can be found in Table 48-5.

The small intestine is an important RT dose-limiting structure in the abdomen; a relatively small volume of the small bowel receiving a high dose of RT may lead to severe, irreversible side effects. In 1991, Emami et al demonstrated the maximal dose limit to the small intestine was 45 Gy to 50 Gy.[270] More recent data from the Quantitative Analyses of Normal Tissue Effects (QUANTEC) investigators at the RTOG compiled data from multiple studies to update the initially identified dose constraints. In general, the RT dose limit to the small intestine should be limited to no more than 195 mL of small bowel receiving greater than 45 Gy (V45, or volume receiving 45 Gy or more, should be <195 mL). MDACC recently reported that duodenal V55 Gy >1 mL is an important dosimetric predictor of grade-2 or greater duodenal toxicity in the management of LUPC with concurrent CRT.[271] With SBRT, definitive dose constraints have not been established; however, a proposed limit is 12.5 Gy in a single fraction (V12.5 <30 mL), or limited to 30 Gy in a 3- to 5-fraction regimen.

Acute side effects of RT to the small intestine include malabsorption, altered gut mobility, diarrhea, nausea, and vomiting, whereas chronic/late side effects may include mucosal ulceration, eventually developing into perforations, fistulae, bleeding, and abscesses. The development of fibrosis may cause a stricture or small bowel obstruction, and chronic malabsorption may lead to severe anemia and hypoalbuminemia. Although many of the acute side effects resolve quickly after RT, late side effects may be severe, progressive, and irreversible. Acute RT enteritis can be managed conservatively by using antidiarrheal, antispasmodic, and antiemetic medications as necessary. In patients with ongoing diarrhea despite medical management, a low-residue diet should be considered. In cases of mild nausea, compazine or ondansetron can be beneficial, whereas total parenteral nutrition may be needed in extreme cases. Given the rapid repair capacity of the small bowel, a short break from RT often leads to functional improvements. Small bowel obstruction after RT may be a consequence of stricture or adhesions leading to bowel loop entrapment, which should be managed as any acute abdomen case would proceed. Initially, patients should have nothing by mouth to allow the bowel to rest and to allow for decompression. In certain cases, strictureplasty or dilation of the affected segment may be an option; however, this is not the preferred technique for treatment. Anastomosis with a proximal, nonirradiated segment of bowel has been performed with good results. With IORT plus EBRT approaches, efforts to decrease overlap of RT treatment fields and confirm removal of normal structures out of the IORT field results in less toxicity.

TREATMENT ALGORITHM, CHALLENGES, AND FUTURE DIRECTIONS

A treatment algorithm for PCA is provided in Figure 48-8.

Given the high risk of systemic progression, upfront CTX is recommended in all stages of nonmetastatic PCA. In general, RT should be considered in patients who have: (1) localized disease with favorable response or stable disease after initial CTX treatment, (2) local progression on CTX, (3) high-risk features following surgery and adjuvant CTX (narrow margin R0, R1-2, N+), and (4) local pain or obstructive symptoms not controlled with other measures (pain medication, stents).

The most optimal results for patients with potentially curable PCA (R0 resection) will likely be achieved with trimodality treatment (surgery, CTX, and RT), including NAdj therapy; however, the safest, most effective, or optimal combination of all three components is yet to be determined. Future trials should address sequencing of systemic treatment and concurrent CRT or SBRT, particularly with regard to optimizing pre-RT CTX regimens.[217,272] The RTOG 0848 study results may help to establish the role of adjuvant CRT in PCA.

TABLE 48-5 Normal Tissue Dose-Volume Recommendations Based on the National Comprehensive Cancer Network Guidelines[81]

Structure	Unresectable/Preoperative Recommendations	Adjuvant/Resected Recommendations
Kidney (right and left)	No more than 30% of the total volume can receive ≥18 Gy. If one kidney is functional, not more than 10% of the total volume can receive †18 Gy.	If two functioning kidneys present, not more than 50% of the right and 65% of the left kidney should receive >18 Gy. For IMRT planning, mean dose to bilateral kidneys should be ≤18 Gy. If only one kidney is present not more than 15% should receive †18 Gy and no more than 30% should receive †14 Gy.
Stomach, duodenum, jejunum	Max dose ≤55 Gy. No more than 30% of the volume can be between 45 Gy and 55 Gy.	Max dose ≤55 Gy; <10% of each organ volume can receive between 50 Gy and 53.99 Gy. <15% of each organ volume can receive 45 Gy-49.99 Gy.
Liver	Mean dose cannot exceed 30 Gy.	Mean dose cannot exceed 25 Gy.
Spinal cord	Max dose to a volume of at least 0.03 mL must be ≤45 Gy.	Max dose cannot exceed 45 Gy.

Max, *maximum.*

However, it is unknown whether the 0848 regimen will be effective enough to prevent local and subsequent systemic relapse in patients with resected PCA. Therefore, future treatment regimens should use IMRT or SBRT to safely escalate the dose of RT or allow for more aggressive molecular, immunotherapy, or CTX treatments to improve outcomes.

The definition of borderline resectable PCA has been evolving, which can complicate the interpretation of BRPC studies. The Alliance A021101 trial will evaluate the efficacy of NAdj FOLFIRNOX followed by capecitabine and EBRT and provide insight into implementation of future multiinstitutional BRPC trials.[83] This trial provides a standardized definition and incorporates centralized review of images, treatment plans, and pathology. Future trials should address the efficacy of novel systemic regimens and targeted therapies in combination with new radiation technologies (IMRT/SBRT/IOERT). Novel tumor or blood prognostic biomarkers are desperately needed.

The future of LUPC treatment requires the development of more effective systemic therapies and RT technologies. In the absence of metastases, high-dose NAdj EBRT with simultaneous maintenance CTX appears to be a valid option for patients with poor PS. Furthermore, EBRT boosts with SBRT should be explored. Preliminary studies with fractionated SBRT suggest similar survival with less acute toxicity and improved QOL; however, additional prospective data is needed. The results of the LAP-07 trial question the benefit of CRT following CTX in LUPC, but problems with the trial along with prior positive studies for CRT over CTX (GITSG, ECOG) cannot be dismissed. The high rates of progression following induction CTX (40%) in LAP-07 may highlight the need for more aggressive NAdj CTX to select a subset of patients who may benefit from RT. An additional challenge is how to select patients who may benefit from resection/IOERT after NAdj CTX plus CRT or SBRT.

Studies investigating more aggressive systemic therapies such as GEM/NP and FOLFIRINOX are under way (CTX alone or in conjunction with CRT). Because the MPACT trial suggested that GEM/NP may improve survival and have limited toxicity in patients with resected PCA, this regimen is currently being explored in the adjuvant setting. A Phase II multicenter randomized trial (NCT01964430) aims to evaluate whether adjuvant GEM/NP is associated with a delay or prevention of relapse or death in comparison with GEM alone. Patients will be randomized to 6 months of GEM (1000 mg/m^2) and NP (125 mg/m^2), or GEM alone (1000 mg/m^2). An additional Phase II study (NCT02047513) aims to evaluate NAdj plus adjuvant versus adjuvant GEM/NP. Patients with resectable PCA will be randomized to either two cycles of NAdj GEM plus NP followed by surgery and adjuvant GEM plus NP, or surgery followed by six cycles of GEM plus NP CTX. A recently initiated Phase III trial (NCT01526135) serves to evaluate mFOLFIRINOX (omission of bolus 5-FU) versus GEM in resected PCA (I = 490). Trial enrollment began in 2012 and endpoints will include DFS, OS, and toxicity. A current Phase I/II trial (NCT01693276) is accruing patients to evaluate survival and local control in patients with LUPC receiving GEM/NP CTX both before and after CRT with 60 Gy IMRT (2-Gy fractions). The Phase II/III SCALOP-2 trial (NCT02024009) has recently been developed in the United Kingdom to analyze survival, toxicity, and QOL associated with CRT including GEM/NP (with or without capecitabine or nelfinavir) as well as GEM/NP alone in the LUPC setting.

The challenge with oligometastatic PCA is when to treat the primary tumor and systemic disease as opposed to primarily providing palliative care. These decisions rely heavily on patient selection; of all patients diagnosed with PCA, there is a subgroup of patients who have a low burden of metastatic disease. If these select patients can be identified, physicians will know when to proceed with aggressive treatment strategies such as SBRT, radioembolization, ablation, or resection.

Novel agents are emerging for the treatment of metastatic PCA such as nonbiologic, nanoparticle paclitaxel (NBN-Pac),[273] sunitinib,[274] and a Hh pathways inhibitor called GDC-0449 (NCT01088815).

The treatment of patients with poor PS remains controversial as approximately 50% of the PCA population (23,000) has a poor PS, advanced age, or other comorbidities preventing them from eligibility for clinical trials. Additional studies are needed to define treatment regimens and develop techniques to improve survival for this patient population.

Research on predictive and prognostic biomarkers is crucial for the future of PCA management. Understanding the genetic mutations and underlying biological processes that are associated with a patient's tumor and proliferation of cancerous cells will confer an advantage in more accurate diagnosis and staging such that individualized treatment decisions may ultimately be possible. SPARC expression is increasingly studied as high expression is suggestive of improved survival. Investigation of tumor radiosensitivity in PCA holds promise as a modern method to predict tumor response and clinical outcome.[275] Furthermore, circulating tumor DNA may be able to differentiate between localized and metastatic disease, detect tumor burden, and evaluate resistance or response to therapy.[276,277] To establish a relationship between genetic features, tumor dynamics (e.g., patterns of failure, sensitivity), and clinical outcome (e.g., tumor response, survival, quality of life), next-generation sequencing and mathematical modeling will be employed as we advance toward personalized medicine.

ACKNOWLEDGMENT

We would like to thank Lauren Rosati, BS, for her substantial assistance in writing and revising the chapter.

CHAPTER

49 Hepatobiliary Cancer

Laura A. Dawson and Michael G. Haddock

INCIDENCE

Globally, hepatobiliary cancer is the fifth-most common cause of cancer and the second cause of cancer death. In 2015, the expected incidence of hepatobiliary cancer in the United States was 46,570 cases, with 28,250 deaths.

BIOLOGIC CHARACTERISTICS

The primary risk factors for hepatocellular carcinoma (HCC) are chronic hepatitis B infection and hepatitis C infection, although liver cirrhosis from any cause increases the risk. The occurrence of cholangiocarcinoma is especially high in patients with primary sclerosing cholangitis. Gallbladder cancer may be related to cholelithiasis.

STAGING EVALUATION

In addition to a history and physical for cancer signs and symptoms, underlying liver disease and liver function need to be considered. The workup includes a complete blood count, liver function tests, liver enzymes, and multiphasic liver computed tomography (CT) or magnetic resonance (MR) imaging, chest and pelvis CT. The evaluation of biliary tumors usually also includes endoscopic retrograde cholangiography or MR cholangiopancreatography.

PRIMARY THERAPY

For hepatobiliary tumors, the best outcomes are seen in patients who are treated with surgery. Patients with resected early stage HCC have a 5-year overall survival (OS) of 30% to 50%; 5-year OS for cholangiocarcinoma ranges from 10% to 40% following surgery, with worse outcomes in hilar cancers. Liver transplantation for selected patients with HCC and hilar cholangiocarcinoma is associated with 5-year OS ranging from 70% to 85% (extrahepatic cholangiocarcinoma [EHCC], transplant alone, 5-year OS 20% to 35%). Preoperative concurrent chemoradiation (chemoRT) plus transplant can result in excellent long-term outcomes (5-year OS of 65% to 74%) in carefully selected patients with EHCC that are unresectable with standard surgery. Five-year OS for gallbladder cancer generally ranges from less than 10% to 30%.

Radiofrequency ablation (RFA) and other ablative techniques can also lead to cure in selected HCC. There is a growing literature on radiation therapy (RT) for early stage HCC, with excellent long-term outcomes in selected patients.

ADJUVANT THERAPY

For HCC, there is no role for adjuvant therapy following surgery or transplant. For biliary carcinoma, it has been suggested that adjuvant chemoRT reduces the risk of relapse, especially in the setting of positive nodes or margins.

LOCALLY ADVANCED DISEASE

For locally advanced HCC, transarterial chemo-embolization (TACE) is associated with a survival benefit compared to best supportive care. Sorafenib is used in patients unsuitable for TACE and also improves survival. RT for locally advanced HCC has been associated with long-term local control, but there is a lack of level-1 evidence.

For locally advanced biliary carcinomas, RT plus concurrent chemotherapy (chemoRT) alone or plus brachytherapy may lead to sustained local control and higher than expected OS. As noted previously, preoperative chemoRT plus liver transplant yields excellent results in carefully selected patients.

PALLIATION

Gemcitabine plus cisplatin had better OS and progression-free survival than gemcitabine alone in a Phase III trial of patients with metastatic or locally advanced biliary cancer (EHCC, gallbladder, or ampullary; 75% had metastases).

Low-dose whole-liver RT may reduce pain or discomfort from HCC unsuitable for standard therapies. RT may also be used for biliary obstruction from cholangiocarcinoma, although biliary stents are the preferred palliative intervention.

Hepatobiliary carcinoma includes HCC, gallbladder cancer, EHCC, and intrahepatic cholangiocarcinoma (IHCC). Globally, hepatobiliary carcinoma is the fifth-most common cause of cancer, and the second-most frequent cause of cancer death.[1] In 2015, the estimated number of new cases in the United States was 46,570, with 28,250 deaths.[2] Relative 5-year survival in the United States has increased from less than 5% in the 1970s to 18% from 2003 to 2009.[1]

Liver cancer is one of the fastest-rising causes of cancer and cancer death in North America, largely as a result of the hepatitis C epidemic.[3] Obesity and nonalcoholic steatohepatitis (NASH) are also an increasing cause of cirrhosis and subsequent HCC. A similar increase in the incidence of IHCC has been reported but for less clear reasons. This may be partially because of the misclassification of hilar cholangiocarcinoma (Klatskin tumors) as IHCC instead of EHCC.[4,5]

The best therapy for hepatobiliary tumors is resection, but only a minority of patients is suitable for surgery because of locally advanced cancer or impaired liver function. Nonsurgical options for HCC include RFA, TACE, sorafenib, and RT. RFA can control HCCs less than 3 cm, which are not adjacent to large vessels. There is a growing literature on the use of RT for the treatment of early stage HCC, with excellent long-term outcomes; however there are no comparative studies. For locally advanced HCC, TACE improves survival compared to best supportive care (2-year OS 63% versus 27% in patients with hepatitis C, and 31% versus 11% in patients with hepatitis B).[6,7] Sorafenib improves survival in HCC unsuitable for TACE. For patients with metastatic or locally advanced biliary carcinoma, gemcitabine plus cisplatin improves median survival from 8.1 to 11.7 months, compared to gemcitabine alone (75% of patients had metastases).[8]

RT did not historically played a role in the treatment of HCC, largely as a result of the low tolerance of the whole liver to RT.[9,10] It was not until conformal RT planning and intensity-modulated radiation therapy (IMRT), that delivery of high doses to focal liver cancers became possible. Protons and more recently stereotactic body radiation therapy (SBRT) have been used to treat selected, hepatobiliary cancers. RT (external beam or brachytherapy) has been associated with improved local control and higher than expected survival rates in locally advanced cholangiocarcinoma, and preoperative chemoRT plus liver transplant can result in excellent 5-year OS in carefully selected patients.

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

The most common hepatobiliary cancer is HCC, followed by gallbladder cancer, EHCC, and IHCC. About half of cholangiocarcinomas arise in the perihilar region (Klatskin tumor).[11] Other cancers of the liver, such as carcinoid tumors, hepatoblastoma, angiosarcoma, and leiomyosarcoma, are rare. HCC and IHCC are twice as common in men as in women, gallbladder cancer is about three times more common in women, and EHCC occurs with approximately equal frequency.[5]

Worldwide, liver cancer is the fifth and seventh most common cancer and the second and sixth most common cause of cancer death in men and women, respectively.[12] HCC accounts for 70% to 85% of liver malignancies, and there is considerable variation in the incidence globally, which largely mirrors the variation in the incidence of hepatitis B infection.[12] In Asia, southeast Asia, and middle/western and sub-Saharan Africa, HCC is 15 to 100 times more common than in North America,[13] although the incidence is increasing in the United States and Europe.[14]

Gallbladder cancer also has substantial geographic variation. The incidence in northeastern Europe is more than 20 times higher than in the United States, and it is common in Chile.[15] Although EHCC has a fairly uniform incidence, IHCC is more common in southeast Asia than in other parts of the world, likely because of the higher incidence of liver fluke in this region.

Hepatobiliary carcinoma accounts for about 2% of new cancer cases in the United States[16]; however, there has been a significant increase in HCC incidence and death from HCC and IHCC, in North America, over the past 30 years. From 1992 to 2010, the incidence of HCC and IHCC increased 3.7% and 2.9% per year in males and females, respectively, while deaths increased 2.3% and 1.4% per year in males and females.[1] This change is as a result in part of increasing hepatitis C infection, increase in immigrants from hepatitis B–endemic countries, and increasing NASH.

In the United States, HCC is about four times more common in Asians than whites, and two times more common in African Americans than in whites.[17] Gallbladder cancer is 15 times more common among Native American women than white women in New Mexico.[18] Other hepatobiliary tumors are of approximately equal distribution or show a slight preponderance among whites.

Etiology

Hepatocellular Carcinoma

The primary risk factor for HCC is chronic viral hepatitis B. In developing countries, approximately 60% of HCC is caused by hepatitis B, and 33% is caused by hepatitis C virus. In Korea and Taiwan, approximately 90% of patients with HCC are positive for hepatitis B surface antigen (HBsAg). Prospective studies found that hepatitis B carriers have a 200-fold increase in relative risk for HCC.[19] The risk of HCC is increased in patients with hepatitis C, with a 17-to 20-fold increase compared to people who are negative for hepatitis C. Cirrhosis resulting from nonviral etiologies, including alcohol, NASH, autoimmune chronic active hepatitis, hemochromatosis, and alpha1-antitrypsin deficiency, is responsible for a substantial proportion of HCC in the United States.[14,20] NASH results from metabolic syndrome, obesity, insulin resistance, hypertriglycerimia, and low low-density lipoprotein. Increased free fatty acids in the liver lead to NFKB activation and inflammation and cirrhosis.

Aflatoxin B, a metabolite of *Aspergillus flavus* found in stored grain and peanuts in humid parts of Africa and Asia, has been linked with HCC development.[20] A reactive intermediate metabolite of aflatoxin B binds to guanine, which is excised and replaced with thymidine. This mutation is commonly found in the *TP53* tumor suppressor gene in HCC occurring in areas of high aflatoxin ingestion.

Gallbladder Cancer

Traditional risk factors for gallbladder cancer are female gender and chronic cholelithiasis.[15] Gallbladder cancer is two to six times more common in women than in men, with significant geographic variability correlating with cholelithiasis prevalence.[21] Although more than two thirds of patients with gallbladder cancer have cholelithiasis, only 1% to 3% of patients with cholelithiasis will develop gallbladder cancer.[22] Among patients with cholelithiasis, typhoid carrier state, smoking, high intake of fried food and green leafy vegetables, and diabetes have been associated with gallbladder cancer.[23,24] Additional reported risk factors include smoking, obesity, chemical exposures, family history of gallbladder disease, and reproductive factors including increasing parity, number of pregnancies, and younger age at menarche.[15,18,24,25]

Cholangiocarcinoma

Risk factors for development of cholangiocarcinoma include liver fluke infection, hepatolithiasis, choledochal cysts, and thorium dioxide exposure.[26] Primary sclerosing cholangitis (PSC) is the most common risk factor in the West, with a lifetime risk of 5% to 10%.[27] IHCC development is associated with both hepatitis B and hepatitis C infection, as well as cirrhosis.[28] Other risk factors for cholangiocarcinoma include inflammatory bowel disease independent of PSC, smoking, alcohol consumption, fatty liver disease, diabetes, cholelithiasis, and choledocholithiasis.[26]

PREVENTION AND EARLY DETECTION

Hepatocellular Carcinoma

The prevention of HCC by hepatitis B vaccination has been supported by the reduced childhood HCC rates in Taiwan after introduction of a nationwide vaccination program in 1986.[19] The incidence of HCC among 6- to 14-year olds significantly declined from 0.7 to 0.36 per 100,000, with corresponding reductions in mortality, and larger differences expected in the future as the immunized population ages.

Serum alpha-fetoprotein (AFP) has limited utility on its own for screening HCC, even in high-risk populations.[29] In contrast, early detection of HCC in endemic areas of hepatitis B was demonstrated with use of liver ultrasonography (US) and AFP for screening high-risk populations. In a Chinese trial, approximately 19,000 people were randomized between screening AFP and US every 6 months compared to observation. Mortality from HCC was significantly lower (83/100,000 versus 132/100,000) and survival was significantly better (5-year OS 46% versus 0%) in screened patients.[30] The National

Comprehensive Cancer Network practice guidelines recommend screening patients at high risk for HCC (hepatitis B carriers and cirrhotics), potentially suitable for treatment, with AFP and US every 6 months.[31]

Cholangiocarcinoma

There is no established screening or early detection method for cholangiocarcinoma. In patients with increased risk as a result of PSC, a screening strategy of serum CA 19-9 along with cross-sectional liver imaging has been employed.[32] Patients with CA 19-9 levels above 20 U/mL or abnormal liver imaging may undergo brushings for cytology, digital imaging analysis (DIA), and florescence in situ hybridization (FISH) analysis for early detection. Preliminary data suggests that the combination aneusomy on FISH and aneuploidy on FISH is associated with 50% to 64% sensitivity, and 100% specificity and positive predictive value.[32]

Potential preventive strategies for cholangiocarcinoma in high-risk regions include preventative and therapeutic programs for liver fluke infection,[33] vaccination against hepatitis B infection,[34] and modification of dietary factors including decreased consumption or alcohol, fermented meats and raw fish, and increased consumption of fruits and vegetables.[35] Even though cholelithiasis is a risk factor for gallbladder cancer[33] and cholangiocarcinoma, there is no evidence to justify cholecystectomy as a preventive measure.[18]

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

Hepatocellular Carcinoma

The hepatitis C virus has been implicated in the pathogenesis of HCC but without evidence of host genome integration of the viral DNA.[13] Fragments of hepatitis B viral DNA are frequently found within the genome of the HCC,[13,20] leading to the hypothesis that viral integration activates oncogenes or interferes with tumor suppressor genes. The normal liver of patients with chronic hepatitis B infection shows viral DNA integration early in the course of the disease, suggesting that the HCC originated from clonal expansion of the affected hepatocytes.[36] Against this argument is the finding that the sites of viral DNA integration are not consistent and do not occur near known oncogenes or tumor suppressor genes. The most frequent amplifications of genomic material involve 1q, 8q, 6p, and 17q. Common losses involve 8p, 16q, 4q, and 17p. The viral DNA itself does not contain any known oncogenes. Therefore, if the integration of viral DNA is necessary for carcinogenesis, the mechanism may be caused by genomic instability from deletions and chromosomal rearrangement rather than specific oncogene activation or disruption of tumor suppressor genes.[36]

Hepatocarcinogenesis involves many pathways, such as those involving vascular endothelial growth factor (VEGF), epidermal growth factor (EGF), hepatocyte growth factor (HGF), and insulin like growth factor (IGF). VEGF binds to VEGFR, promoting HCC angiogenesis. EGF binds to the epidermal growth factor receptor (EGFR), triggering signal transduction via the RAS/MAPK pathway. HGF binds to the c-MET receptor, upstream of the RAS/MAPK pathway. Activation of the RAS/MAPK pathway leads to HCC growth and proliferation. Hepatocarcinogenesis may be related to the ability of the liver to respond to damage by regeneration. The continuous liver damage seen with chronic hepatitis or cirrhosis leads to increased turnover of hepatocytes. During normal hepatocyte regeneration, proto-oncogene activation and inactivation of suppressor genes occur. Chronic liver damage leads to a cellular reproduction, which may allow carcinogenic molecular changes to accumulate without repair.[36] The observation of apparent stepwise progression of small HCCs from regenerating nodules of liver cirrhosis supports this hypothesis.[37]

Cholangiocarcinoma

Inflammation appears to be a contributory factor to cholangiocarcinoma pathogenesis. Inflammatory signaling pathways are associated with DNA damage, blocking of apoptosis, and promotion of cell proliferation.[26] Development of malignant phenotype is associated with overexpression of proinflammatory cytokines in tumor stroma and upregulation of HER-2 signaling in epithelium.[37] Epigenetic factors including promoter region hypermethylation and microRNA dysregulation have been associated with development of cholangiocarcinoma.[8a] Dysregulation of developmental pathways including Notch signaling, Hedgehog signaling, and Wnt signaling may play a role in cholangiocarcinogenesis.[26]

Molecular analysis of IHCC specimens has suggested the presence of two distinct classes of IHCC with different outcomes. The more favorable inflammatory class is characterized by the activation of inflammatory signaling pathways, overexpression of cytokines, and STAT3 activation. The poorer prognosis proliferation class is characterized by activation of oncogenic signaling pathways including RAS, MAPK, and MET.[38] *KRAS* mutations have been associated with poor prognosis and are more commonly found in hilar EHCC than in IHCC or distal EHCC.[26,38a] Genomic profiling of EHCC specimens has suggested a poor prognosis group characterized by HER2 upregulation with frequent coactivation of ERBB3, EGFR, MET, and mTOR.[38]

PATHOLOGY AND PATHWAYS OF SPREAD

Primary liver tumors can be classified as benign or malignant and by their tissue of origin (hepatocyte or biliary). Benign tumors constitute 6% to 12% of all liver tumors and include hepatocellular hyperplasia, adenomas, hepatic cysts, mesenchymal hamartomas or hemangiomas, lipomas and fibromas. Of all malignant primary tumors, 85% to 95% are of epithelial origin (including HCC, fibrolamellar HCC, cholangiocarcinoma, and hepatoblastoma), whereas 1% to 3% are malignant mesenchymal tumors.

Hepatocellular Carcinoma

On gross examination, HCC appears as expanding (well-defined margin), infiltrative (poorly defined margin), or multifocal (with multiple tumors throughout the liver).[39] The microscopic appearance of HCC is similar to normal liver, both in cytologic features and in its platelike growth.[40] HCC commonly invades the portal vein, the inferior vena cava (IVC) and sometimes the hepatic vein. It may also invade the diaphragm. Portal nodes are the most likely nodes to be involved, but spread to celiac, gastric, and peritoneal nodes may also occur.[17] Metastases are uncommon at presentation, most often involving the abdominal cavity, the lungs, or bone.

Fibrolamellar HCC is a unique subtype that makes up about 5% of the cases in North America.[40] It is associated with the longest survival of HCC subtypes and is typically found in young women. Grossly, fibrolamellar carcinoma is an expanding, sclerosing tumor, characterized by septa of retracted collagenous structures radiating from a central region.[39] On cytologic examination, the tumor cells are large and polygonal, with a granular cytoplasm resulting from numerous

mitochondria and abundant fibrous stroma arranged in parallel lamellae around nests, cords, and sheets of tumor cells.[41]

Gallbladder Cancer

More than 98% of gallbladder cancers are adenocarcinomas and two thirds are moderately or poorly differentiated. Rare histologic types include squamous cell carcinoma, adenosquamous carcinoma, carcinoid, gastrointestinal stromal tumor, and small cell carcinoma.[42] Most gallbladder cancers arise in the setting of inflammation and associated gastric type or intestinal type metaplasia that progresses to dysplasia and then cancer.[43] Transformation from adenoma to adenocarcinoma also occurs in the gallbladder but is seen in less than 1% of cases.[42]

The gross appearance of gallbladder adenocarcinoma can vary from localized nodular growths to involvement of the entire organ.[44] Histologically, both grade and vascular invasion are of prognostic value. Papillary adenocarcinoma is a variant histologic type that makes up about 5% of the total number of cases and a significantly better prognosis than the more common type.[45] Mucinous carcinoma is another variant of adenocarcinoma, occurring in about 5% of cases and associated with perforation of the gallbladder.[44] Liver invasion is common and may occur by direct spread through the thin wall and singular muscular layer of the gallbladder or by lymphatic spread along portal tracts.[46] Spread to regional lymph nodes including cystic, pericholedochal, hilar, common hepatic, pancreaticoduodenal, and celiac nodes in found in 45% to 55% of patients treated surgically who undergo pathologic nodal evaluation.[47-49] Up to 80% of T3-4 patients will have involvement of regional nodes.[49] About 40% of patients with gallbladder cancer present with distant metastatic disease, most commonly involving liver or peritoneum.[50] Despite increased use of cholecystectomy for gallstone disease, there has been no decrease in the proportion of patients presenting with advanced disease.[51]

Cholangiocarcinoma

Cholangiocarcinomas are typically classified by location as intrahepatic, perihilar, and distal.[11] Most cholangiocarcinomas are mucin-producing adenocarcinomas arising from cholangiocytes that line the biliary tree.[27,52] IHCC may be classified based on macroscopic growth pattern as mass forming, which is the most common type, periductal infiltrating extending along the bile duct, and intraductal, which may have a papillary or tumor thrombus appearance.[53] EHCC can have an intraductal or exophytic (mass-forming) growth pattern. Exophytic tumors may exhibit a nodular or a periductal infiltrating growth pattern.[54] An abundant fibrous stroma with tumor cells in the center is characteristic.[50] As with gallbladder cancer, the papillary variant histologic type has a better prognosis.[55]

Cholangiocarcinoma typically spreads by direct extension along the biliary tree.[56] Tumor involvement of the cystic, hilar, or celiac lymph nodes is found in 30% to 50% of patients.[11,17,55] The incidence of distant metastases, most commonly involving liver, lung, or distant nodal sites, is about 30%, with a lower incidence of peritoneal disease than for gallbladder cancer.[11,56,57]

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Symptoms and Signs

Site of origin can alter the typical presentation of patients with hepatobiliary cancer. Patients with HCC or IHCC frequently present with right upper abdominal or epigastric pain or discomfort.[13,58-60] The pain is usually dull but may be sharp because of tumors causing capsular stretch. Occasionally, patients with HCC present with sudden, severe pain related to an acute HCC rupture and bleed. Patients may also present with awareness of an abdominal mass or increased girth related to ascites. Occasionally, HCC in patients with known cirrhosis may cause deterioration of liver function, leading to ascites, variceal bleed, jaundice, or encephalopathy. In contrast to primary liver tumors, 90% of patients with EHCC present with painless jaundice.[28] Cholangitis is present in 10% of patients, but more than half have nonspecific symptoms including malaise, abdominal discomfort, nausea, anorexia, and weight loss.[28] Patients with gallbladder cancer commonly present with abdominal pain and jaundice and may also have weight loss, anorexia, and fatigue.[61-63]

The most common physical finding in patients with primary hepatic tumors is hepatomegaly.[59,60] The liver is often smooth but may be nodular from tumor or cirrhosis. Patients with HCC may have a hepatic bruit because of a highly vascular tumor. Splenomegaly is also common in patients with cirrhosis or from portal hypertension secondary to tumor invasion of the portal vein. Ascites is a particularly ominous finding because it represents either peritoneal tumor involvement or hepatic dysfunction resulting from advanced cirrhosis, extensive replacement of the liver with tumor, or vascular tumor invasion. HCC invasion to the hepatic vein may lead to rapid decline in liver function, tense ascites, and tender hepatomegaly.

Patients with EHCC or gallbladder cancer are usually jaundiced and may have hepatomegaly or right upper quadrant tenderness on examination. Although a mass may be palpable, patients with gallbladder cancer are often thought to have benign disease until laparotomy and cholecystectomy.

Laboratory Studies

The goals of the workup of patients with malignant hepatobiliary tumors are to define the extent of the tumor and to assess liver function. The workup includes a complete blood count, liver function tests (albumin, bilirubin and coagulation studies), liver enzymes, and routine biochemistry (Table 49-1).

TABLE 49-1 Diagnostic Algorithm for Hepatobiliary Cancers

GENERAL
• History
• Physical examination
LABORATORY STUDIES
• Complete blood count
• Biochemistry panel, including liver function studies (albumin, bilirubin) and liver enzymes
• Coagulation studies (INR)
• Serum CA19-9 (if suspicious for cholangiocarcinoma)
• Alpha-fetoprotein (if suspicious for hepatocellular carcinoma)
• Hepatitis studies (HBsAg, HBsAb, HBcAb, anti-HCV)
RADIOGRAPHIC STUDIES
• Multiphasic liver CT or MR
• Transhepatic or endoscopic cholangiography (if bile duct blockage is present)

Anti-HCV, *Antibody to hepatitis C virus;* CT, *computed tomography;* HBcAb, *hepatitis B core antibody;* HBsAb, *hepatitis B surface antibody;* HBsAg, *hepatitis B surface antigen;* MR, *magnetic resonance;* INR, *international normalized ratio.*

Serum AFP is a widely used tumor marker for HCC, with normal values of 20 µg/L or less, and levels greater than 400 µg/L (4000 µg/L in patients with hepatitis) strongly suggestive of HCC.[64] Elevations in AFP between 20 µg/L and 400 µg/L may represent either an exacerbation of hepatitis or HCC.[29] Approximately 10% to 15% of HCCs do not secret AFP.[65] Serum CA19-9 has value as a tumor marker for cholangiocarcinoma but is less specific for EHCC than for IHCC as levels are affected by cholestasis and cholangitis.[26]

HCC outcomes in patients with hepatitis B or hepatitis C differ, as does toxicity and tolerability of treatment. High viral load before therapy has been associated with worse survival,[66] and reactivation of hepatitis B has been reported following treatment for HCC. Screening for viral hepatitis should be considered in all at-risk individuals.[67]

Approximately 5% of patients with HCC have a paraneoplastic syndrome,[68] such as hypoglycemia, erythrocytosis, hypercalcemia, or hypercholesterolemia.[59]

Radiographic Studies

Patients with suspected hepatic malignancy are often evaluated initially with US, which is operator dependent and less helpful in obese patients. The use of Doppler contrast US and harmonic imaging have improved its usefulness.[68,69] In planning for treatment, CT and MR imaging are the primary imaging modalities because of their ability to display hepatic segmental anatomy, the extent of tumor invasion to vasculature, and extrahepatic spread. Multislice spiral CT is required for liver imaging to be done in a single breath-hold to improve spatial resolution. Multiphasic imaging (arterial hepatic, portal venous, and delayed phase) is vital for assessing lesion vascularity, extent of tumor, and for diagnosis.[69] HCC is hypervascular and typically displays enhancement during the hepatic arterial phase with washout in venous and delayed phases (Figure 49-1), whereas cholangiocarcinoma demonstrates delayed enhancement. Modern MR protocols usually include parenchymal imaging with one or more types of contrast agents, MR angiography, or MR cholangiopancreatography (MRCP). Some have suggested that MR should be the imaging examination of choice for the liver in patients with cirrhosis because of the superior contrast resolution and inherent capability of multiplanar evaluation.[69,70] CT of the thorax, abdomen, and pelvis is recommended to rule out extrahepatic spread. Positron emission tomography (PET)-CT has been used to evaluate extrahepatic metastases; it is not as sensitive as multiphasic liver CT or MR for evaluating the hepatic extent of tumor, but it may be complementary to CT, MR, and MRCP, especially for Klatskin tumors.

In patients with hilar cholangiocarcinoma, MRCP has limited the role of endoscopic cholangiopancreatography to instances when drainage and decompression of the biliary system are required.[68] In addition to being noninvasive, MRCP has an accuracy of 95% in defining the location and extent of bile duct involvement.[71,72] The accuracy of prediction of vascular involvement and hepatic parenchyma invasion is around 70% to 80%[73,74] PET-CT has not been shown to be better than contrast enhanced CT scan for the detection of cholangiocarcinoma. Both modalities are poor for detection of regional lymph node metastases.[75] Endoscopy US with fine-needle aspiration of regional nodes has the highest sensitivity for the detection of nodal metastases.[54]

The usual appearance of EHCC on cholangiography is a stricture at the site of involvement with dilatation of the biliary

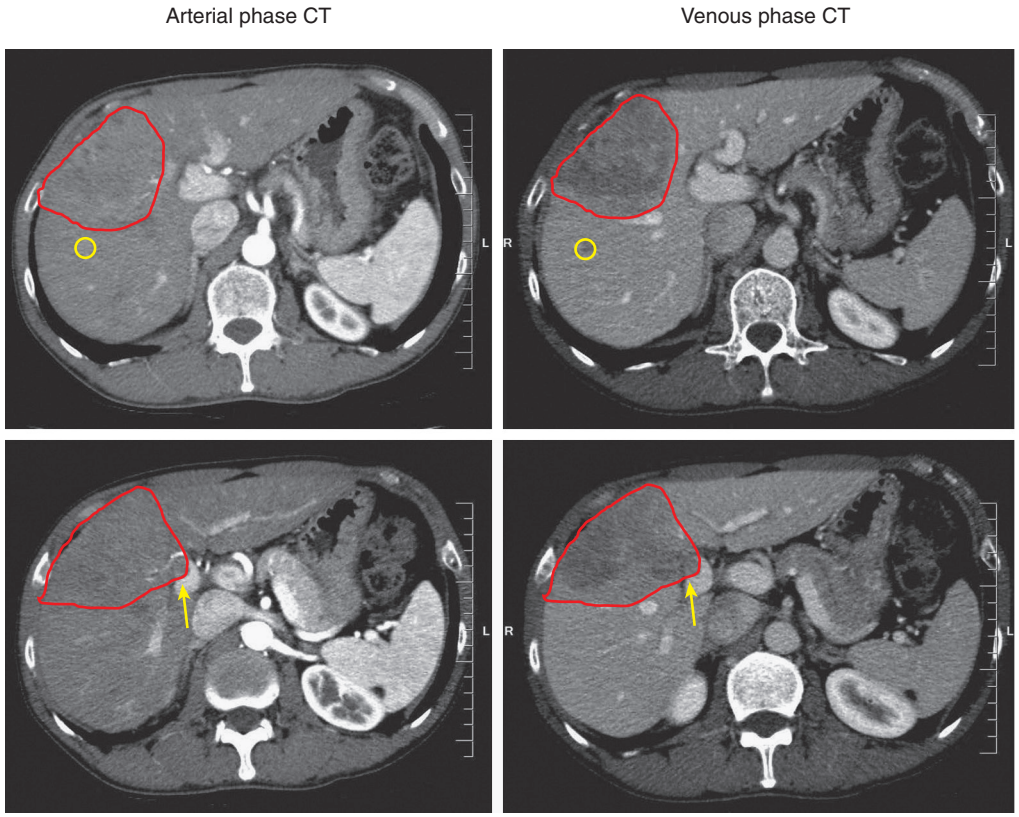

Figure 49-1 Arterial and delayed venous phase exhale breath-hold CT simulation images. The primary HCC *(red)* and satellite HCC *(yellow)* demonstrate arterial enhancement and washout on venous phase images. The *yellow arrow* highlights HCC invasion to the portal vein.

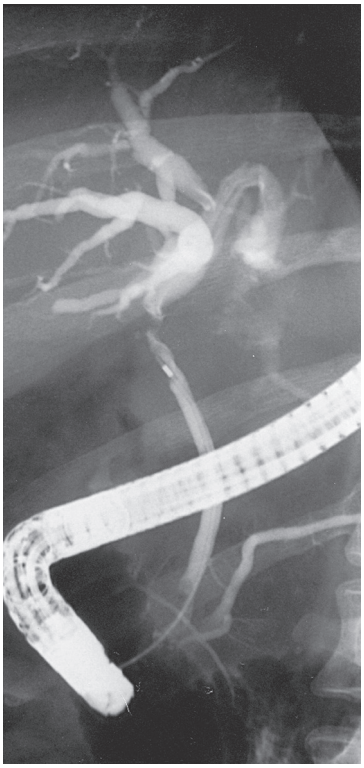

Figure 49-2 Endoscopic retrograde cholangiogram of a patient with a cholangiocarcinoma of the common hepatic duct. A stricture of the common hepatic duct can be seen proximal to the catheter, with dilatation of the intrahepatic biliary tree.

tract proximal to the stricture (Figure 49-2). The tumor itself may extend for some distance along the biliary tract. US, CT, and MR imaging of the abdomen frequently show only intrahepatic biliary dilatation (with or without hepatic atrophy) but no identifiable mass.[76] One area of particular difficulty is distinguishing bile duct cancer from PSC, with the latter typically showing diffuse rather than focal biliary narrowing.[77]

Although US is frequently obtained in patients suspected of having gallbladder disease, it is rarely helpful in diagnosing gallbladder cancer.[63] CT scan is the imaging modality of choice for postoperative evaluation of residual and metastatic disease.

Diagnosis

Hepatocellular Carcinoma

Multiphasic CT or MR imaging is most often used to obtain a HCC diagnosis with high predictive value, so that a biopsy can be avoided in most patients. Guidelines recommend no need for a biopsy of lesions greater than 1 cm in diameter in at-risk patients if there is classic arterial enhancement and delayed washout.[78] If there are nonclassic changes, a second imaging modality should be used. If that imaging study does not demonstrate classic HCC characteristics, then a biopsy is required. Repeat imaging is recommended for lesions less than 1 cm. There is a small risk of bleeding or tumor spillage following percutaneous biopsy.

Cholangiocarcinoma

Establishing a diagnosis of hilar cholangiocarcinoma can be difficult given the desmoplastic nature of the malignancy and the scant number of cells obtained by endoscopic brushing.[52] Conventional exfoliative or brush cytology has a sensitivity of around 50% for detection of cholangiocarcinoma.[79] The finding of polysomy using FISH is specific for malignancy with a positive predictive value approaching 100%.[225,226] The finding of polysomy on FISH combined with a dominant malignant stricture may be considered sufficient for diagnosis of cholangiocarcinoma.[52] Endoscopic US may be useful for evaluation of patients with suspected hilar cholangiocarcinoma, but transperitoneal fine-needle aspiration of the primary tumor is not recommended because of the potential for tumor seeding.[80]

Staging

The American Joint Committee on Cancer staging manual, seventh edition, has defined separate TNM staging systems for HCC, IHCCs, gallbladder tumors, and EHCCs and is divided into perihilar and distal bile duct lesions[81] (Table 49-2). The staging for both gallbladder cancers and EHCC tumors is primarily surgical.

For HCC, the Barcelona Clinic Liver Cancer (BCLC) staging system is widely used for treatment decision making (Figure 49-3). It is dependent on tumor factors, liver function (Child-Pugh score), and performance status. Very early (O) and early (A) BCLC stage HCC are potentially curable, whereas regional and systemic therapies are generally used for intermediate stage (B) and advanced stage (C) BCLC stage HCC.

Follow-up

After transplant or locoregional therapy with surgery, RT or RFA, imaging is recommended every 3 to 6 months for 2 years, and then every 6 to 12 months for 3 more years.

PRIMARY THERAPY

Hepatocellular Carcinoma

Very early and early (BCLC stage O and A) HCC are potentially curable with a variety of treatment. The most established treatments are hepatectomy, liver transplant, and RFA. Resection and transplantation result in the best outcomes, with 5-year OS of 50% to 85%. RFA has excellent outcomes in selected small HCC, with 5-year OS of 50% to 70%.[83-86] There is an emerging literature on the use of definitive RT for early stage HCC.

Surgical Resection

HCC resection is challenging because most patients have underlying liver dysfunction. The potential for tumor control needs to be balanced against the risk of complications. Tumor location, baseline liver function, and tumor biology should all be considered when making the decision for resection. In patients with cirrhosis considered for resection, portal hypertension is one of the strongest predictors of poor outcome, and surgery should not be offered in patients with manifestations of portal hypertension including hepatic encephalopathy, gastrointestinal bleeding, ascites, esophageal varices, splenomegaly, platelet count less than 100,000/mm^3, or a hepatic venous pressure gradient greater than or equal 10 mm Hg. Portal vein embolization (PVE) is sometimes used before hepatectomy to assess the ability of the future liver remnant to hypertrophy following surgery. The ability to hypertrophy after PVE is correlated with lower risk of liver failure postoperatively, and lack of hypertrophy has been suggested to be a contraindication to hepatectomy.

