HPV has been implicated as a major cause of vulvar cancer. Brinton et al established a relative risk of vulvar cancer of 15.2 when there is a history of condylomata acuminata.[24] HPV has been detected widely in sexually active women. The type of HPV is related to the risk for benign versus malignant tumors of the vulva. In patients with condylomata acuminata, the detected HPV is usually type 6 or 11, whereas for vulvar in situ neoplasia or vulvar carcinoma, HPV 16 and 18 are more common.[25,26] Invasive vulvar cancer and condyloma may be present synchronously in the same patient (eFigure 60-1), delaying diagnosis of malignancy in some patients. Similarly, delay in diagnosis may be the consequence of failing to examine a patient with known, symptomatic lichen sclerosus (eFigure 60-2). Multiple studies have investigated the presence of HPV in vulvar carcinoma. It may be detected in both primary tumors and nodal metastases.[27,28] Review of published data employing polymerase chain reaction or hybrid capture assays for HPV DNA detection in 2790 patients with invasive vulvar cancer, 1320 patients with VIN 2/3, and 71 patients with VIN 1 reveals HPV prevalence in invasive cancer to be 40.1% in invasive lesions, 80.4% in VIN 2/3, and 77.7% in VIN 1, respectively.[278] HPV 16 serotype was the most common, detected in 29.3% of invasive cancers and 71.2% of VIN 2/3. Globally, HPV 16, 33, and 18 comprise the causative agents in most HPV-related vulvar malignancies with HPV 16 comprising 72%.[29]

Smoking is an additional risk factor for vulvar carcinoma, and the combination of smoking with a history of genital warts results in a strong increase in the relative risk for vulvar cancer.[13,24] It is possible that smoking and HPV infection have a synergistic effect on the genesis of vulvar cancer with smoking functioning as a promoter.[30,31]

It has been observed that there are two broadly different groups of patients with vulvar cancer. The first consists of younger patients who more frequently smoke, are at higher risk for HPV infection, and whose invasive cancers are commonly associated with VIN. The second, and more common group, consists of elderly patients whose disease may be unrelated to smoking or HPV infection but in whom lichen sclerosus and squamous hyperplasia are common associated findings.[36] These two groups of patients may have different prognoses and may carry different risks for development of second malignancies in residual vulvar tissue when conservative surgery, with or without adjuvant radiation, preserves substantial vulvar tissue.[28,37,38] At this time, data regarding the independent prognostic significance of HPV are conflicting.[28,39] This issue may be resolved through larger series of patients suitable for disciplined multivariant analysis controlling for all other known prognostic factors and treatment modalities.

PREVENTION AND EARLY DETECTION

With the exception of cancers arising in the Bartholin's complex, most vulvar malignancies arise from cutaneous surfaces readily accessible to examination both visibly and palpably. Invasive lesions should be diagnosed when small and easily treated. Unfortunately, most advanced vulvar cancers are a result of patient delay or neglect or physician failure to diagnose. Some elderly patients may be mentally impaired. Modesty, anxiety, or frank denial may lead a patient to ignore

eFigure 60-1 Synchronous presence of vulvar and anal condylomata *(white arrows)* and invasive squamous carcinoma that can delay cancer diagnosis. Condylomata antedated cancer in this immunologically intact patient, illustrating the difficulties inherent in developing effective polyvalent human papillomavirus (HPV) vaccines.

eFigure 60-2 Squamous cancer arising in an elderly patient with clinical stigmata of lichen sclerosis including white thickening of vulvar skin, introital narrowing, and fusion of the major and minor labia.

Data are conflicting as to the etiologic role of vulvar dystrophies (lichen sclerosus and squamous cell hyperplasia) in the cause of vulvar cancer. These epithelial alterations may be seen in approximately half of patients with vulvar cancer.[32-34] Patients with vulvar cancer and associated lichen sclerosus are, on average, significantly older than patients with newly diagnosed lichen sclerosus with or without squamous hyperplasia.[35] However, less than 5% of patients with these epithelial alterations will progress to invasive vulvar malignancy.

or minimize symptoms of pruritus, oozing, bleeding, and pain. There is little justification for failure of a physician to perform a thorough visual inspection and pelvic examination when patients have such symptoms.

No known measures to prevent invasive vulvar cancer exist except for the appropriate treatment of high-grade VIN when it is detected. Encouraging results from Phase III trials of HPV vaccines suggest that substantial reductions can be expected in the incidence of VIN 2/3 and invasive vulvar malignancies in addition to corresponding pathologies of the cervix and vagina when prophylactic immunization is widely implemented.[40] At this time, the target population for whom efficacy seems most likely consists of adolescents who are sexually naïve and unexposed to HPV. Whether comprehensive population coverage can be logistically accomplished given multiple economic, cultural, and logistical barriers to implementation in countries where genital HPV infection is a leading cause of subsequent cancer remains to be seen. As VIN-3 may be associated with an occult invasive lesion in as many as 20% of symptomatic patients, care must be taken when employing treatment techniques that do not include full-thickness histologic evaluation.[41] Excisional techniques, provided that there is minimal loss of functionality and cosmesis, are preferable to ablative techniques without histologic material for study. Wedge biopsy or excisional biopsy of smaller lesions is suggested for most vulvar abnormalities, if necessary under colposcopic guidance. Even if vulvar lesions appear to have a warty appearance and are believed to be benign, confluent warts should undergo biopsy to exclude an underlying diagnosis of squamous cell carcinoma.

A history of smoking tobacco is associated both with VIN and invasive vulvar malignancy. Patients who smoke should be encouraged to quit because the statistical risk of anogenital malignancy associated with former smoking is observed to be substantially less than that associated with current smoking and diminishes with increasing time since cessation of smoking.[31] Additionally, women with vulvar or vaginal cancer appear to have a fourfold increased risk of subsequently developing a second primary cancer of the lung.[42]

Because of the risk for multifocal disease throughout the lower genital tract and anus, it is appropriate to perform pap smear and colposcopy of the cervix, vagina, and vulva, and digital rectal exam or anoscopy to evaluate for the presence of synchronous lesions at other sites.

PATHOLOGY AND PATHWAYS OF SPREAD

Pathology

Squamous cancer is the most common malignant lesion of the vulva and constitutes 80% to 90% of vulvar tumors. Variants of squamous cancer include cancers with discontiguous, infiltrative borders permeating lymphatic spaces with a so-called "spray" pattern of local invasion[43-45] and verrucous cancers[46-49] (Figure 60-1, *A* and *B*).[50] Sarcomatoid differentiation is seen in a minority of squamous cancers and can be associated with an aggressive course.

Poorly differentiated cancers with a trabecular growth pattern manifesting fingerlike projections and an infiltrative border with discontiguous islands and nests of malignant cells may spread to regional nodes, even when small, and frequently recur beyond the margins of local excision within dermal lymphatic channels. Recognition of this pattern of growth should prompt consideration of adjuvant radiotherapy.

Verrucous cancers may clinically manifest a warty appearance resembling a cauliflower, with exuberant hyperkeratosis microscopically. Broad, bulbous borders characterize these tumors, which rarely metastasize to regional nodes. Morphologic and biologic studies on 10 cases of verrucous carcinoma of the vulva suggest the theory that verrucous cancers constitute a discrete clinicopathologic subset of vulvar cancer.[51]

Other, much less common tumors found in the vulva include malignant melanoma, basal cell carcinoma, Merkel cell tumors, carcinoid, transitional cell carcinomas, adenoid cystic carcinoma, vulvar Paget's disease, and a variety of sarcomas. Tumors metastasizing from other sites may become manifest in the vulva.[52]

Melanomas constitute less than 10% of primary tumors, but are the second-most common malignancy of the vulva. Even tertiary referral centers will see only one or two such patients annually. Melanomas may arise de novo or from preexisting junctional or compound nevi. Rare, amelanotic vulvar melanomas may occur. Prognosis correlates with depth of invasion using the classifications of Clark, Breslow, and Chung, and with the presence or absence of spread to regional nodes.[53-55]