Anatomic resections are recommended for HCC, provided that adequate remnant liver volume can be preserved; however, nonanatomic resections are an option, and there is a growing literature on laparoscopic resections. Complications and

TABLE 49-2 TNM Classification for Hepatobiliary Cancers

PRIMARY TUMOR: LIVER	
T0	No evidence of primary tumor
T1	Solitary tumor without vascular invasion
T2	Solitary tumor with vascular invasion, or multiple tumors, none more than 5 cm
T3a	Multiple tumors, any more than 5 cm
T3b	Tumors involving a major branch of the portal or hepatic vein(s)
T4	Tumor(s) with direct invasion of adjacent organs other than the gallbladder or with perforation of the visceral peritoneum
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
M0	No distant metastases
M1	Distant metastases
PRIMARY TUMOR: INTRAHEPATIC BILE DUCT	
T0	No evidence of primary tumor
Tis	Carcinoma in situ (intraductal tumor)
T1	Solitary tumor without vascular invasion
T2a	Solitary tumor with vascular invasion
T2b	Multiple tumors, with or without vascular invasion
T3	Tumor perforating the visceral peritoneum or involving the local extrahepatic structures by direct invasion
T4	Tumor with periductal invasion
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis present
PRIMARY TUMOR: GALLBLADDER	
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor invades lamina propria or muscle layer
T1a	Tumor invades lamina propria
T1b	Tumor invades muscle layer
T2	Tumor invades perimuscular connective tissue; no extension beyond serosa or into liver
T3	Tumor perforates the serosa (visceral peritoneum) or directly invades the liver or one other adjacent organ or structure, such as the stomach, duodenum, colon, pancreas, omentum, or extrahepatic bile ducts
T4	Tumor invades main portal vein or hepatic artery or invades multiple extrahepatic organs or structures
N0	No regional lymph node metastasis
N1	Metastases to nodes along the cystic duct, common bile duct, hepatic artery, or portal vein
N2	Metastases to periaortic, pericaval, superior mesentery artery, or celiac artery lymph nodes
PRIMARY TUMOR: PROXIMAL EXTRAHEPATIC CHOLANGIOCARCINOMA/PERIHILAR (RIGHT, LEFT, AND COMMON HEPATIC DUCT)	
Tis	Carcinoma in situ
T1	Tumor confined to the bile duct, with extension up to the muscle layer or fibrous tissue
T2a	Tumor invades beyond the wall of the bile duct to surrounding adipose tissue
T2b	Tumor invades adjacent hepatic parenchyma
T3	Tumor invades unilateral branches of the portal vein or hepatic artery
T4	Tumor invades main portal vein or its branches bilaterally, common hepatic artery, or the second-order biliary radicals bilaterally, or unilateral second-order biliary radicals with contralateral portal vein or hepatic artery involvement
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis (including nodes along the cystic duct, common bile duct, hepatic artery, and portal vein)
N2	Metastasis to periaortic, pericaval, superior mesenteric artery, or celiac artery lymph nodes
PRIMARY TUMOR: DISTAL EXTRAHEPATIC CHOLANGIOCARCINOMA (FROM CYSTIC DUCT INSERTION INTO COMMON HEPATIC DUCT)	
Tis	Carcinoma in situ
T1	Tumor confined to the bile duct wall
T2	Tumor invades beyond the wall of the bile duct
T3	Tumor invades the gallbladder, pancreas, duodenum, or other adjacent organs without involvement of the celiac axis or the superior mesenteric artery
T4	Tumor involves the celiac axis or the superior mesenteric artery
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
DISTANT METASTASIS	
M0	No distant metastasis
M1	Distant metastasis

From Edge SB, Byrd DR, Compton C, et al, editors: AJCC cancer staging manual, ed 7, New York, 2009, Springer.

postoperative liver insufficiency are closely associated with increased mortality following hepatectomy. State-of-the-art surgery is associated with operative mortality rates of 1% to 3% and 5-year OS of 40% to 50%.[87] Approximately 40% to 80% of patients relapse. Positive resection margins, microvascular invasion, poorly differentiated HCC, and satellite lesions predict for relapse.[87]

Adjuvant Therapy

Adjuvant or neoadjuvant systemic, regional chemotherapy, or TACE has not been shown to be beneficial following surgery in high-risk HCC.[88] There is limited evidence that adjuvant Lipiodol therapy or immunotherapy may improve disease free survival after HCC resection.[89]

Liver Transplantation

An advantage of liver transplantation for patients with HCC and underlying cirrhosis is that the entire liver is removed, eradicating all microscopic and gross hepatic HCC and treating the underlying cirrhosis. Limitations of liver transplantation are the shortage of donor organs and the high cost. Only selected early HCC are eligible for transplantation (e.g., one lesion less than 5 cm),[90] and many patients drop off the wait list for a transplant because of HCC progression. Five-year OS of at least 70% and relapse rates lower than 15% are expected after transplant for HCC.[90,91] TACE, RFA, or RT are often used as bridging therapies for patients with HCC at risk of growing while on the wait list.

Percutaneous Ablation

RFA is an alternative treatment for small HCC with long-term survival in selected patients.[85,92] RFA involves placing a needle electrode in the tumor and applying a high-frequency alternating current to heat the surrounding tissue to produce necrosis. The best results are seen in tumors less than 3 cm that are not adjacent to large vessels.[92] In one review of 3670 patients treated by RFA, the mortality rate was 0.5% and the complication rate was 9%.[93] Subcapsular location and poorly differentiated HCC have been implicated in needle-track seeding. Comparative studies of RFA with surgery have been inconclusive. Ablation may also be accomplished with microwave, laser coagulation, or cryoablation or with the alcohol injection. A randomized trial demonstrated reduced rates of local progression (2% versus 11%) and improved survival (74% versus 57%) with RFA compared with percutaneous ethanol injection.[94] Cryoablation is associated with higher complications and inferior outcomes. Microwave and laser coagulation clinical data are emerging.[95]

Radiation Therapy As Definitive Therapy

Proton therapy has been used to treat early stage HCC with excellent outcomes, as recently reviewed by Dionisi et al.[96] Most studies, predominantly retrospective from Asia, have used standard or hypofractionation (e.g., 77 GyE in 35 fractions for tumors less than 2 cm from luminal tissues, 72.6 GyE in 22 fractions for tumors less than 2 cm from the porta hepatis, and 66 GyE in 10 fractions for peripheral tumors). Excellent 5-year OS ranging from 34% to 45% and 5-year local control (LC) of 83% to 90% have been observed, as summarized in Table 49-3.[97-101] Smaller prospective studies reported similar outcomes for 51 patients with peripheral HCC[101] and complete responses in selected patients who went on to liver transplantation following 63 GyE in 15 fractions.[102] Carbon ions (49.5 GyE to 79.5 GyE in 15 fractions) have also been used to treat early stage HCCs, with 5-year LC and OS of 80% and 25%, respectively.[100,103] Hypofractionated carbons (e.g., 40 GyE in 4 fractions) has also been used with excellent local control.[104]

A French multiinstutional prospective Phase II study of conformal RT (66 Gy in 2 Gy per fraction) in 25 Child-Pugh A and B patients with cirrhosis with early stage HCC (less than or equal to 5 cm for single nodules and less than or equal to 3 cm for two nodules) reported 78% local control at a median follow up of 29 months. Grade-4 toxicities occurred only in patients with Child-Pugh B (22%).[105]

SBRT (33 Gy to 60 Gy in three to eight fractions) results have also been reported in small prospective and larger retrospective studies for definitive treatment,[106-119] or as a bridge to transplant,[120] in patients with early stage HCC (Table 49-3). A Korean registry study of 93 patients with HCC (26% with Child-Pugh B, 1 cm to 6 cm) treated with 30 Gy to 40 Gy in three to four fractions reported 3-year LC and OS of 92% and 54%, respectively.[109] LC was 100%, 93%, and 76% for tumors less than 2 cm, 2 cm to 3 cm, and 3 cm to 6 cm, respectively. A Japanese retrospective study of 185 patients (84% T1, 27 Child-Pugh B) reported 3-year LC and OS of 91% and 70%, respectively, following 35 Gy to 40 Gy in four fractions.[107] A decline in Child-Pugh score was seen in 10% at 3 months. Other studies have had similar outcomes, as shown in Table 49-3.

Intrahepatic Cholangiocarcinoma

Surgery is the treatment of choice for resectable patients, but less than 20% are candidates for resection, usually as a result of the extent of hepatic involvement.[121] Of those who are resected, more than 60% relapse, most commonly in the remnant liver.[121,122] R0 resection is predictive of survival, but positive margins are common.[11] Five-year OS following resection ranges from 17% to 40% for all patients and 44% to 63% for R0 patients[11] and median survival is about 3 years.[121,122] In addition to margin status, other factors predictive of survival include regional node metastases, multiple tumors in the liver, tumor diameter greater than 5 cm, and cirrhosis.[11,121-123] Liver transplantation for IHCC is not standard because of high relapse rates and 5-year OS of only 20% to 30%.[124] The strategy of neoadjuvant therapy with chemotherapy and locoregional therapy with TACE or SBRT before transplant is being investigated.[124]

Gallbladder Carcinoma

Complete surgical resection is the only curative therapy for gallbladder cancer, but most nonincidentally discovered gallbladder cancers are not resectable for cure.[125,126] Even when surgery is performed with curative intent, complete resection (R0) is only achieved in about half of cases.[127] Most T1 cancers are discovered incidentally after cholecystectomy for cholelithiasis.[128] T1a cancers are adequately treated with simple cholecystectomy with 5-year OS of about 60%.[129] Extended cholecystectomy including resection of 2 cm of liver margin and dissection of N1 lymph nodes may be beneficial for patients with T1b cancers.[128,129] Five-year OS may be increased from 40% with simple cholecystectomy to 60% with extended cholecystectomy.[129] Diagnosis of incidental gallbladder cancer laparoscopically may require excision of the port sites given the 10% to 20% rate of port site recurrence.[128]

For patients with T2 cancers, extended cholecystectomy is associated with improved survival.[51,127,128] The most important prognostic factor for relapse is lymph node metastases. Positive nodes are found in about half of T2, most commonly in the pericholedochal and pericystic nodal regions followed by portal vein, hepatic artery, and peripancreatic nodes.[129a,130,131] Five-year OS may exceed 50% in pT2N0 patients, but falls to around 20% in patients who are node-positive.[48]

A minority of patients with T3-4 or node-positive disease may be cured with radical surgery alone.[132-138] Five-year OS is 20% to 25% for T3N0 or T1-2N1 disease but falls to less than 10% for T3N1 or T4 disease.[48] Lymph node metastases are found in 70% to 80% of T3 patients.[48,49] The role of more extensive surgery, including pancreaticoduodenectomy, right colectomy, and nephrectomy, has not been established. Paraaortic lymph node metastasis is present in 19% to 25% of patients with locally advanced disease,[139] but paraaortic lymphadenectomy is not warranted.[140]

Adjuvant Therapy

The majority of patients with gallbladder cancer experience disease relapse following curative intent surgery.[57] Following simple cholecystectomy, one literature review reported an 86% rate of local relapse in patients dying within 5 years of surgery.[141] Although isolated locoregional relapse is less common following extended cholecystectomy, locoregional relapse may approach 30%.[57] Despite the high risk of disease relapse, there are no prospective trials demonstrating a survival benefit to adjuvant therapy.

Retrospective studies suggest the possibility of benefit of adjuvant chemoRT. A Mayo Clinic series evaluated adjuvant chemoRT in 73 patients who underwent curative-intent surgery, 25 of whom received postoperative chemoRT (median dose of 50.4 Gy in 28 fractions with 5-fluorouracil [5-FU]–based concurrent chemotherapy).[142] Patients receiving adjuvant therapy had disease of a significantly higher stage, with 80% of the patients in the adjuvant group having stage II disease compared with only 21% in the surgery alone group ($p < 0.0001$). In the multivariate Cox model, increasing T and N classification as well as histologic type other than adenocarcinoma were significant predictors for worse OS rates. Additionally, adjuvant chemoRT was statistically significant for improved OS after adjusting for these multivariate prognostic factors (hazard ratio [HR] for death, 0.3; 95% CI, 0.13 to 0.69; $p = 0.004$). A Korean retrospective series of 100 patients and a Surveillance, Epidemiology and End Results (SEER) analysis both suggest a survival benefit to adjuvant chemoRT following resection in patients who are node positive.[143,144] In patients with pathologically evaluated lymph nodes, another SEER analysis found adjuvant RT to be associated with a 35% risk of death reduction.[48] A propensity score–matched analysis using SEER data also suggested a survival benefit to adjuvant RT (chemoradiation not evaluated) at 1 year, but not at 5 years.[145]

Extrahepatic Cholangiocarcinoma

Curative options for hilar EHCC include surgical resection and neoadjuvant chemoradiation followed by liver

transplantation.[26] Standard surgical resection consists of lobar hepatic and bile duct resection, regional lymph node dissection, and Roux-en-Y hepaticojejunostomy.[26] Contraindications to standard resection include contralateral or bilateral vascular encasement or extension to secondary biliary branches.[26] Major prognostic factors include margin and nodal status. A minimum of seven lymph nodes should be evaluated.[146] R0 resection is possible in 20% to 40% of patients explored with curative intent.[11,147,148] R0 resection is more likely to be achieved with hepatic resection than with bile duct resection alone.[148] Five-year OS is in the range of 30% to 40% after R0 resection and 10% to 25% after R1 resection.[11] In a series of 44 patients with hilar EHCC from the University of Louisville treated since 2002, R1 resection followed by EBRT with or without chemotherapy was associated with better survival than nonoperative management (median survival 21 months versus 8 months).[149]

Distal cholangiocarcinoma is best treated by pancreaticoduodenectomy.[26] R0 resection is more frequently achieved with rates approaching 80%.[11] Lymph node metastases are more commonly reported compared with hilar EHCC with rates as high as 60%.[11] Five-year OS is usually in the range of 20% to 30%[11,153a-156a] but may exceed 50% in patients who are node-negative who undergo R0 resection.[154] A minimum of 11 lymph nodes should be evaluated in resected patients.[155] For patients who undergo R0 resection, survival rates are similar for hilar and distal EHCC.[156]

Adjuvant Therapy

Potential indications for postoperative chemoradiation include positive margins (R1 resection) and regional lymph node metastases. Locoregional relapse is the predominant failure pattern for hilar EHCC and locoregional relapse has been reported in 50% or more of patients who were resected.[150,151] Locoregional relapses have been reported to comprise 65% of all relapses of hilar EHCC and nearly 60% of patients with relapse have isolated locoregional disease.[57] Despite this, there is a paucity of prospective data evaluating adjuvant therapy following resection.

Retrospective series have suggested the possibility of a survival benefit associated with adjuvant RT. In an EORTC multiinstitutional survey of 55 resected hilar EHCC patients (51 of 55 R1), adjuvant radiation in 38 patients was associated with a 19-month median and 31% 3-year survival compared to 8-month median and 10% 3-year survival in 17 patients treated with surgery alone ($p = 0.0005$).[152] A University of Amsterdam report of 91 patients with resected hilar EHCC found an 8-month median survival in 20 patients with surgery alone compared to 24 months in 71 patients treated with adjuvant EBRT with or without brachytherapy ($p < 0.01$).[153] A systematic review of 20 adjuvant studies evaluated chemotherapy alone, RT alone, and chemoradiation (chemoRT) in EHCC and gallbladder cancer. A trend toward improved survival was observed with any adjuvant therapy (OR, 0.74, $p = 0.06$) with better results in patients treated with chemotherapy or chemoRT. Significant benefit for adjuvant therapy was noted in node positive patients and following R1 resection.[157]

A prospective single arm SWOG (S0809) study evaluating postoperative chemoRT in 80 patients with EHCC or gallbladder cancer has been completed. Eligibility included T2-T4 primary or positive nodes or positive margins and treatment consisted of four cycles of gemcitabine and capecitabine followed by RT with capecitabine (three-dimensional: 54 Gy in 30 for RO, 59.4 Gy in 33 for R1 resection, and 52.5 Gy to 55 Gy in 25 for R0 and R1 resections). Two-year overall survival was 65% in 79 eligible patients (54 R0 67%, 25 R1 60%).

Neoadjuvant Chemoradiation Plus Transplant

Given the predominant local relapse pattern of hilar EHCC, liver transplant has been investigated as a curative option for patients who are unresectable. Early results with transplant alone were disappointing with relapse rates of 53% to 84% and 5-year OS in the 25% to 30% range. Interestingly, about half of the relapses were in the liver allograft.[158,159] A small group of patients at Mayo Clinic were treated with EBRT with 5-FU and brachytherapy with a 22% 5-year OS (Table 49-4).[160] Based on this observation, a protocol of neoadjuvant chemoRT including brachytherapy followed by liver transplantation was developed.[161] Patients with unresectable hilar cholangiocarcinoma above the cystic duct, less than 3 cm maximum diameter without intrahepatic or extrahepatic metastases, are potential candidates for liver transplantation. In addition, any patient with PSC with hilar cholangiocarcinoma is a potential candidate. The diagnosis may be established by transcatheter biopsy or brush cytology or by the combination of a malignant appearing stricture on imaging and a CA 19-9 >100 U/mL or polysomy on FISH. Concurrent chemoradiation, EBRT of 45 Gy in 1.5 Gy fractions twice daily over 3 weeks with concomitant PVI 5-FU or capecitabine, is followed by transcatheter iridium (20 Gy to 30 Gy to a 1-cm radius with low dose rate [LDR] or 16 Gy in four twice daily fractions over 2 days with high dose rate [HDR] brachytherapy). Exploratory laparotomy or laparoscopy with sampling of regional nodes is performed before liver transplant to confirm lymph nodes are not involved.[26,159-164]

From 1992 to 2011, 215 patients initiated neoadjuvant therapy at Mayo Clinic and 136 have undergone liver transplant. Overall survival at 5 years is 56% in patients who initiated neoadjuvant therapy and 74% in transplanted patients (Table 49-4). Five-year OS is higher in transplanted patients with PSC (79% versus 64%). Only 18% of transplanted patients have experienced disease relapse. Vascular complications including portal vein stenosis with or without thrombosis have been observed in 20% of patients.[158,164] Five-year OS in a contemporary group of patients who are resectable treated with standard resection at Mayo Clinic was 21% (Table 49-4).[163]

A multiinstitutional report from 12 transplant centers found neoadjuvant chemoradiation followed by transplant to be associated with 53% 5-year survival in all patients and 65% in patients who underwent transplant.[158] Patients with tumors greater than 3 cm maximum diameter and those who underwent transperitoneal biopsy had shorter survival times[158] In addition, CA 19-9 ≥ 500 U/mL and tumors greater than 3 cm at presentation predicted for dropout before transplant and elevated CA 19-9, portal vein encasement, and residual tumor in explant predicted for disease relapse after transplant.[151]

LOCALLY ADVANCED DISEASE AND PALLIATION

Hepatocellular Carcinoma

Intermediate Stage

BCLC intermediate (B) and advanced (C) stage HCC are most often unresectable and thought to be incurable. If resection may be conducted safely, it is associated with the best outcomes. In patients who are unresectable Child-Pugh A, regional and systemic therapies improve survival. Experience with RT is increasing, although there are no published comparative studies. Prognostic factors for patients with unresectable HCC include Child-Pugh score, AFP levels, portal vein tumor thrombosis, the presence of serologic markers for hepatitis B or C virus, and overall HCC burden.[164,165] More patients

ultimately develop liver failure because of HCC progression, underlying liver dysfunction, or treatment inducted liver toxicity.

Regional Treatment

Because HCC derives 80% of its blood supply from the hepatic artery compared to the liver parenchyma that derives most its blood supply from the portal vein, hepatic arterial–directed therapies are attractive options for HCC. Hepatic arterial chemotherapy, transarterial embolization (TAE), TACE, and transarterial radiation embolization (TARE) have been used on their own or combined with other therapies. Although hepatic arterial chemotherapy has had good response rates,[166] there was no significant improvement in survival in one randomized trial.[167]

TACE refers to delivery of embolization material (typically gelatin sponge, polyvinyl alcohol, or starch microspheres) with or without chemotherapy via injection into the right or left hepatic artery or a first-, second-, or third-order branch, depending on the disease extent. Meta-analyses and Phase III studies have shown a survival advantage to TACE versus supportive care in locally advanced HCC (2-year OS, 33 versus 11% in predominantly patients with hepatitis B[7] and 63% versus 27% in predominantly patients with hepatitis C.[6] The best results have been confined to patients with Child-Pugh A without main branch portal vein thrombosis. TACE is often delivered multiple times until the HCC no longer enhances, if toxicity is acceptable. Common transient complications from TACE include abdominal pain, nausea, fever, fatigue, and elevation of liver enzyme levels. Rare complications include exacerbation of liver failure, liver abscess, gastrointestinal bleeding, and bile duct injury. TAE has not been as extensively studied, but it is sometimes used to treat a ruptured HCC.

There is an emerging experience with TARE, or selective internal RT, which involves delivery of radioactive particles

(e.g., iodine-131 [^{131}I]–labeled Lipiodol or yttrium-90 [^{90}Y]–tagged microspheres) via the hepatic artery, with minimal embolization. Studies of ^{131}I Lipiodol have suggested efficacy, but it is not available in the Unites States.[168] There are many single institutions series of ^{90}Y-tagged microspheres (delivered via glass [TheraSphere MDS Nordion, Ottawa, Canada]) or resin spheres (SIR-Spheres SIRTeX Medical, Lake Forest, IL) showing response rates of 40% to 60% and median time to progression of 7.9 months in one prospective series of 291 patients, with worse outcomes in patients with Child-Pugh B and patients with tumor thrombosis.[169] Side effects include fatigue, pain, nausea/vomiting, and liver toxicity.

Systemic Treatment

Sorafinib, an oral multikinase inhibitor that has activity against Raf-1, B-Raf, VEGFR2, DGFR, c-Kit, and other tyrosine kinases, improves survival in patients with advanced HCC unsuitable for TACE. In the SHARP trial of 602 patients, patients randomized to sorafenib had improved median survival (10.7 months versus 7.9 months, $p < 0.001$), and time to progression (5.5 months versus 2.8 months).[170] Side effects including diarrhea, hand-foot skin reaction, and weight loss were tolerable. A second randomized trial in Asia reported an improvement in median survival from 4.2 months to 6.5 months with sorafenib, ($p < 0.05$).[171] Chemotherapy is generally toxic for patients with HCC and has not been associated with high response rates.[172,173] Doxorubicin has activity against HCC and is being investigated in a Phase III study comparing sorafenib to sorafenib plus doxorubicin (NCT01840592).

Radiation Therapy

Although RT has not been accepted as a standard therapy for locally advanced HCC, HCC is a radiosensitive tumor and should be considered in selected patients, especially if other local therapies are not feasible. The challenge is to delivery enough RT for tumor control, without causing liver toxicity. HCC tends to remain liver confined and frequently invades the portal vein, providing rationale for a local therapy such as RT.

The University of Michigan group first showed that tumoricidal doses could be delivered to focal unresectable HCC, with dose based on volume of spared liver or estimate of normal tissue complication probability (NTCP).[174-177] The prescribed dose ranged from 40 Gy to 90 Gy (median 60.75 Gy) in 1.5 Gy twice daily with hepatic arterial FudR. One-year LC and survival were 81% and 57%, respectively, in 35 patients with unresectable HCC without portal vein invasion.[177]

Conformal RT has been used to treat unresectable HCC, sometimes in combination with TACE, mostly in Asia (Table 49-5).[178-186] A recent review[178] suggested that patients treated with TACE plus RT had improved survival rates compared with patients treated with TACE alone (OR, 2.23); however, there is a need for confirmatory studies. Definitive RT has been used to treat HCC with tumor vascular invasion, with high local control and median survival generally better than that expected following other therapies.[186a,186b,187-192] One notable Phase II study from Korea, reported a median survival of 13.1 months in 40 patients with HCC with portal vein tumor thrombosis after 45 Gy in 25 fractions delivered with concurrent 5-FU.[190]

SBRT has also been used, with or without TACE, for locally advanced HCC, including patient with portal vein tumor thrombosis, with doses ranging from 30 Gy to 50 Gy in doses per fraction of 6 Gy to 15 Gy[186b,193-195] (Table 49-5). In sequential Phase I (Trial 1) and Phase II (Trial 2) trials at Princess Margaret Cancer Centre, SBRT was used to treat 102 patients with unresectable HCC unsuitable for TACE or RFA (55% with vascular invasion). LC at 1 year was 87% following a median dose of 36 Gy in six fractions (24 Gy to 54 Gy in six fractions). Median survival was 17 months and on multivariate analysis, absence of tumor vascular thrombosis and being treated on Trial 2 were associated with improved survival.[195] Five-fraction SBRT is being investigated in a Phase III study comparing sorafenib with SBRT followed by sorafenib (NCT01910909). Protons have also been used to treat locally advanced HCC with excellent outcomes.[196]

Advanced Stage

BCLC terminal stage (D) HCC has a poor prognosis and best supportive care is generally recommended. Many patients develop hepatic pain or discomfort, and low-dose palliative RT may be used with the sole goal of reducing patient pain. In one study, 8 Gy in one fraction to the whole liver resulted in a patient reported improvement of pain in 50% of patients.[197] Other palliative fractionations include 10 Gy in five fractions and 21 Gy in seven fractions.

Intrahepatic Cholangiocarcinoma

For the majority of patients with unresectable disease, a number of locoregional therapies have been investigated. TACE is associated with a 12-month to 15-month median survival in several series.[198] TARE with ^{90}Y has been shown to be tolerable with partial response or stable disease in 85% of patients and median survival of 22 months.[199] Preliminary reports on the use of SBRT for IHCC using doses of 24 Gy to 60 Gy in three to six fractions suggest the treatment is well tolerated with local control rates in excess of 50% and median survival of 11 months to 15 months.[188,200] RFA for IHCC <5 cm in diameter was associated with a 39-month median survival and 15% 5-year survival in a small series of 13 patients.[201]

Gallbladder Cancer and Extrahepatic Cholangiocarcinoma

The combination of gemcitabine and cisplatin was compared to gemcitabine alone in the 410 patient ABC-02 Trial, which included patients with locally advanced or metastatic cholangiocarcinoma, gallbladder cancer, or ampullary cancer. Seventy-five percent of patients on the trial had metastatic disease. A significant survival benefit was demonstrated for the two-drug combination with median survival of 12 months versus 8 months ($p < 0.001$). Progression-free survival was 8 months versus 5 months ($p < 0.001$). Most patients died within 3 years.[8]

Patients with unresectable hilar cholangiocarcinoma experience progressive bile duct obstruction resulting in hepatic dysfunction and potentially fatal sepsis.[202] Palliative of obstruction may be accomplished with operative bilioenteric bypass or preferably with endoscopic or percutaneous stent placement.[203,204] For patients who are not surgical candidates, metal stents are preferred over plastic because of longer patency and fewer re-interventions.[203] The median survival for patients treated with palliative stent placement alone is generally 3 months to 6 months.[202] Small prospective studies evaluating photodynamic therapy (PDT) in addition to stenting have suggested improvement in median survival to 14 months to 16 months compared to 3 months to 6 months with stent alone.[202,205] Three-year survival is less than 10%.[204]

External Beam Irradiation with or without Chemotherapy or Brachytherapy

A summary of published series of high dose RT (alone or plus brachytherapy or concurrent chemotherapy) for EHCC is shown in Table 49-4.[150-152,159-164,207,210-214] The combination of EBRT and brachytherapy has been used in selected patients with unresectable hilar EHCC and is associated with a median survival of approximately 12 months.[206] Some investigators have reported better survival in patients receiving >55 Gy,[207] and brachytherapy allows for significant dose escalation. A SEER analysis found a median survival of 11 months in patients whose treatment included a brachytherapy component compared to 4 months without brachytherapy.[206] In contrast to the predominantly locoregional pattern of relapse observed after surgical resection, some investigators have reported distant relapse, primarily in liver and peritoneal cavity, to be the predominant relapse pattern following chemoRT with or without brachytherapy.[208]

The combination of concomitant 5-FU–based chemotherapy with EBRT and brachytherapy appears promising. In a Mayo Clinic analysis of 24 patients with proximal EHCC treated with EBRT and brachytherapy, 9 patients received concurrent 5-FU and 5-year OS was observed in 22%.[160] In the Mayo Clinic transplant experience with this regimen of concurrent chemoRT plus brachytherapy given before transplant, there was pathologic complete response in 53% of patients.[159,161-164]

Early experience with charged particle therapy also supports the concept of dose response in cholangiocarcinoma. In a series of 28 patients with primary and recurrent cholangiocarcinoma including IHCC, EHCC, and gallbladder cancer treated with protons, biologic effective doses (BEDs) >70 Gy[10] was associated with 83% local control at 1 year compared to 22% for lower effective doses.[209]

Intraoperative RT is another technique that has been used to achieve dose escalation.[210-212]

IRRADIATION TECHNIQUES AND TOLERANCE

Dose-Limiting Organs

The potential for serious treatment related intolerance (RT or concurrent chemoRT) necessitates individualization of prescription dose for patients with hepatobiliary carcinoma, based on the volume of liver that may be spared from RT, baseline liver function (Child-Pugh A, B7 versus higher), and proximity of tumor to luminal gastrointestinal tissues. The major dose-limiting organ for RT to the hepatobiliary system is the liver. RT or chemoRT-induced liver disease (RILD) is separated into "classic" and "nonclassic" RILD. Classic RILD presents with anicteric hepatomegaly and ascites, typically occurring between 2 weeks to 3 months after RT or chemoRT, with an elevated alkaline phosphatase.[214] Nonclassic RILD is more challenging to prevent and includes any liver toxicity occurring within 3 months of radiation (e.g., decline in Child-Pugh score or elevated liver enzymes). It is more likely in patients with baseline cirrhosis or Child-Pugh B or C liver disease. Reactivation of hepatitis B has been reported after RT, and antiviral therapy before RT can reduce this risk.[213,214] For any patients with RILD, restaging, possible paracentesis of the ascitic fluid to rule out disease relapse, and referral to hepatology is recommended. RILD has been treated with diuretics, steroids, and occasionally anticoagulation.[214]

The risk for RILD is dependent on the volume of liver irradiated (or volume of liver spared from RT).[214] For patients with Child-Pugh A, whole-liver RT to a total dose less than 28 Gy in 2 Gy fractions has a low risk of toxicity, whereas 36 Gy in 2 Gy fractions is associated with a 50% risk of toxicity. With conformal RT planning, far higher doses can be delivered to partial liver volumes safely. Using standard fractionation, it is recommended that the mean liver dose be kept less than 28 Gy for patients with Child-Pugh A HCC. For SBRT, it has been recommended to maximize the volume of liver spared from RT (e.g., >800 cc to receive <10 Gy to 18 Gy in three to five fractions). Effective liver volume irradiated (Veff) or mean dose to the liver (minus the GTV) has also been used to allocate dose for SBRT. Patients with Child-Pugh B or C are at far higher risk for liver toxicity than those with Child-Pugh A liver cancer. For patients with Child-Pugh B treated with four to six fractions, the mean liver dose should be kept as low as possible (<6 Gy). Patients with Child-Pugh B7 fare better than those with Child-Pugh scores of B8 or higher,[215] who are not recommended to be treated outside the bridge to transplant setting.[214]

The luminal gastrointestinal (GI) tissues often limit the safe dose that may be delivered to HCCs in close proximity to GI luminal tissues. Of 128 University of Michigan patients with primary hepatobiliary malignant tumors treated with 40 Gy to 90 Gy (in 1.5 Gy per fraction, twice daily), 7% developed upper GI bleeding. The maximum dose to the stomach or duodenum was <68 Gy. A dose of 60 Gy to one third of the stomach has been associated with a 5% risk of ulceration or

perforation.[216] The Mayo Clinic data for biliary tract cancer suggest that a dose of approximately 55 Gy to the stomach or duodenum is associated with a 5% to 10% risk of severe GI complications[217]; and the risk increases to 30% to 40% with doses of more than 55 Gy. For SBRT, the maximal doses to luminal GI tissues should be kept to a minimum (<30 Gy to 36 Gy in five to six fractions), and there is a suggestion that delivering SBRT every other day may reduce the risk of toxicity.[218] The proximity of HCC to luminal GI tissues was an independent risk factor for local failure in one proton series.[100]

Biliary toxicity may lead to biloma and cholangitis 1 to 3 years post RT,[102] and the risk is higher hypofractionation or brachytherapy. It has been suggested that doses less than 40 Gy in five fractions to the common bile duct are associated with a low risk of toxicity, but the number of long-term survivors investigated is low.

Kidney toxicity is a theoretical consideration, although few patients develop clinical toxicity. Mean dose to both kidneys should be less than 18 Gy, and traditional three-dimensional treatment planning goals are to spare at least two thirds of a functioning kidney from 18 Gy or more. Other toxicities such as skin toxicity, rib pain, or fracture are uncommon toxicities seen after SBRT.

Irradiation Technique

Hepatocellular Carcinoma and Intrahepatic Cholangiocarcinoma

Radical RT of hepatobiliary tumors is only possible with three-dimensional CT–based, conformal techniques. Ideally arterial, venous, and delayed phase CT or MR images should be obtained in breath-hold at the time of simulation and fused for optimal contouring (Figure 49-4). If that is not possible, image registration of diagnostic quality images with the planning CT is needed. MR is often complementary to CT. The gross target volume (GTV) should include all enhancing parenchymal tumor and vascular HCC. The clinical target volume should include the GTV as well as any adjacent regions at risk such as a RFA cavity or prior TACE zone. Care is needed to ensure delineation of the entire extent of tumor thrombus, often best seen on delayed phase imaging.

Breathing motion management is important to allow the planning target volumes (PTV) to be reduced, sparing more nontumor liver and reducing the risk of toxicity. Voluntary breath-hold, active breathing control (ABC), gating the beam to a specified phase of the respiration cycle and abdominal compression are common strategies used to reduce the impact of breathing motion. Measuring reproducibility of breath-hold or patient-specific tumor motion is important for individualization of PTV margins. Four-dimensional CT, kV fluoroscopy, and cine MR can be used to measure liver (or tumor) motion. Typical PTV margins for breath-hold or gated patients treated with image guided radiation therapy (IGRT) are 5 mm. PTV margins need to be larger in the cranial-caudal direction and sometimes the anterior-posterior directions for patients who are nonbreath-hold.

Three-dimensional conformal RT, arc therapy, IMRT, volumetric arc therapy (VMAT), and ions have all been used to treat HCC. HDR RT has the advantage of allowing the treatment beam-on time to be reduced, with less chance for patient movement during a single fraction. Planning goals are to cover the PTV with the prescription isodose (e.g., to 95% PTV), maintain dose limits to the luminal GI tissues and other critical organs, and to conform dose to the PTV, with most rapid dose fall off in adjacent critical normal tissues. Sometimes, less conformality is acceptable, to reduce the dose to a fragile cirrhotic liver. Although IMRT and VMAT allow high doses to be more conformal around complex PTVs (Figure 49-5; see Figure 49-4), there is the potential for interplay of residual

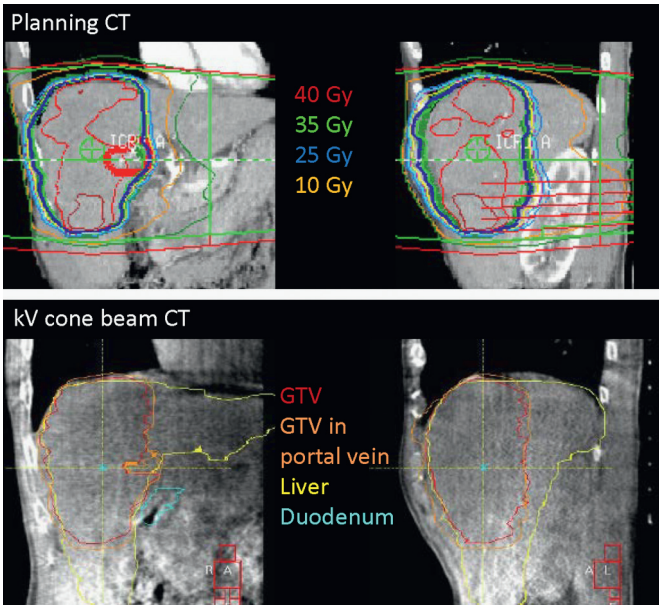

Figure 49-4 Breath-hold SBRT VMAT plan and breath-hold kV cone beam CT (CBCT) for a patient with HCC with invasion to the right portal vein, treated with 35 Gy in five fractions. The PTV around primary HCC I shown in thick blue and the HCC portal vein thrombus is shown in thick red. Contours from planning (GTV, red and orange; liver, yellow; duodenum, light blue) are overlaid on the CBCT to aid in IGRT (based on liver-matching). *CBCT,* Cone beam CT; *HCC,* hepatocellular carcinoma; *IGRT,* image guided radiation therapy; *kV,* kilovoltage; *PTV,* planning target volume; *SBRT,* stereotactic body radiation therapy; *VMAT,* volumetric modulated arc therapy.

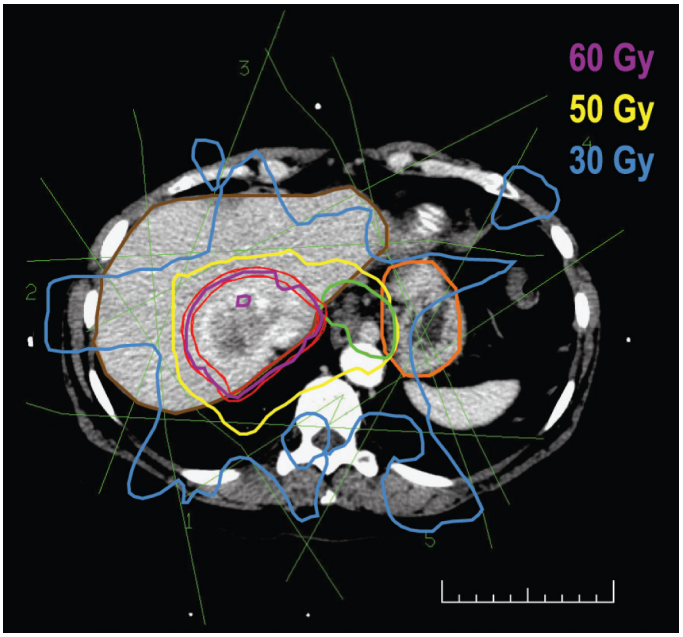

Figure 49-5 IMRT treatment plan for a patient with T3N1 intrahepatic cholangiocarcinoma, treated with definitive chemoradiation. Doses were 61.6 Gy to the primary site *(red)* and 50.4 Gy to regional nodes *(green)*, in 2.2-Gy and 1.8-Gy daily fractions, respectively.

tumor motion with moving multileaf collimators. Thus, a prudent goal should be to reduce the RT plan complexity when possible.[219] The doses required to control small HCCs are lower than those needed to control secondary liver tumors (e.g., high local control following 50 Gy in 20 fractions or 35 to 40 Gy in 5 fractions). The prescription dose may need to be modified based on volume or spared liver or proximity to organs at risk.[220]

IGRT is crucial to account for shifts in the liver position that may occur day-to-day, despite the use of breathing motion management. Such shifts occur even when breathing motion is of a small magnitude, providing rationale for the use of daily, soft-tissue guided IGRT. Inserted radioopaque fiducial markers or Lipiodol from prior TACE treatment may be used with two-dimensional planar kV imaging, fluoroscopy, or cone beam CT for targeting. The liver itself can be used for guidance using kV cone beam CT; accuracy is improved with breath-hold and four-dimensional respiratory sorted CBCT[220-222] (see Figure 49-4).

Gallbladder and Extrahepatic Cholangiocarcinoma

For gallbladder cancer, the treatment fields should be designed to include the gallbladder fossa and the hilar and celiac lymph node-bearing areas (eFigure 49-1). Doses in the range of 45 Gy to 54 Gy (1.8-Gy to 2-Gy fractions) for subclinical disease and 60 Gy to 65 Gy for microscopically positive margins are appropriate. Fields may be reduced to exclude the regional nodes and boost the tumor bed after 45 Gy. IMRT may be used to spare liver or kidney and may be especially useful when high doses are required for treatment of microscopic residual disease. A 25-fraction dose painting regimen with 45 Gy to the regional nodes, 52.5 Gy to the tumor bed following R0 resection and 55 Gy to the tumor bed following R1 resection is appropriate.

The target volume for EHCC can require inclusion of large portions of normal liver if the tumor is located in the hilum. In this case, the target volume may be extended to between 3 cm and 5 cm within the liver to include subclinical spread along the biliary tree. Although more distal EHCC requires considerably less irradiation of the hepatic parenchyma, higher duodenal or distal gastric doses may be necessary. On the basis of Mayo Clinic tolerance data, if doses greater than 55 Gy are indicated for tumor control (i.e., unresectable or residual disease), IMRT should be used to decrease normal tissue high-dose volumes. IMRT may also be indicated for lower doses to spare liver and both kidneys. Caution with regard to liver dose in the adjuvant setting should be exercised because RT may impact liver regeneration following major resection and liver tolerance may be significantly lower.

Brachytherapy[150,160,223] has frequently been used for EHCC and is an excellent technique for dose escalation for unresectable disease. Brachytherapy is typically given as a supplement to 45 Gy to 50 Gy EBRT (1.8-Gy to 2-Gy fractions) of EBRT. For patients who are not having transplants, brachytherapy may be delivered using transhepatic catheters or via endoscopically placed 10-FR nasobiliary catheters.[223] Potential transplant candidates should not have placement of transhepatic catheters. For LDR, a dose of 20 Gy to 30 Gy may be delivered with iridium-190 to a 1-cm radius.[160] With HDR, a dose of 16 Gy in 4 fractions to a 1-cm radius delivered twice daily over 2 days is calculated to have similar biologic effect to 20 Gy with LDR. Endoscopically placed two-catheter brachytherapy is depicted in Figure 49-6. With HDR placement, CT-based treatment planning may be used to limit dose to adjacent duodenum and stomach (Figure 49-7).

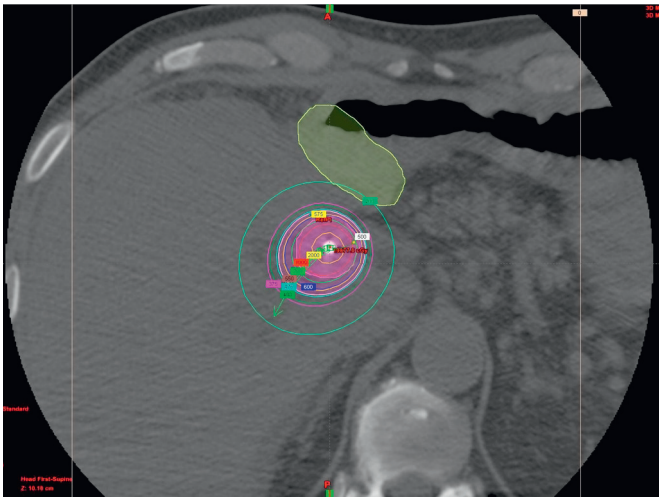

Figure 49-6 Endoscopically placed two-catheter brachytherapy. Low-dose rate iridium-190 lines loaded hot through endoscope inside nasobiliary catheter.

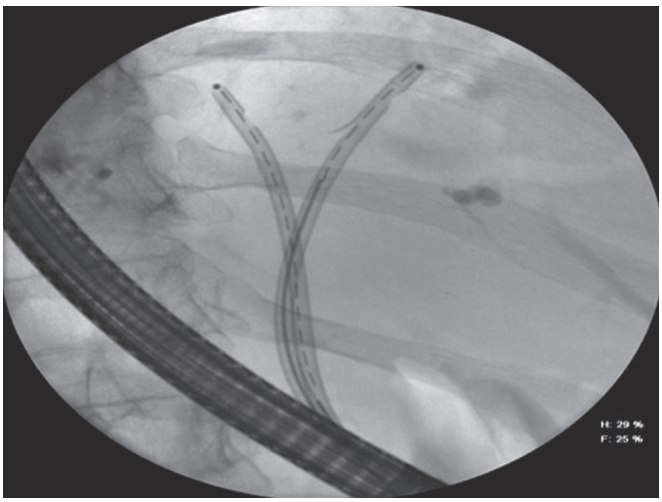

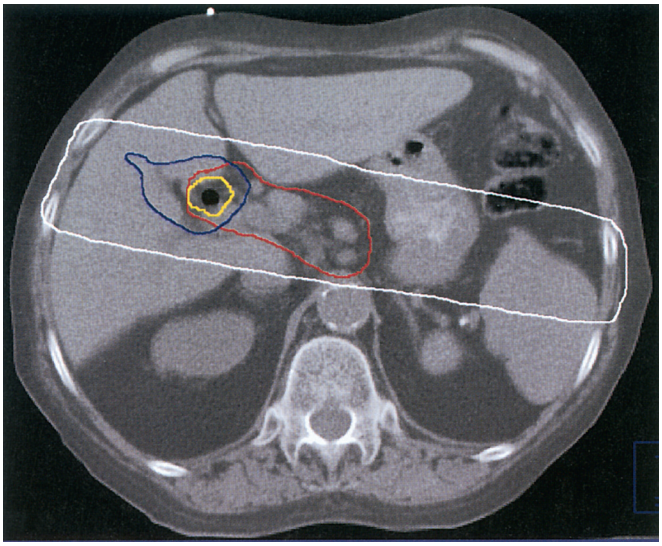

Figure 49-7 Isodose curves for high-dose rate biliary brachytherapy plan for single 5-Gy fraction. Fifteen-Gy in three fractions or 16 Gy in four fractions delivered over 2 days is typically delivered.

TREATMENT ALGORITHM AND FUTURE DIRECTIONS

Treatment algorithms for hepatobiliary cancer are shown in Figures 49-3 and 49-8. Figure 49-3 displays a treatment algorithm for hepatocellular carcinoma, based on the BCLC classification system, with the last rows indicating where RT has the potential to be used.[224] Figure 49-8 reflects a treatment algorithm for EHCC.

The use of state of the art imaging for target delineation, breathing motion management, conformal and IMRT planning, and soft-tissue IGRT have permitted the delivery of much higher doses of RT for hepatobiliary cancers than would have been possible using standard techniques. The addition of brachytherapy to EBRT has done the same for EHCC. However there are many unanswered questions and research opportunities. The potential for liver toxicity in patients with underlying cirrhosis is high; functional liver imaging, novel treatments for liver toxicity, and regenerative medicine are

eFigure 49-1 Treatment plan for a patient with resected carcinoma of the gallbladder. The cystic duct margin was positive and a cystic lymph node contained metastatic disease. The clinical target volumes included the draining regional lymph nodes in the celiac axis *(red)* and the common hepatic and common bile ducts *(yellow)*. Opposed oblique fields were used to deliver an initial dose of 50.4 Gy *(white)*, and an anterior wedge pair was used to deliver a boost to the positive margin to a total dose of 63 Gy *(blue)*.

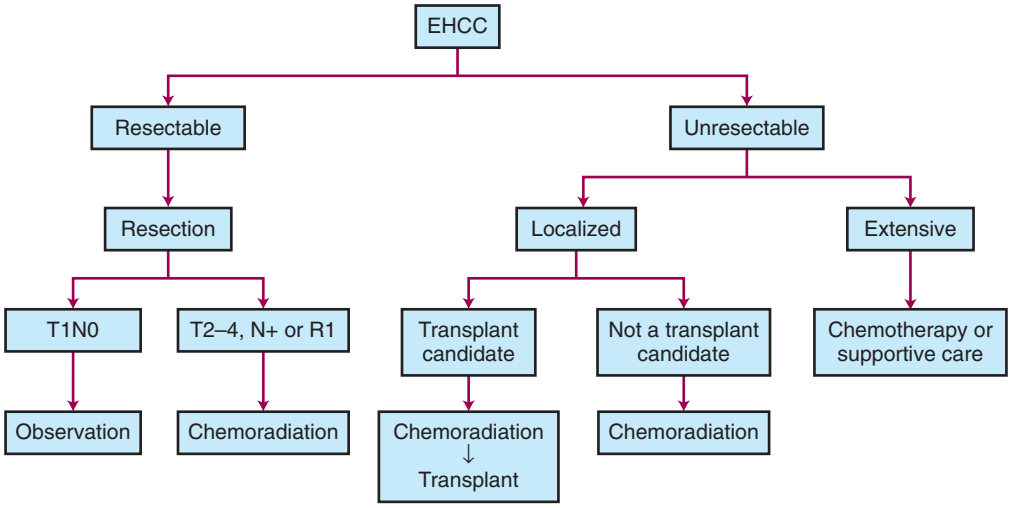

Figure 49-8 Treatment algorithm for extrahepatic cholangiocarcinoma (EHCC).

exciting areas of research that will benefit from collaborations of radiation oncologists with basic and imaging scientists and hepatologists.

Striving for the minimum RT doses required for a local control with a low chance of toxicity is a goal. Although it is becoming apparent that HCC is a relatively RT-sensitive tumor, the most appropriate doses and dose fractionations are not well defined. Collaborative efforts will be required to obtain evidence demonstrating the ideal patients, risk factors for relapse and toxicity, optimal doses and fractionation schedules and how to most appropriately combine RT with other regional and systemic therapies. Despite the growing literature on the use of RT for hepatobiliary cancer, there is a lack of level-1 evidence. At least two Phase III studies are planned for locally advanced HCC (NCT01910909, RTOG1112, PI Dawson) and intrahepatic cholangiocarcinoma (NRGGI001, PI Hong).

CHAPTER

50 Colon Cancer

Brian G. Czito, David Hsu, Manisha Palta, and Christopher G. Willett

EPIDEMIOLOGY/ETIOLOGY

In 2014, it is estimated that nearly 140,000 patients were diagnosed with colon or rectal cancer and 50,000 deaths occurred in the United States.

Linkage between diet and environmental factors with colon cancer is supported by epidemiologic studies. Risk factors include advanced age, race, male sex, family history of colorectal cancer, increasing body mass index, low physical activity level, and red meat and processed meat consumption.

The site of origin is shifting in the United States, with a higher frequency of proximal tumors.

Adenomas are precursor lesions, and polypectomy decreases the subsequent risk of malignancy.

BIOLOGIC CHARACTERISTICS AND PATHOLOGY

Most colon tumors are adenocarcinomas.

The most important prognostic factor is tumor extent, including extension through the bowel wall, nodal spread, and the presence of metastatic disease.

Approximately 10% of colorectal cancers arise in the setting of a hereditary syndrome. These syndromes are characterized by multiple adenomatous polyps (familial adenomatous polyposis) or hereditary nonpolyposis colorectal cancer (Lynch syndrome) with fewer polyps.

Inflammatory bowel disease increases the risk of developing colon cancer.

STAGING EVALUATION

Staging should include history and physical examination, complete blood count, general chemistry panel (liver functions, creatinine), carcinoembryonic antigen (CEA), and computed tomography (CT) of the chest, abdomen, and pelvis with colonoscopy.

In advanced cases, magnetic resonance imaging (MRI) or positron emission tomography (PET) may be helpful in assessing the extent of tumor spread outside the colon.

PRIMARY THERAPY

Resection is the principal therapy of primary and nonmetastatic colon cancers. This treatment modality results in mean 5-year survival rates of approximately 97% (T1N0), 90% (T2N0), 78% (T3N0), 74% (T2N+), 63% (T4N0), 48% (T3N+), and 38% (T4N+).

ADJUVANT THERAPY

For patients undergoing resection with curative intent, recurrence may arise from micrometastatic disease that is present at time of surgery. Therefore, the goal of adjuvant therapy is the eradication of micrometastases. Adjuvant chemotherapy (5-fluorouracil [5-FU] with leucovorin- and oxaliplatin-based therapy) is efficacious for patients with node-positive disease.

Retrospective studies from the Massachusetts General Hospital (MGH) and other centers have evaluated the role of adjuvant external beam radiation therapy (EBRT) in resected colon cancer. These studies found postoperative EBRT with or without 5-FU improved local control and disease-free survival for patients with resected stage T4N0 or T4N+ tumors compared to historical rates with surgery alone.

An Intergroup randomized trial compared 12 months of adjuvant 5-FU/levamisole with or without tumor bed and nodal irradiation in patients who were T4N0-2 and select T3N1-2. Results showed no overall survival or local control difference with the addition of radiation therapy. Interpretation of study results is limited by low accrual, high ineligibility rates, and low rates of preoperative imaging and surgical clip placement to assist radiation field design.

LOCALLY ADVANCED DISEASE

In a Mayo Clinic analysis of locally advanced disease, postoperative EBRT resulted in a 5-year actuarial local failure rate of 54% for patients with microscopic residual disease and 79% for patients with gross residual tumors. In patients receiving intraoperative electron irradiation (IOERT) and EBRT, local failure was observed in 11% of patients compared with 82% of patients receiving EBRT only. The 5-year survival was 76% for patients receiving IOERT and EBRT compared with 26% for patients receiving EBRT alone.

Preoperative radiation therapy and chemotherapy followed by resection with IOERT and maintenance chemotherapy should be considered for patients with locally advanced cancers (T4N0-2).

PALLIATION

For patients with metastatic disease, 5-FU and leucovorin have been given with partial response rates of 20% to 30%. The addition of newer agents (irinotecan, oxaliplatin, bevacizumab, cetuximab, panitumumab) has improved response rates and survival.

Palliative irradiation, often with 5-FU–based chemotherapy, should be considered for patients with symptomatic metastatic disease.

INTRODUCTION

The rationale for adjuvant treatment of colon cancer stems from patterns of failure analyses of patients undergoing resection. Given high rates of distant failure for patients with stages II and III colon tumors, investigators implemented treatment strategies employing systemic (chemotherapeutic) approaches. Early data prompted multicenter randomized prospective trials where survival was improved in patients with resected, "high-risk" colon cancer receiving adjuvant chemotherapy with 5-FU and leucovorin. More recently, the addition of

oxaliplatin to fluorouracil and leucovorin has been shown to significantly improve long-term disease-free and overall survival in patients with stage III disease. Similarly, patterns of failure analyses have suggested that high locoregional failure rates occur in subsets of patients with resected colon cancer. This has stimulated investigation of adjuvant radiation therapy with concurrent and maintenance chemotherapy. Although there is a compelling rationale for adjuvant radiation therapy combined with 5-FU chemotherapy for selected patients with resected high-risk colonic cancer, its efficacy has not been validated by a randomized prospective study. The benefit of adjuvant radiation therapy thus remains unclear. This chapter reviews the rationale for radiation therapy combined with chemotherapy as well as results in patients with resected colon cancer.

ETIOLOGY AND EPIDEMIOLOGY

In 2014, the American Cancer Society estimated that 136,830 patients were diagnosed with colorectal cancer and 50,310 deaths occurred.[1] Although this malignancy may be linked to chemical carcinogens within the bowel lumen, it is not established whether these are ingested, the result of chemical activation of substances in the fecal stream, or a bacterial byproduct.[2] Emerging evidence suggests that infection with *Helicobacter pylori*, *Fusobacterium*, and other potential infectious agents might be associated with an increased risk of colorectal cancer. Environmental and dietary factors have been established as contributing to colorectal cancer. Factors shown to increase the risk of developing this disease include increasing age, race, male sex, family history of colorectal cancer, inflammatory bowel disease, increasing height, increasing body mass index, processed meat intake, diabetes, excessive alcohol intake, smoking, and low folate consumption. Of these risk factors, only increasing age, male sex, and excessive alcohol use have been found to be associated with rectal cancer.[3,4] The value of consumption of fruits and vegetables in the prevention of colon and rectal cancer remains controversial, and some studies have suggested that these associations have been overstated.[5] Contemporary prospective and randomized data do not support a high-fiber diet in the prevention of colorectal cancer.[6] Other studies have strongly suggested that nonsteroidal antiinflammatory drugs may reduce the risk of colorectal cancer. The role of chemopreventive agents (carotenoids, polyamine inhibitors, aspirin, and other nonsteroidal antiinflammatory drugs) in colorectal cancer remains under active investigation. Other preventive factors include physical activity and use of hormone replacement therapy with risk reduction on the order of 20% to 30%. Although less consistent, some data suggest a protective effect of diets rich in dairy products or fish, as well as statin therapy. Epidemiological studies have also demonstrated an inverse association between serum vitamin D concentrations and risk of colorectal cancer, but whether and to what extent this association is valid remains uncertain.[4]

PREVENTION AND EARLY DETECTION

Neoplastic polyps, including tubular adenomas, villous adenomas, and tubulovillous adenomas, are precursors of colon cancers. Most colorectal cancers arise from preexisting polyps.[7] APC gene mutations are an early event in colorectal cancer development and occur in more than 70% of colorectal adenomas. This is promoted by activating mutations of the KRAS oncogene and inactivating mutations of the *TP53* tumor suppressor gene. These mutations are often associated with chromosomal instability. Patients with neoplastic polyps should be considered at high risk for large bowel cancer, and polypectomy may reduce this risk. With the availability of the flexible colonoscope and endoscopic polypectomy, polyps can be removed at a premalignant stage and patients followed closely with an associated decrease in cancer incidence.[4]

Screening

Because the cumulative lifetime risk of developing colorectal cancer in the United States is about 6%,[8] screening programs for the general population have been undertaken. The goal of screening is to detect and remove preinvasive polyps or early invasive cancer. The presence of polyps increases the risk for cancer to approximately 15%. Data from programs in which proctoscopy is performed annually suggests that routinely scheduled polypectomy reduces the development of subsequent bowel cancer by 80% or more.[2] The American Cancer Society has recommended that screening should begin at age 50 in the average-risk patient by (1) flexible sigmoidoscopy every 5 years, (2) double-contrast barium enema every 5 years, (3) colonoscopy every 10 years, or (4) CT colonography every 5 years. The use of barium enema as a screening procedure is uncommon at the present time because of lower sensitivity and inability to resect polyps, and sigmoidoscopy screens only a portion of the bowel. Additional screening tests including yearly fecal occult blood test and fecal immunohistochemical tests using multiple take-home samples and follow up with colonoscopy if positive. More intensive surveillance is recommended for patients at high risk (patients with adenomatous polyps, history of colorectal cancer, first-degree relative diagnosed with colorectal cancer or adenomas, inflammatory bowel disease, or high risk because of family history or genetic testing). Genetic fecal testing continues to be studied as a potential screening tool. Although screening methods can detect colorectal cancer at an early stage, less than 40% of patients are diagnosed with early disease, likely reflecting low rates of disease awareness as well as the infrequency of screening in eligible candidates.[8,9]

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

A detailed discussion of the biologic and genetic pathways of development of colorectal cancer is beyond the scope of this chapter. In brief, it has been established that the development of colon cancer is a multifactorial process, involving changes in many genes including both proto-oncogenes and tumor suppressor genes. Colorectal cancers appear to arise through a complicated process that often includes inactivation of the tumor suppressor genes adenomatous polyposis coli (APC) and P53 as well as mutations in the KRAS proto-oncogene. Wnt pathway signaling alterations occur in almost all patients, with the majority of these related to APC mutations. A large number of other genetic abnormalities occur in these tumors, including copy number alterations, altered methylation with associated gene silencing, and alterations in miRNA. In an effort to characterize somatic alterations in colorectal carcinoma, a genome-scale analysis of 276 samples was performed by investigators from the Cancer Genome Atlas Network. In total, 16% of colorectal carcinomas were found to be hypermutated; three fourths of these had the expected high microsatellite instability, usually with hypermethylation and MLH1 silencing, and one fourth had somatic mismatch-repair gene and polymerase ε (POLE) mutations. Excluding the hypermutated cancers, colon and rectum cancers were found to have considerably similar patterns of genomic alteration. Twenty-four genes were significantly mutated. Recurrent copy-number alterations include potentially drug-targetable amplifications of ERBB2 and newly

discovered amplification of IGF2. Recurrent chromosomal translocations include the fusion of NAV2 and WNT pathway member TCF7L1. Integrative analyses suggested new markers for aggressive colorectal carcinoma and an important role for MYC-directed transcriptional activation and repression. These tumors appear to be categorized broadly as those with chromosomal instability, those with microsatellite instability, and the remainder.[10]

Microsatellites are mutated short-repeat DNA sequences, usually consisting of one to five nucleotides. Microsatellite "instability" is found in a majority of patients with hereditary nonpolyposis colorectal cancer (HNPCC or Lynch syndrome) as well as a minority of patients with sporadic colorectal cancers, and this can be used to identify patients and families affected by Lynch syndrome. Additionally, BRAF mutational analysis can be used to distinguish sporadic versus Lynch-associated colorectal cancers because BRAF mutations are almost exclusively seen in sporadic microsatellite-high type tumors. It has been shown that this instability occurs in patients with mutations in genes encoding enzymes that repair DNA replication errors. These defects in mismatch repair lead to high-frequency microsatellite instability. Studies have suggested that patients with tumors possessing a high-frequency of microsatellite instability have a more favorable outcome and develop fewer metastases.[11] Furthermore, systematic reviews have suggested that microsatellite instability phenotypes may not benefit from adjuvant therapy with 5-FU, although this remains controversial.[12] Further elucidation of the genetic pathways in the development of colorectal cancer remains an active area of investigation and may ultimately impact therapy of this disease.

From a clinical standpoint, analysis of KRAS mutational status has important implications for treatment selection. Such mutations render these tumors unresponsive to treatment with anti-EGFR antibodies,[13] and the same likely holds true for patients with BRAF-activating mutations.

PATHOLOGY AND PATHWAYS OF SPREAD

Tumors of the colon arise in the mucosa and are virtually all (>90%) adenocarcinomas. Other histologic types include squamous cell carcinoma, carcinoid, leiomyosarcoma, and lymphoma. Most grading systems classify adenocarcinoma as well, moderately, or poorly differentiated.

Large bowel tumors invade from mucosa through the bowel wall and beyond, with involvement of lymphatic channels and lymph nodes. Lymphatic drainage from the colon follows the superior and inferior mesenteric nodes, in accordance with the arterial supply of the colon. Specifically, the lymphatics of the ascending colon drain to the ileocolic nodes, whereas those of the transverse colon drain to right and middle colic nodes. These both drain to the superior mesenteric system and subsequently paraaortic nodal basins. The lymphatics of the descending colon enter the left colic nodes, and those of sigmoid colon drain to the sigmoid nodes. These both drain to the inferior mesenteric system and subsequently paraaortic nodal basins. Hematogenous spread can occur, primarily to the lung and liver. There is little propensity for colon cancer to spread longitudinally within the bowel wall, in contrast to esophageal or gastric cancers.

CLINICAL MANIFESTATION, PATIENT EVALUATION, AND STAGING

Colon cancer often produces minimal or no symptoms, emphasizing the need for screening programs in the general population. Many colon cancer symptoms are nonspecific, including changes in bowel habits, weakness, intermittent abdominal pain, nausea, and vomiting. The persistence of such symptoms as well as any evidence of iron deficiency anemia should be investigated.

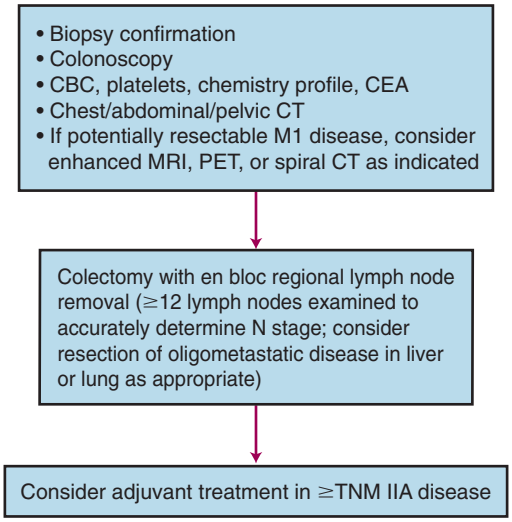

Figure 50-1 Diagnostic algorithm of the management of patients with potentially resectable colon cancer. *CBC*, Complete blood count; *CEA*, carcinoembryonic antigen; *CT*, computed tomography; *MRI*, magnetic resonance imaging; *PET*, positron emission tomography.

The clinical presentation of colon cancer is determined largely by site of the tumor. Cancers of the right colon are often exophytic and commonly associated with iron deficiency anemia as a result of occult blood loss. During the past 20 years, the relative incidence of right colon cancers has increased and accounts for one third of large-bowel cancers. Many of these are diagnosed late.[2] Cancers of the left colon and sigmoid colon are often deeply invasive, annular, and accompanied by partial obstruction and rectal bleeding.

For patients undergoing resection, preoperative evaluation should include pathological confirmation of adenocarcinoma, colonoscopy to evaluate extent of tumor and rule out synchronous primaries (occurring in 3% to 5% of patients), baseline blood counts with liver function tests, and CEA levels. Patients should undergo chest, abdominal, and pelvic CT scan to evaluate extent of locoregional disease as well as the presence or absence of distant metastases. PET scan, MRI, and ultrasound may be useful in evaluating patients with oligometastatic disease who may be appropriate candidates for resection of metastatic disease with curative intent. Figure 50-1 shows a diagnostic algorithm of the management of patients with potentially resectable colon cancer.

Prognostic factors influencing survival in patients with colon cancer include depth of tumor invasion into and beyond the bowel wall, the number of involved regional lymph nodes as well as the presence or absence of distant metastases. The TNM system of the American Joint Committee on Cancer (AJCC) can be used as a clinical (preoperative) or postoperative staging system (Tables 50-1 and 50-2). Additionally, site-specific prognostic factors have been identified and are included in the AJCC staging form (Box 50-1).

PRIMARY THERAPY

Surgery

Surgery remains the primary treatment for patients with colonic tumors. Resection with curative intent is possible in approximately 75% of patients.[14] Surgical resection of primary colon cancer is based on the anatomy and mechanisms by

TABLE 50-1 American Joint Committee on Cancer TNM Staging for Colorectal Cancer (2010)

Stage	Description
PRIMARY TUMOR (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ: intraepithelial or invasion of lamina propria
T1	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades through the muscularis propria into pericolic tissues
T4a	Tumor penetrates to the surface of the visceral peritoneum*
T4b	Tumor is adherent to or directly invades other organs or structures*†
REGIONAL LYMPH NODES (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in one to three regional lymph nodes
N1a	Metastasis in one regional lymph node
N1b	Metastasis in two to three regional lymph nodes
N1c	Tumor deposit(s) in the subserosa, mesentery, or nonperitonealized pericolic or perirectal tissues without regional nodal metastasis
N2	Metastasis in four or more regional lymph nodes
N2a	Metastasis in four to six regional lymph nodes
N2b	Metastasis in seven or more regional lymph nodes
DISTANT METASTASIS (M)	
MX	Distant metastasis cannot be assessed.
M0	No distant metastasis
M1	Distant metastasis
M1a	Metastasis confined to one organ or site (e.g., liver, lung, ovary, nonregional node)
M1b	Metastases in more than one organ/site or the peritoneum

From Edge SB, Byrd DR, Compton CC, et al, editors: Colon and rectum. In American Joint Committee on Cancer staging manual, ed 7, New York, 2010, Springer.

Note: *A satellite peritumoral nodule in the pericolorectal adipose tissue of a primary carcinoma without histologic evidence of residual lymph node in the nodule may represent discontinuous spread, venous invasion with extravascular spread (V1/2), or a totally replaced lymph node (N1/2). Replaced nodes should be counted separately as positive nodes in the N category, whereas discontinuous spread or venous invasion should be classified or counted in the site-specific factor category of tumor deposit (TD).*

**Direct invasion in stage T4 includes invasion of other organs or segments of the colorectum by way of the serosa, as confirmed by microscopic examination (e.g., invasion of the sigmoid by a carcinoma of the cecum). For cancers in a retroperitoneal or subperitoneal location, direct invasion involves other organs or structures by virtue of extension beyond the muscularis propria (e.g., a tumor on the posterior wall of the descending colon invading the left kidney or lateral abdominal wall or a mid or distal rectal cancer with invasion of the prostate with invasion of the prostate, seminal vesicles, cervix or vagina).*

†Tumor grossly adherent to other organs or structures is classified as cT4b. However, if no tumor is present in the adhesion microscopically, the classification should be pT1 to pT4a depending on the anatomic depth of wall invasion. The V and L classifications should be used to identify the presence or absence of vascular or lymphatic invasion where the pN site-specific factor should be used for perineural invasion.

TABLE 50-2 Stage Groupings for Colorectal Cancer

which this disease spreads. Adenocarcinomas of the colon may grow by direct extension into the lymphatics of the submucosa and bowel wall. To avoid cutting across tumor in intramural lymphatics, sufficient lengths of bowel must be resected proximal and distal to the primary cancer. Colon cancer often extends through the serosa into mesenteric lymphatics that run along the blood vessels draining into the portal watershed at the root of the mesentery. Resection includes removal of the major lymphatic drainage system in the mesentery. Because anatomic resections designed to include named blood vessels also include the draining lymphatics, the boundaries for resecting large bowel cancer are relatively uniform (Figure 50-2). Right hemicolectomy, transverse colectomy, left hemicolectomy, and sigmoid resection are performed by adherence to surgical oncologic principles without major sacrifice of large bowel function. More recently, laparoscopic colonic resection has been implemented in the treatment of colon cancer. Several meta-analyses have demonstrated that a laparoscopic approach results in similar

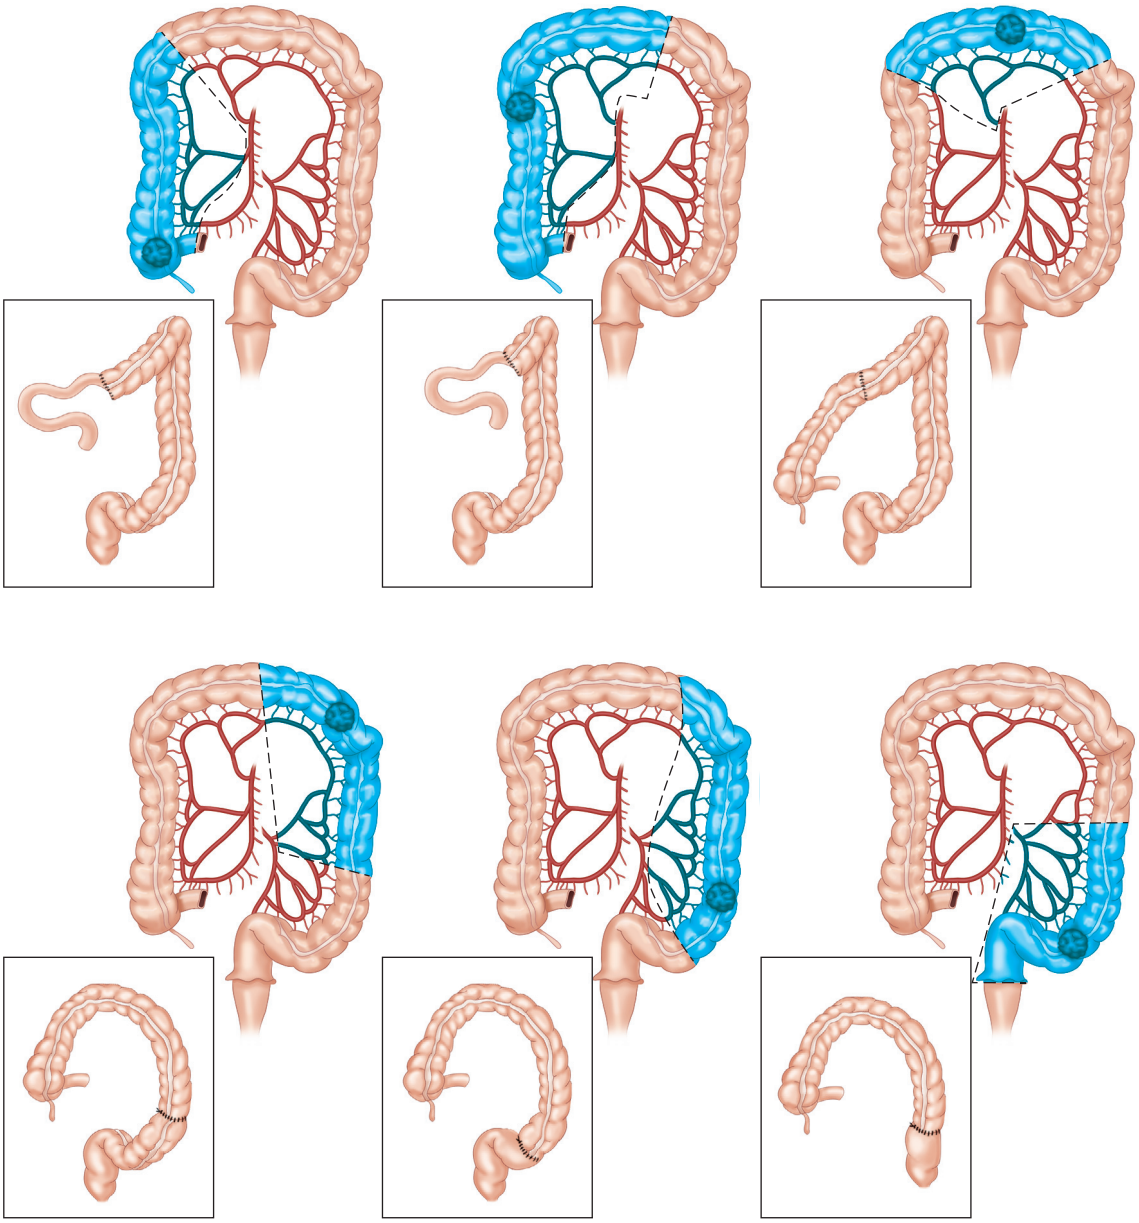

Figure 50-2 Extent of surgical resection at various colonic sites. The *darkened circle* represents primary disease site (anastomoses are shown in the *insets*).

long-term disease-related outcomes and is associated with fewer blood transfusions, faster return of bowel function, and shorter hospital stays postoperatively, albeit at the expense of increased operative time and costs compared to open resection.[15-17]

Resection results in excellent cure rates for lesions limited to the bowel wall with negative nodes (estimated 5-year survival, 97% for T1N0; 85% to 90% for T2N0). With a single high-risk feature of extension beyond the colonic wall (T3-T4N0) or involved nodes (T0-2N+), 5-year survival with surgery falls to 65% to 75%, and adjuvant treatment is often indicated. When both high-risk features are present (T3-4N+), 5-year survival with surgery alone drops to approximately 50% (T3N+) and 35% (T4N+), and adjuvant treatment is usually advised. Recent Surveillance, Epidemiology and End Results (SEER) analyses have allowed further refinement of survival outcomes based on TNM stage (Table 50-3).[18]

Adjuvant Chemotherapy

Patients with stage III colorectal cancer and no treatment other than surgery have a >50% chance of developing recurrent disease, and early trials in the 1980s showed that the risk of death could be reduced by 30% with the use of adjuvant therapy.[14,19] Based on these data, the NIH Consensus Conference panel recommended fluorouracil (FU)-based adjuvant chemotherapy for medically fit patients with completely resected stage III colon cancer.[20] However, it remained unclear whether or not patients with stage II disease, who are generally at a lower risk of recurrence than patients

TABLE 50-3 Surveillance, Epidemiology and End Results (SEER) Survival Outcomes Based on 2010 AJCC TNM Staging

TN Stage	SEER Relative Survival (5-year)*	AJCC Stage	SEER Observed Survival (5-year)
T1N0	97.4%	I	78.7%
T2N0	96.8%	I	74.3%

‡T4aN2a colon lesions did worse than rectal T4aN2a (both categories placed in stage IIIC).

with stage III disease, would derive enough benefit to justify the potential toxicities, cost, and inconvenience of adjuvant therapy.[19]

Fluoropyrimidine (FU) Therapy

5-FU therapy remains the backbone for adjuvant chemotherapy for resected colorectal cancer. Although the use of 5-FU therapy has been clearly shown to be beneficial in stage III colorectal cancer based on the NASBP C-03,[21] NCCTG,[22] and IMPACT trials,[23] the benefits in stage II disease remains controversial. The Quick and Simple And Reliable (QUASAR) Collaborative Group aimed to determine the size and duration of any survival benefit from adjuvant chemotherapy for patients with colorectal cancer at a low risk of recurrence, which largely included patients with stage II disease. This trial randomly assigned 3239 patients (91% with stage II disease) after their curative resections of colon or rectal cancer to FU plus leucovorin (LV) with or without levamisole or to observation. As compared to observation, adjuvant chemotherapy was associated with a relative risk of the primary endpoint, all-cause mortality, of 0.82 (95% confidence interval [CI], 0.7 to 0.95; $p = 0.008$), a relative risk of recurrence of 0.78 (95% CI, 0.67 to 0.91; $p = 0.001$), and an absolute improvement in survival of 3.6% (95% CI, 1 to 6). However, among patients with stage II colon cancer, there was only a trend toward improved overall survival (hazard ratio [HR], 0.86; 95% CI, 0.66 to 1.12). Thus, although the QUASAR trial demonstrates that the adjuvant use of FU with LV shows a trend toward improved survival in patients with stage II colon cancer, it does not demonstrate a statistically significant benefit in these patients.[24]

The International Multicentre Pooled Analysis of B2 Colon Cancer Trials (IMPACT B2) trial was also designed to determine whether FU with LV is effective as adjuvant therapy after potentially curative resection in patients with T3N0 colon cancer. This study analyzed the pooled data from 1016 patients enrolled in five separate trials of FU with LV compared to observation. Over the median follow-up duration of 5.75 years, patients receiving FU with LV did not experience a significant improvement in event-free (HR, 0.83; 90% CI, 0.72 to 1.07) or overall survival (HR, 0.86; 90% CI, 0.68 to 1.07). The event-free survival favored chemotherapy (76%) as compared with observation (73%), though the difference was not statistically significant. The 5-year overall survival was similar between those who received chemotherapy (82%) and those who were observed (80%). The lack of support for adjuvant chemotherapy in patients with stage II or Dukes B2 colon cancer may be the result of the size of the trials; to show a survival benefit, an estimated 4000 patients would need to be enrolled, and neither of these trials enrolled this number of patients.

Beyond these two trials, several meta-analyses also evaluated the benefit of adjuvant FU-based chemotherapy in patients with resected colon cancer. An Intergroup analysis included data from 3302 patients with stage II or stage III colon cancer enrolled in seven randomized trials comparing FU with LV or FU with levamisole to surgery alone. T-stage, histologic grade, and nodal status were the only prognostic factors independently significant for both disease-free and overall survival. In a multivariate analysis, adjusting for these three factors, adjuvant therapy was associated with a significant 30% relative reduction in the risk of recurrence and a 26% relative reduction in the risk of death, and these risk reductions were similar for patients with stages II and III disease. Although patients with stage II disease had a statistically significant improvement in 5-year disease-free survival favoring chemotherapy (76% versus 72%), the difference in overall survival was not statistically significant (81% versus 76%).[25]

In comparison, the Cancer Care Ontario Program in Evidence-Based Care's Gastrointestinal Cancer Disease Site Group analysis looked at a subset of 4187 patients in 12 trials that had at least one arm that had an 5-FU–containing chemotherapy and an arm that was a surgery-alone control; it found that chemotherapy was associated with a small but significant absolute improvement in disease-free survival that ranged from 5% to 10%.[26] However, this did not translate into a statistically significant difference in overall survival (risk ratio 0.87; 95% CI, 0.75 to 1.10; $p = 0.07$).

Recently, the use of orally active fluoropyrimidines such as capecitabine has been shown to have similar clinical benefit as compared to 5-FU therapy. The European/Canadian X-ACT randomized patients with resected stage III disease to either capecitabine or 5-FU.[27] This study showed that 3-year disease-free survival (64% versus 61%, $p = 0.05$) and overall survival (81% versus 78%, $p = 0.07$) were similar in both arms. However, more than half of the patients receiving capecitabine required dose reduction secondary to hand-foot syndrome.

The difficulty in interpreting these data is that the majority of these trials included patients with both stage II and stage III disease. Although subgroup analyses have shown a trend toward improved overall survival or significantly improved disease-free survival favoring adjuvant FU-based chemotherapy in stage II disease, these trials were not powered to demonstrate an overall or disease-free survival advantage these patients. To date, no trial has demonstrated statistically significant data supporting the use of routine adjuvant FU-based therapy in patients with stage II colon cancer. An expert panel convened by the American Society of Clinical Oncology concluded that evidence from randomized trials does not support the routine use of adjuvant chemotherapy for these patients.[19]

Oxaliplatin

Although the standard adjuvant treatment for colon cancer used to be 5-FU alone, the addition of oxaliplatin to 5-FU has been found to improve the efficacy of this combination in the adjuvant setting. The MOSAIC trial evaluated the efficacy of treatment with 5-FU and oxaliplatin in the adjuvant setting for patients with stages II or III disease.[28] In this trial, 2246 patients who had undergone curative resection for stage II or III colon cancer were randomly assigned to receive either 5-FU or 5-FU with oxaliplatin for 6 months. After a median follow-up of 37.9 months, 5-FU with oxaliplatin led to fewer cancer-related events (HR 0.77, $p = 0.002$). The rate of disease-free survival at 3 years was also higher in the 5-FU with oxaliplatin group (78.2% versus 72.9%, $p = 0.002$).

A follow-up study confirmed an improved disease-free survival rate of 73.3% in the group given oxaliplatin as compared to 67.4% in the group given 5-FU alone (HR, 0.8; 95% CI, 0.68 to0.93; $p = 0.003$).[29] The secondary endpoint of 6-year overall survival was significantly improved at 78.5% in patients who received oxaliplatin, as compared to 76% in the patients who did not (HR, 0.84; 95% CI, 0.71 to 1.00; $p = 0.046$). In the analysis of patients with stage III disease, the 6-year overall survival rate was 72.9% with oxaliplatin and 68.7% without (HR, 0.8; 95% CI, 0.65 to 0.97; $p = 0.023$). However, no difference in 6-year overall survival was seen in patients with stage II disease.

Like the MOSAIC trial, the National Surgical Adjuvant Breast and Bowel Project C-07 (NSABP C-07) was a Phase III trial that evaluated the impact on disease-free survival of adding oxaliplatin to bolus weekly FU as adjuvant therapy for stages II and III colon cancer.[30] In this study, 2207 patients with stage II or III colon cancer were randomly assigned to bolus 5-FU or bolus 5-FU plus weekly oxaliplatin. Oxaliplatin resulted in a significant improvement in 4-year disease-free survival (73.2% versus 67%; HR for recurrence, 0.8; 95% CI, 0.69 to 0.93). In the subgroup analysis based on stage, patients with stage II disease had less of a disease-free survival benefit from the addition of oxaliplatin (4-year disease-free survival 84% versus 81%, which was not statistically significant).

The benefit of oxaliplatin in stage II disease remains unclear, despite the data from the MOSAIC and NSABP-07 trials. Though each trial had a suggestion of a rather small benefit on disease-free survival in the stage II population, the identical 6-year survival in the MOSAIC trial suggests that even if oxaliplatin is shown to increase survival in patients with stage II disease, the effect is likely to be minimal.

Irinotecan

Irinotecan is not a standard approach in the adjuvant setting based on negative results from three separate trials. In the CALGB 89803 study, 1264 patients were assigned to either weekly bolus FU with LV or weekly bolus irinotecan plus FU with LV. There was no difference in overall survival or disease-free survival.[31] In the PETACC-3 trial, patients with stages II and III colon cancer were randomized to receive 5-FU with LV with or without irinotecan. In 2094 treated patients with stage III disease and a median follow-up of 66.3 months, the 5-year disease-free survival was 56.7% with irinotecan and 54.3% without irinotecan ($p = 0.106$). The addition of irinotecan did not significantly improve overall survival, but it was associated with an increased incidence of grade-3 to grade-4 gastrointestinal toxicity and neutropenia.[32] Finally, the ACCORD trial randomized 400 patients with postoperative N1 or N2 disease to 5-FU with LV or 5-FU with LV plus irinotecan for 12 cycles with no improvement in disease-free or overall survival.[33]

Bevacizumab

Whereas bevacizumab has been shown to improve the outcomes in patients with metastatic disease, the National Surgical Adjuvant Breast and Bowel Project C-08 trial was designed to investigate the safety and efficacy of adding bevacizumab to modified FOLFOX6 (infusional/bolus 5-FU, LV, and oxaliplatin) for the adjuvant treatment of patients with stages II and III colon cancer.[34] In this trial of 2672 analyzed patients with a median follow-up of 35.6 months, the addition of bevacizumab did not result in a significant improvement in disease-free survival (HR, 0.89; 95% CI, 0.76 to 1.04; $p = 0.15$). A second multicenter trial, the European AVANT trial, assessed the use of bevacizumab in combination with oxaliplatin-based chemotherapy in the adjuvant treatment of patients with resected stage III or high-risk stage II colon cancer.[35] In this Phase III, randomized trial, patients with curatively resected stage III or high-risk stage II disease were assigned to receive FOLFOX4, FOLFOX4-bevacizumab, or XELOX (capecitabine/oxaliplatin)-bevacizumab in the adjuvant setting. After a median follow-up of 48 months, 25% in the FOLFOX4 group, 29% in the FOLFOX4-bevacizumab group, and 27% in the XELOX-bevacizumab group had relapsed, developed a new colon cancer, or died. The overall survival hazard ratios favored the no bevacizumab arm with FOLFOX4-bevacizumab compared to FOLFOX4 was 1.27 (95% CI, 1.03 to 1.57; $p = 0.02$), and for XELOX-bevacizumab compared to FOLFOX4 was 1.15 (95% CI, 0.93 to 1.42; $p = 0.21$). Serious adverse events were more common in the bevacizumab-containing groups than in the FOLFOX4 group. Therefore, this study demonstrated that bevacizumab does not prolong disease-free survival when added to adjuvant chemotherapy in resected stage III colon cancer, and the overall survival data even suggest a potential detrimental

effect with bevacizumab plus oxaliplatin-based adjuvant therapy. Bevacizumab use in the adjuvant setting is not recommended.

Cetuximab

Cetuximab is not indicated for any group of patients with resected colon cancer. The N0147 trial randomized 2686 patients (1863 patients with wild-type KRAS, 717 patients with mutated KRAS, and 106 patients with indeterminate KRAS) to mFOLFOX6 with or without cetuximab, but it was closed prematurely when an interim analysis demonstrated no benefit in terms of disease-free survival in any group with cetuximab.[36] Among all patients, grade-3 or higher adverse events and failure to complete the prescribed 12 cycles was significantly higher with cetuximab.

Adjuvant Irradiation with or without Chemotherapy

Rationale: Patterns of Relapse and Surgery Alone

Because of the documented efficacy of adjuvant chemotherapy as well as the perception by many oncologists that colonic (as opposed to rectal) cancer is much more likely to relapse distantly than locally, there has been little evaluation of the efficacy of postoperative irradiation with chemotherapy. The potential indications for adjuvant radiation therapy in colon cancer are based on analyses of patterns of failure following resection[37,38] (Table 50-4). Advanced stage predicts for local failure in both colon and rectal cancer; however, local failure in colon cancer also depends on anatomic origin. The ascending and descending colon are considered "anatomically immobile," and their close proximity to the retroperitoneal tissues often limits wide surgical resection (Figure 50-3). Limitations in achieving satisfactory circumferential margins increase the risk of residual disease and consequently local failure. In contrast, the midsigmoid and midtransverse colon are relatively "mobile" with a wide mesentery permitting the surgeon to obtain wide margins regardless of extent of disease invasion into the mesentery. Unless there is adjacent organ adherence or invasion by tumor, local failure at these sites is uncommon. Local failure rates for cecal, hepatic or splenic flexure, and proximal or distal sigmoid tumors are variable depending on the amount of mesentery present, tumor extension, and the adequacy of radial margins. When colon cancers adhere to or invade adjacent structures, local failure rates exceed 30% following surgery alone.

Adjuvant Irradiation, Single Institution

Most of the data evaluating the use of adjuvant radiation therapy in patients with high-risk colon cancer is from single-institution retrospective analyses.[39-43] To summarize, these studies have suggested that operative bed failures in high-risk patients undergoing resection alone are at least 30% and that the risk of local failure is reduced by the administration of adjuvant radiation therapy. These are discussed in detail here.

TABLE 50-4 Five-Year Actuarial Local Control and Relapse-Free Survival after Surgery Plus Postoperative Radiotherapy versus Surgery Alone, According to Stage: Massachusetts General Hospital Series

*$p < 0.05$.