Primary malignant tumors of the vulva may arise in the Bartholin's complex, and some of these are variants of adenocarcinomas. Adenoid cystic carcinomas uncommonly disseminate to regional nodes and may have an indolent natural history with late local recurrence and hematogenous dissemination. Perineural invasion is a common feature, and these tumors resemble adenoid cystic cancers of the salivary glands.[56] Tumors in the Bartholin's areas may also be squamous and are thought to arise in ductal squamous epithelium. Bartholin's tumors tend to be deeply infiltrative and solid, often with the overlying skin remaining intact. This clinical presentation may be confused with benign cysts or infection, causing delay in diagnosis, and difficulty in accomplishing surgical clearance with wide, negative margins because of proximity to the anorectum and the ischial ramus.[57]

The International Society for the Study of Vulvar Disease (ISSVD) recommended abandoning the term *microinvasion*

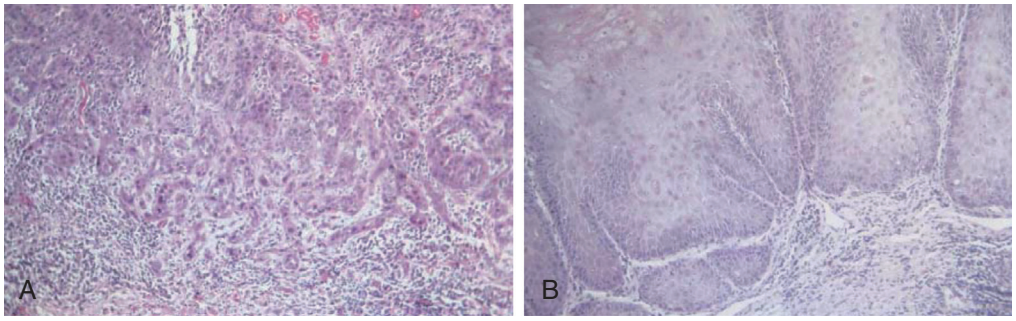

Figure 60-1 Variants of squamous cell cancer of the vulva. **A,** Infiltrative pattern of growth with discontinuous satellites of malignant cells, sometimes called a *spray pattern* of growth. **B,** Verrucous cancer with a bulbous, pushing front of invasion into the surrounding stroma.

when applied to carcinoma of the vulva and proposed the current use of stage IA that incorporates criteria for both tumor size and depth. The depth of invasion is defined as the distance from the epithelial stromal junction of the most superficial adjacent dermal papillae to the deepest point of invasion. Stage IA is defined as a solitary squamous cancer of the vulva measuring less than 2 cm in diameter, with clinically negative nodes where the depth of invasion is 1 mm or less.[58,59] This definition encompasses the previous understanding of microinvasion because the risk of nodal involvement with invasion less than 1 mm is close to 0%. In addition to tumor stage and depth, other pathologic features of the primary should be noted including presence or absence of vascular space invasion, tumor grade, and tumor growth pattern.[60]

Pathways of Spread

Vulvar cancer spreads by direct extension to adjacent structures including the vagina, urethra, perineum, anus, and ischial rami. Tumor may spread by embolization through the lymphatics to the regional nodes. Permeation of local lymphatics is uncommon (eFigure 60-3), but may account for the occasional patient with recurrence in the skin bridge conserved when surgery has employed separate incisions for the primary and the regional node dissection. This is rare in the absence of extensive groin node metastases.[61]

The lymphatics of the vulva (Figure 60-2) consist of a network that covers the entire labia minora, fourchette, prepuce, and distal vagina below the hymenal membrane.[50] Lymphatics coalesce anteriorly, forming larger trunks, which run lateral to the clitoris to the mons veneris, acquiring tributaries from the lymphatics of the labia majora, which run in a parallel fashion anteriorly from the perineal body. At the mons veneris, the vulvar lymphatic trunks diverge laterally to the inguinal nodes. Study of the localization of dye or radiolabeled tracer in regional lymph nodes after focal injection of discrete sites in the vulva and on the perineum reveals that the lymphatic drainage of the perineum, clitoris, and anterior labia minora is often bilateral, whereas the lymph flow from well-lateralized sites (>2 cm from midline structures) in the vulva is predominantly to the ipsilateral groin.[62,63]

The vulvar lymphatics run through the vulva and do not traverse the labiocrural fold. Perineal lymphatics course lateral to the labiocrural fold through the superficial tissues of the upper medial thigh. In the radiation treatment of patients with advanced vulvar cancer that extends to the perineal skin, these lateral channels should be taken into consideration. Advanced vulvar cancer extending up the vagina proximal to the hymenal ring may spread through vaginal lymphatics directly to pelvic nodes.

Primary lymphatic drainage is usually to the superficial inguinal nodes with secondary lymphatic drainage through the cribriform fascia to the femoral nodes, with subsequent tertiary flow under the inguinal ligaments to the external iliac nodes. However, metastases have been reported to the femoral lymph nodes without involvement of the superficial inguinal lymph nodes, especially from carcinomas of the clitoris and Bartholin's gland.[63,64] Sentinel node studies have demonstrated primary lymphatic flow to deep nodes in as many as 15% of cases, and a Gynecologic Oncology Group (GOG) study also found an unexpectedly high incidence of ipsilateral groin recurrences secondary to presumed involvement of lymph nodes deep to the cribriform fascia despite prior negative superficial inguinal lymphadenectomy.[65] The actuarial risk of groin recurrence at 5 years was 16% (19 of 119) among a series of patients with vulvar cancer whose groins were treated with lymphadenectomy alone at M. D. Anderson Cancer Center, of whom 111 of 119 had only superficial inguinal node dissections. Of these 119 patients, 117 had groin node specimens negative for metastases.[66] In contrast, groin recurrence after superficial and deep groin dissection retrieving histologically negative nodes is 2% or less.[67-69]

Clinical assessment of groin node status by palpation is notoriously inaccurate; approximately 20% of groins judged

Primary Tumor (cm)	Clinically Occult Node Metastases (%)
0-1.0	3/43 (7)
1.1-2.0	14/63 (22.2)
2.1-3.0	14/52 (26.9)
3.1-5.0	14/41 (34.1)
>5.0	3/15 (20)
Total	48/214 (22.4)

clinically nonsuspicious harbor occult node metastases, and approximately 20% of groins considered clinically suspicious for metastases containing only reactive or inflammatory nodes (Table 60-1). The frequency of inguinofemoral lymph node metastases is related to the depth of stromal invasion (Table 60-2). The incidence of occult nodal involvement in clinically nonsuspicious groin nodes treated by complete lymphadenectomy is cross-tabulated by primary tumor size in Table 60-3.

Metastases to the contralateral groin in the absence of ipsilateral groin metastases may be seen in up to 15% of patients with advanced primaries.[81] Metastases to contralateral groin nodes in the setting of uninvolved ipsilateral groins have been reported in patients with Bartholin's gland primaries,[82] and tumors of the anterior labia minora.[75] In the absence of spread to ipsilateral nodes, discrete (2-cm diameter or less), well-lateralized primary cancers limited to the vulva and not approaching midline structures manifest spread to contralateral groin nodes in less than 1% of patients undergoing bilateral lymphadenectomy.[75-78,83-85] However, 5 patients (2.6%) of 192 pooled patients with T1 lateralized cancers managed with ipsilateral groin dissection that was negative have manifested contralateral groin recurrence.[65,77,86-90] A theoretic explanation for this discrepancy is the possibility that dissection of negative groin nodes may be therapeutic in a small number of patients in whom routine sectioning of groin nodes (as opposed to pathologic ultrastaging) may fail to detect minute micrometastases consequent to undersampling.

The overall incidence of pelvic lymph node metastases is 5%. Lymphadenectomy will detect metastatic involvement in pelvic nodes in 15% to 28% of patients with metastases to inguinal nodes.[70-73,81,91,92] Pelvic node metastasis is extremely rare in the absence of groin node metastases and uncommon in the context of occult, microscopic involvement of a single groin node.