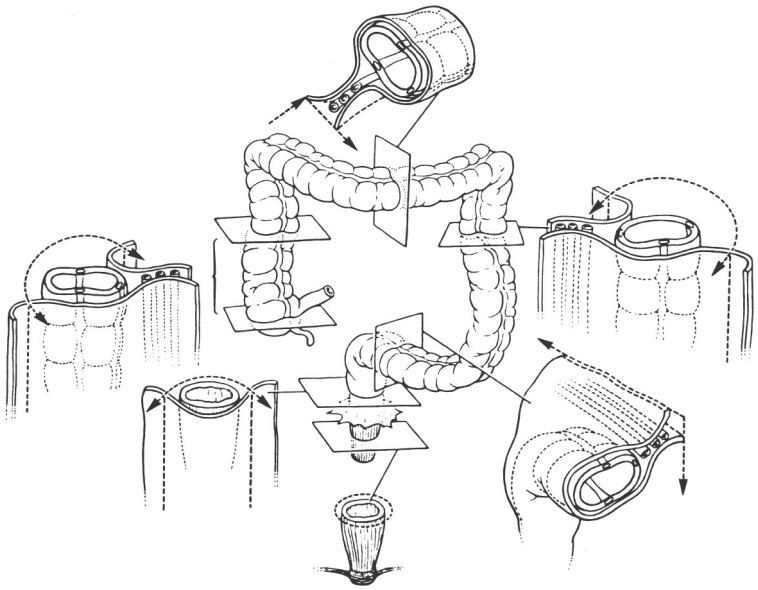

Figure 50-3 Idealized depiction of peritoneal relationships in the colon and rectum. The transverse and sigmoid colon are intraperitoneal, with a complete peritoneal covering (serosa) and mesentery. The ascending and descending colon are retroperitoneal, lack a true mesentery, and usually do not have a peritoneal covering posteriorly or laterally. The upper rectum begins above the peritoneal reflection and has peritoneum anteriorly and laterally. The lower half to two thirds of the rectum is below the peritoneal reflection (infraperitoneal). *Reproduced with permission from Gunderson LL, O'Connell MJ: Postoperative chemotherapy/irradiation adjuvant strategy. In Cohen AF, Winawer SJ, Friedman MA, et al, editors: Cancer of the colon, rectum, and anus, New York, 1995, McGraw-Hill, pp 631–645.*

A report from the Massachusetts General Hospital (MGH) evaluated outcomes in high-risk patients undergoing resection followed by adjuvant radiation therapy and compared these to a similar cohort of patients treated over the same period undergoing surgery only. Irradiated patients included those with T4N0/N+, T3N+ disease (excluding midsigmoid and midtransverse colon), and T3N0 patients with margins of less than 1 cm. A total of 171 patients received postoperative radiation therapy, with 63 patients receiving concurrent chemotherapy, usually with bolus 5-FU (500 mg/m^2/d) for three consecutive days during the first and last weeks of radiation therapy. Radiation treatment was administered through parallel opposed or other multifield techniques to treat the tumor bed with an approximate 3-cm to 5-cm margin to a total dose of 45 Gy, followed by reduced fields to a total dose of 50.4 Gy to 54 Gy. Draining nodes were included if thought to be at high risk for involvement. This cohort was compared to 395 patients with T3-4N0/N+ tumors undergoing surgery alone during the same time period.

Table 50-4 shows 5-year actuarial local control and relapse-free survival in the adjuvant group compared to patients undergoing surgery alone. Local control rates in T4N0 and T4N+ patients treated with radiation therapy were 93% and 72%, respectively, compared to 69% and 47%, in patients undergoing surgery alone. Similarly, relapse-free survivals were 79% and 53%, respectively, in T4N0/T4N+ patients undergoing adjuvant radiation, compared to 63% and 38%, after surgery alone. No significant outcome differences were observed in patients with T3N0 and T3N+ lesions; however, there may be an element of selection bias in the radiation group given most patients were referred because of concerns of adequacy of local control following surgery alone. There was a trend toward improved local control in patients receiving 5-FU (Table 50-5). The rate of acute enteritis in patients receiving irradiation and 5-FU was 16% compared with 4% in patients undergoing irradiation only. This rate of enteritis is similar to data from studies of concurrent 5-FU and radiation therapy in rectal cancer. Late bowel complication rates were not increased by concomitant 5-FU administration. The conclusion was that patients with T4 tumors or tumors with abscess or fistula formation or margin positive resection may benefit from postoperative radiation.[39]

In an updated analysis from MGH, 152 patients with T4 tumors received adjuvant irradiation. On pathological examination, 42 patients had tumors with positive margins. For patients with negative margins the 10-year actuarial local control in T4N0 and T4N+ patients was 78% and 48%, respectively. In patients with node negative tumors, the 10-year actuarial local control and relapse-free survival rates were 87% and 58%, respectively, compared to 65% and 33% in patients with node-positive tumors. For patients with one involved lymph node, local control and relapse-free survival rates were similar to those without nodal involvement; however, with increasing numbers of nodes involved, survival steadily decreased.[43]

A report from the Mayo Clinic described a series of 103 patients receiving radiation therapy following surgery for locally advanced colon cancer.[42] Microscopic and gross residual disease was present in 18 and 35 patients, respectively. More than 90% of patients had T4N0/N+ disease. A median dose of 50.4 Gy was delivered through multifield techniques and most patients received concurrent 5-FU–based chemotherapy. Eleven patients received an intraoperative "boost" of 10 Gy to 20 Gy. Five-year actuarial overall local control was 40%. Patients with margin negative tumors had a 5-year local control rate of 90%, compared to 46% for patients with microscopic residual tumor and 21% with gross residual tumor (Figure 50-4). In patients with residual disease, local control rates in patients undergoing intraoperative boost were 89% compared to 18% in patients undergoing external irradiation alone (Figure 50-5). Similarly, 5-year survival rates were improved in patients undergoing margin negative resection (66%) compared to those with microscopic residual (47%) or gross residual (23%) (Figure 50-6). Additionally, patients undergoing intraoperative boost demonstrated improved survival (76% versus 26%) (Figure 50-7).

A report from the University of Florida of patients with locally advanced but completely resected colon cancers receiving adjuvant radiation therapy reported a local control rate of 88%, similar to the 90% reported at the Mayo Clinic in patients who had completely resected tumors.[40] In addition, there appeared to be a dose response relationship to local control. The 5-year rate of local control was 96% for patients receiving 50 Gy to 55 Gy versus 76% for patients receiving less than 50 Gy ($p = 0.0095$).

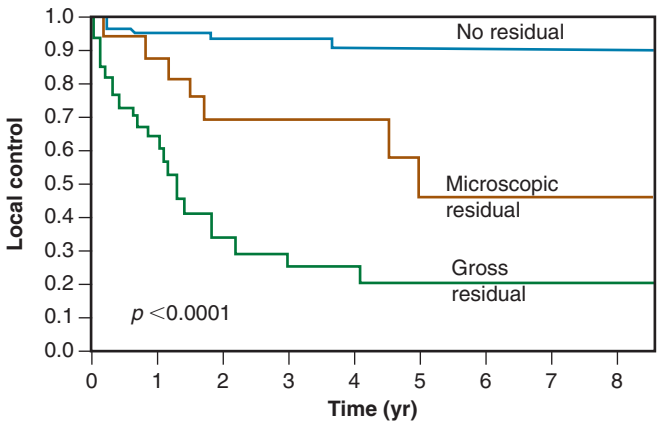

Figure 50-4 Local control by extent of residual disease after maximal resection in a Mayo Clinic series of 103 patients with colon cancer treated with external beam irradiation (EBRT) with or without chemotherapy (concomitant with or without maintenance) with or without intraoperative electron irradiation (IOERT).

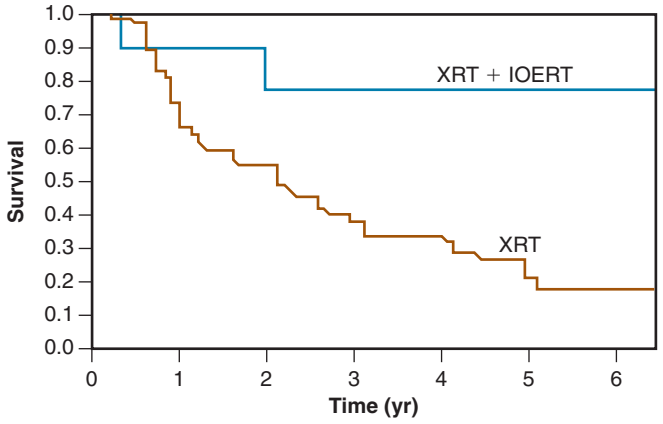

Figure 50-7 Survival results by intraoperative electron beam irradiation (IOERT) administration after maximal resection in a Mayo Clinic series of 103 patients with resected colon cancer treated with external beam irradiation (EBRT) with or without chemotherapy (concomitant with or without maintenance).

A review from the University of Toronto evaluated 33 patients with potentially resectable but locally advanced, adherent colon cancer. Of the 33 patients, 22 had undergone prior laparotomy and surgical exploration without resection given that an R0 resection was not deemed achievable. Patients received neoadjuvant radiation therapy with concurrent infusional 5-FU. All patients then underwent follow-up resection and achieved negative margins. One patient had pathologic complete response and 3 patients had microscopic residual disease only, with approximately two thirds demonstrating ypT4b disease. Three-year overall and disease-free survivals were 86% and 74%, respectively, with two patients developing local recurrence. The authors concluded that neoadjuvant chemoradiotherapy with en bloc multivisceral resection may result in high rates of R0 resection and excellent local control with acceptable morbidity and mortality.[41]

Phase III Intergroup Trial

In 1992 the US GI Intergroup initiated a randomized, prospective trial to assess whether the addition of radiation therapy to adjuvant chemotherapy would result in superior survival and lower locoregional failure rates in patients who were resected with high-risk colon cancer. Eligibility criteria included margin negative tumors with adherence to or invasion of surrounding structures (i.e., T4N0 or N+ disease, excluding peritoneal invasion) or tumors arising in the ascending or descending colon with metastatic regional nodes (T3N+). Patients were randomized to receive weekly 5-FU combined with levamisole for 12 months duration or 5-FU and levamisole for 12 months with combined radiation therapy and chemotherapy beginning 1 month after the first 5-FU administration. The recommended total radiation dose was 45 Gy in 25 fractions over 5 weeks with an optional 5.4 Gy boost.

The initial trial accrual goal was 700 patients; however, the study was closed in 1996 because of poor accrual (222 patients; 189 evaluable) resulting in a decreased statistical power to detect any differences between the groups. No difference in overall or disease-free survival was seen. Five-year overall survival of patients receiving chemotherapy only was 62% compared to 58% for patients randomized to chemoradiation ($p > 0.50$). Local recurrence rates were identical in both arms (18 patients each). Grade-3 and grade-4 hematologic toxicity was higher in patients receiving radiation therapy.[44] Interpretation of the study results was limited by decreased statistical power, high ineligibility rates, and lack of surgical clips or preoperative imaging to assist the definition of appropriate EBRT fields in a high percentage of patients. No definitive conclusions can be made regarding the efficacy of routine postoperative irradiation with 5-FU and levamisole based on this study; however, this study provides no data supporting its routine use.

A subsequent SEER database analysis evaluating patients with colon cancer diagnosed in the United States between 1988 and 2005 showed that tumor location, age, gender, stage, time of diagnosis, and geographic location were significantly associated with radiation therapy use in this disease. Patients diagnosed in 1988 were 2.5 times more likely to receive radiation that those diagnosed in 2005. The authors concluded that radiation therapy is infrequently used for colon cancer and use varies according to patient and tumor characteristics, and that although radiotherapy use had declined markedly since the 1980s, it continued to be used for nonmetastatic disease in a highly individualized manner.[45]

Our current policy is to consider adjuvant tumor bed irradiation in patients with tumors (1) invading adjoining structures, (2) complicated by perforation or fistula, and (3) where incomplete excision is performed. Patients are generally given continuous fluoropyrimidine-based chemo-

therapy 5 days per week throughout the course of radiation therapy.

LOCALLY ADVANCED DISEASE, METASTATIC DISEASE, AND PALLIATION

For patients with metastatic disease, fluoropyrimidine-based chemotherapy is usually administered as a single agent or in combination with oxaliplatin or irinotecan. Prospective randomized trials have shown that multiple agents improve survival in patients with metastatic colorectal cancer. Saltz et al reported the results of a three-arm randomized trial comparing (1) irinotecan, 5-FU, and leucovorin (IFL); (2) 5-FU with IFL; or (3) irinotecan alone. Patients receiving IFL had an improved survival (median survival 14.8 months versus 12.6 months, $p = 0.04$) and response rate (39% versus 21%, $p < 0.001$) compared to 5-FU and IFL alone. The incidence of grade-3 or higher diarrhea was significantly higher with the three-drug regimen.[46]

A study by Goldberg et al randomized 795 patients with previously untreated, metastatic colorectal cancer to receive (1) irinotecan, 5-FU, and IFL; (2) oxaliplatin, 5-FU, and IFL; or (3) irinotecan and oxaliplatin. Patients receiving oxaliplatin, 5-FU, and IFL had an improved median survival compared to those receiving irinotecan, 5-FU, and IFL or irinotecan and oxaliplatin (19.5 months versus 15 months versus 17.4 months; $p < 0.05$ for oxaliplatin-containing regimens versus irinotecan only regimen). Response rates in patients receiving 5-FU, IFL, and oxaliplatin were significantly higher than those receiving irinotecan, 5-FU, and IFL or irinotecan with oxaliplatin (45% versus 31% versus 35%, $p < 0.05$).[47]

Currently, cytotoxic chemotherapy is frequently combined with a targeted agent such as bevacizumab, a monoclonal antibody directed against vascular endothelial growth factor (VEGF), or cetuximab or panitumumab, monoclonal antibodies directed against the epidermal growth factor receptor (EGFR). Cetuximab is a chimeric (mouse/human) antibody and panitumumab is a fully humanized antibody and both are currently only indicated for only tumors without KRAS mutation.

Hurwitz et al reported a randomized trial comparing irinotecan, 5-FU, and IFL with or without bevacizumab. Median survival was significantly improved in the bevacizumab arm (median survival 20.3 months versus 15.6 months, $p < 0.001$). Additionally, response rates were improved in the bevacizumab-containing arm (45% versus 35%, $p = 0.004$).[48] Cunningham et al randomized 329 patients with metastatic colorectal cancer refractory to irinotecan-based chemotherapy regimens to receive cetuximab or cetuximab with irinotecan. Response rates in patients receiving combination therapy were significantly higher (23% versus 11%, $p = 0.007$) as was median time to progression (4.1 versus 1.5 months, $p < 0.001$). No difference in survival was observed.[49] The NO16966 trial evaluated the efficacy and safety of bevacizumab in combination with an oxaliplatin-based regimen. In this trial, 1401 patients were randomly assigned to an oxaliplatin-based therapy, and then to bevacizumab versus placebo, with a primary endpoint of progression-free survival. Although progression-free survival was significantly improved in the bevacizumab group when compared to placebo (9.4 months versus 8.0 months, $p = 0.0023$), the overall survival difference (21.3 months versus 19.9 months, $p = 0.077$) approached but did not reach significance.[50]

In the CRYSTAL trial, 1198 patients with EGFR-positive tumors were randomly assigned to first-line irinotecan-based therapy with or without cetuximab. This trial showed that patients with wild type KRAS had an improvement in overall survival (median 23.5 versus 20 months) and progression-free survival (9.9 versus 8.4 months).[51] Similarly, for oxaliplatin-based therapy, the OPUS trial showed that for patients with KRAS wild-type tumors, the addition of cetuximab to oxaliplatin-based therapy significantly improved response rate (61% versus 37%, $p = 0.0027$) and median progression-free survival (median 7.7 versus 7.2 months, $p = 0.0064$).[52] Finally, in the PRIME trial, a progression-free survival benefit was seen by adding panitumumab to first-line oxaliplatin-based therapy (median progression-free survival 9.6 versus 8 months, $p = 0.02$) and a trend toward improved overall survival (median 24 versus 20 months).[53]

Unfortunately, it remains unclear which targeted agent should be used first. This issue is currently being addressed in two trials; the FIRE-3 trial, in which 735 patients with previously untreated metastatic colorectal cancer are randomly assigned to an irinotecan-based therapy with either bevacizumab or cetuximab, and the US Intergroup C80405 trial, which randomizes patients with KRAS wild-type tumors to cetuximab or bevacizumab with either oxaliplatin- or irinotecan-based therapy. The results of this trial should help to answer the issue of optimal first-line therapy for patients with KRAS wild-type tumors. However, trials evaluating the combination of chemotherapy plus bevacizumab, with or without panitumumab, demonstrated increased toxicity and decreased progression-free survival in patients receiving both anti-VEGF and anti-EGFR therapy, suggesting that dual antibody therapy is not appropriate in these patients.[54] Other novel agents remain the focus of ongoing investigation in both the metastatic and nonmetastatic setting.

Palliative irradiation, sometimes in combination with fluoropyrimidine–based chemotherapy, is considered for patients with specific symptoms referable to metastatic disease—brain, bone, and other sites. Although beyond the scope of this chapter, the use of SBRT is being increasingly used in colorectal cancer patients with oligometastatic disease, including hepatic metastases. The combination of radiation therapy and targeted agents (bevacizumab, cetuximab) remains a topic of investigation.

TECHNIQUES OF IRRADIATION

Treatment field design in colon cancer is based on patterns of failure data. As is true in the treatment of rectal carcinoma, care must be taken in the design of postoperative treatment of adenocarcinoma of the colon. Field arrangement will vary depending on the site of the primary disease as well as areas judged to be at high risk for local recurrence.[55] Patient positioning (supine, prone, decubitus) should be considered in planning. Small bowel is often a dose-limiting structure, and it is often advantageous to position patients in the right or left decubitus position for at least a portion of their treatment, which may facilitate displacement of the small bowel away from the treatment field. Immobilization devices may improve reproducibility. Small-bowel contrast helps define small bowel volume within the treatment field. It may be useful to compare images in both the decubitus and supine positions to determine the actual amount of small bowel displacement. CT-based planning facilitates definition of the tumor bed, determining beam orientation, as well as estimating the volume of small bowel included within the treatment fields. As in other abdominal malignancies, a portion of one kidney may be irradiated. Unilateral renal irradiation results in minimal long-term clinical sequelae, assuming baseline function in the contralateral kidney is normal.[56]

The total radiation dose used in the adjuvant treatment of colon carcinoma depends on the volume of suspected residual disease and tolerance constraints of surrounding normal tissue. Generally, an initial dose of 45 Gy in 25 fractions of 1.8

Gy per fraction is delivered through larger fields to the primary tumor and at risk tissues. Reduced fields may be treated to 50 Gy if only a small portion of small bowel is included. For patient with T4 tumors, the general goal is to treat the tumor bed to a total dose of 54 Gy to 60 Gy. Treatment beyond 50 Gy generally mandates exclusion of all small bowel from the field. Spinal cord dose should generally be limited to 45 Gy. In addition, at least two thirds of one functional kidney should receive no more than 18 Gy to 20 Gy, and at least two thirds of the total liver volume should not receive more than 30 Gy. In a Mayo Clinic analysis, small bowel obstruction rates were lower when more than two treatment fields were used, and attempts should be made to implement multifield techniques, which is aided by CT-based planning.[57] Three-dimensional treatment planning as well as the use of intensity-modulated radiation techniques may facilitate small bowel as well as other normal organ sparing.

Generally, the primary tumor site should be covered with generous margin to cover areas of potential residual disease. The more proximal mesenteric nodal basins beyond the region of the primary tumor are usually not treated if satisfactory margin clearance is obtained in these sites. An exception to this may be right colon tumors where both small bowel and right colon are supplied by ileocolic vessels, limiting the extent of resection. In some instances, treatment of the paraaortic nodes may be indicated, particularly with extensive retroperitoneal involvement by tumor. In many situations, it may be appropriate to exclude treatment of paraaortic nodal basins, based on operative and pathological findings. Treatment of proximal mesenteric nodes may be appropriate if nodes adjacent to the surgical or resection margin are involved. Figures 50-8 and 50-9 show example radiation fields for a cecal as well as sigmoid cancer. Because of improved disease-related outcomes seen in patients with rectal cancer treatment with concurrent radiation therapy and fluoropyrimidine-based chemotherapy, as well as survival benefit seen in node-positive colon cancer receiving 5-FU–based chemotherapy, adjuvant irradiation in patients with resected high-risk colon cancer should be administered concurrently with fluoropyrimidine-based based chemotherapy.

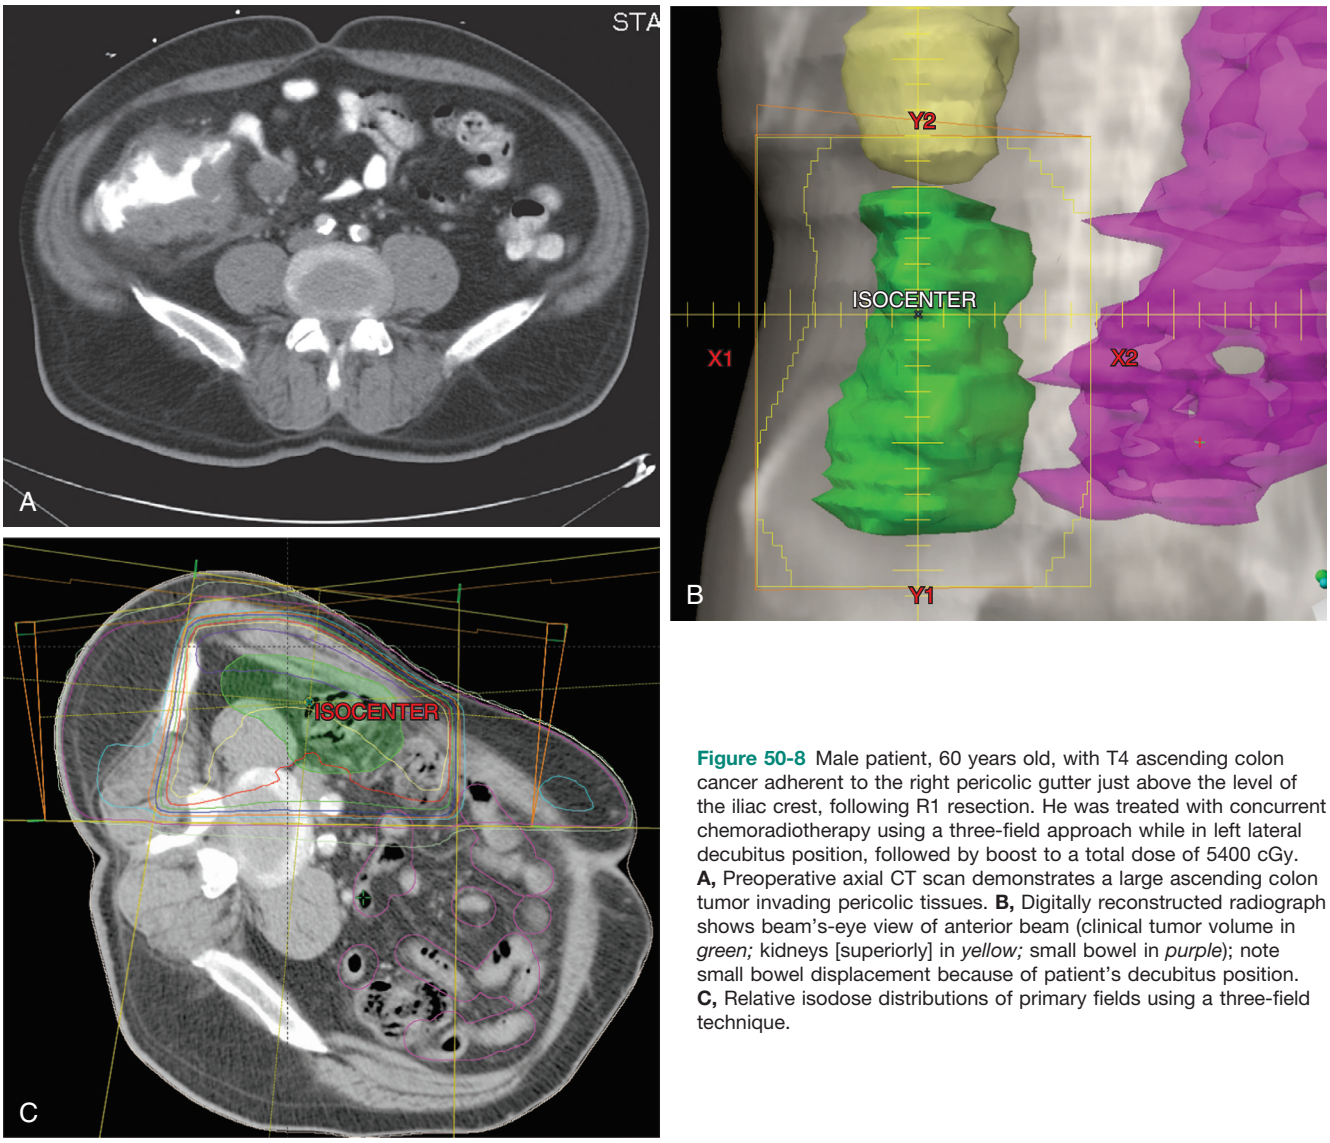

Figure 50-8 Male patient, 60 years old, with T4 ascending colon cancer adherent to the right pericolic gutter just above the level of the iliac crest, following R1 resection. He was treated with concurrent chemoradiotherapy using a three-field approach while in left lateral decubitus position, followed by boost to a total dose of 5400 cGy. **A,** Preoperative axial CT scan demonstrates a large ascending colon tumor invading pericolic tissues. **B,** Digitally reconstructed radiograph shows beam's-eye view of anterior beam (clinical tumor volume in *green;* kidneys [superiorly] in *yellow;* small bowel in *purple*); note small bowel displacement because of patient's decubitus position. **C,** Relative isodose distributions of primary fields using a three-field technique.

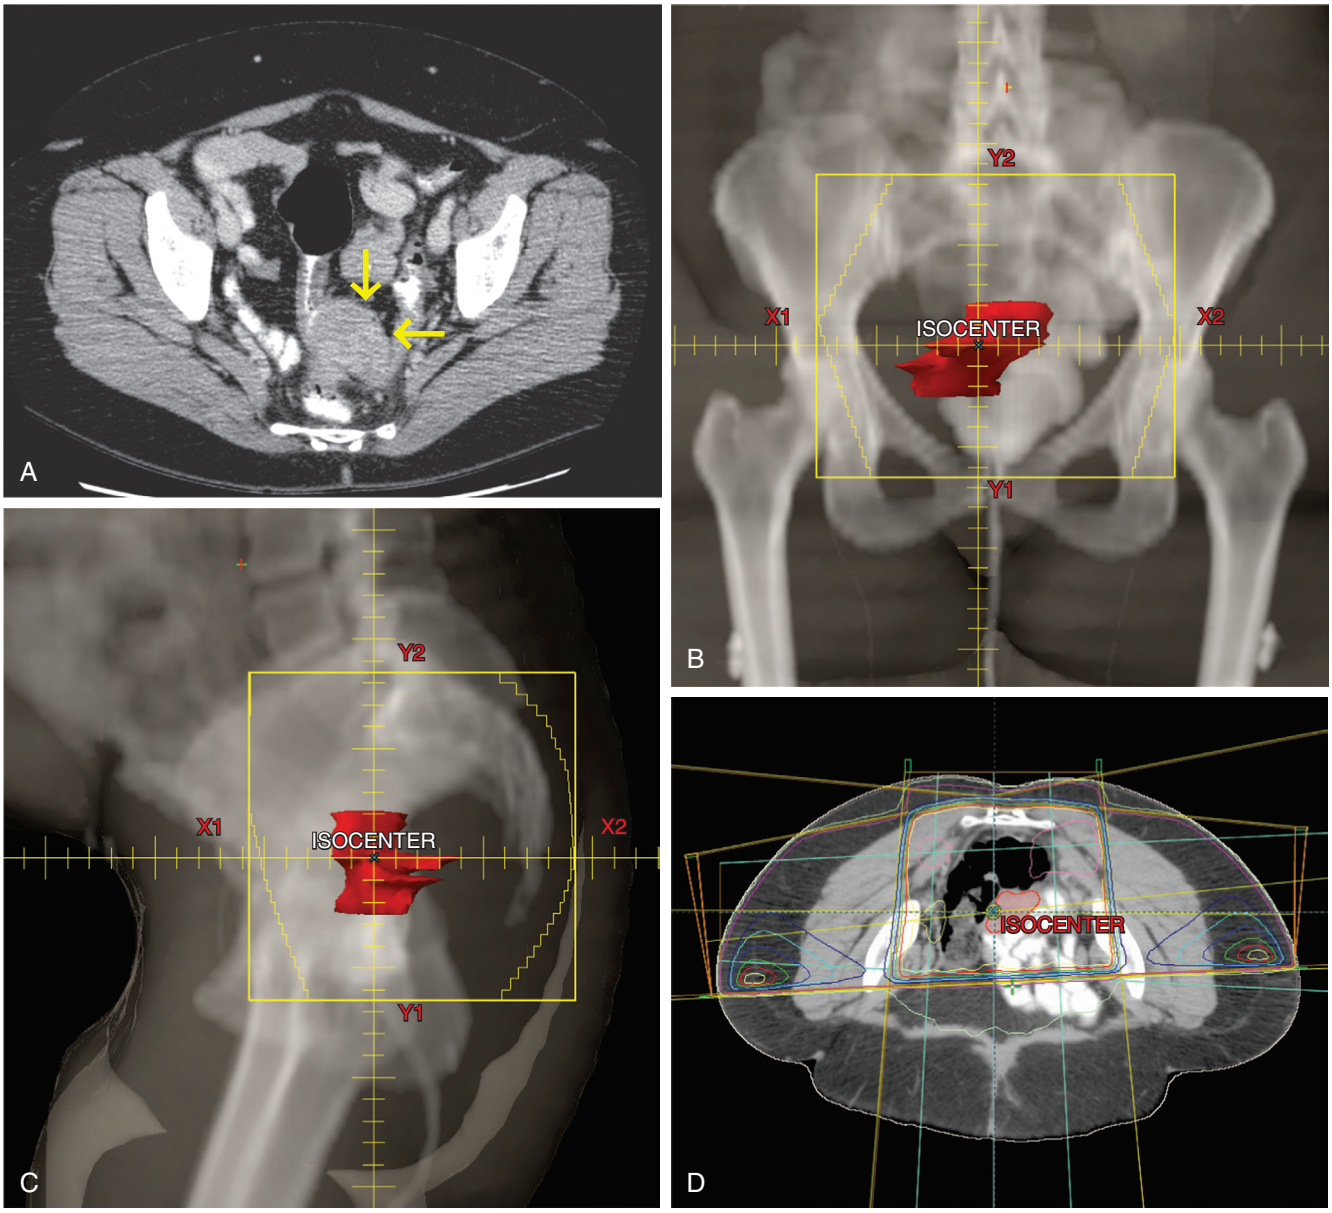

Figure 50-9 Female patient, 54 years old, with nearly obstructing sigmoid lesion at 35 cm from the anal verge. During left hemicolectomy, a perforated sigmoid cancer was found eroding into the proximal rectum with possible vaginal cuff involvement. She was treated with concurrent chemoradiotherapy using a three-field approach, in prone position with false tabletop, to a total dose of 4500 cGy. **A,** Axial CT slice shows sigmoid tumor *(yellow arrows)* invading adjacent rectum. **B,** Digitally reconstructed radiograph shows beam's-eye view of posterior beam (reconstructed gross tumor volume in *red*). **C,** Digitally reconstructed radiograph shows beam's-eye view of lateral beam. **D,** Relative isodose distributions of primary fields.

TREATMENT ALGORITHM, CONCLUSIONS, AND FUTURE POSSIBILITIES

Subsets of patients with colon cancer have local recurrence rates similar to patients with rectal cancer if surgery only is undertaken. Because of encouraging pilot study results with postoperative irradiation with or without 5-FU for patients with resected high-risk colon cancers, and the positive results of 5-FU and levamisole in high-risk adjuvant colon cancer, an Intergroup randomized trial was undertaken, randomizing patients to 5-FU and levamisole or 5-FU and levamisole with tumor bed irradiation in patients at high risk for local recurrence following surgical resection. There was no survival benefit seen in patients receiving adjuvant radiation therapy; however, interpretation of these results is limited by inadequate accrual and significant flaws as previously discussed.

The value of adjuvant postoperative irradiation combined with systemic therapy for patients at high-risk for local relapse is unlikely to be further addressed in a definitive randomized trial. Treatment recommendations should be made on a case-by-case basis with existing data in the setting of an informed consent. A potential treatment algorithm for these patients is shown in Box 50-2 and reflects the personal preference of the chapter authors.

The use of intraoperative irradiation as a supplement to EBRT in certain T4 tumors (i.e., those with uncertain margins) may also be appropriate. For patients with tumors adherent to or invading adjacent structures, the preferred treatment

BOX 50-2 Treatment Algorithm: Approach to the Therapy of Colon Cancer

1. TNM stages T1-2N0: complete resection
2. TNM T3N0: complete resection with consideration of adjuvant chemotherapy
3. TNM T4N0: complete resection with consideration of adjuvant chemotherapy; consider tumor bed/nodal irradiation with fluoropyrimidine-based chemotherapy
4. TNM T1-3N+: complete resection with consideration of adjuvant chemotherapy; for T3N1 tumors arising in immobile bowel with narrow resection margins, consider tumor bed/nodal irradiation with fluoropyrimidine-based chemotherapy.
5. TNM T4N+: complete resection followed by adjuvant chemotherapy; consider tumor bed/nodal irradiation with fluoropyrimidine-based chemotherapy.
6. Patients with fixed tumors: Preoperative irradiation with fluoropyrimidine-based chemotherapy followed by resection with intraoperative irradiation (electrons or brachytherapy) and maintenance chemotherapy.
7. Patients undergoing subtotal resection: External beam irradiation with fluoropyrimidine-based chemotherapy with intraoperative irradiation (electrons or brachytherapy) where possible with maintenance chemotherapy

sequence would be preoperative EBRT plus fluoropyrimidine–based chemotherapy followed by resection with or without IOERT and postoperative systemic therapy, based on excellent results in preliminary IOERT reports from both U.S. and European institutions.[42,57-59] A similar approach would be reasonable for patients with locally recurrent cancers or with regional nodal relapse.[59-62]

CHAPTER

51 Rectal Cancer

Bruce D. Minsky, Claus M. Rödel, and Vincenzo Valentini

INCIDENCE

Colorectal cancer is the fourth most common form of cancer worldwide, with an estimated 800,000 new cases diagnosed each year, accounting for roughly 10% of all cancers. Approximately two thirds of cases occur in the colon and one third in the rectum. In the United States, an estimated 39,610 new cases of rectal cancer were estimated to occur in 2015.

BIOLOGIC CHARACTERISTICS

The most important prognostic factor for overall survival is the pathologic extent of disease as determined by the degree of bowel wall penetration by the tumor and the presence or absence of lymph node metastases or distant metastases (TNM stage).

Several biologic markers are now being prospectively evaluated in clinical trials to determine their prognostic utility. At the present time, the TNM staging system is the most reliable.

STAGING EVALUATION

The pretreatment evaluation of a patient with rectal cancer should include a careful history and physical examination. The primary imaging modalities for assessing the extent of the primary tumor are endorectal ultrasound (ERUS), computed tomography (CT), and magnetic resonance imaging (MRI). Both ERUS and high-resolution pelvic MRI are accurate in predicting T category. High-resolution MRI is highly accurate in identifying mesorectal fascial involvement (circumferential resection margin [CRM] positivity). Identifying nodal disease is still a diagnostic problem with CT, MRI, and ERUS, which rely on size criteria for predicting nodal metastases whereas positron emission tomography (PET)/CT does not rely on size criteria and is accurate, when indicated.

PRIMARY THERAPY

The primary therapy for potentially curative rectal cancer is surgery. Identification of radial microscopic lymphatic spread within the mesorectum has led to the use of total mesorectal excision (TME). With this type of surgery, local control rates have markedly increased. However, even with TME, the local failure rate for pathologic node-positive disease is 21% and adjuvant chemoradiation is still necessary.

ADJUVANT THERAPY

The conventional treatment for uT3 to T4 or node-positive clinically resectable rectal cancer is preoperative chemoradiation followed by surgery and postoperative adjuvant chemotherapy. In the German Rectal Cancer Phase III trial, which compared preoperative and postoperative chemoradiation, patients who received preoperative therapy had a significant decrease in rates of local failure, acute toxicity, and chronic toxicity and a significant increase in the rate of sphincter preservation in patients felt to need abdominoperineal resection before treatment. The primary disadvantage of preoperative irradiation or chemoradiation is the possible overtreatment of patients with early-stage (pT1-2N0) disease or undetected metastatic disease. For patients who undergo surgery first, if the tumor is pT3-4N0 or TanyN+, the treatment is commonly postoperative chemoradiation.

LOCALLY ADVANCED DISEASE

With the exception of the uncommon suture line-only recurrence, patients with primary or recurrent unresectable disease should receive preoperative chemoradiation. Although 50% to 90% will be able to undergo resection with negative margins, depending on the degree of tumor fixation, 24% to 55% still develop local recurrence. The addition of intraoperative irradiation decreases the rate of local recurrence.

PALLIATION

Pelvic irradiation offers effective palliation. In most patients, it decreases pelvic pain and bleeding.

Rectal cancer treatment is one of the best examples in oncology of how patients derive benefits from cooperative multimodal treatment strategies. These strategies are as variable as the clinical presentations of the disease. For example, this type of cancer can present as an early tumor suitable for local excision, a locally advanced tumor that requires preoperative therapy plus radical surgery, a tumor invading an adjacent organ or structure with no evidence of distant metastases, or a tumor with distant metastases. Radiation therapy has a well-established role in the treatment of rectal cancer and is used in the definitive, adjuvant, neoadjuvant, and palliative settings. Identifying which patients may benefit most from preoperative, postoperative, or intraoperative radiotherapy and which regimen would be best for which individual patient is undergoing active investigation.

ETIOLOGY AND EPIDEMIOLOGY

The etiology of colorectal cancer appears to be multifactorial and includes both environmental and genetic factors. Approximately 75% of colorectal cancers are sporadic, whereas 15% to 20% develop in those with either a positive family history or a personal history of colorectal cancer or polyps. The remaining cases occur in people with genetic predispositions, such as hereditary nonpolyposis colorectal cancer (HNPCC, Lynch syndrome; 2% to 4%) or familial adenomatous polyposis (FAP; 1%), or in people with inflammatory bowel disease, particularly chronic ulcerative colitis (1%).

The fundamental role of environmental factors is supported by observations in migrant populations. Generally, migrants from low-incidence regions in Africa and Asia who

relocate to high-incidence regions of North America or Australia assume the incidence of the host country within one generation.[1] Specifically, a high-fat, low-fiber diet is associated with the development of colorectal cancer. Conversely, the ingestion of a high-fiber diet is associated with protection against colorectal cancer. Fiber causes the formation of a soft, bulky stool that dilutes out carcinogens; it also decreases colonic transit time, allowing less time for carcinogenic substances to contact the mucosa. The more sedentary lifestyle in Western countries, cigarette smoking, and alcohol consumption also appear to be linked with the risk of colorectal neoplasia.

Most colorectal cancers arise from benign adenomatous polyps lining the wall of the bowel. Those that grow to a large size (>2 cm) and have a villous appearance or contain dysplastic cells are most likely to progress to cancer. This progression from adenoma to carcinoma is associated with an accumulation of genetic alterations, including activation of oncogenes and inactivation of tumor suppressor genes.[2] One of the early steps in this process is the interruption of the APC/β-catenin/TCF-4 pathway, allowing unchecked cellular replication at the crypt surface. This can occur in the germline of patients with FAP, with the second allele being inactivated somatically, or in sporadic cancers, in which both alleles are somatically inactivated.

There are likely three pathways that lead to colorectal cancer: chromosomal instability (CIN), microsatellite instability (MSI), and CpG island methylator phenotype (CIMP).[2] These pathways are not mutually exclusive, with some tumors exhibiting features of more than one pathway. CIN is the genetic reason for tumor formation in 50% to 70% of colorectal cancers and the mechanism operative in FAP. It is characterized by gain or loss of whole chromosomes or chromosomal regions, subsequently resulting in aneuploidy, telomerase dysfunction, or defects in DNA damage response. It is typically coupled with mutations in the APC, KRAS, and TP53 genes, ultimately leading to loss of heterozygosity of TP53 and malignant transformation. MSI is found in more than 90% of HNPCCs that carry a germline inactivation in DNA mismatch repair genes, but it is also found in 15% of sporadic cancers, in which epigenetic hypermethylation silences gene transcription of hMLH1. With MSI, multiple frameshift mutations at microsatellite sequences occur, including those in exon coding sequences of the transforming growth factor-beta receptor II, the proapoptotic BAX gene, and the DNA mismatch repair genes (hMSH3 and hMSH6 genes). The third type, CIMP, is a relatively heterogeneous subgroup and occurs in approximately 10% to 30% of patients, is predominantly associated with KRAS gene mutations but sometimes with BRAF gene mutations, usually lacks chromosomal instability, and has the poorest prognosis of the three types and perhaps a poorer response to chemotherapy. Of the numerous molecular markers examined to date, MSI, 18q, thymidylate synthase, and TP53 overexpression are among those which appear to have the most prognostic significance in colon cancer.[3]

Colorectal cancer is the fourth-commonest form of cancer and the second-leading cause of death in the United States. Approximately two thirds of cases occur in the colon and one third in the rectum. In the United States, annually approximately 132,270 new cases of large bowel cancer are diagnosed, of which 93,090 are colon and 39,610 are rectal cancers.[4] The occurrence of sporadic colorectal cancer increases continuously older than the age of 45 to 50 years for both genders and peaks in the seventh decade. Subgroups of patients, including those with inherited syndromes, such as FAP, HNPCC, or hamartomatous polyposis conditions (e.g., Peutz-Jeghers syndrome), can experience colorectal cancer at a much earlier age.

PREVENTION AND EARLY DETECTION

Primary Prevention

Primary prevention involves the identification and elimination of factors that cause or promote colorectal cancer or interfere with the adenoma-to-carcinoma cascade. Dietary and lifestyle approaches employ higher-fiber, lower-fat components, and increased physical activity to inhibit the carcinogenic process. Prospective studies have suggested that vitamin D deficiency may contribute to the incidence of colorectal cancer.[5] Other dietary components, such as selenium, carotenoids, and vitamins A, C, and E, may also have protective effects by scavenging free oxygen radicals. Folic acid, a component of fresh fruits and green vegetables, supplies methyl groups necessary for nucleotide synthesis and gene regulation. Prospective studies generally support an inverse association between folate intake and colorectal cancer risk.[6]

COX-2 is overexpressed in more than 50% of adenomas and 80% to 85% of adenocarcinomas. Chemopreventive strategies are based on population-based studies that strongly support an inverse relationship between the use of nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin, sulindac, or the new selective COX-2 inhibitors, and the risk of colorectal adenomas or carcinomas. Nevertheless, the consumption of NSAID and COX-2 inhibitors may cause serious adverse events to the gastrointestinal, renal, and cardiovascular system. Thus, the optimal dosage and duration, and proper patient selection stills need to be established.[7]

Screening for Early Detection

The process of malignant transformation from adenoma to carcinoma takes several years. The goal of screening is to prevent rectal cancer deaths through the detection and treatment of benign or premalignant lesions and curable-stage cancers. For the average-risk population, screening should begin at age 50 years and should follow one of the following testing options: fecal occult blood testing (FOBT) or fecal immunochemical testing (FIT) every year, flexible sigmoidoscopy every 5 years, double-contrast barium enema every 5 years, CT colonography (virtual colonoscopy) every 5 years, or colonoscopy (preferably) every 10 years.[8]

Some individuals are at increased risk for colorectal cancer. For example, if there is an affected first-degree relative, a family history of FAP or HNPCC, or a personal history of adenomatous polyps, colorectal cancer, or chronic inflammatory bowel disease, screening should begin earlier (at age 40 years) or it should be done more often than in average-risk persons. In some settings such as a personal history of genetic predisposition, screening should be done at an even younger age, as detailed in the NCCN Guidelines for Colorectal Cancer Screening (to view the most recent version, visit www.NCCN.org).

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

The most important prognostic factor for overall survival is the pathologic extent of disease as determined by the degree of bowel wall penetration by the tumor (T category), and the presence or absence of lymph node metastases (N category) or distant metastases (M category). Tumor differentiation (grading) is also prognostically important because poorly differentiated adenocarcinomas are associated with lymph node metastases in more than 50% of cases and also correlate with the likelihood of lymphatic and venous invasion. An elevated

carcinoembryonic antigen (CEA) level at the time of presentation has an adverse impact on survival times independent of tumor stage.[9] Detection of occult metastases in lymph nodes, blood, or bone marrow by molecular techniques may allow further refinement in pathologic staging.

Molecular strategies added to the more traditional histopathologic information may help in the future to identify patients at a lower stage whose tumors are likely to behave like higher-stage lesions, and vice versa. Several biologic markers, including allelic loss of 18q, alteration in KRAS, MSI, thymidylate synthase, thymidine phosphorylase, vascular endothelial growth factor (VEGF), epidermal growth factor receptor (EGFR), P21, P27, BCL2, BAX, and TP53, among others, are now being prospectively evaluated in clinical trials to determine their prognostic utility. At the present time, however, the TNM staging system is the most reliable.

PATHOLOGY AND PATHWAYS OF SPREAD

Histopathology

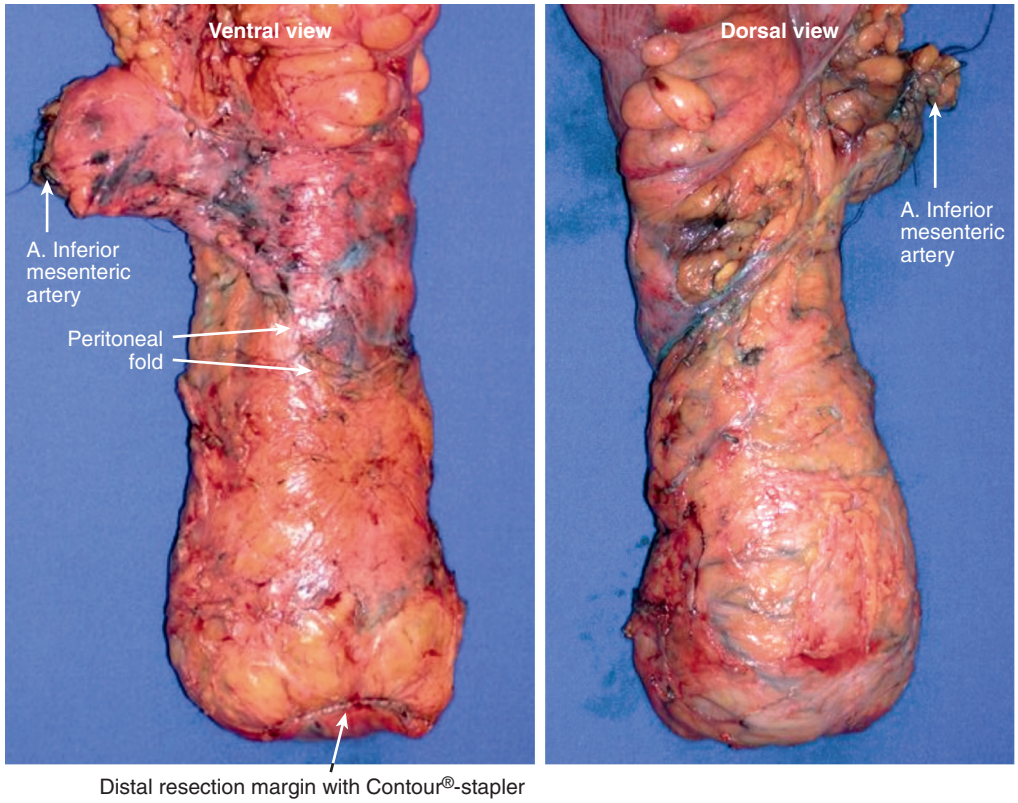
The majority (>90%) of colorectal cancers are adenocarcinomas. Some adenocarcinomas have mucin, which can be extracellular (colloid) or intracellular (signet-ring cell). Colloid cancer, which occurs in 15% to 20% of adenocarcinomas, is not an independent prognostic factor, whereas signet-ring cell carcinoma, which occurs in 1% to 2% of adenocarcinomas, is an independently poor prognostic factor for survival.[10] Other histologic types are rare and include carcinoid tumors, leiomyosarcomas, lymphomas, and squamous cell cancers. The grading system used for adenocarcinomas refers to the degree of differentiation. Most institutions use a three-grade system (well, moderate, and poor). Despite substantial interobserver and intraobserver variability in tumor grading, poorly differentiated tumors have consistently been found to be associated with a worse prognosis in multivariate analysis.

Anatomy and Pathways of Spread

The rectum is about 15 cm long. In cancer staging, because of differences in treatment and prognosis, the rectum is subdivided into three parts according to the distance of the lower margin of the tumor from the anal verge (assessed by rigid proctoscopy): upper third, 12 to 16 cm; middle third, 6 to 12 cm or less; and lower third, less than 6 cm. When reporting results, it should be stated whether the reference point is the anal verge (i.e., lowermost portion of the anal canal), the dentate line, or the anorectal ring. Distances measured from the anal verge are approximately 2 cm to 3 cm longer than distances from the dentate line. The anorectal ring (also known as the dentate line) is at the level of the puborectalis sling and levators, representing the pelvic floor from within the pelvis. The anterior peritoneal reflexion represents the point at which the rectum exits the peritoneal cavity (approximately 12 cm to 15 cm from the anal verge) and becomes an extraperitoneal structure. Patients entered into postoperative adjuvant rectal trials in the United States were required to have tumors with the inferior aspect at or below the peritoneal reflection. For entry into preoperative trials, most use tumors with a distance of less than 12 cm from the anal verge for eligibility. However, the German trial (CAO/ARO/AIO-94) allowed tumors at a distance of as much as 16 cm.[11,12]

Below the peritoneal reflection, there is a mesorectal fascia (MRF). This layer of visceral fascia encloses both the rectum and mesorectum with the perirectal lymph nodes and thus forms a separate compartment within the pelvis. With TME, the entire specimen is removed by sharp dissection along the mesorectal plane (eFigure 51-1). The CRM is related more to the type and quality of the surgical procedure than to an anatomic landmark. Although distal intramural spread usually extends no more than millimeters beyond the grossly recognizable margin of the tumor, microscopic tumor nodules (satellites) are found in the mesorectum, predominantly in a radial direction but also in a distal one, some centimeters from the lower tumor margin.[13]

The major portion of the lymphatic drainage of the rectum passes along the superior hemorrhoidal arterial trunk toward the inferior mesenteric artery. Only a few lymphatics follow the inferior mesenteric vein. The pararectal nodes above the level of the middle rectal valve drain exclusively along the superior hemorrhoidal lymphatic chain. Below this level (≈7 cm to 8 cm above the anal verge), some lymphatics pass to the lateral rectal pedicle. These lymphatics are associated with nodes along the middle hemorrhoidal artery, obturator fossa, and hypogastric and common iliac arteries. The risk of their involvement increases with tumor stage, presence of mesorectal positive nodes, infiltration of mesorectal fascia, and low location of the primary tumor. Extensive lymphatics are also present in women contiguous with the rectovaginal septum and in men along Denonvilliers' fascia. The venous drainage of the upper rectum is to the inferior mesenteric vein via the superior hemorrhoidal vein and then to the portal system, whereas the lower rectum can, in addition, drain to the internal iliac veins and inferior vena cava. Therefore, liver or lung metastases, or both, can occur with rectal cancers.



CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Clinical Manifestations

Rectal cancer is usually symptomatic before diagnosis. Common symptoms include gross red blood (mixed or covering stool, or by itself, sometimes accompanied by the passage of mucus) and a change in bowel habits such as unexplained constipation, diarrhea, or reduction in stool caliber. Hemorrhoidal bleeding should always be a diagnosis of exclusion. Obstructing rectal cancers frequently present with diarrhea rather than constipation. In cases of locally advanced rectal cancer with circumferential growth and extensive transmural penetration, urgency, inadequate emptying, and tenesmus occur. Urinary symptoms and buttock or perineal pain from posterior extension are grave signs. Sciatic pain is indicative of tumor invasion into the sciatic notch, and surgery will likely leave gross disease.

Pretreatment Evaluation and Imaging

The standard diagnostic algorithm for rectal cancer is seen in Table 51-1. The pretreatment evaluation of a patient with rectal cancer should include a careful history and physical examination. By digital rectal examination (the average finger can reach approximately 7 cm to 8 cm), tumors can be assessed for size, ulceration, and fixation to surrounding structures. This examination also permits evaluation of sphincter function, which is critical when determining whether a patient is a candidate for a sphincter-sparing procedure. Rigid proctoscopy allows direct visualization of the lesion and provides an estimation of the size of the lesion and degree of obstruction. This procedure is used to obtain biopsies and gives an accurate measurement of the distance of the lesion from the anal verge. A complete evaluation of the large bowel, preferably by colonoscopy, should be done to rule out synchronous neoplasms.

eFigure 51-1 TME specimen after preoperative chemoradiation and perioperatively performed staining with methylene blue via the inferior mesenteric artery.

TABLE 51-1 Diagnostic Algorithm for Rectal Cancer

History	Including family history of colorectal cancer or polyps
Physical examination	Including assessment of size, minimum diameter of lumen, mobility, distance from anal verge, and cursory evaluation of sphincter function
Rigid proctoscopy	Including assessment of mobility, minimum diameter of lumen, and distance from anal verge. Allows biopsy of the primary tumor.
Colonoscopy	To detect possible synchronous colorectal neoplasm
Endorectal ultrasound*	To assess depth of tumor penetration through the rectal wall and involvement of adjacent mesorectal lymph nodes.
Pelvic MRI*	To assess depth of tumor penetration through the rectal wall, tumor invasion of mesorectum, and involvement of mesorectal and pelvic lymph nodes. Particularly useful for assessment of distance of tumor to mesorectal fascia.
Chest, abdominal, or pelvic CT*	With intravenous and oral contrast; to detect possible metastatic disease.
PET/CT scanning	Not routinely indicated; should only be used if contrast CT or MRI show equivocal findings or in patients with strong contraindications to IV contrast.
CEA levels	To obtain baseline CEA level (a prognostic factor and important for follow-up)
Complete blood count	To check for anemia secondary to bleeding

CEA, *Carcinoembryonic antigen*; CT, *computed tomography*; MRI, *magnetic resonance imaging*; PET, *positron emission tomography*.
**For sensitivity and specificity of endorectal ultrasound, pelvic CT and pelvic MRI for local staging see Table 59.2.*

With the shift to preoperative therapy, clinical staging to accurately identify both T category and N category is critical. The primary imaging modalities to assess the extent of the primary tumor are ERUS, multidetector 4- to 16-slice CT, and phased array MRI. ERUS is an accurate tool in predicting T category of rectal cancers, especially T1 compared to T2 (eTable 51-1, eTable 51-2 and eFigure 51-2). Thus, ERUS has been recommended as the investigation of choice in selection of potentially curative local excision, which should be restricted to patients with T1 tumors without further risk factors (such as G3, L1, sm3), as well as in selection of patients with early T3 tumors (versus T2) for neoadjuvant treatment. ERUS cannot be reliably used in patients with high or stenosing tumors.

Because of limited acoustic penetration by ERUS, invasion of bulky tumors into the perirectal fat, adjacent organs, and pelvic side walls is better evaluated by multislice-CT scan and phased array MRI. The involvement of the anal sphincter and levator ani muscles cannot be truly seen on CT scans, whereas high-resolution MRI techniques using phased-array coils have led to improved spatial resolution and have been shown to identify the anal sphincter, puborectalis, and especially the mesorectal fascia (Figures 51-1, *A* and *B*). This latter finding is an important feature to predict negative circumferential margins between the tumor and the mesorectal fascia, and makes phase array MRI superior to CT especially for lower-third rectal tumors. Moreover, substaging of T3 tumors (T3a/b with tumor spread ≤5 mm into the mesorectal compartment) has been validated prospectively by the MERCURY study group and has shown direct agreement between pretreatment imaging and corresponding pathology.[15]

The identification of positive lymph nodes is more difficult. Involvement is mainly assessed by size criteria (> 8 mm), although enlarged lymph nodes are not pathognomonic of tumor involvement. Morphological features such as the presence of mixed signal intensity and irregularity of the borders of the lymph nodes may be more reliable.[16] In the meta-analysis of Bipat et al, the sensitivity and specificity in detecting positive lymph nodes with the aforementioned techniques were comparable (51-2).[17] However, only CT and MRI can evaluate iliac, mesenteric, or retroperitoneal nodes. Clearly, adequate clinical detection of lymph node involvement remains a challenge that is critically important with the increasing use of preoperative treatment strategies.

Screening for distant metastatic disease is accomplished routinely by chest and abdominal contrast-enhanced CT or abdominal MRI. Bone scan and brain imaging are required for clinical symptoms only. The major advantage of a PET scan is to differentiate between recurrent tumor and scar tissue by measuring tissue metabolism of an injected glucose-based substance. Scar tissue is inactive, whereas tumor generally is hypermetabolic. This test generally is not used in a routine preoperative metastatic workup.

Imaging after Chemoradiation

Although ERUS, CT, and MRI can be used to assess downsizing and staging of the tumor after neoadjuvant multimodal treatment, it is not accurate in distinguishing between ypT0, ypT1, ypT2, or ypT3 residual cancers. Overstaging is common, especially when there is a fibrotic thickening of the rectal wall. A reasonably high level of accuracy has been observed by phased array MRI for differentiating ypT0-2 from ypT3.[18] Diffusion-weighted MRI has been investigated to monitor therapy response and to predict outcome to preoperative therapy; however, further studies are needed.[19] For the identification of responders to neoadjuvant therapy, 18-FDG-PET has a larger role. Many studies have reported a significant decrease in standardized uptake values (SUV) on mid- or post-radiation FDG-PET in responders when compared to nonresponders, but the clinical value of this information remains to be determined.[20]

TNM Staging

The first practical staging system was the Dukes' classification in the 1930s.[21] This system classified colorectal tumors from A to C, with stage A indicating penetration into but not through the bowel wall, stage B indicating penetration through the bowel wall, and stage C indicating involvement of lymph nodes, regardless of the extent of bowel wall penetration. The system has since been modified by many authors to better reflect levels of penetration and nodal metastases. In 1998, the American Joint Commission on Cancer (AJCC) and the Union Internationale Contre le Cancer (UICC) proposed a joint TNM classification staging system.

In the sixth edition of the AJCC staging manual, stage II colorectal cancer was subdivided into IIA (T3N0) and IIB (T4N0) and stage III was subdivided into IIIA (T1-2N1M0), IIIB (T3-4N1M0), and IIIC (any TN2M0), based on improved

eTABLE 51-1 Sensitivity and Specificity of ERUS, Pelvic CT, and MRI in the Staging of Rectal Cancer*

Tumor Extent	Imaging Modality	Sensitivity (%)	Specificity (%)
Muscularis propria invasion	ERUS	94	86
	MRI	94	69
	CT	NA	NA
Perirectal tissue invasion	ERUS	90	75
	MRI	82	76

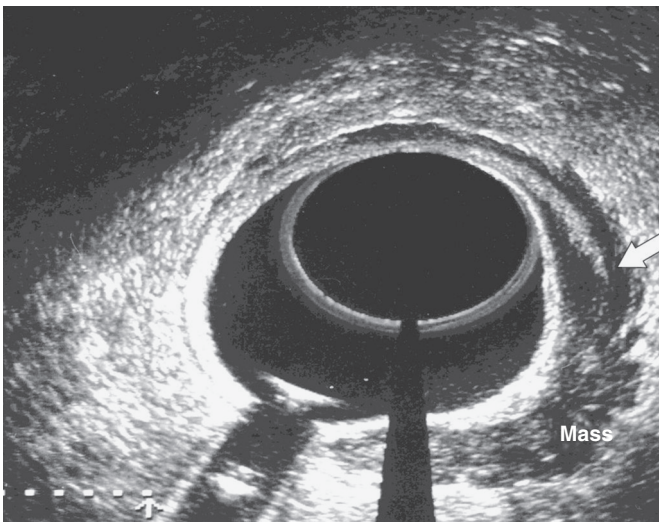
**According to Bipat S, Glas AF, Slors FJM, et al: Rectal cancer: local staging and assessment of lymph node involvement with endoluminal US, CT, and MR imaging—a meta-analysis. Radiology 232:773–783, 2004.*



eTABLE 51-2 Grading of Surgical TME Specimen According to Quirke[14]

Good (grade 1): intact mesorectum with only minor irregularities of a smooth mesorectal surface; no defects larger than 5 mm; no coning on specimen; smooth circumferential resection margin on slicing.

Moderate (grade 2): moderate bulk to mesorectum but irregularity of the mesorectal surface; moderate coning of the specimen toward the distal margin; at no site is the muscularis propria visible with the exception of the area of insertion of levator muscles; moderate irregularity of the circumferential resection margin.

Poor (grade 3): little bulk of mesorectum with defects down into muscularis or very irregular circumferential resection margin.

Of note, overestimation of staging with this technique occurs more often than understaging. In the German CAO/ARO/AIO-94 study, 18% of patients in the immediate surgery arm clinically staged by ERUS to have T3 or N+ disease had lymph node negative tumors confined to the rectal wall (pT1/2 pN0) on pathologic assessment of the resected specimen.[12,14] This probably is as a result of the inflammatory and desmoplastic processes caused by the tumor (or by taken tumor biopsy within 1 week before ERUS was performed), but it is also operator dependent. Endorectal coil MRI is an alternative to ERUS but does not appear to be superior to ERUS for T staging.

eFigure 51-2 Endorectal ultrasound (ERUS) visualizes the rectal wall as alternating hyperechoic and hypoechoic layers of tissue. The first layer is the hyperechoic water-filled balloon or mucosal interface, which is bounded by the hypoechoic mucosa and muscularis mucosa, the hyperechoic submucosa, the hypoechoic muscularis propria, and finally, the hyperechoic muscularis propria or perirectal fat interface. Depth of penetration is determined by identifying which of these layers is disrupted by the tumor. The figure shows a mass infiltrating beyond the muscularis propria *(thick arrow)* into the perirectal fat (bright area in the lower part), indicating an uT3-rectal tumor.

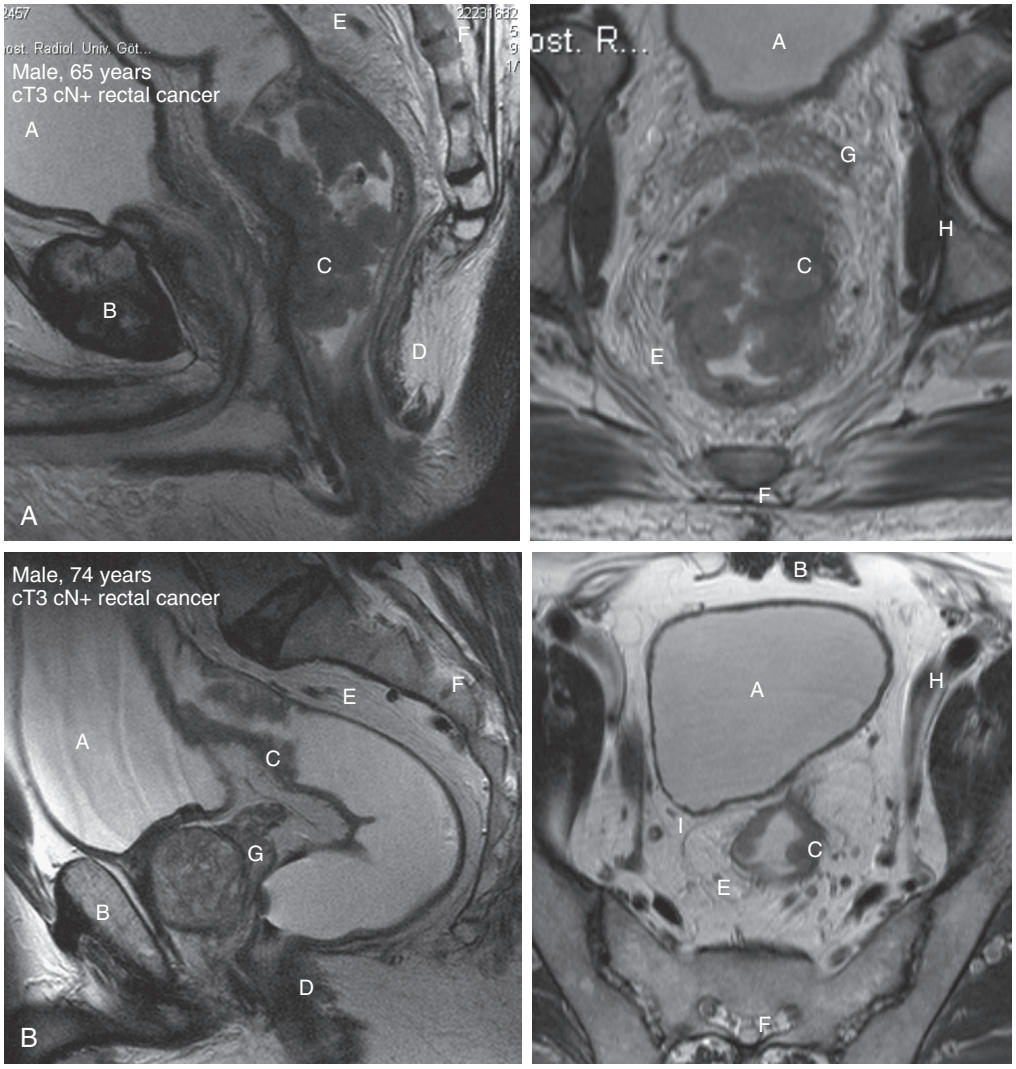


Figure 51-1 **A,** Pelvic MRI scan: Rectal cancer of the lower third of the rectum. **B,** Pelvic MRI: Rectal cancer of the upper third of the rectum A: bladder, B: os pubis, C: rectal cancer lower third **(A)** and upper third **(B)** of the rectum, both uT3 uN+, D: sphincter area, E: mesorectum, F: coccygeus, G: seminal vesicle, H: veins.

outcomes for patients with IIA versus IIB disease and IIIA versus IIIB disease.[22] The prognostic validity of this change was supported by a subsequent pooled analysis of the U.S. GI Intergroup and National Surgical Adjuvant Breast and Bowel Project (NSABP)[23] postoperative trials and the retrospective analysis of the American College of Surgeons National Cancer Database (NCDB).[24] The placement of all TN2 patients into stage IIIC, however, was not based on in-depth outcomes analyses because the impact of depth of bowel wall invasion (T category) in N2 patients had not been evaluated in detail.

Before making substantive changes in the AJCC 7th edition staging manual for colon and rectal cancer (Table 51-2), the AJCC Hindgut Task Force sought population-based validation that depth of invasion and nodal status interact to affect survival rates. Surveillance, Epidemiology, and End Results (SEER) survival data were obtained for patients with invasive colon and rectal cancer and evaluable TN category of disease (35,829 patients with rectal cancer and 109,953 patients with colon cancer).[25] T4N0 cancers were stratified by "tumors that perforate visceral peritoneum" (T4a) versus "tumors that invade or are adherent to adjacent organs or structures" (T4b). N1 and N2 were stratified by number of involved nodes (N+): N1a/N1b (one versus two or three nodes) and N2a/N2b (four to six vs. ≥seven nodes). Rates of 5-year observed and relative survival were obtained for each TN category. The analyses indicated the following information: survival rates are better for T1-2N0 cancers than T3N0 cancers, better for T3N0 cancers than T4N0 cancers, better for T1-2N2 cancers than T3-4N2 cancers, and similar for T4bN1 and T4N2 cancers. In addition, patients with T4a lesions have better survival rates than those with T4b lesions by N category, and the number of positive lymph nodes affects survival for each T category. The SEER population-based colon and rectal cancer analyses supported subdividing T4 (T4a/T4b), N1 (N1a/N1b), and N2 (N2a/N2b) and supported revised substaging of stages II and III (shift of T1-2N2 lesions from IIIC to IIIA/IIIB and T4bN1 lesions from IIIB to IIIC.[25,26]

Clinical staging is designated as cTNM and is based on physical examination, radiologic imaging, and endoscopic, biopsy, and laboratory findings. Pathologic staging is designated as pTNM and depends on data acquired clinically in addition to surgical and pathologic findings. The prescript "y" is used to indicate that the tumor has been treated with neoadjuvant therapy before surgical resection. Recurrent tumors

There are additional descriptors that do not affect the stage grouping but do indicate cases needing separate analysis. The AJCC TNM staging system should be used routinely for staging and treatment purposes. Although CEA has prognostic importance, it was not added to the staging system.[9]

TABLE 51-2 AJCC TNM Staging System for Colorectal Cancer

TNM Category	
Primary Tumor (T)	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ: intraepithelial or invasion of the lamina propria*
T1	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades through the muscularis propria into pericolorectal tissues
T4a	Tumor penetrates to the surface of the visceral peritoneum
T4b	Tumor directly invades or is adherent to other organs or structures†‡
Regional Lymph Nodes (N)	
Nx	Regional nodes cannot be assessed
N0	No regional nodes
N1	Metastasis in 1-3 regional lymph nodes
N1a	Metastasis in 1 regional lymph node
N1b	Metastasis in 2-3 regional lymph nodes
N1c	Tumor deposit(s) in the subserosa, mesentery, or nonperitonealized pericolic or perirectal tissues without regional nodal metastasis
N2	Metastasis in ≥4 regional lymph nodes
N2a	Metastasis in 4-6 regional lymph nodes
N2b	Metastasis in ≥7 regional lymph nodes
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis
M1a	Metastasis confined to one organ or site (e.g., liver, lung, ovary, nonregional node)
M1b	Metastases in more than one organ or site or the peritoneum
SUFFIX	**REASON**
M	The presence of multiple primary tumors in a single site and is recorded in parenthesis: pT(m)NM.
y	Cases in which classification is performed during or following initial multimodality therapy. The cTNM or pTNM category is identified by a *y* prefix. The ycTNM or ypTNM categorizes the amount of tumor actually present at the time of the examination. The *y* categorization is not an estimate of tumor before multimodality therapy.
r	Indicates a recurrent tumor when staged after a disease-free interval and is identified by the *r* prefix: rTNM.
a	Designates the stage determined at autopsy: aTNM.
LYMPHATIC VESSEL INVASION (L) AND VENOUS INVASION (V)	
Lympho-vascular invasion not present/not identified *Lympho-vascular invasion present/identified* *Not applicable* *Unknown/indeterminate*	

Stage Groupings			
Stage	**T**	**N**	**M**
0	Tis	N0	M0
I	T1-2	N0	M0

	T4b	N1-2	M0
IV	T any	N any	M1

From Edge SB, Byrd DR, Compton C, et al, editors: AJCC Cancer staging manual, ed 7, New York, 2010, Springer.
Additional descriptors: Although they do not affect the stage grouping, additional prefixes are used that indicate the need for additional analysis.
NOTE: A satellite peritumoral nodule in the pericolorectal adipose tissue of a primary carcinoma without histologic evidence of residual lymph node in the nodule may represent discontinuous spread, venous invasion with extravascular spread (V1/2), or a totally replaced lymph node (N1/2). Replaced nodes should be counted separately as positive nodes in the N category, whereas discontinuous spread or venous invasion should be classified and counted in the site-specific factor category tumor deposits (TD).
**This includes cancer cells confined within the glandular basement membrane (intraepithelial) or mucosal lamina propria (intramucosal) with no extension through the muscularis mucosa into the submucosa.*
†Direct invasion in T4 includes invasion of other organs or other segments of the colorectum as a result of direct extension through the serosa, as confirmed on microscopic examination (e.g., invasion of the sigmoid colon by a carcinoma of the cecum) or, for cancers in a retroperitoneal or subperitoneal location, direct invasion of other organs or structures by virtue of extension beyond the muscularis propria.
‡Tumor that is adherent to other organs or structures, grossly, is classified T4b. However, if no tumor is present in the adhesion, microscopically, the classification should be pT1-4a depending on the anatomic depth of wall invasion. The V and L classifications should be used to identify the presence or absence of vascular or lymphatic invasion, whereas the PN site-specific factor should be used for perineural invasion.

are designated with the *r* prefix. If there is uncertainty regarding the appropriate T, N, or M category, the lower (less advanced) category should be used. The role of the pathologist is critical to proper staging. Following surgery alone, a minimum of 12 pelvic nodes must be examined to obtain an accurate pN stage.[27] Tumors treated with preoperative chemoradiation are downstaged, however, and the number of lymph nodes retrieved is significantly less than those treated by surgery alone. Thus, the feasibility and clinical significance of the 12 lymph node threshold guideline in patients who receive neoadjuvant therapy has been challenged.[28]

Posttreatment Assessment

Circumferential Resection Margin

Surgeons identify margins that can be involved by tumor spread at a variety of sites. The completeness of the resection is scored as R0 for negative margins, R1 for microscopic involvement of margins, and R2 for gross residual tumor. The proximal and distal resection margins are involved in only 1% to 2% of cases in randomized trials. The most important margin is that created around the mesorectum (circumferential resection margin or CRM; eFigure 51-3). This margin is under threat by direct involvement but also by the incomplete removal of lymph nodes that lie just under the mesorectal fascia, and any small deviation from the correct surgical plane could enter them, potentially compromising cure. Studies by Quirke and others have shown that local recurrence is greatly increased and survival halved when tumor can be demonstrated at or within 1 mm from the radial surgical plane of resection (CRM+).[14]

Recording of Surgical Quality

Apart from the recording of the surgical CRM, the plane of surgery and the integrity of the total mesorectal excision specimen are key indicators of surgical quality and prognosis. Quirke first introduced the concept of pathological audit of the quality of rectal cancer surgery in the MRC CR07 trial (eTable 51-2).[14] In this trial, the plane of surgery achieved was classified as good (mesorectal) in 52% of 1156 included patients, intermediate (intramesorectal) in 34%, and poor (muscularis propria plane) in 13%. The plane of surgery achieved was significantly associated with the risk of local recurrence both in univariate and multivariate analysis, and therefore should be assessed and reported routinely.

Tumor Regression Grading

Neoadjuvant chemoradiation is able to induce T-level downsizing and UICC- or nodal-downstaging in locally advanced rectal cancers. In approximately 5% to 30% of cases this can lead to complete disappearance of tumor cells (i.e., a pathological complete response [pCR or ypT0N0]). Patients with pCR have consistently been shown to have better outcomes.[29,30] Variation in sampling protocols may explain some of the differences in reporting pCR rates. Moreover, various tumor regression grading (TRG) systems, based on the relative amount of tumor cells and fibrotic reactions, have been proposed. These classifications were often derived from esophageal or gastric cancer, and little information on the extent of inter- and intraobserver variability in defining TRG has been published. The College of American Pathologists Guidelines recently suggest that tumor response should be graded on a scale of 0 (complete response; no viable cancer cells) to 3 (poor response; minimal or no regression, extensive residual cancer).[31] This classification system needs to be prospectively tested on multiple datasets to validate the predictive value in terms of long-term outcome, and its reproducibility in a broader setting.

PRIMARY AND ADJUVANT THERAPY FOR RESECTABLE DISEASE

Adjuvant Irradiation without Chemotherapy

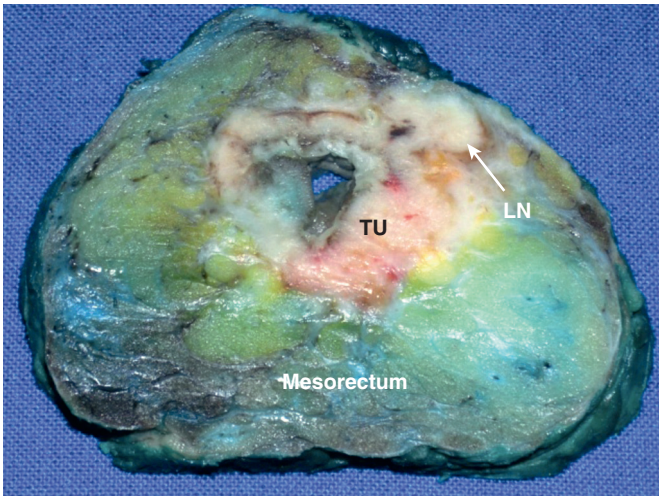
There are two general approaches in which radiation therapy has been used in the adjuvant treatment of resectable rectal cancer: postoperative treatment and preoperative treatment. A third approach known as the sandwich technique includes a short preoperative course of radiation (5 Gy to 15 Gy) followed by surgery, and in patients with pT3-4N1-2 disease, an additional 40 Gy to 45 Gy postoperatively. This technique is no longer used.[32,33]

Postoperative Irradiation

Until 1990, most patients in the United States underwent surgery and, if needed, received postoperative external beam radiation therapy (EBRT). The primary advantage with this approach was pathologic staging and avoiding overtreatment with preoperative therapy. Lastly, if the patient has undergone an APR, the radiation field must be extended to include the perineal scar.

There are five randomized trials examining the use of adjuvant postoperative irradiation without chemotherapy in stage pT3 or N1-2 rectal cancer.[34-38] None have shown an improvement in overall survival (OS). Two reveal a decrease in local failure rates; NSABP trial R-01 (16% versus 25%; $p = 0.06$) and the Medical Research Council (MRC) trial (21% versus 34%; $p = 0.001$).[37] Although there was no survival benefit, it must be emphasized that local control by itself is an important endpoint. Patients with recurrent rectal cancer experience a detriment in quality of life because of pelvic pain.[39]

Preoperative Irradiation



There are two approaches to preoperative therapy. The first, developed in Northern Europe and Scandinavia, is short-course radiation (25 Gy in 5 fractions). In contrast, most other investigators recommend a standard course (50.4 Gy in 28 fractions) combined with concurrent chemotherapy (chemoradiation).

Short-Course Preoperative Irradiation

There are 12 modern randomized trials of short-course preoperative radiation therapy (without chemotherapy).[40] All use low to moderate doses of radiation. Most of the trials showed a decrease in local recurrence rates, and in five of the trials, this difference reached statistical significance. Although in some trials a subset analysis revealed a significant improvement in survival rates, the Swedish Rectal Cancer Trial is the only one that reported a survival advantage for the total treatment group. Two meta-analyses report conflicting results. Although both revealed a decrease in local recurrence rates, the analysis by Camma et al[41] reported a survival advantage, whereas the analysis by the Colorectal Cancer Collaborative Group[42] did not.

In the Swedish Rectal Cancer Trial, patients with cT1-3 rectal cancer were randomized to receive 25 Gy in 1 week followed by surgery 1 week later versus surgery alone.[43] Those who received preoperative irradiation had a significant decrease in local recurrence rates (12% versus 27%; $p < 0.001$) and a correspondingly significant improvement in 5-year OS (58% versus 48%; $p = 0.004$) (see Table 51-5). After 13 years, the OS was still significantly improved (38% versus 30%; $p = 0.008$).[44] The local recurrence rate in patients who are node positive and underwent surgery alone was 46%, illustrating the inferior results of surgery before the adoption of TME.

The Dutch CKVO 95-04 trial randomized 1805 patients with cT1-3 disease to TME or short-course preoperative

eFigure 51-3 Mesorectum and circumferential resection margin (CRM). This margin is under threat by direct tumor *(TU)* involvement but also by the incomplete removal of lymph nodes *(LN)* that lie just under the mesorectal fascia.

Likewise, the assessment of the abdominoperineal excision specimens to measure the amount of tissue removed at the anorectal junction and to determine whether levator muscle is included in the resection is also strongly recommended.

radiation therapy followed by TME.[51] Irradiation significantly decreased the local recurrence rate (8% versus 2%; $p < 0.0001$), but there was no difference in the 2-year survival rate (82%) (Table 51-3). With longer follow-up, the 5-year local failure rate was higher with TME (11%) but was still significantly decreased (to 6%) with preoperative irradiation.[52] A subset analysis of 593 patients with negative margins revealed that although there were 11% fewer deaths resulting from disease in the preoperative radiation compared to TME alone arm (40% versus 51%, $p = 0.01$) there was a corresponding 11% increase in deaths as a result of other causes, including toxicity (51% versus 40%, $p = 0.01$). Therefore, OS was equivalent.

Despite the use of multiple field radiation techniques there was a substantial incidence of acute toxicity including 10% neurotoxicity, 29% perineal wound complications, and 12% postoperative leaks in the radiation arm.[57] It is not clear if the increased toxicity was the result of the learning curve associated with TME, the 1-week interval between the completion of radiation and surgery, or both.

The presence of a positive radial (circumferential) margin is an important negative prognostic sign. In the Dutch CKVO trial, 17% had positive circumferential margins. Although they received 50 Gy postoperatively, this did not compensate for positive margins.[58] MRI is able to identify those patients likely to have close or positive radial margins who undergo initial surgery and therefore, would be better treated by preoperative therapy.[59-61]

Patients selected for treatment with short-course radiation historically have included those with cT1-3 disease, whereas those selected for chemoradiation include T3 or N+ disease. Therefore, a retrospective comparison of trials is not feasible. Two randomized trials of short-course radiation compared to chemoradiation, which have included patients with cT3 or N+ disease and are discussed in another section.

Adjuvant Chemoradiation

Chemoradiation can be delivered preoperatively or postoperatively. For patients with cT1-2N0 disease, the initial treatment is surgery, and if the tumor is pT3-4N0 or TanyN1-2, this is commonly followed by postoperative chemoradiation.[62] For patients with cT3-4N0 or TanyN+ lesions, preoperative chemoradiation is given, followed by surgery (alone or plus intraoperative irradiation therapy [IORT] for T4 lesions) and postoperative adjuvant chemotherapy.

Postoperative Chemoradiation

The National Cancer Institute (NCI) Consensus Conference concluded in 1990 that chemoradiation was the standard postoperative adjuvant treatment for all patients with pT3 or N1-2 disease.[62] This recommendation was based on Phase III trials that compared postoperative chemoradiation arms with control arms of either surgery alone or surgery plus postoperative irradiation (Mayo/NCCTG 79-47-51) and demonstrated improvements in both disease-free survival (DFS) and OS.[63] The standard design in U.S. trials was to deliver six cycles of bolus 5-fluorouracil (5-FU)–based chemotherapy; concurrent irradiation was also given during cycles 3 and 4.

The U.S. GI Intergroup 86-47-51 trial did not demonstrate an incremental benefit to semustine when it was added to postoperative irradiation plus concurrent and maintenance 5-FU.[64] However, a 2-×2-component of the study demonstrated a positive benefit for giving protracted venous infusion (PVI) 5-FU (also known as continuous infusion 5-FU) rather than interrupted bolus 5-FU concurrently with pelvic irradiation. Patients randomized to receive concurrent PVI 5-FU (225 mg/m²/d, 7 days/week or until intolerance) had improvements in rates of disease control, DFS (at 4 years, 63% versus 53%; $p = 0.01$), and OS (at 4 years, 70% versus 60%; $p = 0.005$).

The successor INT 0114 four-arm trial randomized patients with pT3-4N0 or TanyN+ rectal cancer to postoperative irradiation and bolus 5-FU with or without leucovorin, levamisole, or leucovorin plus levamisole (INT 86-47-51 results were not available before INT0114 study design and completion). There was no significant difference in local control or survival rates among the four arms.[65] With longer follow-up, the study also revealed that local control and survival results continued to deteriorate after 5 years. At 7 years, the local failure rate was 17% and the survival rate was 56%, compared with 14% and 64%, respectively, at 5 years. Patients with high-risk (pT3N+ or T4) disease had a lower survival rate compared with lower-risk (pT1-2N+ or T3N0) disease (45% versus 70%).

The subsequent INT 0144 postoperative adjuvant rectal trial was designed to follow up on the positive results achieved with concurrent PVI 5-FU during irradiation in trial 86-47-51.[66] Patients were randomized to three arms: arm 1, bolus 5-FU/PVI 5-FU + RT/bolus 5-FU (control arm from 86-47-51); arm 2, PVI 5-FU/PVI 5-FU + RT/PVI 5-FU; arm 3, bolus 5-FU–leucovorin(LV)–levamisole/bolus 5-FU–LV–levamisole + RT/bolus 5-FU–LV–levamisole. The concurrent PVI 5-FU arms did not confirm a survival benefit relative to the bolus 5FU/LV/levamisole arm, but arm 2 did report a lower incidence of grade 3+ hematologic toxicity.

Do Patients with Pathologic Node-Negative Rectal Cancer Require Pelvic Irradiation?

The 1990 NCI Consensus Conference recommendation for postoperative chemoradiation was published nearly three decades ago and was based on trials where neither a TME nor an examination of 12 nodes or more was required. Retrospective data suggest that there may be a subset of patients with pT3N0 disease who may not require adjuvant therapy. As noted by Gunderson et al, data in the rectal pooled analysis (U.S. GI Intergroup and NSABP Phase III trials) found that use of trimodality postoperative adjuvant treatment for all patients with intermediate risk T1-2N1 and T3N0 cancers may be excessive treatment because 5-year OS was equivalent with surgery with chemotherapy as a single adjuvant.[24] In the Dutch CVKO Phase III trial 2-year local relapse was 5.7% with TME alone compared to. 1% with preoperative radiation ($p = 0.01$).[51] In a subsequent analysis by Nagtegaal et al, local relapse with TME alone was higher with a radial margin 2 mm or less compared with >2 mm (16% versus 5.8%, $p < 0.0001$).[67] Nissan et al reported results of 100 patients with uT2-3N0 disease who underwent TME alone and had 12 nodes or more examined.[68] In the subset of 49 patients with uT3N0 disease, the overall local recurrence rate was 4%. For the total group, the local recurrence rate was significantly higher in those with lymph vessel invasion tumors (32% versus 6%; $p = 0.006$) and an elevated (>5 ng/mL preoperative CEA level (21% versus 0%).

Patients who undergo high-quality TME, have at least 12 nodes examined, and have pT3N0 disease may not need the radiation component of chemoradiation, dependent on the adequacy of radial and distal margins of resection. The small benefit in local control with irradiation may not be worth the risks, especially in women of reproductive age. However, patients with pT3N0 tumors with adverse pathologic features, who undergo resection without TME, or who have fewer than 12 nodes examined should still receive postoperative chemoradiation.

Preoperative Chemoradiation

Based on the German CAO/ARO/AIO 94 trial, preoperative chemoradiation is standard treatment for patients with cT3-4N0 or TanyN+ disease.[53] The disadvantage of preoperative therapy is the possible overtreatment of patients with either early-stage disease (pT1-2N0) or undetected metastatic disease. A number of questions and issues exist with regard to patient selection for preoperative chemoradiation and optimization of treatment that will be addressed in the following subsections. A subsequent section will also address the question of preoperative chemoradiation compared with short-course radiation.

The Role of Concurrent and Postoperative Chemotherapy

Since INT 0144, most trials of chemoradiation have used preoperative chemoradiation. There has been some debate as to which fluoropyrimidine (PVI 5-FU or capecitabine) is the preferred radiosensitizer. Two trials have examined this question. The NSABP R-04 trial compared preoperative chemoradiation with PVI 5-FU to capecitabine (with or without oxaliplatin). Compared with PVI 5-FU, capecitabine had similar rates of pCR (22% versus 19%), sphincter sparing surgery (63% versus 61%), and grade 3 + diarrhea (11%).[70] Hofheinz et al randomized 401 patients with PVI 5-FU–based chemoradiation compared with capecitabine-based chemoradiation. Patients who received capecitabine had equivalent pCR rates (6% versus 7%) and their 5-year OS was noninferior (76% versus 66%, $p = 0.0004$) compared with PVI 5-FU.[71] Therefore, PVI 5-FU–and capecitabine–based chemoradiation regimens are equivalent.