Hematogenous spread, usually to lung and bone, is unusual in the absence of prior inguinofemoral lymph node involvement and generally occurs late in the course of the disease. Most patients die with uncontrolled local-regional disease. However, in patients with three or more positive lymph nodes, the ultimate risk of hematogenous spread is 66%. In contrast, patients with fewer than three positive lymph nodes have only a 4% risk of hematogenous spread.[93,94]

BIOLOGY AND PROGNOSTIC FACTORS

In multivariate analysis the presence or absence of lymph node involvement remains the single-most important prognostic factor in outcomes of treatment for local-regional vulvar cancer.[95] For those with negative lymph nodes, the average 5-year survival from nine large literature series is 91% (range, 83% to 100%).[70-72,81,91,96-99] For those with involved lymph nodes treated with curative intent, the average 5-year survival is 52% (range, 38% to 61%).[3,70,72,91,96,97,100] Ninety-five percent of relapses after primary surgical treatment occur in the vulva, perineum, or groins.[68,76,101-105] The extent of lymphatic involvement is prognostic and includes type of nodal spread (unilateral or bilateral), volume of tumor in the involved nodes, extracapsular penetration number of positive nodes, and level of metastatic disease in the nodal chain.[3,5,27,97,106]

Because of the dominant negative impact of inguinal node metastasis, some investigators only examine primary tumor–related characteristics in relation to their correlation with nodal involvement rather than their impact on risk of recurrence of disease at the primary site.

A number of primary tumor–related characteristics, identified on multivariate analysis, predict for vulvar relapse regardless of nodal involvement, among them tumor size and depth of invasion.[72] Depth of invasion correlates not only with locoregional recurrence but also with the risk of node metastasis. Because most relapses after primary surgical treatment occur in the vulva or groin, to improve outcomes it is necessary to understand not only factors predictive of overall survival (OS), but those predictive of local recurrence and nodal relapse as well. Although risk probably increases continuously with depth, two data sets suggested that a sharply defined classification into low-risk versus high-risk groups may occur depending on tumor depth (first series—low risk <5 mm and high risk ≥5 mm; second series—low risk <9 mm, high risk ≥9 mm).[84,104] Heaps identified stage, width of surgical margin, depth of invasion, tumor thickness, growth pattern (infiltrative as opposed to pushing), and presence of vascular space

TABLE 60-4 Width of Surgical Margin and Risk of Local Recurrence[60,107,108]

Series/Author	Margin <8 mm	Margin ≥8 mm
Heaps	21/44 (48%)	0/91
Chan	13/61 (21%)	0/29

invasion as factors predictive of local recurrence following primary surgery.[60]

Three publications (Table 60-4) have reported a clear association between risk of vulvar recurrence and width of surgical resection margins.[60,107,108] When microscopic margins are 8 mm or less in formalin-fixed tissue, local recurrence has been observed in 43 of 145 patients (30%). Allowing for estimated fixation shrinkage artifact between 25% and 45%, this correlates with a margin of at least 1.0 cm to 1.45 cm in unfixed tissue. A minimal clinical free space of 1 cm of uninvolved normal tissue provides a practical guideline for identifying patients who are highly likely to be advised to undergo further excision or postoperative local radiation for inadequate margins if treated by initial surgery. Under such circumstances, preoperative chemoradiation may be preferable to secure better margins and to reduce the scope of subsequent conservative surgery.

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Clinical Manifestations

The virus-related cause of vulvar cancer in some patients, its association with preinvasive or invasive cancers in other parts of the lower genital tract, and the risk of recurrent or second cancers in conserved vulvar tissues in patients with cancer arising in association with lichen sclerosus suggests that vulvar cancer may be one manifestation of a multifocal disease or "field cancerization" in some patients.[37,109,110] However, at the time of diagnosis only about 5% of vulvar cancers are multifocal (eFigure 60-4).

Patients usually present with a vulvar mass or ulcer often following a variable history of pruritus or vulvar pain. Depending on the location and size of the lesion within the vulva, the patient may also complain of dysuria, difficulty with defecation, bleeding, or discharge. Rarely, patients may present with advanced inguinal node involvement, occasionally with ulcerating masses in the groins or with lower extremity lymphedema resulting from obstruction (eFigure 60-5, *A* and *B*). In rare instances, neglected vulvar cancer may directly extend to, or invade, adjacent bone (eFigure 60-6, *A* and *B*). Progressive organ destruction by untreated stage IV vulvar cancer may progress to incompetence of anal or bladder sphincters or urinary or fecal incontinence from fistula formation (eFigure 60-7).

Patient Evaluation

The diagnosis of vulvar cancer requires biopsy. For lesions smaller than 1 cm, a definitive excisional biopsy, including surrounding skin, underlying dermis, and connective tissue, may be preferable to obtain surgical margins of at least 1 cm grossly in all dimensions around the lesion. For larger lesions, a wedge biopsy should be performed. When vulvar dystrophy is present and the vulva is more difficult to assess visually, use of a colposcope may assist in identifying abnormal areas for appropriately directed biopsies. The remainder of the lower genital tract and anus should be examined, if necessary by colposcopy and anoscopy, to evaluate for the presence of synchronous preinvasive or invasive cancers.

Clinical evaluation of the groin nodes by palpation is inaccurate (see Table 60-1). Assessment of groin nodes is particularly compromised in the patient who is obese, when even superficial inguinal nodes may be several centimeters below the skin. Because of the imprecision of clinical assessment and the importance of the influence of nodal status or management, pathologic verification of nodal status is vital when feasible.