Almost every randomized trial for the past three decades has confirmed a 10% to 15% survival benefit of a total of 6 months of adjuvant 5-FU–based chemotherapy for patients with lymph node-positive colon or rectal cancer. For patients who receive preoperative chemoradiation and are selected to receive postoperative adjuvant chemotherapy, 4 months (eight cycles) of mFOLFOX6 is recommended. However, two randomized trials question whether postoperative chemotherapy is necessary.[55,56]

The European Organization for Research and Treatment of Cancer (EORTC) trial 22921 was a four-arm randomized trial of 1011 patients who received preoperative irradiation of 45 Gy with or without a concurrent bolus of 5-FU/leucovorin followed by surgery with or without four cycles of postoperative 5-FU/leucovorin.[55] Only 37% had a TME. There was a significant decrease in the local failure rate in those patients who receive chemoradiation compared with irradiation (8% to 10% versus 17%; $p < 0.001$) but no difference in the 5-year OS (65%) (see Table 51-3). An update with 10-year follow-up revealed no significant differences in survival among the four arms.[72] Only 43% of patients received 95% or more of the planned postoperative chemotherapy, which may explain the negative results. Furthermore, a subset analysis of the EORTC trial revealed that patients who responded to preoperative chemoradiation had a survival benefit from postoperative chemotherapy.[73]

A trial by the Fédération Francophone de la Cancérologie Digestive (FFCD 9203) was a two-arm trial of 742 patients randomized to preoperative irradiation of 45 Gy with or

Although the number of nodes is defined in the AJCC staging system, the location of pelvic nodes is not. Leibold et al[69] treated 121 patients with preoperative chemoradiation and found that the incidence of metastatic disease was higher in those patients with positive nodes in the proximal pelvis compared with positive nodes anywhere in the pelvis (46% versus 32%). Of note, the proximal nodes are above the superior border of the typical radiation field (L5/S1) because they are located along the apical and midportion of the inferior mesenteric artery.

without bolus 5-FU/leucovorin.[56] All patients were scheduled to receive postoperative chemotherapy, and 73% received such. The FFCD trial reported a similar decrease in local failure rates (8% versus 17%; $p < 0.05$) and a corresponding increase in pCR (11% versus 4%; $p < 0.05$) with preoperative compared to irradiation alone but no survival benefit (68% versus 67%) (see Table 51-5).

Because most patients did not receive adequate doses of postoperative chemotherapy in the EORTC trial and the FFCD trial only tested the impact of concurrent chemotherapy with preoperative irradiation, preoperative chemoradiation followed by surgery and 4 months of postoperative adjuvant chemotherapy remains the standard practice in most centers. Valentini et al proposed the use of nomograms based on staging and treatment factors to support the decision in multidisciplinary groups. However, there remains considerable controversy in some European countries regarding its use. An international consensus conference failed to reach a definitive recommendation regarding its use.[74] Lastly, because preoperative chemoradiation will decrease the number of nodes harvested from the postoperative specimen, the ypN stage cannot be used to determine the need for postoperative chemotherapy.[75,76]

Selective Use of Radiation

As previously discussed, the risks of chemoradiation (chemoRT) in patients with pT3N0 disease may outweigh the potential benefits.[24,68] Despite advances in preoperative imaging, molecular markers, and clinicopathologic factors, however, none can reproducibly identify patients with pN+ disease more that 70% to 80% of the time.[77]

In the German CAO/ARO/AIO-94 trial, 18% of patients clinically staged as cT3N0 and underwent initial surgery without preoperative therapy had pT1-2N0 disease and would have been over treated if they had received preoperative therapy. Although not ideal, preoperative therapy is still preferred to performing surgery first in this subset of patients. Even after preoperative chemoradiation which downstages tumors, Guillem et al reported that 22% of patients still have ypN+ disease at the time of surgery.[78] In patients who undergo surgery alone this number is as high as 40%.[79]

Given the improvements in systemic chemotherapy there may be an opportunity to use preoperative radiation more selectively. In a prospective pilot trial, Shrag et al treated 32 selected patients with stages uT2N1 or uT3N0-1 mid to upper rectal cancer with neoadjuvant FOLFOX with bevacizumab.[80] Patients who by preoperative assessment required an abdominoperineal resection were not eligible. Pelvic radiation was reserved for patients who progressed preoperatively or, following surgery, had pT4, pN2, or positive margins. Of the 30 patients who underwent surgery none required radiation, the pCR rate was 25%, and 2 required postoperative radiation. This approach remains investigational and is being prospective tested in the ongoing Phase II/III Alliance N1048 trial.

Positive Radial (Circumferential) Margins

Although the distal margin is predictive of both local recurrence as well as the feasibility of a sphincter-preserving operation, the radial (circumferential or CRM) margin also has the most important impact on the local recurrence rate. An analysis of more than 17,500 pathologic specimens by Nagtegaal et al[81] reported inferior survival rates in patients with positive CRMs after neoadjuvant treatment compared with immediate surgery (hazard ratio [HR], 6.3; 95% CI, 3.7 to 16.7 versus HR, 2; 95% CI, 1.4 to 2.9, respectively).

In the Dutch CKVO trial, 17% of patients had positive circumferential margins. In a subset analysis by Nagtegaal et al,[67] patients with positive radial margins who underwent TME alone had a local recurrence rate of 17% after an LAR and 30% after an APR.

In a retrospective analysis reported by Bail et al,[82] despite receiving preoperative chemoradiation, 504 patients with positive radial margins had a higher local recurrence rate (35% versus 11%) and a lower 5-year OS (27% versus 73%) compared with those with negative radial margins. Although high-resolution MRI can help identify patients who will have positive margins,[60,61] not all centers perform the necessary pathologic examination to detect positive circumferential margins.[83]

As reported with preoperative therapy, postoperative treatment has limited ability to control positive radial margins. In the MRC CR-07 trial, patients with positive radial margins who received postoperative chemoradiation had an 11% local recurrence rate.[84] Likewise, in a subset analysis of the Dutch CKVO trial, 50 Gy postoperatively did not compensate for positive margins.[58]

Distance from the Anal Verge

There are no prospective randomized data examining the impact of the distance from the anal verge on local recurrence. The available data are subset analyses from randomized trials that were not stratified by distance.

On univariate analysis, "high" tumors in both the Dutch CKVO and Swedish trials (defined as ≥10.1 cm and ≥11 cm, respectively) had a lower incidence of local recurrence compared with mid and lower tumors (eTable 51-3). Short-course irradiation did not significantly decrease local recurrence rates. By multivariate analysis, tumor location was an independent prognostic variable in the Dutch trial. It is interesting to note that irradiation did significantly decrease local recurrence rates for midtumors in both trials, whereas for lower tumors it was helpful only in the Swedish trial. In contrast, there was no significant difference between mid and upper tumors in the German trial.[86]

In summary, given the conflicting data combined with the report from Guillem et al[78] confirming that the incidence of ypN+ disease following preoperative chemoRT (which are most predictive of local failure) is the same from 0 cm to 12 cm from the anal verge, treatment decisions based solely on the current definitions of low, mid, and high should not be used. However, some women of reproductive age elect to forego radiation with the hope that their nodes are pathologically negative and therefore will not require postoperative radiation.

Patients with cT3N0 tumors should be examined with a straight proctoscope, and if the tumor is 12 cm or less from the anal verge, they should be referred for preoperative chemoRT. If the tumor is more than 12 cm from the anal verge and imaging reveals that the tumor is clearly not adjacent to the presacral hollow, initial surgery is recommended with decisions for postoperative chemoRT based on surgical-pathology findings previously discussed.

Sphincter Preservation with Preoperative Chemoradiation

From the viewpoint of sphincter preservation, the advantage of preoperative therapy is to decrease the volume of the primary tumor. This has relevance only if the surgeon is willing to change the operative technique based on tumor response. When the tumor is located in close proximity to the dentate line, this decrease in tumor volume may allow the surgeon to perform a sphincter-conserving procedure that would not otherwise be possible. However, if the tumor directly invades the anal sphincter, sphincter preservation is unlikely even when a clinical complete response is achieved.

Furthermore, the incidence of positive nodes is not dependent on the distance from the anal verge.[78] In this series, of the 103 patients with tumors from 0 cm to 5 cm from the anal verge, 23% were ypN+, whereas of the 85 patients with tumors 6 cm to 12 cm from the anal verge, the incidence was 20%. These data suggest that up to 12 cm from the anal verge the risk of positive nodes, and likely the corresponding incidence of local recurrence, is similar.

Of the three trials, two used short-course preoperative irradiation and included patients with cT1-2N0 disease (Dutch CKVO and the Swedish Rectal Cancer Trials),[44,52] whereas the German trial used chemoradiation and was limited to patients with cT3N+ disease. The MRC-C07 trial performed a similar subset analysis and measured the distance from the anal verge by rigid sigmoidoscopy. There were additional variables that could have contributed to the differences in local failure rates. For example, TME (and its associated impact on radial margins) was used in the Dutch CKCO and German trials and not in the Swedish trial. All three trials included patients with tumors more than 12 cm from the anal verge in the "upper or high" category. Because the peritoneal reflection varies from 12 cm to 16 cm, some patients with tumors above the peritoneal reflection (colon cancer) were included in the three trials. Most investigators now limit preoperative treatment to tumors less than 12 cm from the anal verge.[78] Lastly, distance measurements using a flexible proctoscope are less accurate than straight proctoscope measurements. Flexible scopes were used in the Dutch CKVO trial. The German trial used a straight scope. In the Swedish trial, proctoscopic information was not mentioned. However, eligibility was limited to tumors "below the promontory as identified by barium enema." The Polish trial is not discussed because all tumors were palpable by digital examination.[85]

An ongoing controversy is whether the degree of downstaging is adequate to enhance sphincter preservation and, if so, which regimen (short-course radiation or standard-course chemoradiation) is preferred. An analysis of 1316 patients who received short-course preoperative irradiation revealed that downstaging was most pronounced when the interval between the completion of irradiation and surgery was at least 10 days.[87] In the Dutch CKVO 95-04 trial, where the interval was 1 week, there was no downstaging.[88]

When the goal of preoperative therapy is sphincter preservation, standard course chemoradiation with conventional irradiation doses and techniques are recommended. These include multiple-field techniques to a total dose of 45 Gy to 50.4 Gy at 1.8 Gy per fraction. Surgery should be performed 4 to 8 weeks following the completion of chemoradiation. Unlike the short-course irradiation regimen, this conventional design allows for two important events to occur. First is the recovery from the acute side effects of chemoradiation, and second is adequate time for tumor downstaging. Data from the Lyon R90-01 trial of preoperative irradiation suggest that an interval of longer than 2 weeks following the completion of irradiation increases the chance of downstaging.[89] Most series recommend a 4- to 8-week interval.[90-92] However, more recent data suggest that an even longer interval may be helpful. Sloothaak et al reported a retrospective analysis of 1593 patients treated with preoperative chemoradiation by members of the Dutch Colorectal Group.[93] A delay of almost 16 weeks following chemoradiation was needed to achieve the maximum pCR rate of 16% (eFigure 51-4). However, the ultimate impact on outcome is unknown.

Whether increasing the interval between the end of short-course irradiation and surgery to more than 4 weeks will increase downstaging is not known. This question is being addressed in the ongoing three-arm Stockholm III trial. Interim results reveal a significant increase in grade 3+ postoperative complications in patients who received short-course radiation (5 Gy × 5) followed by surgery 1 week later (53 compared to either 5 Gy × 5 (39%) or 2 Gy × 25 (41%) followed by surgery 4 to 8 weeks later.[94]

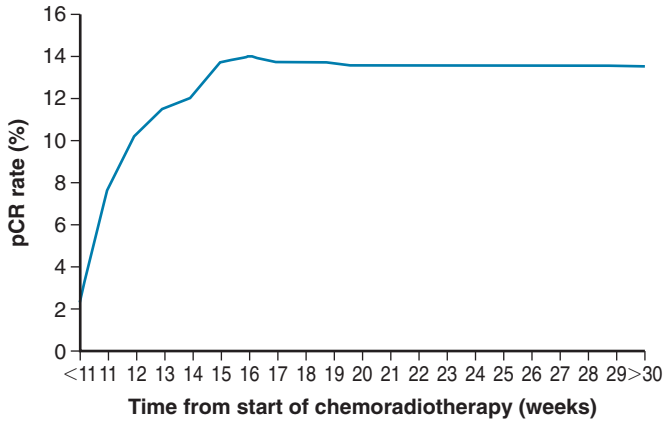
Preoperative Prospective Clinical Assessment. The most accurate method by which to determine if preoperative therapy increases sphincter preservation is to perform a prospective clinical assessment. The operating surgeon examines the patient before the start of preoperative therapy and declares the type of operation required. The German CAO/ARO/AIO 94 trial reported that this assessment is accurate in 80% of patients.

Clinical Experience with Sphincter Preservation. A valid concern of surgeons is that to perform sphincter preservation in those patients who would otherwise require an APR, the distal resection margin may be suboptimal (<1 cm). Can preoperative therapy compensate for this? Retrospective data from the Memorial Sloan Kettering Cancer Center reveal that with preoperative chemoradiation, the 3-year local control rates were similar regardless of the margins being more than 2 cm, less than 2 cm, more than 1 cm, or less than 1 cm, providing they were negative.[83,95] Similar data have been reported from other investigators.[96]

Sphincter preservation without good function is of questionable benefit. In a series of 73 patients who underwent surgery, Grumann et al[97] reported that the 23 patients who underwent an APR had a more favorable quality of life compared with the 50 who underwent a low anterior resection. However, Krouse et al[98] reported that both men and women with ostomies had significantly worse social well-being compared with those without ostomies.

Preoperative chemoradiation may adversely affect sphincter function.[99] However, the impact is most likely less than postoperative chemoradiation.[100] Most Phase II trials that examine functional outcome report good to excellent results. Functional results continue to improve up to 1 year after surgery.

Is Surgery Needed after Preoperative Chemoradiation?



Although the conventional adjuvant treatment for rectal cancer is preoperative chemoradiation there are clinical settings where surgery has not been performed. These include patients with early stage tumors, those with medically inoperable disease, and patients who have refused surgery following a favorable response to preoperative chemoradiation. In these settings, radiation has been delivered by a variety of techniques including endocavitary (contact) treatment, brachytherapy, and pelvic external beam.

Retrospective Series. Treatment of rectal cancer without surgery is not a new concept. Although patients can be cured, the results are inferior to surgery.

A number of modern retrospective series report the use of radiation alone or chemoradiation, most commonly for patients who are medically inoperable or refuse surgery.[101-103] In general, patients received pelvic radiation followed by a boost with either external beam or brachytherapy. Brierley et al from the Princess Margaret Hospital reported the results of pelvic radiation alone (40 Gy to 60 Gy) in patients who refused surgery or had unresectable or medically inoperable disease.[101] The 5-year OS was 27% and by the mobility of the primary tumor was; mobile: 47%, partially fixed: 27%, and fixed: 4%. Gerard et al reported the combination of pelvic radiation, endocavitary, and brachytherapy in 63 patients with uT2-3 tumors.[102] For patients with uT3 disease the 5-year local failure and survival rates were 20% and 35%, respectively. A total of 48 patients with cT3 disease who received radiation or chemoradiation alone because of medical inoperability or patient refusal was reported by Lim et al.[103] The clinical complete response (CR) rate was 56% and, with a median follow-up of 49 months, 37% had progression of disease.

Prospective Series. Five series advocate close observation alone following preoperative chemoradiation (eTable 51-4). The 2004 series by Habr-Gama et al included 265 patients were treated with preoperative 50.4 Gy plus 5-FU and leucovorin.[104] Of those, 27% achieved both a clinical complete response (cCR) and were selected for observation only. Close follow-up was required including frequent exams, biopsy, and abdominal/pelvic CT scans every 6 months. With a mean follow-up of 57 months there was a 3% luminal recurrence rate, 4% distant metastasis rate, and 100% 5-year survival. In an update of 361 patients, the local recurrence rate was 5% and 5-year overall survival was 93% in the 28% who achieved a cCR.[105] It should be emphasized that patients with cT1-3 disease were included and any patient who developed a local recurrence in the first year were excluded from analysis.

In their 2013 series, patients with rectal cancer seen between 2006 and 2010 with tumors located at a maximum of 7 cm from the anal verge underwent high resolution MRI or three-dimensional (3D) transrectal ultrasound and 70 were identified with cT2-4 or N1-2 disease.[109] Chemoradiation included 54 Gy (45 Gy pelvis followed by a 9 Gy cone down) plus three cycles of concurrent chemotherapy (bolus 5-FU/leucovorin at 450/50 mg/m^2 for 3 days every 3 weeks. This was followed by an additional three cycles of chemotherapy. At 10 weeks postchemoradiation repeat staging (various combinations of MRI, TRUS, and PET-CT) was performed. If there was no

eFigure 51-4 A delay of almost 16 weeks following chemoradiation is needed to achieve the maximum pathological complete response (pCR) rate of 16%.
From Sloothaak et al, Br J Surg 2013 {3700}.

eTABLE 51-4 Nonoperative Treatment of Rectal Cancer with the Watch-and-Wait Approach

Series	Patients Treated	Patients Observed	Patients Outcome
Habr-Gama[105] (2004 series)	265	28	5% luminal recurrence 93% 5-yr survival
Mass[106]	192	21	89% 2-yr DFS 100 2-yr survival
Dalton[107]	49	12	50% NED at 26 months
Smith[108]	x	32	21% 2-yr local failure 9% 2-yr distant failure
Habr-Gama[109] (2013 series)	70	47	17% local failure 72% 3-yr DFS, 90% 3-yr survival

DFS, *Disease free survival,* NED, *no evidence of disease,* x, *data not reported;* yr, *year.*

residual abnormality by proctoscopy and staging was negative, patients were staged as initial cCR and placed on the "watch-and-wait" strategy, which included frequent exams and repeat imaging every 2 to 6 months. If at 10 weeks there was a residual abnormality, patients underwent a local excision, and if there was a ypT0 tumor, then they were also placed on the watch and wait strategy. Patients in these two groups who had no evidence of disease at 1 year were staged as sustained cCR. All other patients (defined as incomplete responders) underwent salvage radical surgery. There were 69 evaluable patients with a minimum of 12 months follow-up following the completion of chemoradiation. The overall results were impressive. A total of 68% achieved and initial cCR however 17% developed a local failure. Of the 56% who had a sustained cCR, 4 (10%) developed a local failure. Those four were salvaged with radical surgery and are without evidence of disease at a median follow-up of 26 months. Overall, 51% of patients who completed chemoradiation had a sustained cCR and did not require radical surgery after a median of 56 months. With a total median follow-up of 53 months the 3-year survival was 94%.

Most series suggest an improved outcome in patients who achieve a pCR following preoperative chemoradiation. Patients who are downstaged to ypT0 following chemoradiation have a 5% incidence of positive nodes and a corresponding low nodal recurrence rate.[111] Mass et al reported a pooled analysis of 27 series reporting patients who underwent preoperative chemoradiation and achieved a pCR.[29] There was a significant increase in 5-year DFS compared to those who did not achieve a pCR (83% versus 63%, $p = 0.0001$).

In summary, radical surgery remains a standard component of the treatment of rectal cancer. The wait-and-see approach is encouraging but remains investigational. More accurate methods for postchemoradiation assessment are needed.

Randomized Trials of Preoperative versus Postoperative Chemoradiation

Two randomized trials of preoperative versus postoperative chemoradiation for clinically resectable rectal cancer have been performed, NSABP R0-3[54] and the German CAO/ARO/AIO 94 trial (see Table 51-3).[53] These trials were based on pilot data suggesting that chemotherapy increased the response rate of preoperative radiation,[113] and because of less small bowel in the radiation field,[114] the acute toxicity of preoperative chemoradiation was less then postoperative chemoradiation.[115]

The German trial completed the planned accrual of more than 800 patients and randomized patients with uT3-4 or LN+ rectal cancers less than 16 cm from the anal verge to preoperative chemoradiation (with PVI 5-FU during weeks 1 and 5) compared to postoperative chemoradiation. The trial was stratified by surgeon. Compared with postoperative chemoradiation, patients who received preoperative therapy had a significant decrease in rates of local failure (6% versus 13%; $p = 0.006$), acute toxicity (27% versus 40%; $p = 0.001$), and chronic toxicity (14% versus 24%; $p = 0.012$), and in the 194 patients judged by the surgeon before treatment to require an APR, there was a significant increase in rates of sphincter preservation (39% versus 20%; $p = 0.004$). With a median follow-up of 40 months, there was no difference in 5-year OS (74% versus 76%) In an update with a median follow-up of 11 years, preoperative chemoradiation continued to offer a significantly lower incidence of local failure (7% versus 10%; $p = 0.009$). However, there was no difference in distant failure (28%) or OS (60%).[12] The lack of improvement in distant failure and OS has lead to new trials investigating novel chemotherapy agents and sequencing.

The NSABP R-03 study accrued only 267 of a planned 900 patients with cT3-4 rectal cancers.[54] Patients received induction 5-FU/leucovorin chemotherapy followed by conventional chemoradiation and were randomized to receive it either preoperatively or postoperatively. TME was not required, and some patients underwent local excision. Patients who received preoperative versus postoperative therapy had a significant improvement in 5-year DFS (65% versus 53%; $p = 0.011$) and a borderline significant improvement in 5-year OS (75% versus 66%; $p = 0.065$). There was no difference in 5-year local recurrence rates (11%). There was a correspondingly higher incidence of grade 4+ toxicity, almost all related to early diarrhea (33% versus 23%), but the incidence of grade 3+ toxicity was lower (41% versus 50%). Lastly, based on a prospective office assessment by the operating surgeon, there was no improvement in rates of sphincter preservation (48% versus 39%). The results do not parallel the German trial, likely because of the fact that only 267 of the 900 planned patients were accrued, thereby limiting the statistical power to detect differences.

Given the improved local control rates, acute and long-term toxicity profiles, and sphincter preservation rates reported in the German trial, patients with cT3-4 rectal cancer who require chemoradiation should receive it preoperatively. Although not ideal, this is preferred to performing surgery first because 20% to 40% will have LN+ disease at the time of surgery and require postoperative chemoradiation, which has inferior rates of local control, higher rates of acute and chronic toxicity, and, if a low anastomosis is performed, inferior functional results.[78] Clearly, the development of more accurate methods to identify LN+ disease, including imaging techniques or molecular markers, is essential because more patients are being treated with preoperative chemoradiation.

The UK Medical Research Council trial (MRC C07) randomized 1350 patients with clinical stages I to III rectal cancer to preoperative irradiation of 5 Gy × 5 or selective postoperative chemoradiation (45 Gy with concurrent 5-FU), which was delivered only to patients with a histologic radical margins of less than 1 mm (12% of all patients with immediate surgery).[84] With a median follow-up of 4 years, patients who received preoperative compared with selective postoperative treatment had significantly lower 3-year local recurrence rates (4.4% versus 10.6%; $p < 0.0001$) and higher 3-year DFS (77.5% versus 71.5%; $p = 0.013$).

Preoperative Chemoradiation: Alternate Regimens and Issues

Both cytotoxic and targeted chemotherapeutic agents have been incorporated into preoperative chemoradiation regimens. The most common endpoint of these trials is pCR because, as will be discussed later, most studies suggest that it is associated with improved results.[29] Many of the Phase I/II regimens report higher pCR rates compared with historical rates seen with 5-FU alone.

Concurrent Oxaliplatin Regimens

Five randomized trials have examined the impact of addition of oxaliplatin to 5-FU– or capecitabine-based chemoradiation on response rates and acute toxicity in patients with cT3-4 and/N+ rectal cancer[70,116-119] (eTable 51-5).

Because four of five randomized trials reveal an increase in acute toxicity with no benefit in the pCR rate the current

Mass et al reported their experience of 192 patients with rectal cancer.[110] Patients were staged with diffusion weighted MRI and had cT4, cT3 with threatened margins, or node-positive disease. They received 50.4 Gy plus capecitabine and 6 to 8 weeks later underwent MRI restaging. A strict definition of clinical CR was used that included meeting all of the following criteria: (1) substantial downsizing with no residual tumor or residual fibrosis only, (2) no lymph nodes, (3) endoscopy revealing no tumor or a small residual erythematous ulcer or scar, (4) negative biopsy, and (5) no palpable tumor. A subset of 21 patients had a cCR and, based on patient preference, were included in a wait-and-see policy. Of the 21, 10 had distal tumors, which would have required an APR. The mean follow-up was 25 months. One patient developed an endoluminal local recurrence without nodal recurrence at 22 months and was salvaged with transanal endoscopic microsurgery (TEM) surgery. The cumulative probability of 2-year DFS was 89% and OS was 100%.

Dalton et al from Exeter treated 49 patients with 45 Gy plus capecitabine.[107] Twelve achieved a cCR by MRI and underwent biopsy 6 to 8 weeks later. Patients were then followed closely by PET, CT, MRI, and endoscopy. The 6 who were biopsy negative were all without evidence of disease with a median follow-up of 26 months and 2 of the 6 who were biopsy positive developed distant failure.

The series from Smith et al reported 32 patients with uT2-4 or N+ disease who received 50.4 (45-56 Gy) with 5-FU or capecitabine.[108] A cCR was defined as a negative endoscopy at 4 to 10 weeks. Biopsy and imaging were optional. The local failure rate was 19% crude and 21% 2-year actuarial. The median time to local failure was 11 months and all were salvaged and without evidence of disease at 17 months. Of note 5 of the 6 local failures were endoluminal. The incidence of distant failure was 9%. Their current recommendation for follow-up following chemoradiation is a two-stage process. At 6 to 7 weeks patients undergo and examination and endoscopy. If they have a cCR they are followed. If there is not cCR then it is repeated at 10 to 12 weeks. Patients who have a cCR at 14 months will likely remain in cCR.

Selecting patients for a nonoperative approach based on response is reasonable. The challenge is identifying a surrogate method to surgery to accurately identify patients who have achieved a pCR. Current methods include endoscopy and physical examination, ultrasound, CT, MRI, and PET either alone or in combination. With the exception of the rigorous approach used by Mass et al series,[110] most have not been consistently successful. Glynne-Jones et al reviewed 218 Phase II and 28 Phase III trials of preoperative radiation or chemoradiation and confirmed that clinical or radiologic response does not sufficiently correlate with pathologic response and do not recommend a wait and see approach to surgery following preoperative therapy.[112] However, further refinements in imaging may improve the selection process.

The STAR-01 trial randomized 747 patients to preoperative chemoradiation with 50.4 Gy with PVI 5-FU with or without oxaliplatin (60 mg/m^2 weekly).[116] There was a significant increase in grade 3+ toxicity with oxaliplatin (24% versus 8%; $p < 0.001$) with no improvement in the pCR rate (15% versus 16%).

In the ACCORD 12/0405 PRODIGIE trial, 598 patients were randomized to preoperative chemoradiation with 50 Gy plus capecitabine with oxaliplatin (CAPOX) compared to 45 Gy plus capecitabine.[117] There was a similar significant increase in grade 3+ toxicity with oxaliplatin (25% versus 11%; $p < 0.001$) with no improvement in the pCR rate (19% versus 14%). Oxaliplatin did not improve 3-year local recurrence (6% versus 4%) or survival (88% versus 83%).[118]

The NSABP R-04 trial was a four-arm trial (2 × 2 comparison) of PVI 5-FU compared to capecitabine-based preoperative chemoradiation (50.4 Gy) with or without oxaliplatin.[70] A total of 1606 patients with cT3 and or N+ disease were randomized. The addition of oxaliplatin (to either 5-FU or capecitabine) was associated with a significantly higher incidence of grade 3+ diarrhea (15% versus 7%, $p = 0.0001$) with no improvement in the incidence of pCR (21% versus 19%) or sphincter sparing surgery (60% versus 64%).

The German CAO/ARO/AIO-04 randomized 1265 patients with cT3-4 or N+ disease to the preoperative arm of CAO/ARO/AIO-94 (50.4 Gy + 5-FU) versus 50.4 Gy/5-FU with oxaliplatin (50 mg/m^2 weekly).[119] In contrast with the STAR-01, ACCORD, and NSABP R-04 trials, patient who received oxaliplatin-based chemoradiation had a significant improvement in pCR (17% versus 13%, $p = 0.045$) with no corresponding increase in acute grade 3+ toxicity (23% versus 22%). The preliminary results (published in abstract form at ECCO 2013) of the fifth trial (PETACC-6) did not result in any improvement in tumor downstaging or in anal sphincter preservation.

standard is not to include oxaliplatin with 5-FU/capecitabine–based preoperative chemoradiation regimens. However, local control and survival data are not available and this recommendation may need to be modified once these data are reported.

Targeted Biologic Agents

The role of targeted biologic agents such as bevacizumab and cetuximab are being defined. Phase I/II trials using preoperative chemoradiation with CAPOX with bevacizumab reveal pCR rates of 18% to 24%.[120,121] Two recent trials combining bevacizumab with preoperative FOLFOX[106] or capecitabine-based[122] chemoradiation were stopped early because of excessive toxicity. A recent Phase I trial combined the AKT inhibitor nelfinavir with chemoradiation.[123] Although the report from Heidelberg of CAPEIRI-based chemoradiation reported a pCR rate of 25%[124] other trials combining chemoradiation with cetuximab plus 5-FU, capecitabine, or CAPOX have more limited rates of 5% to12%.[125,126]

Patient selection for treatment based on KRAS expression is useful in patients with metastatic disease.[121] The preliminary results from the Phase II EXPERT-C trial (50.4 Gy, CAPOX, Cetuximab) reveal a survival benefit from the addition of cetuximab in the subset of patients with KRAS wild type compared to mutant (96% versus 81% 3-year OS; $p = 0.034$); however the primary endpoint of the trial (pCR) was not changed (11% versus 9%).[127] As an alternative, the SAAK 4/07 trial used panitumumab-based chemoradiation in patients with KRAS wild-type cancers.[128]

RTOG Phase II Randomized Preoperative Chemoradiation Trials

The RTOG had reported two Phase II randomized trials. RTOG 0012 enrolled 106 patients who received preoperative chemoradiation with PVI 5-FU plus twice-a-day irradiation compared to FOLFIRI plus conventional daily fractionated irradiation. There were no significant differences in the rate of pCR (30% versus 26%), local recurrence (16% versus 17%), and a corresponding decrease in 5-year OS (61% versus 75%), respectively.[129] Grade 3+ toxicity rates were 42% and 55%, respectively.

In a more recent trial, the RTOG compared preoperative chemoradiation with CAPEIRI compared to CAPOX in 101 patients with cT3-4 disease (RTOG 0247).[130] Although not statistically significant, patients who received CAPOX had a higher pCR rate (21% versus 10%) with similar hematologic (4% versus 8%) and nonhematologic toxicity rates (29% versus 24%). Neither of these preoperative regimens was moved into Phase III trials.

Impact of Tumor Response to Preoperative Chemoradiation

Most series suggest that there is improved outcome with increasing pathologic response to preoperative therapy.[29,131,132] A retrospective review of 566 patients who achieved a pCR after receiving a variety of preoperative chemoradiation regimens at multiple European centers was reported by Capirci et al.[131] With a median follow-up of 46 months the local recurrence rate was only 1.6% and the 5-year DFS and OS were 85% and 90%, respectively. A pooled analysis of 3105 patients from 14 studies confirmed a significant improvement in local recurrence, distant failure, DFS, and OS for the 16% of patients who achieved a pCR (ypT0N0M0) compared to those without a pCR.[29] Acellular mucin pools are seen in 15% of tumors following chemoradiation and do not have a significant impact on outcome.[133]

Although a number of molecular markers are predictive of outcome in colorectal cancer,[121,134,135] they have had varying success in identifying patients who may respond to preoperative therapy.[136-138]

Konski et al performed pre-treatment and post-treatment 18-FDG PET scans on 53 patients receiving preoperative chemoradiation.[141] By multivariate analysis the percent decrease in SUV was marginally trended in predicting pCR ($p = 0.07$). In contrast, Guillem et al found that neither FDG-PET nor CT can distinguish between a pCR and an incomplete response following preoperative chemoradiation.[142]

Preoperative Short-Course Radiation versus Chemoradiation

Historically short-course radiation has not been recommended for patients with cT3 or N+ disease. This is because of its lack of sphincter preservation, the inability to safely combine it with adequate doses of systemic chemotherapy, and the associated acute toxicity.[145] The KROH 10-01 trial, reported by Yeo et al, treated 73 patients with cT3-4 disease with 5 Gy × 5 (intensity-modulated radiation therapy [IMRT] technique) and concurrent chemotherapy (modified Mayo regimen of 5-FU 400 m^2 and leucovorin 20 mg/m^2) followed by surgery 4 to 8 weeks later.[146] The pCR rate was only 1.4% and the acute grade 3+ toxicity was 38%. However, these shortcomings may be mitigated by increasing the interval between the completion of radiation and surgery as well as delivering chemotherapy sequentially, as opposed to concurrently, with radiation.

Interval between Short-Course Radiation and Surgery

The Stockholm III trial is examining if increasing the interval between radiation and surgery improves sphincter preservation and reduces toxicity. Patients are randomized to 5 Gy × 5 followed by surgery one week later compared with 5 Gy × 5 followed by surgery 4 to 8 weeks later compared with 2 Gy × 25 (50 Gy) followed by surgery 4 to 8 weeks later. An interim analysis has revealed that the pCR rate was 0.8% in arm 1, 12.5% in arm 2, and 5% in arm 3.[147] Final results are pending.

Sequential Chemotherapy

The Dutch Colorectal Group has tested the role of sequential chemotherapy following short-course radiation. A total of 50 patients with primary rectal cancer (8% T2, 76% T3, 16% T4) and synchronous resectable metastasis (84% liver, 10% lung, 6% both) were enrolled on a Phase II trial of short-course radiation followed 2 weeks later by six cycles of CAPOX with bevacizumab.[149] After a 6 to 8 weeks rest they underwent resection of the primary and resection or ablation of the metastasis. For the total patient group, 72% had a R0 resection at all sites however the 2-year relapse rate was 64%. The 2-year OS was 80%. Limiting the analysis to the pelvis, 26% achieved a pCR and with a median follow-up of 32 months the local recurrence rate was 6%.

This approach serves as the experimental arm of the Dutch RAPIDO Phase III trial. Patients with locally advanced but nonmetastatic disease are randomized to short-course radiation followed by CAPOX × 6 and TME compared to standard-course chemoradiation followed by TME. A similar trial is being performed by the Polish Colorectal Cancer Study Group.

In a U.S. pilot trial, 44 evaluable patients were treated with short-course radiation followed by sequential chemotherapy.[150] They received five fractions (25 Gy to the involved mesorectum and 20 Gy to the pelvic nodes), followed by four cycles of mFOLFOX6. Postoperatively, 33 (75%) had ypT0-2 disease including 13 (30%) who were ypT0 and 14 (32%) were ypN0.

Kuremsky et al reviewed 1204 studies examining a total of 36 molecular biomarkers which potentially have predictive value.[139] He et al reported that PIK3CA mutations predict local recurrence after surgery alone.[140] Restricting the analysis to patients treated with preoperative chemoradiation and to gene products examined by five or more studies, only p53, EGFR, thymidylate synthase, Ki-67, p21, and bax/bcl-2 met these criteria. Of these, quantitatively evaluated EGFR or EGFR polymorphisms, thymidylate synthase polymorphisms, and p21 have been identified as promising candidates that should be evaluated in larger prospective trials for their ability to guide preoperative therapy. Because the studies are limited retrospective trials and most do not examined multiple markers, the need for adjuvant therapy should still be based on T and N category of disease.

The pCR rate may provide an alternative endpoint for assessing the efficacy of novel preoperative chemoradiation regimens. Because patients with rectal cancer who receive adjuvant chemoradiation can develop late relapses, however, a minimum follow-up of 7 years is needed.[143] Current intergroup rectal trials prospectively collect tissues for these and other markers.

Short-course radiation (25 Gy in 5 fractions) was established as a standard therapy in the Dutch CKVO and Swedish trials,[51,144] and chemoradiation was established as a standard therapy by the German Rectal Cancer Trial CAO/ARO/AIO-94 (45-50.4 Gy in 25 to 28 fractions plus concurrent chemotherapy).[12,53] These two trials cannot be directly compared because patients selected for treatment with short course included patients with cT1-3 disease, whereas 95% of the patients in the German trial had cT3 and/or N+ disease. Recently, randomized trials of short-course radiation have included patients with stages cT3 or N+ thereby allowing a more relevant comparison between these two approaches.

The sequential approach is based on data from Garcia-Aguilar et al in patients treated with chemoradiation.[148] They reported a randomized Phase II trial of 144 patients with cN+ rectal cancer who received either preoperative chemoradiation (50.4 Gy + continuous infusion 5-FU) followed by surgery 6 weeks later or initial chemoradiation, and if there was a clinical response, mFOLFOX6 followed by surgery 11 weeks later. The pCR rate was increased in the mFOLFOX arm (25% versus 18%) with no associated increase in postoperative complications (40% in each arm). These preliminary data suggested that delivering additional chemotherapy and delaying surgery in patients who respond to preoperative chemoradiation was not detrimental to the response or surgical complication rates.

The Dutch Colorectal Group is also testing the role of postoperative chemotherapy following short-course radiation. In the ongoing SCRIPTS CKTO 2003-16 Phase III trial (Simply Capecitabine in Rectal cancer after Irradiation Plus TME surgery) patients with clinical stage II or III disease located below the level of S1/S2 or the inferior margin within 15 cm of the anal verge receive 5 Gy × 5 followed by TME. Patients are then randomized postoperatively to either capecitabine or observation.

Randomized Trials

Polish Trial

Bujko et al randomized 316 patients with cT3 rectal cancers to preoperative short-course radiation compared to chemoradiation.[85,151] All tumors were above the anorectal ring and TME was performed for distal tumors only. Postoperative chemotherapy was optional. There was no radiation quality control review and TME was performed only for distal tumors. As seen in Table 51-4, compared with short-course radiation, patients who received chemoradiation had a higher pCR rate (16% versus 1%) and a lower incidence of positive radial margins (4% versus 13%, $p = 0.017$). However, there were no significant differences in sphincter preservation (58% versus 61%), crude local recurrence (14% versus 9%), DFS (56% versus 58%) and 4-year OS (66% versus 67%). Of note, the surgeons who participated in this trial were not willing to change surgical techniques from an APR to sphincter preserving based on the response to preoperative therapy. Although acute toxicity was significantly higher with chemoradiation (18% versus 3%; $p < 0.001$), there was no difference in overall postoperative complications.

TROG, AGITG, CSSANZ, and RACS Intergroup Trial

A similar trial from Australia and New Zealand was reported from the Tasman Radiation Oncology Group (TROG).[152] A total of 326 patients with ultrasound or MRI-staged cT3Nany adenocarcinoma located in the lower two thirds of the rectum were randomized to short-course radiation compared to chemoradiation. In contrast with the Polish trial, all patients received 6 months of postoperative adjuvant 5-FU/leucovorin chemotherapy. The median potential follow-up time was 5.9 years and the primary endpoint was 3-year local recurrence.

Compared with short-course radiation, patients who received chemoradiation had a 3% lower cumulative local recurrence rate at 3 years (4.4% versus 7.5%; p = NS), and 2% at 5-years (5.7% versus 7.5%; p = NS). Likewise, there were no significant differences in distant failure, OS, or late radiation toxicity. A subset analysis of the 79 patients with distal tumors revealed a cumulative incidence of local recurrence of 12.5% for short-course radiation and there were no failures with chemoradiation.

Alternative Methods for Sphincter Preservation

Early localized tumors (3% to 5% of rectal cancers) include small, exophytic, mobile tumors without adverse pathologic factors (e.g., high grade, blood vessel invasion, lymphatic vessel invasion, colloid histologic type, or penetration of tumor into or through the bowel wall) and are adequately treated with a variety of local therapies such as local excision or endocavitary irradiation.

Endocavitary Irradiation

Endocavitary irradiation alone[153-155] has been used for early, noninvasive tumors. For more advanced tumors (cT2-3 or LN+), it is combined with a temporary iridium-192 (^{192}Ir) implant or pelvic irradiation.[156-158] This technique is also known as the *Papillion technique.* Before delivery, the anus is dilated and a 4-cm proctoscope is introduced. A low-energy x-ray unit is placed through the scope almost against the tumor. Generally, 50-kV x-rays are delivered at 30 Gy per fraction in three or four fractions over 1 month. Patients who develop local failure can successfully undergo surgical salvage.[159]

Clinical outcomes with endocavitary irradiation alone or combined with pelvic radiation have been reported. At the Mayo Clinic, 29 patients were treated with curative intent with endocavitary irradiation alone to a total dose of up to 155 Gy in one to five fractions. The local control rate was 76% at 10 years, and OS was 65% at 5 years and 42% at 10 years, respectively.[153] At Washington University, patients received pelvic irradiation (20 Gy in 5 fractions for those with cT1; the remainder received 45 Gy in 25 fractions) followed 6 to 7 weeks later by two endocavitary treatments of 30 Gy each.[160] Results by T-category were uT1, 100% DFS; uT2, 85% local control rate; and uT3 (patients with uT3 tumors were not optimal candidates for surgery) or tethered uT2, 56% local control rate (67% after salvage surgery). Gerard et al[159] have reported a similar experience in 44 patients. Because the 50-kVp radiation machine is not currently available, there are limited centers that continue to treat patients with contact irradiation.

Local Excision with or without Radiation Therapy

Given the morbidity of standard surgery as well as the frequent need for adjuvant therapy, the use of a more

Although a well-designed and performed trial, there were two criticisms of the trial. First, although patient numbers were slightly larger than the Polish trial they still were relatively small. Second, rather than powered to show equivalence it was designed to have an 80% power to detect a difference in the projected 3-year local recurrence rate of 15% for short-course radiation compared with 5% for chemoradiation. Although the 3% lower incidence of local recurrence with chemoradiation compared to short-course radiation did not reach statistical significance ($p = 0.24$), the 95% CI for the difference included an 8% difference in favor of (i.e., 10% versus 2%). Overall, the data suggest a small local control advantage for chemoradiation, especially for distal tumors.

In summary, the most common treatment for T3 or N+ rectal cancer is preoperative chemoradiation. Emerging data are challenging the chemoradiation approach. Randomized trials comparing short-course radiation with chemoradiation are encouraging; however, longer follow-up is needed. The addition of sequential chemotherapy following short-course radiation is feasible and is being tested prospectively. The impact on outcome, acute and chronic toxicity, and sphincter preservation need to be determined.

conservative approach such as local excision plus adjuvant therapy (radiation or more commonly chemoradiation) as primary therapy for selected cases of rectal cancer has been investigated. Unfortunately, the data reported confirm that this approach is a compromise treatment, and in patients with long-term follow-up (>5 years), the local recurrence rates are substantially higher than with radical surgery, even with the addition of chemoradiation. Local recurrences occur both in the primary excision site and the pelvic nodes.

The results of local excision depend on a number of factors such as the type of surgery (full-thickness compared to piecemeal excision) and clinicopathologic factors such as tumor size, T category, grade, margins, and lymphatic and perineural invasion.

Local excision has been performed both before and after radiation therapy. The advantage of performing a local excision before irradiation is that pathologic details can be well characterized. Highly selected patients with pT1 tumors without adverse pathologic factors have local failure rates of 5% to 10%. However, once adverse pathologic factors are present (high grade, vascular invasion, or signet-ring cells) or the tumor invades into or through the muscularis propria, the local failure rate is at least 17% and the incidence of positive mesorectal or pelvic nodes is at least 10% to 15%.[161]

Local Excision Alone

Local excision alone is recommended only for selected patients with pT1 tumors. Nash et al performed a retrospective analysis of patients with cT1N0 disease who underwent a local excision (137 patients) or radical surgery (145 patients) and were found to have pT1Nx disease.[164] With a median follow-up of 5 years, there was a significantly lower local recurrence rate (3% versus 13%; $p < 0.05$) and a higher 5-year disease-specific survival rate (96% versus 87%; $p < 0.05$) in those who underwent radical surgery compared to a local excision. By multivariate analysis, both local excision and perineural invasion were independent prognostic factors associated with lower DFS.

Local Excision Followed by Postoperative Therapy

When all series are combined, the average crude local failure rate after local excision followed by postoperative radiation increases with T category: pT1, 5%; pT2, 14%; and pT3, 22%.[165-175] However, when the analysis is limited to the series with a minimum of 4 years of follow-up,[169,172,175,176] the incidence of local recurrence for pT2 disease is 14% to 24% (eTable 51-6). Therefore, patients who are treated with local excision and postoperative adjuvant therapy require close follow-up beyond 5 years. Surgical salvage is possible, with most series reporting that approximately half of the patients who undergo an APR can be cured.[177]

The CALGB performed a Phase II trial of local excision and selective postoperative chemoradiation (CALGB 8984).[180] A total of 91% underwent a full-thickness local excision. Patients with pT1 disease were observed, and pT2 patients received postoperative treatment with 54 Gy plus concurrent 5-FU. With a median follow-up of 4 years, the local recurrence rate in 59 patients with pT1 disease was 5% and with pT2 disease was 14%.