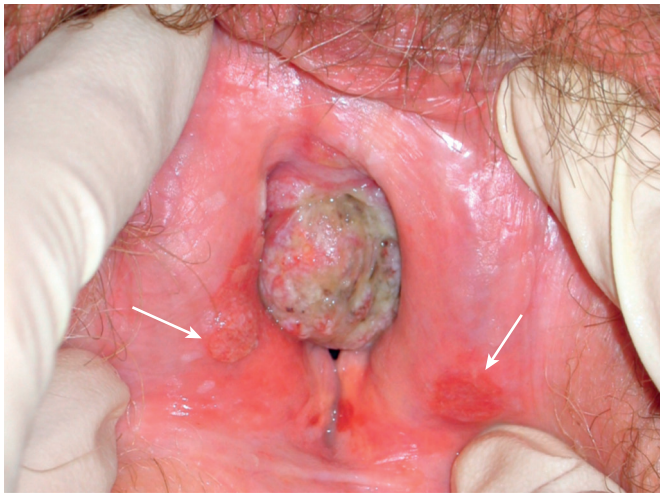

TABLE 60-5 FIGO Staging of Cancer of the Vulva

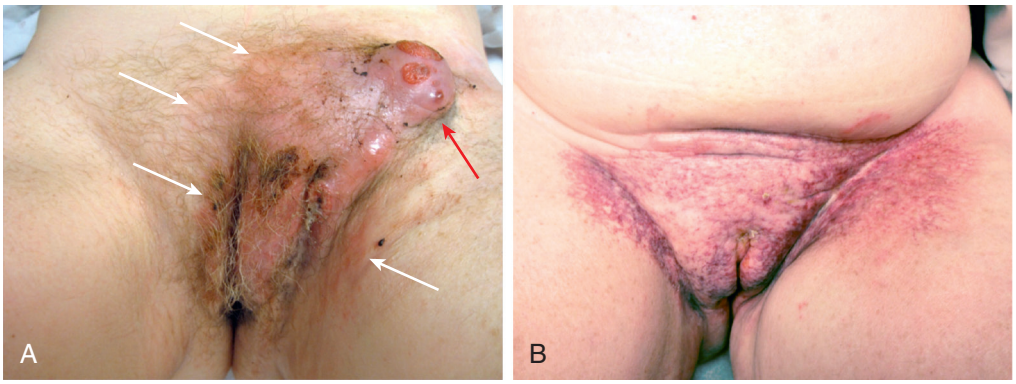
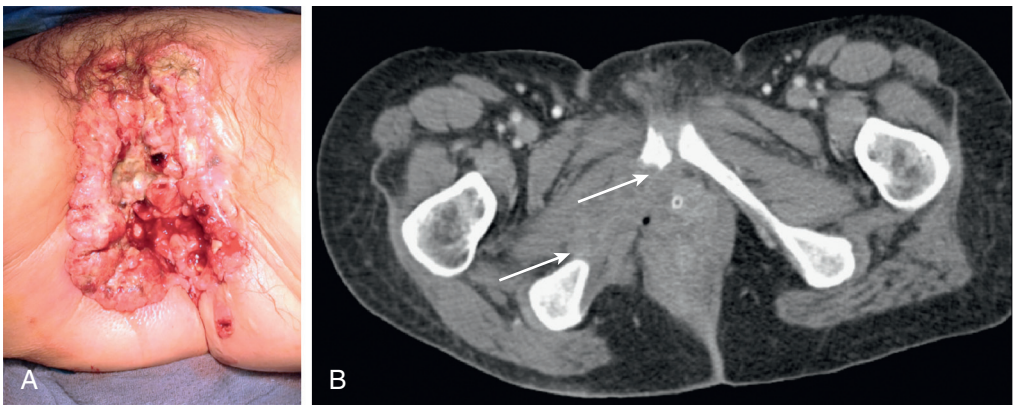
Stage	Description
Stage I	Tumor Confined to the Vulva
IA	Lesions ≤2 cm in size, confined to the vulva or perineum and with stromal invasion ≤1.0 mm,* no nodal metastasis
IB	Lesions >2 cm in size or with stromal invasion >1.0 mm,* confined to the vulva or perineum, with negative nodes
Stage II	Tumor of any size with extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus) with negative nodes
Stage III	Tumor of any size with or without extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus) with positive inguinofemoral lymph nodes
IIIA	(i) With 1 lymph node metastasis (≥5 mm), or (ii) 1-2 lymph node metastasis(es) (<5 mm)
IIIB	(i) With 2 or more lymph node metastases (≥5 mm), or (ii) 3 or more lymph node metastases (<5 mm)
IIIC	With positive nodes with extracapsular spread
Stage IV	Tumor invades other regional (2/3 upper urethra, 2/3 upper vagina), or distant structures
IVA	Tumor invades any of the following: (i) upper urethral or vaginal mucosa, bladder mucosa, rectal mucosa, or fixed to pelvic bone, or (ii) fixed or ulcerated inguinofemoral lymph nodes
IVB	Any distant metastasis including pelvic lymph nodes

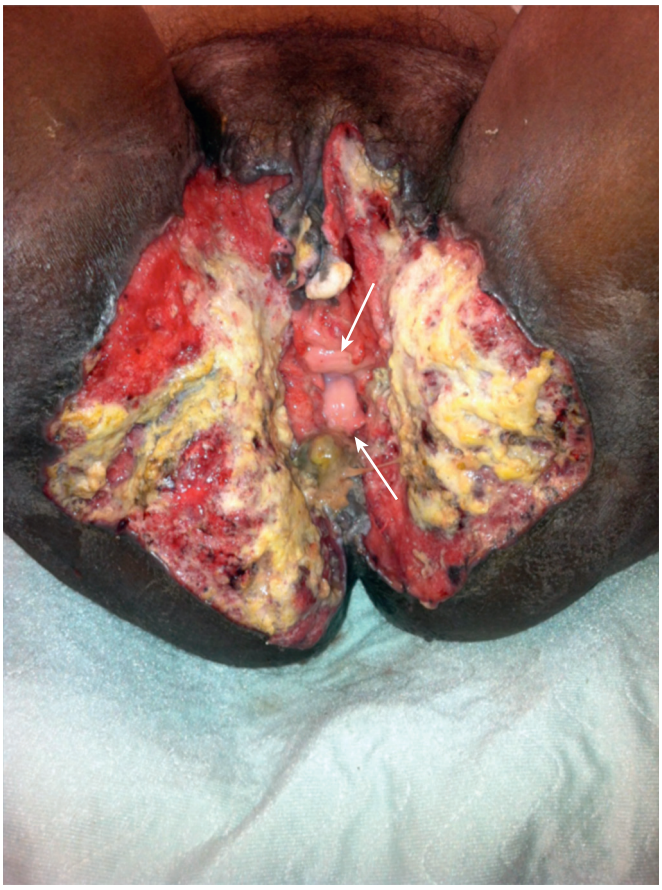


**The depth of invasion is defined as the measurement of the tumor from the epithelial stromal junction of the adjacent most superficial dermal papilla to the deepest point of invasion.*

Staging



In 1988 FIGO introduced a surgical staging system for vulvar cancer that has since undergone several revisions, most recently in 2009 (Table 60-5).[2] Staging systems are intended to standardize reporting of treatment efficacy allowing comparison of the outcomes of treatment from different institutions and comparison of results employing different treatment strategies. Ideally, stage should not be employed to determine therapy and should be assigned before any major therapeutic intervention such as surgery. Unfortunately, the current clinical-pathologic system defines stage for many patients based, in part, on information derived subsequent to surgical treatment of the groin nodes. Because of the strong association between prognosis and the number and size of groin node



eFigure 60-4 Multifocal squamous cancer of the vulva with dominant mass involving distal urethra and vagina. Bilateral, somewhat symmetric, noncontiguous foci of invasive disease *(white arrows)* may represent autotransplantation of malignant cells onto moist mucosal surfaces, so-called *contact lesions*.

eFigure 60-5 **A,** Pretreatment photograph of a 50-year-old patient with a large vulvar cancer with bilateral groin metastases and extensive dermal lymphatic permeation *(white arrows)*. Bulky left inguinofemoral node metastases encased the femoral artery and vein and eroded through overlying skin *(red arrow)*. **B,** Photograph of patient 2.5 years after completion of high-dose chemoradiation consisting of three cycles of 5-fluorouracil/cisplatin with predominantly twice daily radiation and planned volume reductions. Treatment was initiated urgently with three-dimensional technique because of intermittent arterial bleeding from a branch of the femoral artery. Subsequent reduced volumes were treated with intensity-modulated radiation therapy (IMRT). Cumulative dose to gross disease was 65 Gy. Extensive bolus was employed to assure full dose to areas of dermal lymphatic permeation based on both clinical assessment and imaging findings (positron emission tomography/computed tomography [PET/CT] and magnetic resonance imaging [MRI]). The patient remains clinically cancer-free with late sequelae attributed to radiation including severe skin changes (atrophy, telangiectasis, fibrosis) and left leg edema with multiple episodes of cellulitis mandating chronic prophylactic antibiotic administration.

eFigure 60-6 **A,** Neglected, locally extensive vulvar cancer in a 47-year-old woman with a remote history of vulvar surgery for extensive condylomata. Despite extensive destruction of soft tissues, the patient remained continent of urine and feces. Progressive pain from bone destruction (see Figure 60-8, *B*) ultimately brought the patient to medical attention. **B,** Destruction of the inferior ischial ramus *(white arrows)* by direct extension of locally advance squamous cancer of the vulva.

eFigure 60-7 Locally extensive squamous cancer of the vulva in an African immigrant with inadequately treated HIV. Progressive destruction of the entire vulva and adjacent organs (urethra, anus) resulted in the functional equivalent of a cloaca. Visible at the center of the photograph is grossly normal distal vaginal epithelium covering anterior and posterior walls *(white arrows).*

metastases, the staging system appears to implicitly endorse surgical management of the groin nodes but this may not be prudent or feasible in all clinical circumstances. In a patient with a locally advanced primary requiring preoperative chemoradiation in an effort to avoid compromise of functionally important midline structures, it may be reasonable to electively include the groins in the irradiated volume provided that they appear grossly uninvolved by physical examination and diagnostic imaging. Without subsequent groin dissection and without sampling of groin nodes before treatment, such patients are reported to have a low probability of groin failure if treatment is carried out with appropriate technique.[111,112] They are, however, strictly speaking "unstaged." Comprehensive pretreatment evaluation of disease extent may be less important when institutional treatment policy is to carry out initial surgery in all patients who are medically operable and technically resectable, even in the presence of limited node metastases. If the detection of nodal disease pretreatment will impact the selection, sequencing, or intensity of treatment modalities, the diagnostic cascade illustrated in Figure 60-3 may help to guide therapy. It must be emphasized that there exists no consensus standard for the pretreatment evaluation of disease extent. Experience with sentinel node identification is not universal, and its routine use outside tertiary referral centers remains controversial. Thus the algorithm in Figure 60-3 may not be applicable in all venues.

Confirmation of node status is often accomplished by surgical exploration of the inguinal nodes. The most common surgical practice is to obtain histologic examination of the ipsilateral inguinal lymph nodes for lateralized lesions of the vulva and of bilateral nodes for lesions considered to be midline. Although there is no widely accepted definition of midline, a minimum of 1 cm of clinically involved tissue separating the border of the tumor from a structure which has bilateral lymphatic drainage should be mandatory before considering omission of contralateral node assessment or treatment, and many clinicians recommend 1.5 cm to 2 cm. Because lymphatic drainage from the anterior labia minora may be bilateral,[62,113] bilateral groin assessment should be considered for lesions arising in these areas even if otherwise apparently lateralized as contralateral groin metastases with negative ipsilateral groin nodes have been described with primary tumors in this location.[75] Possibly because precise tumor extent may be more difficult to appreciate on physical examination, contralateral groin node metastases with negative ipsilateral groin nodes have similarly been reported in patients with primary cancers of the Bartholin's gland, suggesting consideration of bilateral histologic groin assessment in such patients as well.[82]

For those with primary cancers <4 cm diameter, sentinel nodes may be identified for selective excisional biopsy by injection of blue dye, fluorescent dye, or radiocolloid at the primary.[114-124] It is increasingly clear that use of a blue dye

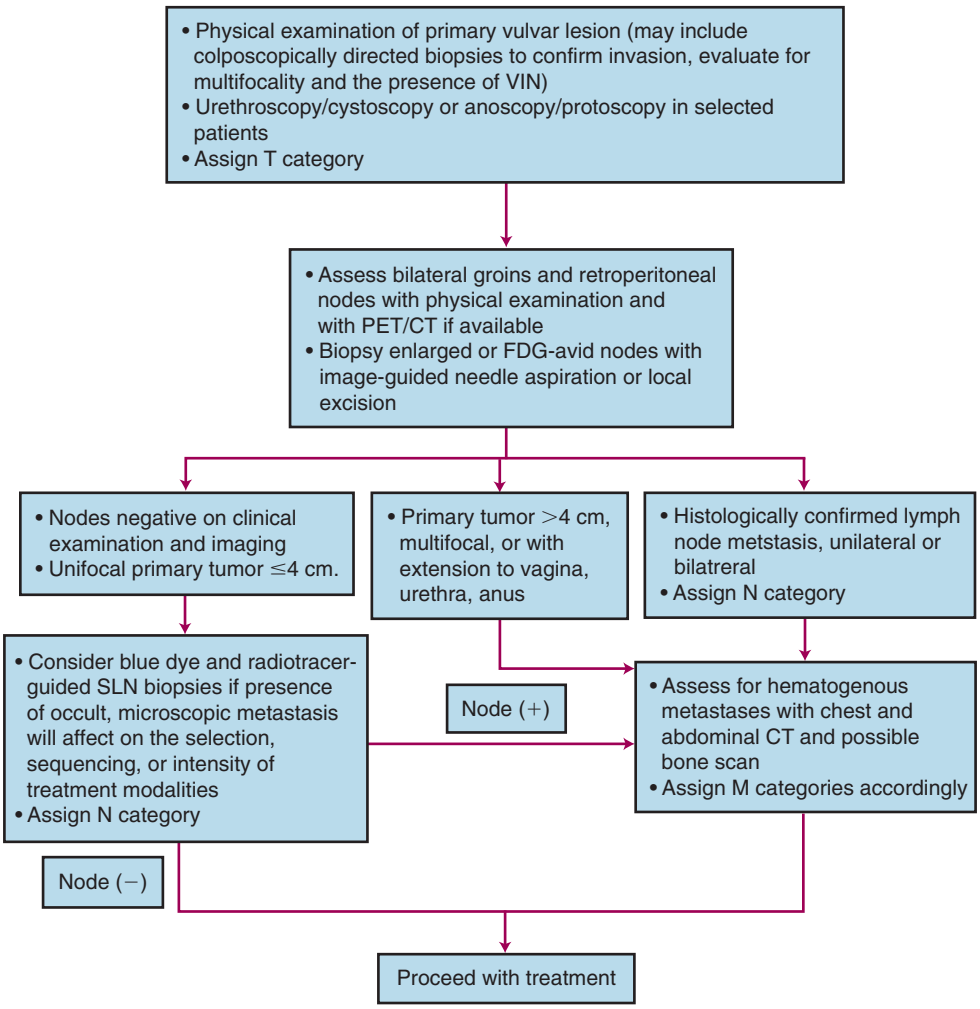


Figure 60-3 Diagnostic algorithm for vulvar cancer. *CT,* Computed tomography; *FDG-PET,* ^{18}F-fluorodeoxyglucose positron emission tomography; *M,* metastasis; *N,* node; *SLN,* sentinel lymph node; *T,* tumor; *VIN,* vulvar intraepithelial neoplasia.

alone is insufficient to identify sentinel nodes. Results are better when a radioactive tracer is used in combination with blue dye. Sentinel nodes should ideally be both "hot and blue" because greatest accuracy although radiotracer alone appears to be as accurate for other anatomic sites where sentinel node evaluation is performed. Use of indocyanine green fluorescent dye intraoperatively in patients who are lean is currently under investigation.[124] Meta-analysis of published vulvar sentinel node work reports a 92% sensitivity (by patient and by groin) with negative predictive values of 97% (by patient) and 98% (by groin).[125] Results will be most accurate when use of the technique is restricted to patients with intact (un-excised) tumors ≤4 cm in diameter in the absence of palpably enlarged groin nodes and nodes enlarged or considered suspicious for metastatic contamination by medical imaging (ultrasound [US], MRI, PET/CT).

Pathologic ultrastaging of groin nodes has been used to increase the sensitivity of sentinel node excisional biopsy in the discovery of occult microscopic groin node metastases not detected by routine processing.[120,126] Ultrastaging may include thin step-sectioning of retrieved nodes with hematoxylin and eosin staining with or without immunohistochemical staining,[127] however immunohistochemical staining will identify some metastatic deposits in nodes otherwise missed by routine hematoxylin and eosin processing.[123] When nodal disease is advanced and initial surgery to the groin area is not planned, histologic confirmation of metastatic contamination may be obtained by fine-needle core biopsy or aspiration cytology.

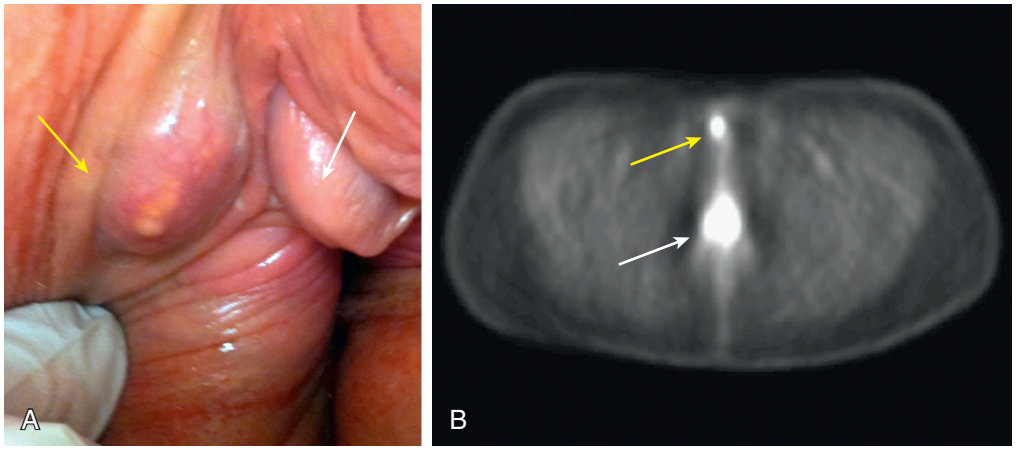
Noninvasive imaging with PET/CT, US, or MRI (with diffusion-weighted imaging) may assist in assessing lymph node status, particularly in patients who are larger or obese in whom femoral nodes may be many centimeters below the skin, beyond a depth where node palpation is feasible.[128-132] Metabolic imaging may sometimes detect metastases in the absence of gross nodal enlargement. PET/CT may occasionally detect in-transit dermal metastases as well as nodal spread (eFigure 60-8, *A* and *B*). CT using size criteria alone is less accurate because of the frequency with which groin nodes are nonspecifically enlarged as a result of inflammatory or reactive changes or fat replacement. Spatial imaging may identify nodes accessible for image-guided fine-needle biopsy.