Sphincter Function

Prospective assessment of functional results after local excision and radiation therapy is limited. The groups from the Memorial Sloan Kettering Cancer Center[173] and Gemelli Hospital in Rome[170] report rates of 94% and 100%, respectively, for good to excellent function. Using a different scale, investigators from the Fox Chase Cancer Center[171] reported an 82% rate of good to excellent function; the University of Pennsylvania[168] reported a 92% rate of satisfactory function; and the M. D. Anderson Cancer Center[167] reported that all patients were continent. In the preoperative setting, sphincter function was reported as good to excellent in 88% to 91%.[181,182]

Preoperative Therapy Followed by Local Excision

Experience with preoperative chemoradiation followed by local excision is more limited.[181-188] Most series selected patients with cT3 disease who were either medically inoperable or refused radical surgery. Local recurrence rates ranged from 0% to 20% and 5-year OS ranged from 78% to 90%. Borschitz et al[187] reported local recurrence rates by pathologic stage as ypT1, 2%, and ypT2, 6% to 20%. Rates were as high as 43% in ypT3 tumors that did not respond to chemoradiation.

This approach was being prospectively tested in the ACOSOG 06031 trial. In this Phase II trial, 77 patients with uT2N0 disease received preoperative CAPOX and radiation therapy. After local excision, if patients have ypT0-2 tumors with negative margins, they undergo observation only. If the pathology extent is ypT3 or if the margins are positive, patients undergo radical surgery. The pCR rate was 44%.[188]

LOCALLY ADVANCED DISEASE AND PALLIATION

Locally advanced rectal cancer is a heterogeneous group of diseases. Based on digital examination it can vary from a tethered or "marginally resectable" cancer to a fixed cancer with adherence to or direct invasion of adjacent organs or vital structures. With the introduction of MRI staging the definition has broadened. Additional radiological features including the proximity to or involvement of the mesorectal fascia (MRF) that surrounds the mesorectal fat outside the rectum and involvement of the sphincter are now considered locally advanced rectal cancers.

The diagnostic workup must evaluate the local spread and the presence and location of pelvic nodes and of metastases. The choice of one or more imaging studies should include pelvic MRI, abdomen with thorax CT scan, or PET depending on the patient's presenting symptoms. Involvement of the sciatic notch indicated by symptoms or scans predicts a situation unlikely to be helped by surgery alone. This has prognostic implications because patients with gross invasion of tumor into vital pelvic structures may be approached in a palliative rather than a curative fashion.

Standard Treatment (Preoperative Chemoradiation and Resection)

With the exception of the uncommon suture line-only recurrence, patients with locally unresectable or MFR with primary or recurrent disease should receive preoperative chemoradiation. Braendengen et al[190] randomized 207 patients with locally nonresectable T4 primary rectal carcinomas or local recurrence from rectal carcinomas to chemotherapy (5-FU/leucovorin) concurrent with 50 Gy plus postoperative adjuvant therapy for 16 weeks compared to 50 Gy alone. Patients who received chemoradiation had a higher R0 resection rate (84% versus 68%; $p = 0.009$), pCR rate (16% versus 7%), and 5-year local control rate (82% versus 67%; $p = 0.03$) but a nonsignificant improvement in the OS (66% versus 53%; $p = 0.09$).

Given the high probability of distant metastatic disease in this group of patients it is reasonable to develop treatment programs, which maximize the amount and duration of systemic therapy, while still delivering pelvic radiation. In this setting, short-course preoperative radiation is an attractive approach. Bujko et al randomized patients with unresectable

CT, *Concurrent chemotherapy;* yr, *year.*
**Analysis is limited to the 110 patients (T2-2 disease) who met the full eligibility criteria (4 cm, full-thickness local excision, and negative margins).*

Most series include some patients who have undergone suboptimal surgery such as a piecemeal excision or have positive or unassessable margins. Because few of the published series have adequate numbers to perform a meaningful multivariate analysis, it is difficult to determine the influence of these selected clinicopathologic features on one another.

There are a variety of surgical approaches, including transanal local excision, posterior proctotomy, and transsphincteric excision. TEM has emerged as another option for local treatment of rectal cancer, either alone for T1 tumors or combined with irradiation for selected patients with T2-3 disease.[162] Regardless of the technique, the excision should be full thickness and nonfragmented and should have negative margins.[163]

A separate analysis of the 110 patients who met the full eligibility criteria in CALGB 8894 was reported by Greenberg et al.[179] The criteria were limited to tumors less than 4 cm, full-thickness excision, and negative margins. Patients with pT1Nx tumors underwent local excision alone, and those with pT2Nx received postoperative chemoradiation. With a median follow-up of 7.1 years, the rates of local recurrence and 10-year actuarial survival were T1, 8% and 84%, and T2, 18% and 66%, respectively. The median time to failure was T1, 4 years, and T2, 2 years.

A similar trial in France (GRECCAR 2) is designed to accrue 300 patients with cT2-3 disease. They receive 50 Gy with concurrent CAPOX. If the clinical T category following chemoradiation is cT1-2, patients are randomized to undergo local excision versus radical surgery. If the clinical extent is cT3, all have radical surgery.

Bujko et al reported 89 patients with unfavorable cT1N0 or cT2-3N0 rectal cancer who received preoperative therapy with either 5Gy × 5 followed by a 4-Gy boost or chemoradiation. Patients then underwent a local excision and if there was ypT0-1 disease they were observed and if there was less of a response they underwent surgery. A total of 63 patients underwent a local excision and the local failure was 12% in those who received short-course radiation compared with 6% for chemoradiation.[189]

This was based on data from the mid-1980s reporting that involvement of the CRM (also known as lateral or radial margins) was not only the most important factor for the risk of local recurrence following rectal cancer surgery but considerably more relevant than the distal or proximal resection margins.[13] A positive CRM refers to the presence of tumor in the margin or in close proximity to the MRF, irrespective of whether that distance is 1 mm or 2 mm. A positive CRM is predictive not only for local failure but also for distant failure.[81] The ability to obtain a negative CRM depends to the extent of the operation the surgeon is able to perform and ultimately the associated loss of function the patient is willing to accept.

or locally recurrent tumor involving or abutting adjacent organs or structures (cT4) or palpably fixed cT3 disease to receive either preoperative 5-×5-Gy irradiation over 5 days and consolidative chemotherapy with three cycles of FOLFOX4 (schedule I) versus long-course chemoradiation (50.4 Gy in 28 fractions of 1.8 Gy over 5.5 weeks) concomitantly with oxaliplatin, 5-FU, and leucovorin (schedule II). The interval between the start of radiation and surgery was 12 weeks in both groups. The primary endpoint of the study was microscopic negative margins and the accrual goal is 540 patients.

Extended surgery to include the infiltrated organs should be considered if there is a favorable response after preoperative therapy. Even in patients who do not respond adequately to preoperative therapy, surgery should still be considered, balancing the benefits and risks.[191] Given the limitation of the total EBRT dose that can be delivered to the bulky tumor in the pelvis[192] and the frequent problem of local recurrence, the surgeon should be aggressive.[193] Overall, approximately 10% of rectal cancers require extensive surgery such as a pelvic exenteration to obtain negative margins.[194] These include tumors invading the prostate, the base of the bladder, or the uterus and vagina where the disease can be resected en bloc with negative margins. Midline posterior tumors adherent to or invading the distal sacrum may be resectable for cure with APR extended to include the lower sacrum. The 5-year OS ranges between 33% and 50%, with significant rates of morbidity and mortality up to 6%.[192] Improvements in perioperative care, patient selection, and surgical technique, such as vascularized tissue flaps to facilitate the healing of pelvic and perineal wounds, have improved the results[195] In IORT institutions, an excellent alternative to pelvic exenteration is marginal gross total resection (R0 or R1) plus IORT (see subsequent section).

Although sphincter preservation is a major goal for patients with primary resectable disease, this should be a lesser goal for patients with locally recurrent cancers. In view of the extensive surgery required for patients with local recurrence and the likelihood of high-dose EBRT, patients may have a better functional outcome with a permanent colostomy than with coloanal anastomosis or a low anterior resection.

In general, patients with local recurrence have an unfavorable prognosis. Common symptoms include pain, hemorrhage, pelvic infection, and obstructive symptoms. Patients with local recurrence should receive preoperative chemoRT if feasible. However, some patients who present with locally recurrent disease series have had prior adjuvant EBRT and can receive only a limited or no dose.[196]

Intraoperative

The primary advantage of IORT is that radiation can be delivered at the time of surgery to the site with the highest risk of local failure (the tumor bed) while decreasing the dose to the surrounding normal tissues. IORT can be delivered by two techniques: electron beam or brachytherapy. Brachytherapy is most commonly delivered by the high-dose-rate technique, and the dose rate is similar to that used for electron beam IORT.[197-199] The results (and recommended dose) of IORT depend on whether the patient has primary unresectable or recurrent disease and on whether the margins of resection are negative or there is microscopic or gross residual disease. In general, series have used 10-Gy to 20-Gy IORT depending on the volume of residual disease and the dose of EBRT that can be safely delivered with concurrent chemotherapy, preferably before the attempted resection. For example, at the Mayo Clinic, patients with locally unresectable primary cancers receive preoperative chemoRT (45 Gy to 50.4 Gy/25 to 28 fractions) plus an IORT dose of 10 Gy after R0 resection with narrow margins, 10 Gy to 12.5 Gy after R1 resection, and 15 Gy to 20 Gy after R2 resection.[49]

It is difficult to clearly separate treatment-related complications from disease-related complications in patients with unresectable primary or recurrent rectal cancers. The total incidence ranges from 15% to 50% in most series and is highest in patients with the most advanced disease (recurrent unresectable tumors). Complications such as delayed healing, an increase in infection, fistula formation, and neuropathy may be the result of recurrent tumor, aggressive surgery, radiation therapy, or a combination of these.[49,200,201] The incidence of IORT-related peripheral nerve toxicity appears to increase with IORT doses of 15 Gy to 20 Gy. In a series from the Netherlands, 79 patients surveyed reported fatigue (44%), perineal pain (42%), sciatic pain (21%), walking difficulties (36%), and voiding dysfunction (42%).[200] In addition, functional impairment consisted of requiring help with basic activities (15%), sexual inactivity (56%), the loss of former lifestyle (44%), and the loss of professional occupation (40%). The University of Navarra reported peripheral neuropathy up to 5 years after IORT.[201] These consequences must be weighed against the chance of cure if the patient is treated and the disability eventually caused by uncontrolled tumor progression if the patient is not treated.

The long-term morbidity in the Mayo Clinic IORT series of 146 patients with locally unresectable colorectal cancers was 53% and included neuropathy (in 28 of 146 patients, or 19%), small bowel obstruction (14%), and ureteral obstruction (12%).[49] Severe toxicity (grade 3 or 4) was evident in 32 of 146 patients (22%), with small bowel obstruction in 14 patients (9.5%) and severe neuropathy in only 3 (2%).

Primary Unresectable Disease

Results of selected series with or without IORT are seen in Table 51-5. The results of the series from Rotterdam,[47] Madrid,[202] Eindhoven,[203] and Montpellier[204] include patients with both cT3 and cT4 disease and do not report the data separately. The Rotterdam and Eindhoven series examined outcome and did not find a significant difference. However, indications for IORT with T3 primary rectal cancers are questionable, unless used to replace a portion of the EBRT dose in patients with node negative disease. The overall incidence of local failure is approximately 10% to 15%, and central failure in the IORT field is uncommon (i.e., 2% in the Mayo Clinic IORT series of 146 patients with locally unresectable T4 colorectal cancer).[49]

A French multiinstitutional randomized trial performed with 142 patients, T3-4 or N+, M0 stages, has not demonstrated an improvement in local control and DFS in the context of 40-Gy preoperative irradiation with or without 18-Gy IORT pelvic boost.[204] The 5-year local control rates were 92% compared with 93%, and postoperative complications incidence were 30% (IORT) compared to 19% ($p = 0.15$). Topography of pelvic recurrences and technical characteristics of IORT boosting were not reported.

The most favorable results are obtained in patients with gross total resection and negative margins (R0 resection) or microscopically positive margins (R1 resection). The 5-year local recurrence and OS in the Eindhoven IORT series were R0, 8% and 73%, and R1-2, 38% and 31%, respectively.[145] Valentini et al[205] treated 100 patients with primary, clinical, T4M0, extraperitoneal rectal cancer with preoperative chemoRT with or without IORT. The R0 resection rate was 78%; 5-year local control in R0 patients was 90%, better in the IORT group (100%). The 5-year OS was 59% and was better after an R0 versus an R1-2 resection (68% versus 22%). Although the numbers are small, in the Rotterdam series, the 5-year local

Bujko reported outcomes of 49 patients—reported outcome of 49 patients treated according to schedule I, and 48 according to schedule II. Grade 3+ acute toxicity was observed in 26% of patients in group I and in 25% in group II. There were two toxic deaths, both in group II. The microscopically radical resection (primary endpoint) rate was 73% in group I and 71% in group II. Overall and severe postoperative complications were recorded in 27% and 9% of patients compared to 16% and 7%, respectively. Pathological complete response was observed in 21% of the patients in group I and in 9% in group II. Final outcome data are pending.

A similar randomized trial (RAPIDO Trial) is ongoing in Sweden and the Netherlands. Eligibility includes at least one of the following criteria on pelvic MRI: overgrowth to an adjacent organ or structure, cT4b, extramural vascular invasion (EMVI+). N2, MRF+, enlarged lateral nodes, or >1 cm (lat LN+). Patients are randomized between short course 5-×5-Gy followed by six cycles of CAPOX chemotherapy and surgery compared with long-course chemoradiation followed by surgery and eight cycles of postoperative CAPOX. The primary endpoint is 3 years DFS and data are expected for 2016.

§Median IORT dose.

recurrence rate was lower in the 11 patients with positive margins who received IORT compared with the 8 who did not (58% versus 100%; $p = 0.016$).

In the Mayo Clinic IORT series of 146 patients with colorectal cancer with T4 lesions, R0-1 resection was accomplished in 128 patients and R2 resection in 18. Those with IORT after R0-1 resection had better 5-year OS than those with R2 resection (56% versus 22%; $p = 0.0006$. Patients who received preoperative chemorRT ($n = 124$) had improved survival compared with those who received postoperative chemoRT ($n = 20$) with 5-year OS of 55% versus 38% ($p = 0.02$).

In the Massachusetts General Hospital (MGH) series of 145 patients with rectal cancer,[45] local failure in patients with negative margins decreased from 18% without IORT to 11% with IORT. In patients with positive margins, local failure was 83% without IORT versus 43% with IORT for gross residual disease and 32% with IORT for microscopic residual disease. For all patients in the series (with or without IORT), the 5-year DFS was 63% for patients with negative margins and 32% for patients with positive margins.

The results in both MGH and Mayo series underscore the importance of delivering preoperative therapy to help achieve negative margins. If negative margins cannot be obtained, then microscopic residual disease is preferable to gross residual disease. Reports from other centers are similar.

At the MGH, of the 95 patients with T4 disease who received preoperative irradiation and underwent complete resection, 40 patients had an IORT boost and 55 did not because it was not indicated secondary to either a favorable response or it was not technically feasible.[206,207] Regardless of the response to preoperative therapy, higher local failure rates were seen in patients not receiving IORT (responders, 0% versus 16%; nonresponders, 12% versus 27%) these data suggest that IORT should be delivered independent of the extent of tumor downstaging.

Locally Recurrent Disease

Recurrences can be heterogeneous, and the pattern of extension is more infiltrative within the operative bed compared with primary rectal cancers. Localized pelvic recurrences may be classified according to the tumor location within the pelvis. At the Mayo Clinic, 106 patients with local recurrence, treated by subtotal resection alone or with IORT (42 patients) or EBRT, were stratified during the surgical procedure according to no pelvic infiltration of the tumor (F0) or infiltration of the tumor to one pelvic site (F1), two pelvic sites (F2), or more than two pelvic sites (F3).[208] This classification system significantly correlated with survival. At the Catholic University of the Sacred Heart, Rome, 47 patients with locally recurrent, nonmetastatic rectal carcinoma were treated by preoperative chemoradiation plus IORT and were classified by CT scan according to the Mayo Clinic system.[209] A further (F4) class was added when tumor infiltrated small bowel or bone structures. The classification system significantly predicted R0 resectability ($p = 0.01$) and survival ($p = 0.008$).

Results in selected series with or without IORT are seen in Table 51-6. As seen in patients treated for primary unresectable disease, the margin status and delivery or nondelivery of IORT have an impact on outcome for patients with locally recurrent disease.

In the MGH IORT series of 49 patients, the 5-year local control rate was 35% and was higher with negative versus positive margins (56% versus 13%).[207] The 5-year OS for the total group was 27%; higher in patients with negative versus positive margins (40% versus 12%).

Kusters et al[217] from Eindhoven treated 170 patients with locally recurrent rectal cancer with preoperative irradiation with or without chemotherapy followed by surgery (154 patients received IORT). The local recurrence rate in patients with negative margins was 32% and with positive margins was 71%. The 154 patients selected to receive IORT had a local recurrence rate of 47%. Patients with posterior (presacral) recurrences were more likely to have positive margins than those with anastomotic recurrences (72% versus 23%) and the 5-year OS was lower than with relapse in other pelvic sites at 19% ($p = 0.03$).

The most recent Mayo Clinic Rochester analysis included 607 patients with recurrent colorectal cancer receiving IOERT as a component of treatment (colon, 180 patients; rectum, 427 patients).[134] Survival at 5 years was 30% for the total group of patients. On multivariate analysis, complete resection, no prior chemotherapy, and treatment after 1996 were associated with improved survival rates. In patients with an R0 resection (227 patients) compared to an R1 resection (224 patients) or R2 resection (156 patients), 5-year OS were 46%, 27%, and 16% ($p < 0.0001$, multivariate analysis), respectively.

Investigators at the M. D. Anderson Cancer Center (MDACC) and in Oslo reported no benefit of IORT for patients with positive margins.[218] In the report from Oslo, 107 patients with isolated pelvic recurrence received 46 Gy to 50 Gy preoperatively followed by resection alone or plus IORT.[214] Regardless of the volume of residual disease, there was no significant difference in local recurrence or survival rates whether or not patients received IORT.

To evaluate disease control, OS and prognostic factors in patients with locally recurrent rectal cancer after IORT-containing multimodal therapy Röder et al analyzed 97 patients with locally recurrent rectal cancer treated with surgery plus IOERT.[219] IOERT was preceded or followed by EBRT in 54 previously untreated patients (median dose 41.4 Gy) usually combined with 5-FU–based chemotherapy (89%). Median OS was 39 months. Estimated 5-year rates for central control (inside the IOERT area), local control (inside the pelvis), distant control, and OS were 54%, 41%, 40%, and 30%, respectively. Resection margin was the strongest prognostic factor for OS (3-year OS of 80% [R0], 37% [R1], 35% [R2]) and LC (3-year LC 82% [R0], 41% [R1], 18% [R2] in the multivariate model. OS was further significantly affected by clinical stage at first diagnosis and achievement of local control after treatment in the univariate model.[220]

In summary, it is unclear in some series if those with R2 resection benefit from aggressive therapy in contrast to patients with R0 or R1 resection. Although the Oslo study reported no long-term survivors for patients with R2 resection, U.S. IORT series report 10% to 18% 5-year OS in this subset of patients which includes those with prior EBRT.

Reirradiation Followed by Surgery

The combination of chemoradiation and TME has significantly decreased the incidence of local recurrence. However, there is a subset of patients who present with local recurrence only who have received previous pelvic irradiation. In these patients, the recurrence is often not resectable with clear margins and reirradiation would be expected to be associated with a high risk of late toxicity.

Few studies have analyzed the role of radiation retreatment in pelvic recurrence. Data from Mohiuddin et al[221] suggest that reirradiation with doses of 30 Gy (and if the small bowel can be excluded from the irradiation field, 40 Gy) can be used for limited volumes. A total of 103 patients with recurrent disease underwent reirradiation with concurrent 5-FU–based chemotherapy. The initial radiation dose to the pelvis ranged from 30 Gy to 74 Gy, with a median dose of 50.4 Gy. Irradiation techniques consisted of two lateral fields with or without a

Calvo et al analyzed prognostic factors associated with survival in patients after IORT for locally recurrent rectal cancer in 60 patients. Overall, 47% also received EBRT (range, 30.6 Gy to 50.4 Gy). The median follow-up time was 36 months (range, 2 months to 189 months), and the 1-year, 3-year, and 5-year rates for locoregional control and OS were 86%, 52%, and 44%; and 78%, 53%, 43%, respectively. EBRT improved the ability to achieve a radical resection and to avoid fragmented resection specimens and in these settings, was associated with improved local regional control. Patients who underwent a R1 resection and no tumor fragmentation showed a significant lower OS after adjustment for other covariates.[219]

†*Excluding 10 patients with multifocal or extrapelvic disease.*

posterior pelvic field to include recurrent tumor with a margin of 2 cm to 4 cm. Doses ranged from 15 Gy to 49.2 Gy (median, 34.8 Gy). After reirradiation, 34 underwent surgical resection for residual disease. For the total group, median survival was 26 months and 5-year OS was 19%. Patients who underwent resection had significantly higher median survival (44 months versus 14 months) and 5-year OS (22% versus 15%; $p = 0.001$). Late complications were seen in 22 patients and were unrelated to radiation dose.

A multicenter Italian trial of 59 patients with recurrent disease who had received less than 55 Gy were retreated preoperatively with concurrent PVI 5-FU plus 30 Gy (1.2 Gy twice daily) to the gross tumor volume (GTV) plus a 4-cm margin.[222] A boost was delivered, with the same fractionation schedule, to the GTV plus a 2-cm margin (10.8 Gy). Grade 3+ toxicity was 5% for acute toxicity and 12% for late toxicity. The prior median radiation dose was 50.4 Gy. The pCR rate was 9%, and 83% of those with pelvic pain before treatment had a symptomatic response. With a median follow-up of 36 months, the rate of local failure was 48%, median survival was 42 months, and 5-year OS was 39% (R0, 67% versus R1-2, 22%). Multivariate analysis confirmed the impact of a longer DFS on local control ($p = 0.016$) and DFS ($p = 0.002$). Patients who underwent an R0 resection had improved local control and DFS ($p = 0.016$).

In the recent Mayo Clinic IORT analysis of 607 patients with locally recurrent colorectal cancer, 248 had received prior EBRT.[134] Additional EBRT was given in 228 patients (median, 27.5 Gy; range, 5 Gy to 39.6 Gy). Prior in-field EBRT versus none was associated with an increased risk of local relapse (3-year rate, 31% versus 17%; $p < 0.0001$) and trends for decreased 5-year OS that did not reach significance (26% versus 32%; $p = 0.07$), Table 51-12. Mayo Clinic investigators prefer to give preoperative EBRT (25 Gy to 30 Gy in 1.8-Gy fractions) plus concurrent CI 5-FU or oral capecitabine before resection and IOERT in this group of patients.

At the MDACC 50 patients with a history of prior pelvic radiotherapy were treated with hyperfractionated accelerated radiotherapy for primary ($n = 2$ patients) or recurrent ($n = 48$ patients) rectal adenocarcinoma.[196] Patients were treated with 1.5 Gy fractions twice daily, with a total dose of 39 Gy ($n = 47$ patients) if the retreatment interval was >1 year or 30 Gy ($n = 3$) if the retreatment interval was <1 year. Concurrent chemotherapy was administered to 48 (96%) patients. Eighteen (36%) patients underwent surgical resection following radiotherapy. The 3-year rate of grade-3 to grade-4 late toxicity was 35%. The 3-year rate of freedom from local progression was 33% (47% in patients undergoing surgery and 21% in those with no surgery, $p = 0.057$). The 3-year OS was 39% for the total group, 66% compared with 23% in patients undergoing surgery compared to not ($p = 0.003$) and 53% compared to 21% in patients with a retreatment interval of >2 years compared with < 2 years ($p = 0.001$).

Irradiation Alone for Locally Unresectable or Recurrent Disease

Some investigators have advocated the use of radiation therapy alone, most commonly in patients who are medically inoperable or refuse surgery.[102,157,223] A variety of techniques have been used, including various combinations of EBRT, brachytherapy, and intracavitary irradiation. In most series, patients received pelvic radiation therapy followed by a boost with EBRT or brachytherapy.

Wang et al[224] from the Princess Margaret Hospital (PMH) reported the results of EBRT alone (40 Gy to 60 Gy) in 227 patients who refused surgery or had unresectable or medically inoperable disease. The 5-year OS was 27% for all patients; if the primary tumor was mobile, the rate was 47%; if partially fixed, 27%; and if fixed, 4%. These data suggest that patients with mobile or partially fixed rectal cancers who are medically inoperable should be treated aggressively with pelvic irradiation as a component of their therapy.

Gerard and et al[102] reported the combination of EBRT, intracavitary therapy, and brachytherapy in 63 patients with uT2-3 tumors. For patients with uT3 disease, the 5-year local failure and survival rates were 20% and 35%, respectively.

Pelvic irradiation offers effective palliation. A recent review the efficacy and toxicity of palliative pelvic radiotherapy of symptomatic rectal cancer and to evaluate different fractionation schedules, based on systematic literature searches of Medline, Embase, and Cochrane databases showed large variations in applied radiotherapy regimens. Pooled overall symptom response rate was 75%, and positive responses were reported for pain (78%), bleeding and discharge (81%), mass effect (71%), and other pelvic symptoms (72%). Toxicity and quality-of-life results were not evaluable.[225] In a subset of 80 patients with metastatic disease who received pelvic irradiation, Crane et al[226] reported that 94% had complete resolution of pelvic symptoms and the 2-year pelvic symptom-free control rate was 82%. The PMH series reported similar palliative benefits.[101] In the subset of 84 patients who received more than 45 Gy, the following presenting symptoms were palliated by 6 to 8 weeks following the completion of radiation therapy: pain, 89%; bleeding, 79%; neurologic symptoms, 52%; mass effect, 71%; discharge, 50%; urologic symptoms, 22%; and other symptoms, 42%. In the Thomas Jefferson University series, complete plus partial symptomatic relief was achieved in the following categories: pain (65% + 28%), bleeding (100%), and mass effect (24% + 64%), respectively.[221] The duration of palliation was 8 to 10 months. In patients who are unable to receive irradiation, laser treatment or stenting[227] offers some palliative benefit.

Treatment of Patients with Metastatic Disease

With the development of more effective systemic chemotherapy, the median survival of patients with metastatic colorectal cancer is greater than 2 years.[228] Aggressive techniques to address liver metastasis with surgery and nonsurgical ablative techniques such as radiofrequency ablation, cryosurgery, microspheres, and EBRT have further improved median survival.[229] Innovative radiation techniques such as stereotactic body radiotherapy of liver metastases are under active investigation.[230]

With these advances, the historical notion that chemoRT is not necessary because patients die before developing a local recurrence is being challenged. In the setting of disease presentation with distant metastasis, there is no standard of care and treatment should be decided on a case-by-case basis with the help of a multidisciplinary tumor board. In general, patients who respond to chemotherapy and have a risk of developing local recurrence should be considered for treatment consolidation with chemoradiation.

Approximately 2% to 5% of colorectal cancers are diagnosed with one or a few synchronous metastases in one organ, usually liver. These patients are staged as having oligometastatic disease and can be treated in a potentially curative fashion. The treatment strategy synchronous oligometastatic rectal cancer should be based on the possibility to achieve R0-resection, either initially or after induction treatment for both the systemic disease and the primary tumor in a multidisciplinary team discussion.[231] It has been shown that surgical resection of colorectal liver and lung metastases is a potentially curative treatment, with reported 5-year survival rates

ranging from 30% to 50%.[232,233] The ideal timing for the surgery of the primary, either concomitant with resection of the metastases or delayed until after chemoradiation, remains controversial. It should be based on the individual patient by a multidisciplinary team discussion.

IRRADIATION TECHNIQUES AND TOLERANCE

Patterns of Relapse That Define Radiation Portals

The design of pelvic radiation therapy fields is mainly based on the pattern and incidence of local recurrence after surgery. For locally advanced disease, recurrences in the soft tissues may arise from tumor extension to the pelvic sidewall, the bladder, the prostate in men, the vagina in women, and the presacral space in all patients. This is especially true for tumors penetrating the mesorectal fascia or those with involved or close (<1 mm) circumferential margins. Incomplete mesorectal excision also has a higher risk of leaving residual microscopic tumor cells behind.

The major lymphatic spread is in a cephalad direction contained within the perirectal fascia and along the mesenteric system, which is commonly dissected by standard TME surgery. Outside the mesorectum is a space containing vessels, nerves, and lymphatics, which is not usually dissected. Tumors at or below the peritoneal reflexion tend to spread laterally along the internal iliac and obturator chains. The external iliac nodes only become at risk with anterior tumor extension and adjacent organ involvement. Lesions that extend to the anal canal or the lower third of the vagina can spread to the inguinal nodes. In this setting, the bilateral inguinal nodes should be considered for inclusion in the pelvic radiation fields.

The relative frequency and sites of pelvic failures were delineated by the seminal work of Gunderson and Sosin.[234] In this reoperative series of 75 patients (initial APR), locoregional failures occurred in the soft tissue of the pelvis or the anastomotic site in 69%, pelvic lymph nodes in 42%, and perineum in 25%. A more contemporary series of 269 patients studied by Hruby et al[235] confirmed that the majority of local failures occurred in the posterior central pelvis (47%) or at the anastomosis (21%), whereas anterior recurrences (11%) were mainly restricted to T4 tumors. Perineal recurrences occurred in 16% of patients who underwent APR.

At the University of Wurzburg, sites of failure were analyzed in 155 patients.[236] The incidence of failure sites was similar for APR compared to LAR: local plus nodal disease, 61% versus 66%; isolated lymph node disease, 4% versus 5%; internal iliac and presacral node disease, 47% versus 59%; and external iliac disease, 7% versus 2%. Local recurrence was most commonly seen in the presacral pelvis and in patients who underwent an LAR; the anastomosis was involved in 93%.

A study to evaluate local recurrences fully in three dimensions in patients treated in the Dutch TME trial, comparing preoperative short-course radiation plus TME with TME alone, showed that the most cranial recurrences were located a few centimeters caudal of the promontory, irrespective of whether radiation was delivered.[237]

Two-dimensional Irradiation Field Design

The whole-pelvic radiation field should adequately cover the primary tumor and tumor bed as well as the primary nodes at risk. The intent of the boost is to treat the primary tumor and tumor bed and not to include the nodes. The exact size is determined by the size and location of the primary tumor.

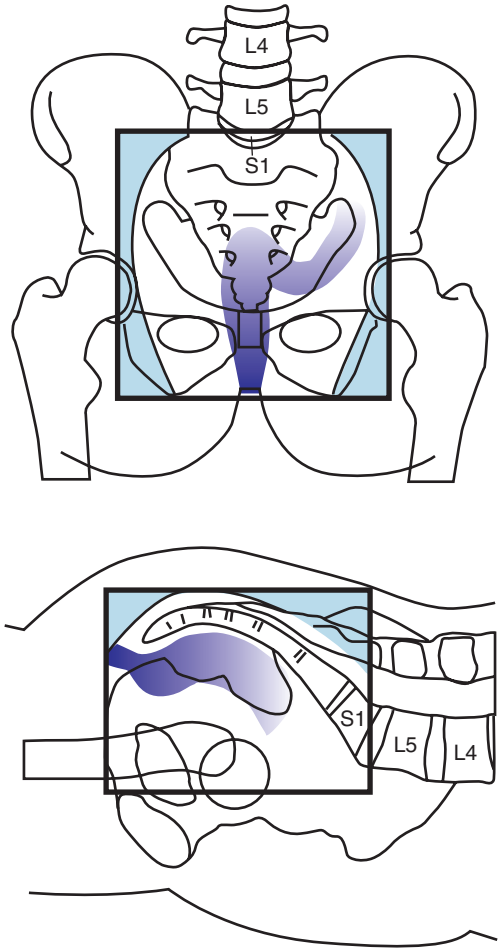

Figure 51-2 Treatment fields following a LAR for a T3N1M0 rectal cancer at 8 cm. Angle is from the anal verge. In this example, the distal border is at the bottom of the obturator foramen and the perineum is blocked. Because the tumor was a T3, the anterior field is at the posterior margin of the symphysis pubis (to treat only the internal iliac nodes).

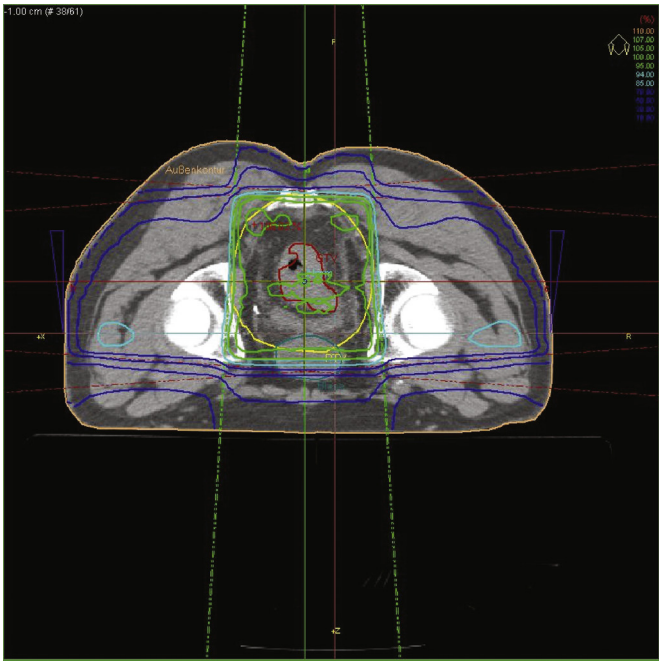

Whole pelvic and boost fields are usually treated with a three-field (posterior-anterior and laterals) or four-field technique. Field shaping by blocks is used to spare additional small intestine anteriorly and superiorly, the posterior muscle and soft tissue behind the sacrum, and the region inferior to the symphysis pubis. General guidelines for the design of two-dimensional (2D) fields as well as specific examples of field arrangements with conventional techniques for a variety of presentations are seen in Figures 51-2 to 51-4.

Three-dimensional Treatment Planning and Delineation Recommendations

Techniques using CT-based 3D treatment planning have replaced fluoroscopy-based simulators (eFigure 51-5). Using a 3D planning system, Koelbl et al[238] found that in patients receiving postoperative EBRT, the use of the prone position plus a belly board decreased the small bowel volume treated versus the supine position. Guidelines for the definition and delineation of the clinical target volumes (CTVs) are now available from a number of investigators.[239,240]

After the introduction of conformal radiotherapy, a number of investigators published recommendations for contouring.[239-242] The goal of guidelines is to standardize the

Interestingly, a CRM+ does not necessarily mean that the recurrence appears at the same level as the primary tumor. The most cranial recurrences were presacral, with the highest recurrence halfway to the level of S1, which was easily covered by the radiation field. Interestingly, the most cranial recurrences originated from tumors less than 5 cm from the anal verge. In addition, these cranial recurrences originated from patients with primary nodal involvement and a positive CRM. The most cranial recurrence for patients who are N0 and CRM- was found at the junction between S2 and S3 in the group that received radiation and at the level of S3 in the group that did not receive radiation. Recurrences in patients following a LAR were found mainly in the presacral and anastomotic regions, whereas in patients with an APR of Hartmann resection, recurrences were found in all regions.

eFigure 51-5 Three-dimensional treatment plan for rectal cancer.

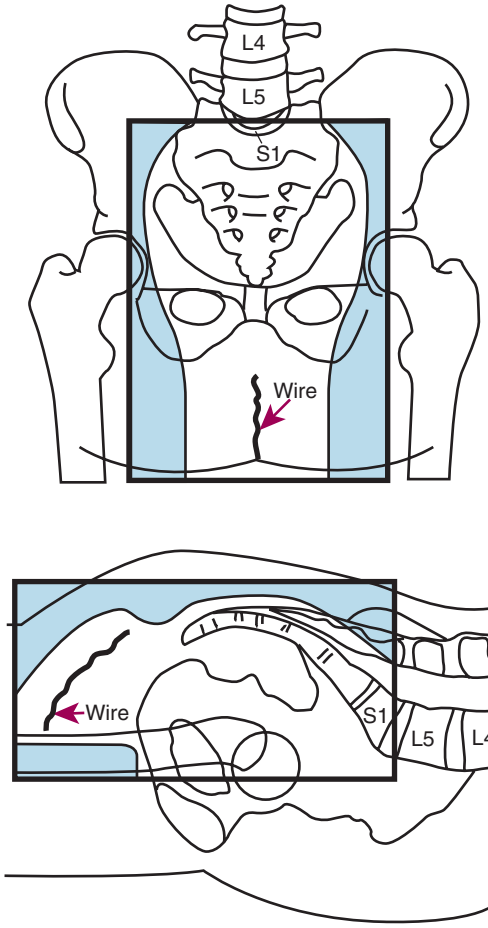

Figure 51-3 Treatment fields following an APR for a T3N1M0 rectal cancer 2 cm. Angle is from the anal verge. In this example the distal border is extended to include the perineal scar. Because the distal border is being extended only to include the scar, the remaining normal tissues can be blocked.

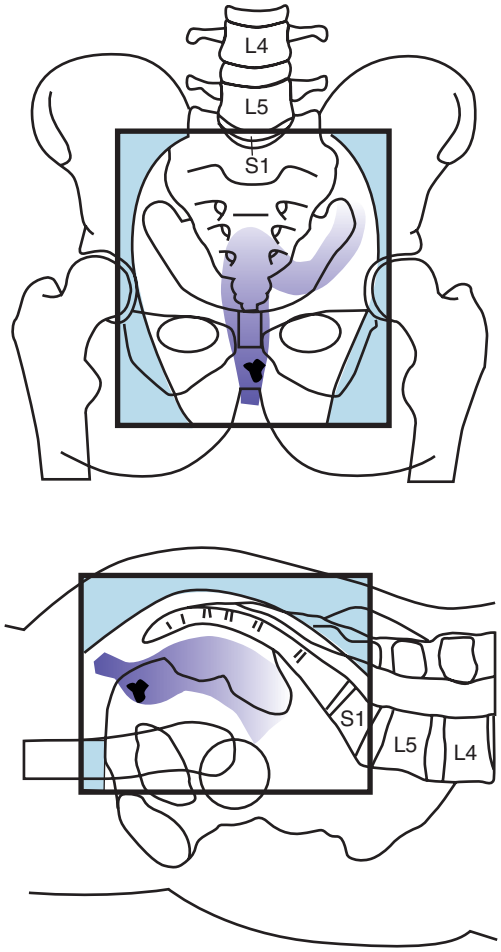

Figure 51-4 Treatment fields for preoperative radiation therapy for a low lying T3NXM0 (or following a LAR for a T3N1M0) rectal cancer. In this example the distal border is extended 3 cm beyond the primary tumor and the perineum is blocked. Because the tumor was a T3, the anterior field is at the posterior margin of the symphysis pubis (to treat only the internal iliac nodes).

target volume delineation; however, some uncertainties still remain and a uniform approach has not yet been reached.[242] The sites of recurrence and the involvement of lymph nodes in the lateral spaces of the pelvis reported by Japanese surgeons who systematically removed them have identified different pelvic subsites.[243-249] There are a number of subsites in common with mostly of these guidelines. First is the mesorectum. It is easy to identify in the mid to low pelvis in relation to the location of the pelvic organs (bladder, uterus/vagina, prostate). However, in the superior pelvis, the anterior part of the mesorectal subsite does not have an anatomical boundary. In the presacral subsite space is small and it is often not visible on CT scan. It is usually delineated together with the mesorectum as only one subsite. Lastly, the internal iliac node area is represented by a triangular lymphovascular fat area located between the pelvic wall and the mesorectum behind the external iliac vessels. In some guidelines the obturator nerve is used to split it into two subsites: the obturator subsite encompassed by the external iliac vessels and the obturator nerves and the internal iliac subsite, posterior to the obturator nerve. The external iliac subsite is the easiest to identify, because of the external iliac arteries and veins, which are well visualized on CT scan.

The inclusion of lateral nodes in the pelvic target volume for preoperative radiotherapy should be personalized according to tumor stage, tumor site, and lymph node location.[241] This is illustrated in Figure 51-5, *A-C* (eFigure 51-5, *A-B*). For cT3 tumors the primary tumor, the entire mesorectum, presacral space, and internal iliac nodes should be included. In addition, the obturator nodes should be added in case of low and medium rectum MRF+, clearly positive internal iliac nodes, and posterior cT4 disease. In cT4 tumors with anterior organ invasion, or for cT3 tumors with clear obturator node involvement, the addition of the external iliac nodes is recommended.[240,250] The lower edge of the CTV may be modified according to tumor extension and invasion based on the following criteria: (1) for tumors located at >1.5 cm above the anal-rectal ring, the lower border should be limited at the end of the mesorectum; (2) for tumors located <1.5 cm from the anal-rectal ring, the lower border should extend to encompass 1 cm of the anal canal; (3) for tumors extending through the anal canal, the entire anal canal and the sphincter complex should be included—although in published literature, adding a margin around the sphincter complex is not indicated, it is recommend to contour 5 mm to 10 mm of fat around it—and (4) when the rectal fossa is directly infiltrated by the tumor, both ischiorectal fossae should be included. Inguinal nodes generally are not targeted in rectal cancer. However, when most of the anal canal or the ischiorectal fossa is infiltrated, they should be part of the CTV.

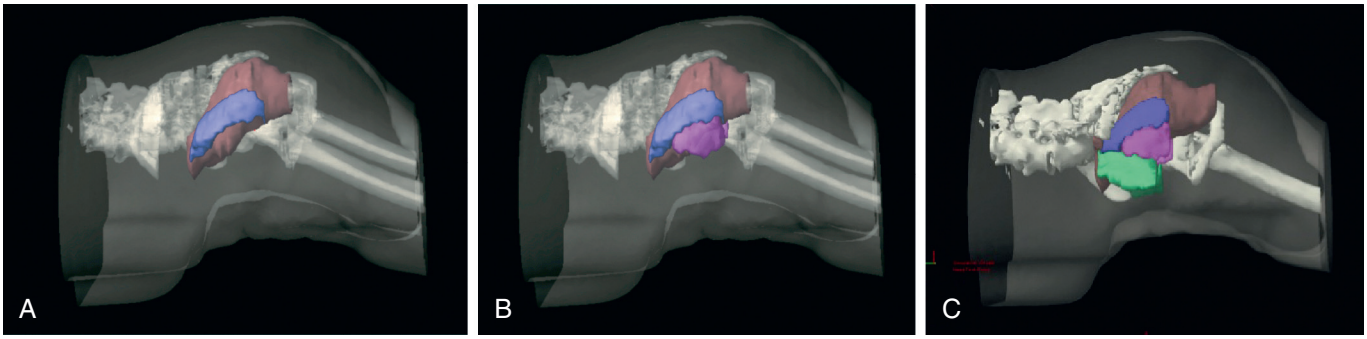

Figure 51-5 Contouring clinical target volumes in rectal cancer delineation (patient in prone position on an up-down table): **(A)** Mesorectum with internal iliac nodes; cT3 MRF (-). mid/high rectum. **(B)** Mesorectum with internal iliac and obturator nodes: cT3 low/mid rectum, MRF(+) or internal iliac positive node(s). **(C)** Mesorectum with internal iliac, obturator and external iliac nodes: cT4 for anterior infiltration or obturator positive node(s).