PRIMARY THERAPY

The treatment of patients with vulvar cancer has been in a state of evolution for more than three decades. Previously, en bloc radical vulvectomy with bilateral groin dissection with or without bilateral pelvic node dissection was the treatment of choice for all patients with vulvar cancer.[7,10,135] Although extirpative surgery improved cancer outcomes compared with results obtained during previous eras, it was associated with substantial acute and chronic postoperative morbidity as well as major psychological sequelae. Leg lymphedema following radical groin and pelvic node dissection may be temporary or permanent and disabling.[91,136] Pelvic relaxation, organ prolapse, and urinary incontinence can develop in some patients, particularly when removal of the distal urethra or a portion of the lower vagina is required to achieve surgical clearance. Vaginal introital stenosis can occur, and the absence of the vulva and venereal fat can have the functional equivalence of shortening effective vaginal depth and removing a protective cushion from the pubic arch. These changes may contribute to dyspareunia in many patients. Additionally, clitorectomy will profoundly diminish capacity for arousal and climax. The psychosexual consequences of vulvectomy are frequently devastating.[137-139]

The clinical extent of vulvar cancer at the time of diagnosis may be decreasing, possibly consequent to more enlightened attitudes regarding the pathogenesis of the disease and improved access to health care. Among operable patients undergoing radical groin dissection, the frequency of lymph node metastasis fell from approximately 50% in reports from the 1940s and 1950s[7,10,135] to approximately 30% in surgical literature from the 1970s and 1980s.[3,71,97-99] As younger, sexually active patients were being diagnosed with preinvasive disease or unifocal disease of minimal volume and depth of invasion, modifications in the surgical approach to vulvar cancer were provoked by concerns about the chronic morbidities of ablative surgery particularly in patients with disease of limited extent.

Refined understanding of pathologic predictive factors, patterns of failure after standard radical surgery, and efficacy and tolerability of radical radiation in vulvar cancer has led to progressive change from the recommendation for radical surgery in all patients. The focus of vulvar cancer management has moved toward decreasing the morbidity and mortality of radical vulvectomy in patients with early-stage, prognostically favorable tumors, and improving results without increasing morbidity in patients with advanced, poor-prognosis disease by using integrated multimodality therapy that includes radiation, chemotherapy, and functionally conservative surgery.[9] The diversity of the disease and the afflicted patients requires tailoring the nature and extent of treatment to the location and severity of the cancer, cognizant of the activity, efficacy, and toxicity of each available treatment modality used alone or in combination.



Decisions regarding management of the primary tumor in the vulva are made on the basis of primary tumor volume, location and anatomic extent (direct involvement or impingement on functionally important midline structures) taking into consideration the potential impact of both biopsy and definitive surgery on anatomic function and cosmesis.

Decisions regarding management of the groin nodes are directed by whether or not histologically confirmed node metastases are present, their extent, and the size, location, and depth of invasion of the vulvar primary.

Surgical Trends Including Sentinel Node Studies

Radical surgery for vulvar cancer has moved away from the classic radical vulvectomy with en bloc bilateral inguinal lymph node dissection toward less extensive vulvar and groin surgery, particularly in patients with early-stage lesions. Indicators of this trend include: (1) the use of separate vulvar and groin incisions (so-called "triple incision") with preservation of the intervening skin bridges; (2) use of sentinel lymph node procedures and less comprehensive groin node surgery coupled with adjuvant radiation where indicated; (3) the use of chemoradiation in patients with gross inguinofemoral node metastases, and (4) use of pelvic radiation in lieu of pelvic node dissection in patients with confirmed groin node metastases.[78,84,140] The definition of radical vulvar surgery has changed with the realization that the efficacy of radical surgery is best defined by the closest resection margin rather than by achievement of total organ ablation (vulvectomy).[60,107,141]

In patients with limited disease and clinically negative groin nodes or occult groin node metastases, utilization of separate incisions for the primary and groins is associated with decreased acute and morbidity without compromise of disease-specific survival (DSS) or OS compared to en bloc resection.[142] However, when corrected for other prognostic variables in a multivariate analysis, the type of surgical treatment (triple incision versus en bloc) was an independent predictor for vulvar recurrence but not for inguinal and pelvic relapse.[143] The lack of impact on DSS and OS may be attributed to high salvage rates for isolated vulvar recurrence reported

eFigure 60-8 **A,** Mass in the right labia *(yellow arrow)* in a phenotypically female patient with XXY karyotype (Klinefelter's syndrome) with X-linked androgen insensitivity and ambiguous genitalia. Note the clitoral hypertrophy *(white arrow)*. The primary squamous cancer was in the right Bartholin's complex. The labial mass was initially thought to be a sebaceous cyst. However sebaceous cysts are usually at the hairline along the crests of the labia majora, and the presence of subtle neovascularity over this mass was concerning. **B,** When positron emission tomography/computed tomography revealed both groin node metastases and intense radiotracer uptake in the labial mass, a biopsy confirmed an in-transit labial metastasis. Intense fluorodeoxyglucose (FDG) uptake at the primary site *(white arrow)* involving the posterior fourchette and perineal body, and at the in-transit metastasis in the right labia *(yellow arrow)*.

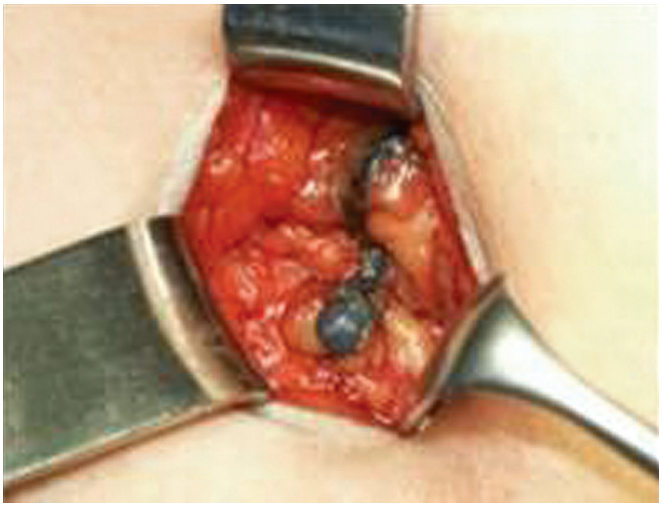
Although clinically useful in some patients, the results of imaging assessment, unless confirmed histologically, do not alter assignment of FIGO stage. Accurate measurement of the depth of femoral nodes below the anterior skin surface at the level of the femoral artery as it passes under the inguinal ligament is critical in the design and implementation of radiation-based therapy of undissected groins as well as in the context of adjuvant irradiation of the groins after superficial or total inguinal lymph node dissection.[133,134] Axial imaging is probably the most precise means of making this measurement.

in some clinical series.[103,144] However, a 2-year actuarial survival after vulvar recurrence has been reported to be as low as 25% and uncontrolled local recurrence was a contributing cause of death in 15 of 16 patients dying from cancer in one series.[141] Risk of recurrence in preserved skin bridges appears related to trapped dermal lymphatic emboli in patients with extensive groin adenopathy and is rare in the absence of groin adenopathy because lymphatic dissemination in vulvar cancer is characteristically embolic rather than permeative.

Radical excision for invasive tumors extends to the level of the deep perineal fascia usually 1 cm to 2 cm below the skin and should have a minimal margin of 1 cm of clinically uninvolved tissue in all dimensions. For tumors less than 2 cm in diameter with less than 1 mm of invasion (stage IA) treatment of the groins may be omitted. For stage IB tumors, surgical treatment must include the ipsilateral groin unless a successful sentinel node study confirms at least one negative sentinel node. For patients with well-lateralized primaries, preferably approximately 1.5 cm or more from midline structures, exploration and treatment of the contralateral groin may be omitted unless the ipsilateral groin is involved.

Although there is some uncertainty about the optimal extent of surgical margin after wide local excision, data from three clinical series reveal high local control rates for cases in which the surgical margin was greater than 8 mm in the fixed state postoperatively (Table 60-4). This suggests that, in the nonfixed state, tumor margins of at least 1 cm to 1.5 cm in all dimensions are desirable to achieve high local control rates. Many clinicians endorse a clinical margin of 1.5 cm to 2 cm. Implicit is the understanding that radical local excision should include dissection down to the deep perineal fascia. Although radical local excision is widely accepted in the treatment of small lesions, there is a growing trend to extend its use to lesions larger than 2 cm. Unless preservation of the clitoris and sexual function are priority patient concerns, radical vulvectomy is generally the best surgical option for patients with multifocal invasive disease, patients with invasive cancer associated with extensive VIN, and patients with cancer associated with symptomatic vulvar dystrophy unresponsive to topical therapies.

Optimal management of the inguinal nodes is essential because >90% of patients who experience relapse in regional lymph nodes after unsuccessful primary nodal therapy will ultimately die of cancer.[68,103,105,145-148] Patients whose primary lesion in the vulva invades to a depth less than 1 mm and is smaller than 2 cm have a minimal risk of groin node metastasis and do not require treatment of the inguinal region (see Table 60-1). In every patient with a primary tumor larger or more deeply invasive, treatment must include groin node management.



The move toward more conservative, tailored surgical management has led to changes in the extent of groin dissection and the use of unilateral groin dissection for selected patients. The previous standard radical bilateral superficial and deep inguinofemoral lymph node dissection results in as much as a 50% incidence of acute wound breakdown, lymphangitis, or lymphocyst formation, and a 10% to 25% incidence of chronic lower extremity lymphedema.[72,91,136,149] The surgical morbidity associated with limited, superficial groin dissections is less than that with superficial and deep dissections.[140] The rationale for limiting the extent or depth of groin dissection relates to the somewhat orderly sequence of metastatic progression in the groin nodal chain and the observation that involvement of the deep femoral nodes without involvement of the superficial is uncommon.[140] However, the actuarial risk of groin relapse at 5 years was 16% among patients with vulvar cancer treated with superficial groin node dissection alone at MDACC.[66]

Anatomic study of sentinel node location has shown that sentinel nodes will include deep femoral nodes in as many as 16% of patients thus explaining the relapse rate.[122] Surgical results might be improved by extending the superficial groin dissection to remove the medial portion of the cribriform fascia and underlying femoral nodes en bloc with the superficial inguinal fat pad.[150] Routine study of sentinel nodes by combined injection of blue dye and lymphoscintigraphy might further reduce the risk of groin failure by identifying the minority of patients with direct lymphatic pathways to deep nodes.[114-123] A sentinel groin node identified by blue dye is illustrated in eFigure 60-9.

If the sentinel nodes show no evidence of tumor contamination, full-therapeutic groin dissection may be sensibly omitted in patients with discrete, unifocal vulvar tumors less than 4 cm in diameter as subsequent groin relapse will be rare. A large international observational study, GROningen INternational Study on Sentinel nodes in Vulvar cancer (GROINSS-V), on sentinel node detection using radioactive tracer and blue dye was conducted in 15 institutions.[151] Team skill verification in sentinel node biopsy technique was required before patient enrollment. Patients with a unifocal primary tumor confined to the vulva and less than 4 cm in diameter with one or more sentinel nodes identified and histologically negative by ultrastaging were treated by vulvar surgery without groin dissection. A total of 623 groins were studied in 403 assessable patients. Among 259 patients meeting criteria for groin observation, six groin recurrences were subsequently diagnosed (2.3%). The 3-year DSS rate for patients with unifocal disease and negative sentinel nodes was 97%.[151]

A parallel multiinstitutional study was conducted by the Gynecologic Oncology Group in the United States (GOG protocol 173) that enrolled 452 eligible patients commencing in December 1999.[123] Skill verification in sentinel node biopsy technique was not required before study participation, and patients with primary cancers ≤2 cm and ≤6 cm in diameter were included as well as some patients with prior gross total local excision. Initially the node identification was accomplished by blue dye technique with lymphoscintigraphy optional, but in 2001 the protocol was amended to require preoperative lymphoscintigraphy with intraoperative radiolocalization. Following sentinel node retrieval, complete groin dissection was performed. In 34 patients, sentinel nodes could not be identified. Sentinel nodes underwent ultrastaging by processing the nodes into blocks of 3-mm thickness with a minimum of 2 sections 40 microns apart being obtained from each block. Of the 418 patients in whom sentinel nodes were identified, 132 patients were ultimately found to have lymph node metastases. The sensitivity of the sentinel node procedure was 91.7% with a false-negative rate of 8.3%. Because of protocol compliance issues, immunohistochemical analysis was performed on only 200 of 285 patients (71%) with negative sentinel nodes. Twenty-three percent of true-positive cases were identified by immunocytochemistry when routine hematoxylin and eosin staining did not reveal micrometastases.

If one or more sentinel nodes were involved with tumor in the GROINSS-V study and other sentinel node studies, surgery would generally proceed to complete the therapeutic superficial and deep groin node dissection. However, radiation or chemoradiation to undissected nodes after a positive sentinel node biopsy was thought to be a sensible alternative to completion of the groin dissection perhaps carrying a lower risk of chronic lymphedema and erysipelas, particularly if groin radiation might follow full groin dissection because multiple nodes are found to be contaminated. This alternative was the subject of the initial study design of a second observational study (GROINSS-V II) from the Netherlands, which has

eFigure 60-9 Sentinel groin node identified by blue dye technique.

Short-term morbidity was decreased in patients after sentinel node dissection only compared with patients who had a positive sentinel node biopsy who underwent complete inguinofemoral lymphadenectomy.[151] Acutely, groin wound breakdown was seen in 11.7% of sentinel node biopsy only patients compared with 34.0% of patients undergoing complete groin dissection. Cellulitis was observed in 4.5% compared with 21.3% of patients, respectively. Chronic morbidity also was less frequently observed after removal of only the sentinel node compared with sentinel node removal and inguinofemoral lymphadenectomy.[151] Recurrent erysipelas was seen in 0.4% compared with 16.2% of patients respectively, and lymphedema of the legs observed in 1.9% of patients undergoing sentinel node biopsy compared with 25.2% of patients undergoing full groin dissection.

accrued patients since 2006. Eligible patients are limited to those with unifocal squamous cancers confined to the vulva <4 cm. In diameter without encroachment on the urethra, vagina, or anus and with clinically and radiographically negative groin nodes. Patients who have successful identification of negative sentinel node(s) undergo no further therapy directed to the groins. Patients with positive sentinel node(s) initially would undergo groin radiation or chemoradiation (at individual investigator discretion) as an alternative to conventional completion of a therapeutic superficial and deep inguinofemoral lymphadenectomy. The study design was modified when interim safety monitoring revealed an unexpectedly high rate of in-field groin failures in patients with nodal metastases exceeding 2 mm in size who were treated with 50 Gy of radiation alone to the affected groin. The study was reopened in 2011 modified so that patients with nodal micrometastases exceeding 2 mm in size would undergo full groin node dissection followed by radiation (50 Gy to 56 Gy) with concurrent chemotherapy at investigator discretion. Because in-node–positive cervical cancer the addition of concurrent chemotherapy to adjuvant pelvic radiation after radical hysterectomy substantially improved local control compared with radiation alone,[152] the use of concurrent chemotherapy with adjuvant groin radiation is reasonable in patients with groin node metastases from squamous cancer of the vulva.

Rob et al published the most detailed study concerning sentinel node anatomical location in vulvar cancer.[122] They divided groin nodes into four regions: the superficial medial group located above and medial to the femoral vein and medial to the saphenous vein; the superficial intermediate group located in the vicinity of but superior and lateral to the saphenous and femoral veins; the superficial lateral group located in the outer third of the groin; and the profundum nodes located deep and medially along the femoral vein. Of the 118 sentinel lymph nodes found in 82 groins in this study, 84% were in the superficial medial region or in the superficial intermediate region, and 16% were in the profundum group. Importantly, no sentinel lymph nodes were found in the superficial lateral region. These findings are informative for the determination of radiation target volumes and the design of radiation ports for patients with clinically and radiographically negative groins undergoing elective or prophylactic groin radiation. Covering only tissues overlying and medial to the femoral vessels allows substantial reduction in radiation dose to the femoral necks and metaphyseal regions while assuring that first echelon nodes are comprehensively included. As insufficiency fractures of the femur[153] constitute a rare but serious complication of groin node irradiation, tailored treatment volumes based on understanding of the relative risk of different node groups within the groin may be a sensible way to help reduce the risk of this major cause of delayed treatment morbidity.