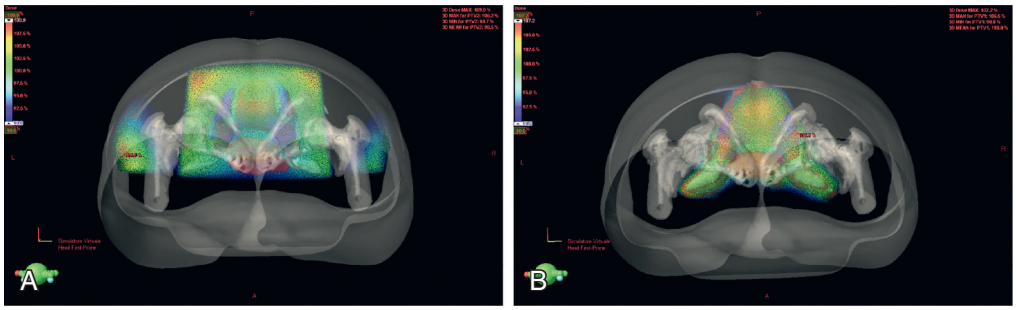

Figure 51-6 Comparison of three-dimensional **(A)** compared with intensity-modulated radiation therapy **(B)** plans in a patient with clinical target volume including mesorectum with internal iliac, obturator, and external iliac nodes (see Figure 51-5, *C* for corresponding clinical target volumes).

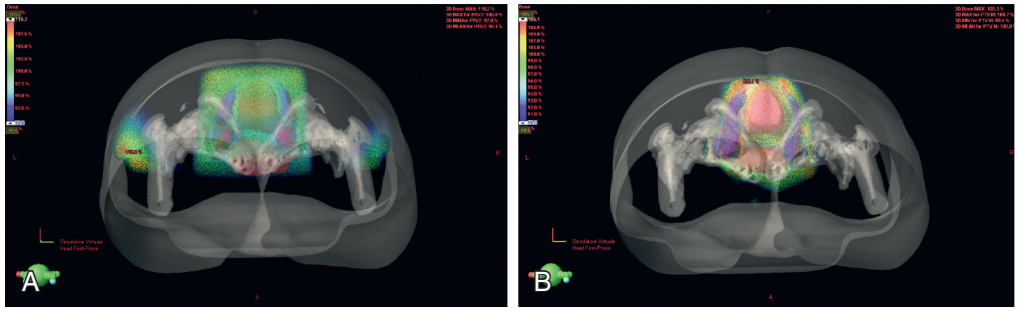
Introduction to IMRT and IGRT

With IMRT, the conformality and homogeneity of the dose to the planning target volume (PTV) are further improved.[251] In addition to having a limited number of beam angles (step and shoot), the IMRT can also be delivered in a continuous fashion during which the collimator, rotation speed and intensity can be modulated (intensity-modulated arc therapy [IMAT]).[252] The required PTV margin is based on geometrical uncertainties, which describe the differences between how the radiation was planned and the actual treatment situation. With the introduction of image-guided radiotherapy (IGRT), geometrical uncertainties can be measured and corrected during treatment, allowing for a reduction of the PTV margin. The acquired IGRT images also enable visualization of the target volume during treatment, for example, with cone beam CT scans, enabling better understanding of the treatment delivery.



In current clinical practice, 3D conformal three- or four-field dose delivery techniques are used most often but IMRT can be of great value if external iliac lymph nodes needed to be included in the CTV. For each field, the shape of the beam is adapted to the shape of the target volume using a multileaf collimator, while using a uniform intensity for the field. With this type of treatment, it is impossible to fully conform to the "horseshoe" shape of the CTV, resulting in delivery of dose to the organs at risk anterior of the CTV, especially the small bowel (Figure 51-6, *A-B* and eFigure 51-6, *A-B*). With IMRT, it is possible to deliver more concave dose distributions, which also have a more uniform dose distribution. However, these often have less homogeneity with IMRT. Important parameters for prediction of acute and late bowel toxicity, such as the volume of small bowel receiving 15 Gy or more (V15) are significantly reduced using IMRT.[253-255]

The clinical utility of routine 3D and IMRT treatment planning techniques is being investigated.[256,257] An analysis of 3D treatment planning techniques at the MGH suggests that the volume of small bowel in the radiation field is decreased with protons as compared with photons.[258] IMRT treatment planning techniques can also decrease the volume of small bowel in the field when compared with 3D conformal techniques.[259] However, the clinical benefit of IMRT compared with 3D or conventional treatment delivery remains to be determined.[257]

Samuelian et al[259] compared 92 consecutive patients of which 61 were treated with conformal radiation and 31 were treated with IMRT. In the IMRT group, significantly fewer patients (32%) experienced acute grade-2 or higher GI toxicity compared with 62% in the conformal radiation group, primarily with differences in diarrhea (23% versus 48%) and enteritis (6% versus 30%). Although these findings were not based on randomized data, they do indicate that the theoretical dosimetric benefit of IMRT does translate into a clinical benefit.

IMRT has also shown to be an ideal technique to deliver a boost to the GTV, simultaneously delivering the standard dose to the CTV[260] without compromising the organ at risk dose. The boost dose can be used to increase downstaging, improve the ability to have an R0 resection and increase the percentage of pathologic complete responders.[261] However, IMRT cannot be safely implemented without careful attention to details unique to IMRT (e.g., monitoring target volume during treatment with cone beam CT scans).

Apart from the aforementioned CTV and delineation uncertainties, geometrical uncertainties as inter- and intrafraction set-up errors and inter- and intrafraction target volume variation need to be compensated for to ensure safe application of IMRT in rectal cancer. All these factors together will

eFigure 51-6 Comparison of three-dimesional **(A)** compared with intensity-modulated radiation therapy **(B)** plans in a patient with clinical target volume including mesorectum with internal iliac and obturator nodes.

finally result in a CTV-PTV margin that ensures sufficient coverage of the clinical target volume. The introduction of the cone beam CT has made a reliable estimate of these uncertainties possible.

Few data are available concerning the shape variation of the CTV in patients with rectal cancer. Nuyttens et al described the movement of the anterior border of the CTV, ranging from 0.4 cm SD at the level of the anus to 1.0 cm SD at 10 cm from the anus.[266] In a recent repeat CT study, Nijkamp et al investigated the shape variation of the entire CTV, both for short- and long-course radiation.

Correcting for shape variation errors using IGRT is more complex than adjusting for set-up errors. Online shape variation correction would involve on-site treatment planning or choosing the most appropriate plan out of a library of plans. Although these strategies seem promising, they have not been translated into general clinical practice.

Irradiation Fractionation, Modality, and Dose

At Vejle Hospital (Denmark), Appelt et al examined the radiation dose-response curves for various grades of tumor regression in 222 patients after preoperative chemoradiation.[268] Radiation therapy consisted of a combination of EBRT and brachytherapy. Response at the time of operation was evaluated from the histopathologic specimen and graded on a 5-point scale (TRG1-5). The radiation dose-response relationship for a specific grade of histopathologic tumor regression was defined in terms of the dose required for 50% response, D50, and the normalized dose-response gradient, γ50. A highly significant dose-response relationship was found ($p = 0.002$). Both tumor size and N category had a significant effect on the dose-response relationships. The study confirmed a significant dose-response relationship for tumor regression after preoperative chemoradiation for locally advanced rectal cancer for tumor dose levels in the range of 50.4 Gy to 70 Gy, which is higher than the dose range usually considered.

A meta-analysis concluded that biologically effective preoperative doses above 30 Gy resulted in a statistically significant reduction in locoregional recurrence rates.[42] With conventional fractionation, the doses necessary to treat microscopic disease with a high level of local control are in the range of 45 Gy to 50.4 Gy in 5 to 6 weeks.[269] A retrospective comparison of 143 patients treated in three Phase II trials of chemoradiation with 40 Gy, 46 Gy, and 50 Gy revealed a significant improvement in 2-year OS for those receiving 46 Gy and 50 Gy (94% and 92%, respectively) compared with 40 Gy (72%; $p = 0.03$).[270]

A meta-analysis of individual patients included in European randomized trials published after 2000, showed that a radiation dose of more than 50 Gy improved local control and survival.[271] The association between higher dose and improved local control but inferior sphincter function has been well recognized, although the impact of either factor such as concomitant chemotherapy continues to be debated.[272]

After the dose level of 45 Gy in 25 fractions over 5 weeks, a boost of 5.4 to 9 Gy may be delivered to the primary tumor or tumor bed may be delivered if the small bowel is excluded from the high-dose field. Higher preoperative doses up to 60 Gy are associated with increased pCR rates; however, they may also significantly increase acute and long-term morbidity rates. The RTOG R-0012 Phase II randomized trial compared twice-daily preoperative chemoradiation of up to 60 Gy (1.2 Gy to 45.6 Gy, with a boost of 9.6 Gy to 14.4 Gy) with conventional fractionation (1.8 Gy to 45 Gy, with a boost of 5.4 Gy to 9 Gy) plus 5-FU/irinotecan.[129] Both regimens resulted in a 28% pCR rate but were also associated with a more than 40% rate of grade-3 to grade-4 acute toxicity.

Hyperfractionated radiation has been examined in Phase I and II trials.[273] In general, the pCR rates may be improved but at the expense of increased acute toxicity.

In the postoperative setting, if there is incomplete resection (R1 or R2 resection), radiation doses of more than 60 Gy are required. EBRT is limited by normal tissue tolerance, and results for patients with residual disease who received postoperative EBRT alone are disappointing.[279] As previously discussed, IORT may help to overcome this problem by direct visualization and irradiation of the persistent tumor.

Methods to Reduce Acute and Chronic Toxicity

Complications of pelvic radiation therapy are a function of the volume of the radiation field, overall treatment time, fraction size, radiation energy, total dose, technique, and sequence of radiotherapy.[114]

Acute side effects such as diarrhea and increased bowel frequency (small bowel), acute proctitis (large bowel), and dysuria are common during treatment.[280] These conditions are usually transient and resolve within a few weeks following the completion of irradiation. The symptoms appear to be a function of the dose rate and fraction size rather than the total dose. Symptoms are usually more severe if concurrent chemotherapy is given during EBRT. The mechanism is primarily the depletion of actively dividing cells in what is otherwise a stable cell renewal system. In the small bowel, loss of the mucosal cells results in malabsorption of various substances, including fat, carbohydrate, protein, and bile salts. Examination during treatment frequently reveals an inflamed, edematous, and friable rectal mucosa. The bowel mucosa usually recovers completely in 1 to 3 months following irradiation. Management usually involves the use of antispasmodic or anticholinergic medications. Small bowel-related complications are proportional to the volume of small bowel in the radiation field.[254] In patients receiving combined irradiation and chemotherapy, the volume of small bowel in the radiation field limited the ability to escalate the dose of 5-FU.[114]

Delayed complications occur less frequently but are substantially more serious. The initial symptoms commonly occur 6 to 18 months following completion of irradiation. Complications may include persistent diarrhea and increased bowel frequency, proctitis and strictures at the anastomotic site, small bowel obstruction, perineal and scrotal tenderness, delayed perineal wound healing, urinary incontinence, and bladder atrophy and bleeding. Injury to the vascular and supporting stromal tissues is the presumed pathophysiology. Analysis of pooled patients from 1599 patients treated in Swedish rectal cancer trials revealed a 1.5% increase in in-field secondary tumors for those treated with irradiation compared with those not receiving irradiation.[281] However, irradiation still had a positive effect on local control rates.

The most common delayed severe complications result from small bowel damage and include small bowel enteritis, adhesions, and small bowel obstruction requiring surgery. The incidence of small bowel obstruction requiring surgery following postoperative pelvic irradiation for rectal cancer is 4% to 12% in historical series. In the MGH series, the incidence of small bowel obstruction with conventional postoperative radiation therapy was 6% as compared with 5% with surgery alone.[282] It was 2% in the preoperative chemoradiation arm of the German CAO/ARO/AIO-94 trial.[53]

Even with appropriate doses and techniques of irradiation, approximately 1% of patients will have significant long-term toxicity of pelvic organs. Active inflammatory bowel disease is a relative contraindication to pelvic irradiation, although there are some reports of such patients who have tolerated

Set-up errors are measured at the treatment machine using electronic portal imaging devices,[262] cone beam CT,[263] or tomotherapy CT.[264] Corrections for set-up errors can be applied directly before treatment, by applying a table shift. These online corrections use daily imaging and come with increased imaging dose and treatment time. Corrections can also be applied in an offline setting, using statistical models such as shrinking action level or no action level protocols.[265]

For 33 patients receiving short-course radiotherapy, daily repeat CT scans were acquired.[267] In 30 patients receiving preoperative chemoradiation, daily repeat CT scans were acquired, followed by weekly scans. On a total of 482 CT scans, the CTV, bladder and rectum were delineated and the CTV shape variation was determined. The heterogeneous shape variation as shown by Nuyttens et al was confirmed.[266] A negative time trend in rectal volume was present, which translated in a group mean error of approximately 0.5 cm at the upper anterior border of the mesorectum.

Current IGRT is effective in minimization of the set-up errors, but not as effective for the other uncertainties. Additional research in online adaptive replanning or plan selection needs to be performed to really utilize IGRT for rectal cancer.

Coucke et al[274] treated 250 assessable patients with cT3-4 or N+ disease with 41.6 Gy at 1.6 Gy twice daily and reported a 92% actuarial 5-year local control rate but a survival rate of only 60%. The rate of acute grade 3+ toxicity was 42% in the 5-FU plus twice-a-day radiation arm of RTOG R-0012 (1.2 Gy to 45.6 Gy, with a boost of 9.6 Gy to 14.4 Gy). Hyperfractionated and accelerated fractionated radiation, especially in combination with chemotherapy, remains investigational. Other investigational approaches such as neutrons,[275] carbon ions,[276] and hyperthermia[277,278] have been examined. None have shown a clear advantage compared with conventional pelvic EBRT.

EBRT.[283,284] Although historic data suggested that pelvic fractures are rare a more recent retrospective analysis of imaging from 492 patients revealed an incidence of 7.1% with a median follow-up of 3.5 years.[285] Independent risk factors included osteoporosis, female gender, and age older than 60. However, it should be emphasized that most fractures were asymptomatic and did not require any intervention. Testosterone levels are decreased when the testicles are near or in the radiation field.[286,287] Radiation, alone or in combination with surgery can have a negative impact on sexual function.[288,289] In the Dutch CKVO trial, patients experienced new or worsening sexual dysfunction following treatment (men, 76%, and women, 62%).[290] By multivariate analysis, independent factors included irradiation in men and the psychological presence of a stoma in both men and women. The authors concluded that despite the additional effect of irradiation, sexual dysfunction was mainly caused by surgery.

Randomized trials have investigated the use of sucralfate enemas to decrease acute radiation proctitis, olsalazine and mesalazine to decrease acute enteritis, and butyric acid to decrease chronic radiation proctitis.[291] All of these trials have been negative. The radioprotector WR-2721 did not reduce toxicity in early trials, but there is a suggestion of a benefit in a more recent study.[292,293] Rectally administered amifostine is well tolerated. However, its efficacy remains to be determined.[294] Other trials of amifostine have not shown clear benefits.[295]

TREATMENT ALGORITHMS, CONTROVERSIES, PROBLEMS, CHALLENGES, AND FUTURE POSSIBILITIES

Treatment Algorithms

The treatment of rectal cancer is multidisciplinary. It is important to develop treatment algorithms using a balanced approach with representation from all medical specialties, including radiation, medical, and surgical oncology as well as radiology, gastroenterology, and pathology. Treatment algorithms developed by representatives of a single modality or institution may be biased.

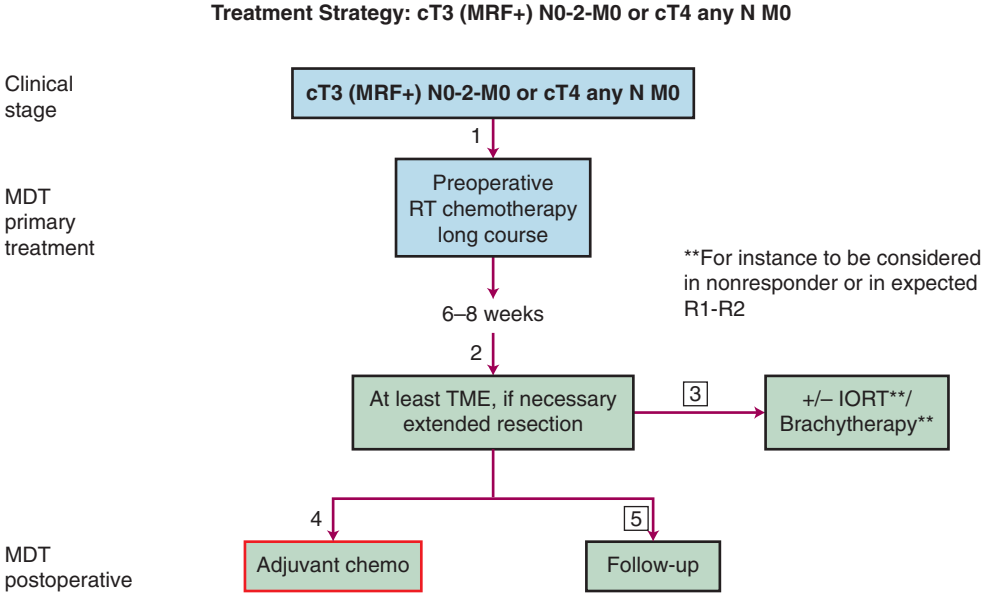
The National Comprehensive Cancer Network (NCCN) clinical practice guidelines for rectal cancer current guidelines can be found at www.nccn.org/professionals/physician_gls/f_guidelines.asp#site.

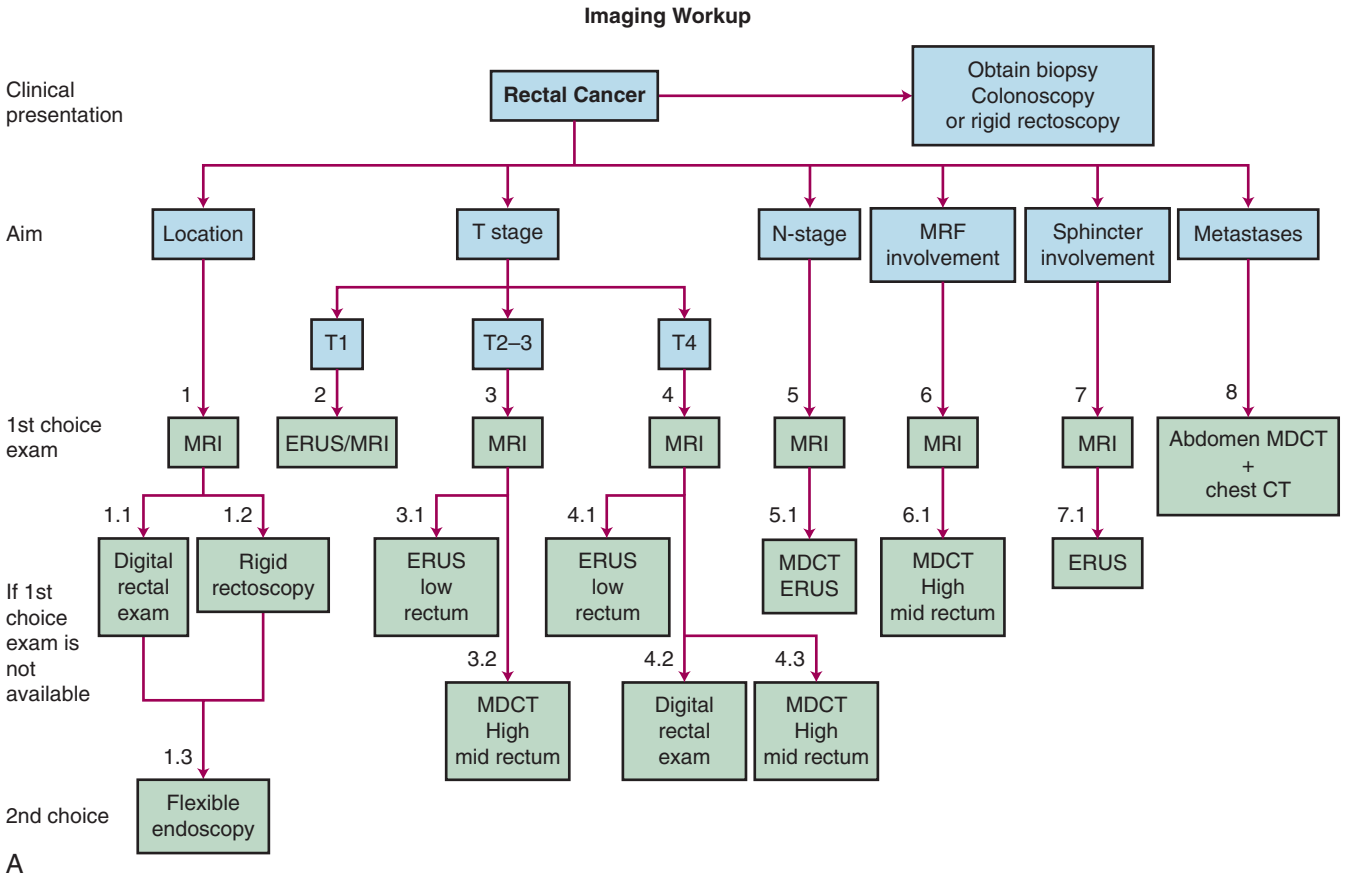
Recently, a European coalition of oncology societies plus allied disciplines (radiology, pathology, biology, epidemiology, and patient groups) proposed recommendations for the diagnosis and treatment of rectal cancer.[233] These are seen in Figure 51-7 (Figure 51-7, and eFigure 51-7, *A-H*). The goal of the European Registration of Cancer Care (EURECCA) is to reduce variance and improve cancer care in Europe through registry, feedback, and definition of core treatment strategies. It supports the development of a European audit structure to improve the quality of care for all patients with colon and rectal cancer.

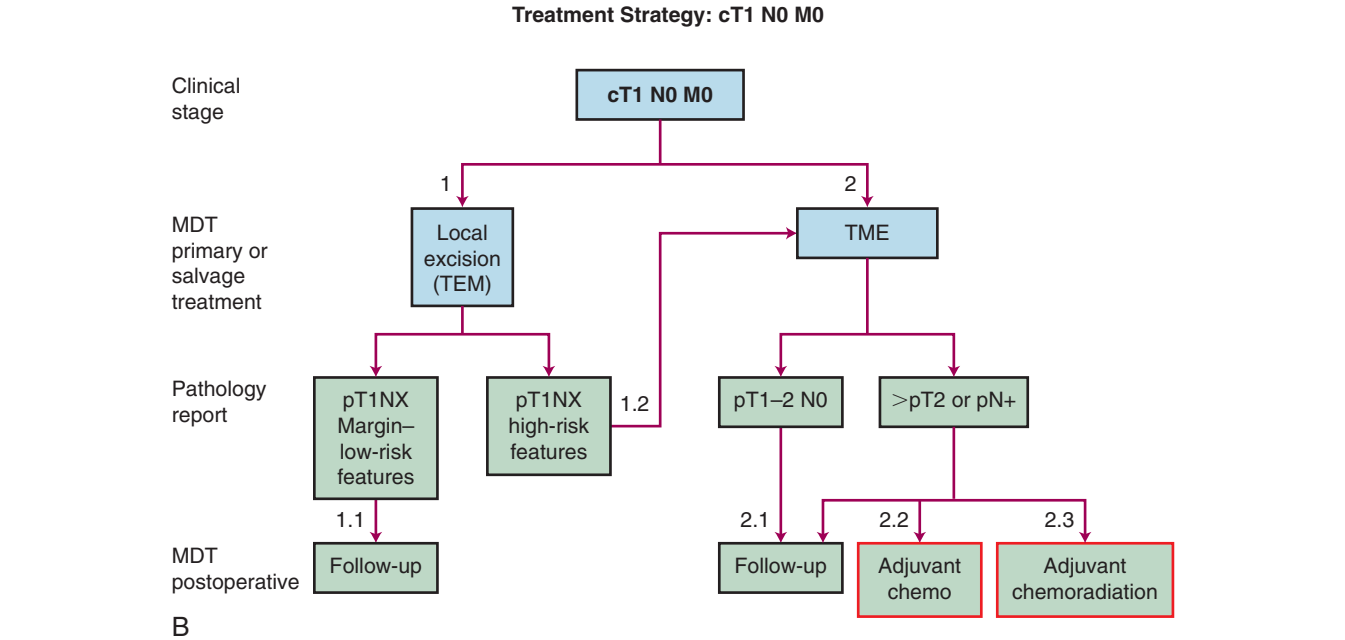
Decision Supportive Tools

Clinical decision making for a single patient has become more complex because of the increased amount of data from genetics, proteomics, and diagnostic imaging. Human cognitive capacity is limited and this increase in decision-making complexity requires decision support systems and computational support on different levels and steps in the treatment process. Several applications of data sharing for cancer-related data have been initiated in the last decade: EUROCAT (www.eurocat.info); MISTIR (www.mistir.info); RODA (www.elekta.com); Oncospace (www.hopkinsmedicine.org); caBIG (cabig.nci.nih.gov); and CancerData (www.cancerdata.org).

A more public approach is to make prediction models available on the Internet; some of them also have applications also for rectal cancer. A prediction website that focuses more on decision support for radiotherapy was recently set up by MAASTRO Clinic (http://www.predictcancer.org). Also, the







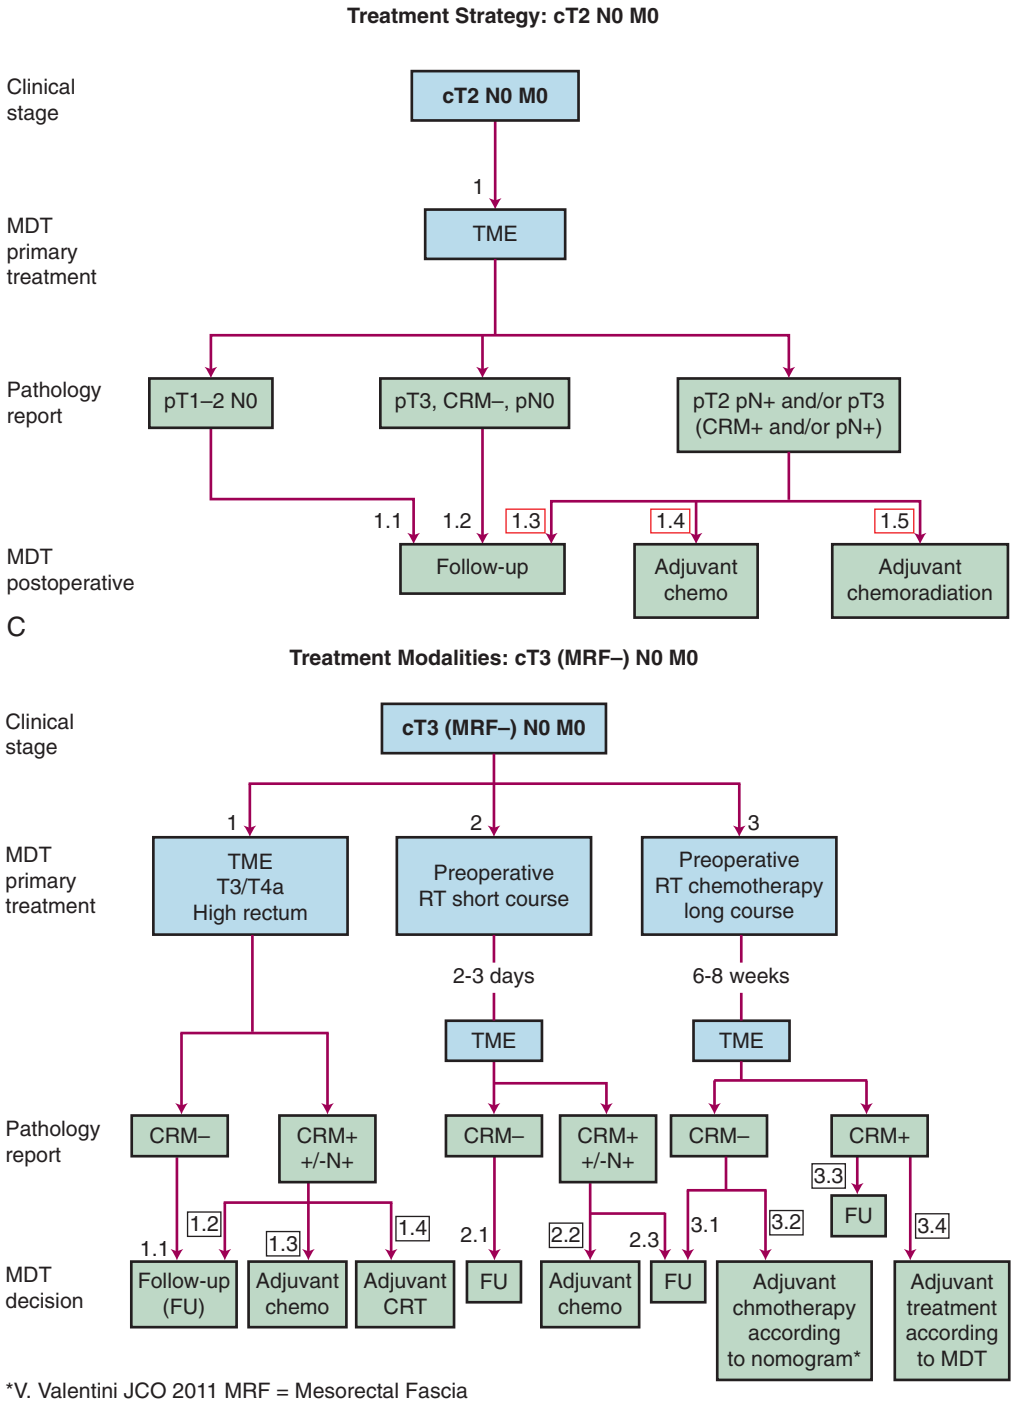


Figure 51-7 European treatment algorithm for rectal cancer based on multidisciplinary consensus conference. Treatment modalities: cT3 (MRF+) anyN M0 or cT4 any N. Moderate consensus was achieved for step 3 and 5, minimum consensus indicated with red borders was achieved for step 4 in the decision making. *IORT,* intraoperative radiation therapy; *MDT,* multidisciplinary team; *MRF,* mesorectal fascia; *TME,* total mesorectal excision.

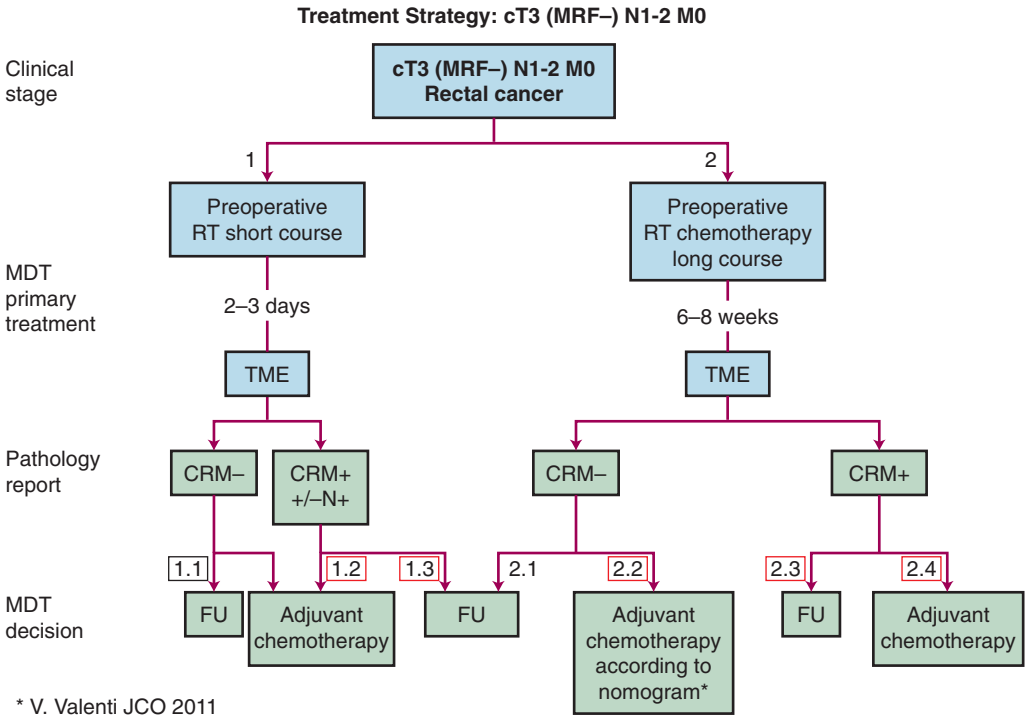
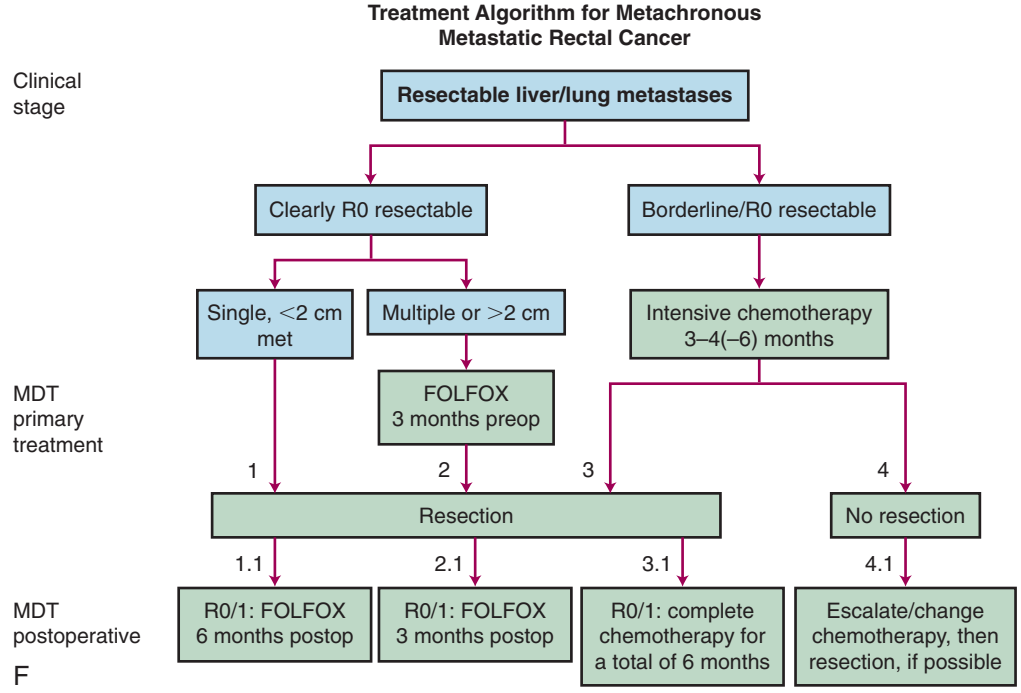
Treatment algorithms can be based on evidence, consensus, or both. Although purely evidence-based algorithms are the most rigorous, there are a variety of clinical settings where prospective trials do not specifically address a treatment controversy. Therefore, multidisciplinary panels that use evidence from randomized trials as well as lower-level sources such as clinical experience reports offer a more practical approach. The National Comprehensive Cancer Network (NCCN) has published clinical practice guidelines for rectal cancer based on multidisciplinary panels that use evidence from randomized trials as well as lower-level sources such as clinical experience reports.



eFigure 51-7 A-H, **European workup and treatment algorithms for rectal cancer** based on multidisciplinary consensus conference. **A, Elective imaging workup algorithm for rectal cancer.** Almost all imaging decisions achieved large consensus with exception of the two lesser choice examination decisions. Moderate consensus was achieved on imaging step 1.1 and moderate consensus on step 3.1. **B, Treatment strategy rectal cancer: cT1N0M0.** Two decisions in the clinical T1 rectal treatment algorithm did not achieve large consensus, indicated with red border; being minimal consensus for step 2.2 to give adjuvant chemotherapy after primay TME or salvage TME after TEM; and no consensus was achieved on step 2.3 to decide on postoperative chemotherapy and radiation.



eFigure 51-7, cont'd **C, Treatment strategy: cT2N0M0 rectal cancer.** Three decisions in the clinical T2 treatment algorithm did not achieve large consensus, indicated with red lining; being minimum consensus for step 1.3 to go to follow up in case of positive nodal stage, positive CRM or pT3; and no consensus was achieved on step 1.4 and 1.5 to decide on postoperative chemotherapy and chemoradiation in these patients. **D, Treatment strategy: cT3 N0M0 rectal cancer.** Nine decisions in the algorithm did not achieve large consensus. Indicated with red lining is the "no consensus" for decision 1.3 and 3.2; and "minimum consensus" for 1.2, 1.4 and 3.4. With moderate consensus it was agreed to decide on steps 2, 3, 2.2, and 3.3.

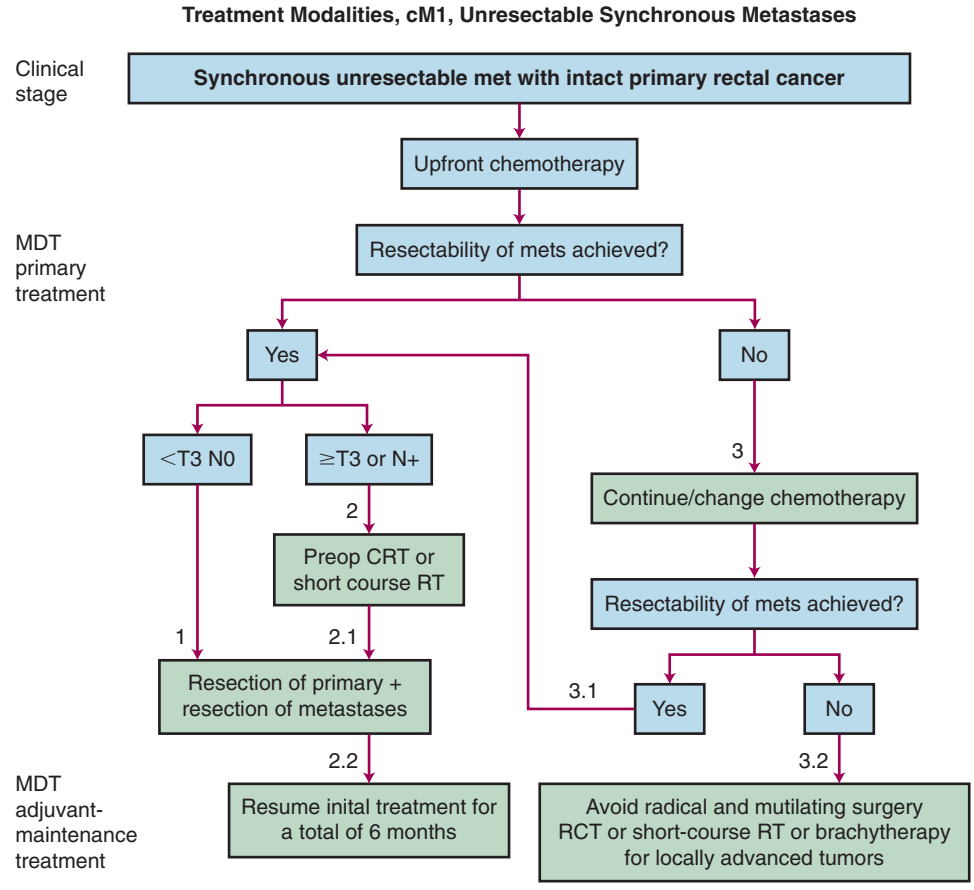
E



F

eFigure 51-7, cont'd **E, Treatment strategy: cT3 N+ M0 rectal cancer.** Six decisions in the algorithm did not achieve large consensus, indicated with red lining; being no consensus for decision 2.2 adjuvant chemotherapy according to the nomogram; minimum consensus for decision 1.2, 1.3, 2.3, and 2.4. There was moderate consensus for decision 1.1. The large variation in agreement illustrates that there is little evidence for adjuvant chemotherapy in rectal cancer. **F, Treatment modalities: metachronous metastatic rectal cancer.**

H

eFigure 51-7, cont'd **G, Treatment modalities, cM1, resectable synchronous metastases.** For patients with resectable synchronous colorectal metastases, with moderate consensus it was agreed on decision 4; decision 1.2 agreed with the mimimum consensus indicated by red borders. **H, Treatment modalities, cM+, unresectable synchronous metastases.** All decisions were agreed with large consensus. *CRM,* Circumferential resection margin; *CT,* computed tomography; *ERUS,* endorectal ultrasound; *FU,* follow-up; *MDCT,* multidetector computed tomography; *MDT,* multidisciplinary team; *MRF*, mesorectal fascia; *MRI,* magnetic resonance imaging; *postop,* postoperative; *preop,* preoperative; *RCT,* radio-chemo therapy; *RT,* radiation therapy; *TEM,* transanal endoscopic microsurgery; *TME,* total mesorectal excision.
Modified from Van de Velde CJ, et al, EURECCA colorectal: Multidisciplinary management: European consensus conference colon and rectum. Eur J Cancer 2013, [Epub ahead of print].

Finally, two caveats. All treatment guideline recommendations should be interpreted with caution. Radiation oncology, like other medical specialties, is both an art and a science. Therefore, guidelines should serve as a "guide" rather than a "cookbook." Lastly, the ideal management for patients with rectal cancer is in a clinical trial, and participation in these is encouraged.

Multidisciplinary Teams

Cancer management using the multidisciplinary team (MDT) approach has been implemented in cancer care systems throughout much of Europe, the United States, and Australia, and forms a core component of guidelines in all cancer care services. There is almost universal approval for this strategy, which indeed some consider crucial, despite the fact that there is little evidence for its effectiveness in improving outcomes.[296] This is particularly relevant in rectal cancer, in which preoperative radiotherapy and chemoradiation are often delivered according to clinical findings and staging (particularly in terms of the MRI) and many different surgical options are available with varying levels of radicality and implications for future quality of life in the patient. For example, an international survey of 173 colorectal surgeons (of whom 123 responded) showed that working in regular MDTs made the use of MRI for staging more likely and hence significantly influenced the use of neoadjuvant chemoradiation (RR = 5.67, $p = 0.03$) for a threatened circumferential margin on MRI.[297]

Memorial Sloan Kettering Cancer Center has prediction tools for different cancer types (http://www.mskcc.org/mskcc/html/5794.cfm).

Controversies and Future Directions

Significant progress has been made in the three conventional modalities used to treat rectal cancer: surgery, irradiation, and chemotherapy. Identification of radial microscopic lymphatic spread within the mesorectum has led to the use of TME. With this type of surgery, local recurrence rates have appeared to decrease. However, in patients with pN+ disease there is still a 21% local recurrence rate and adjuvant chemoradiation remains standard. The use of short-course radiation has increased as the techniques to integrate it with chemotherapy have improved. Technical advances in irradiation planning and delivery techniques as well as refinements in the sequencing of radiotherapy, chemotherapy, and surgery will likely lead to further improvements. Moreover, cytotoxic chemotherapeutic agents as well as novel targeted therapies, such as bevacizumab and cetuximab, which have improved results of patients treated in the adjuvant or metastatic setting, are currently being studied in chemoradiation programs. Clinicopathologic and molecular features as well as the development of more accurate preoperative imaging and staging methods will also play an important and integrative part in the multimodality treatment of rectal cancer. Lastly, more selective approaches to the use of surgery (watch-and-wait approach) as well as radiation (PROSPECT trial) are being investigated.

Recent data from Phase III trials are helping to clarify some of the issues about both the benefit and type of concurrent/maintenance chemotherapy in chemoradiation regimens. In NSABP RO4, chemoradiation regimens using PVI 5-FU and capecitabine had similar pCR rates and tolerance. In three separate Phase III trials, the addition of oxaliplatin to either PVI 5F-U or capecitabine did not improve pCR but added toxicity. Accordingly, the current standard is not to include oxaliplatin in preoperative chemoradiation regimens, pending longer-term outcomes of local control and survival. Additional text is found on the Expert Consult website with regard to the benefit of concurrent chemoradiation, sequencing with surgery, and the impact of type of concurrent chemotherapy on outcomes.

There are many controversies remaining, which lead to the following questions: Should patients receive short-course irradiation (i.e., 25 Gy in 5 fractions in 1 week) or standard-course preoperative chemoradiation (i.e., 45 Gy to 50.4 Gy in 25 to 28 fractions over 5 to 5.5 weeks)? Is postoperative adjuvant chemotherapy necessary for all patients? Should the type of surgery following chemoradiation be based on the response rate? Can we develop more accurate imaging techniques or molecular markers to identify patients with positive pelvic nodes to reduce the chance of overtreatment with preoperative therapy? Will more effective systemic agents improve the results of chemoradiation as well as modify the need for pelvic irradiation in some TN categories of disease? These questions and others remain active areas of clinical investigation.