For patients with lateralized lesions and no involvement of the ipsilateral nodes, the incidence of contralateral groin node involvement is extremely low[62,84] and routine dissection of the contralateral nodes is omitted. Bilateral dissections are recommended for patients whose tumors involve or approach within 1 cm of midline structures or involve the anterior labia minora.

When nodal disease is fixed or ulcerating, the local tumor burden is large and unlikely to be controlled by either surgery or radiation alone. In such patients, combined therapy with initial chemoradiation followed by surgery may offer the best chance of local control if groin nodes become resectable.[154] In rare patients with unresectable groin nodes, local and regional control can sometimes be obtained with high-dose chemoradiation (eFigure 60-5, *A* and *B*).

Radiation Therapy

Radiation therapy for vulvar cancer was pioneered in Europe in the early 20th century in an era when surgical options for advanced vulvar cancer were limited. As radical surgery became more feasible and surgical results improved consequent to improvements in anesthesia, postoperative nutritional support, blood transfusion, antibiotics, and refinements in reconstructive surgery and wound care, primary radiation therapy (RT) with its attendant morbidity was largely abandoned. Because of the acute desquamation accompanying radical irradiation of the vulva and the severe late effects of radiation on the vulva in long-term survivors, the use of RT was largely restricted to palliative use and patients with anatomic extent of disease or medical comorbidities precluding operative intervention.[155-159] With focused hindsight, RT equipment and techniques were primitive in comparison to current technology, and radiation fractionation and total dose were naïve with respect to potential late normal tissue effects. The perception that radiation was a poor second choice as a curative modality stemmed, in part, from the low survival rates reported in early series for patients selected for RT who were unsuitable for primary surgery because of poor general medical condition, locally advanced tumors, or both.

In the past three decades, the use of RT (alone or in concert with concurrent radio-potentiating chemotherapy) in the treatment of vulvar cancer has increased dramatically. Commonly administered as adjuvant therapy before, or following conservative surgery, chemoradiation has also emerged as an alternative treatment for patients whose extent of disease would require exenterative procedures or other extensively deforming surgical interventions. Two important prospective clinical trials of the Gynecologic Oncology Group (GOG 37, GOG 101) helped form the foundation for these changes in management. Additionally, two randomized prospective trials demonstrated the superiority of chemoradiation to RT alone in the treatment of the analogous cancers of the anal canal.[160,161] Extension of chemoradiation to treat patients with vulvar cancer was a natural extrapolation and has led to publication of a number of single-institution series reporting encouraging results in limited numbers of patients.[112,162-177]

Adjuvant Postoperative Radiation

The GOG conducted a randomized trial (GOG 37) to determine whether pelvic radiation could improve survival over the standard pelvic node dissection. Ipsilateral pelvic lymphadenectomy (n = 55) was compared to RT (45 Gy to 50 Gy, n = 59) administered to the bilateral groins and pelvis (excluding the tumor bed and residual vulva) in 114 patients who were surgically treated and were found to have groin node metastasis.[92] Metastases were detected in pelvic nodes in 15 of 53 patients (28%) undergoing pelvic lymphadenectomy, 9 of whom expired within 1 year. With median follow-up in survivors of 74 months, the OS was 51% in irradiated patients at 6 years compared to 41% in patients treated by pelvic node dissection. The cancer-related death rate was 51% in patients undergoing pelvic node dissection, compared to 29% in patients undergoing RT (p = 0.015). The major benefit of RT was in patients with gross node metastasis, extracapsular extension, or metastases to two or more nodes. The major effect of RT was a reduction in groin failures in the patients who were irradiated who had a 5% crude incidence of groin relapse compared to a 24% crude incidence in patients treated surgically. The tumor bed and residual vulvar tissues were not irradiated, and a 12% crude incidence of vulvar recurrence was observed across both treatment arms. Data from two other studies suggest that macroscopic involvement of a single node and extracapsular invasion confer a risk of inguinal

recurrence after surgery that is as high as in those with multiple lymph node involvement, suggesting that such patients may also benefit from postoperative groin and pelvic nodal irradiation.[5,178] After therapeutic groin dissection, patients with microscopic intracapsular metastasis to a single groin node do not appear to benefit from the addition of radiation.

The target volume for adjuvant postoperative RT depends on the indications for adjuvant therapy. For patients with negative groin nodes but adverse histopathologic factors discerned on study of the excised primary, focal RT targeted at the primary tumor site, is appropriate. For patients with unilateral node metastases in whom the contralateral groin has been dissected and is uninvolved, generally most do not treat the contralateral groin and pelvic nodes although they were routinely treated in the GOG 37 study of adjuvant radiation, which showed the survival benefit.[92]

Many patients with node involvement will also have indications to treat the primary tumor bed and residual vulva. However, whether or not to routinely include the tumor bed and residual vulva in all patients undergoing adjuvant postoperative RT because of node metastasis remains an issue of controversy. Dusenbery et al reported 27 patients with squamous carcinoma of the vulva and 1 to 15 (average 4) histologically involved inguinal lymph nodes who were treated after radical vulvectomy and bilateral lymphadenectomy (25 patients), radical vulvectomy and unilateral lymphadenectomy (1 patient), or hemivulvectomy and bilateral lymphadenectomy (1 patient). Postoperative RT was directed at the bilateral groin and pelvic nodes (19 patients), unilateral groin and pelvic nodes (6 patients), or unilateral groin only (1 patient). Twenty-six patients had the midline (primary tumor bed) shielded. Actuarial 5-year OS and DFS estimates were 40% and 35%. Relapses developed in 63% (17 of 27) of the patients at a median of 9 months from surgery (range 3 months to 6 years). Central recurrences (under the midline block) were present in 13 of these 17 patients (representing 50% of the patients treated with the midline blocked), as central only (8 patients), central and regional (4 patients), or central and distant (1 patient), leading the authors to conclude that the target volume for adjuvant postoperative RT for patients with node metastases should include the tumor bed.[179] Unfortunately the presence or absence of recognized risk factors for vulvar recurrence was not presented.

Some late local recurrences may actually represent true second primary cancers in conserved vulvar tissue that is predisposed to malignant transformation. This is more recognizable where second lesions develop in residual contralateral vulva following wide local excision of initially well-lateralized lesions. Whether adjuvant radiation to all of the remaining vulva would reduce or increase the risk of such second primary cancers is unknown. However, morbidity is definitely increased if the entire vulva is included in adjuvant treatment of a localized lesion. Assessment of risk factors associated with the primary tumor may assist in making this determination.

Whether adjuvant local radiation can overcome the negative prognostic impact of close or positive margins, capillary lymphatic space involvement, and depth of invasion is unproven. However, strongly suggestive evidence regarding margins is provided by the outcomes observational study of Faul et al.[141] Sixty-two patients with invasive vulva carcinoma and either positive or close (less 8 mm) margins of excision were retrospectively studied. Thirty-one patients were treated with adjuvant RT to the vulva and 31 patients were observed after surgery. Local recurrence occurred in 58% of observed patients and 16% of patients treated with adjuvant irradiation. Adjuvant RT appeared to significantly reduce local recurrence rates in both the close-margin and positive-margin groups. On multivariate analysis, adjuvant radiation and margins of excision were significant prognostic predictors for local control. The positive margin observed group had a significantly worse 5-year OS than the other groups ($p = 0.0016$) and adjuvant RT appeared to significantly improve survival for this group. The 2-year OS after developing local recurrence was only 25%, lower than is often reported for salvage therapy, and local recurrence was a significant predictor for death from vulva carcinoma (risk ratio 3.54).

The optimal pathological margin for reducing the risk of local recurrence width remains controversial. In one report local recurrence was observed in 8 of 21 patients with pathologic margins between 5 mm and 8 mm.[60] In another report, there were 0 of 18 recurrences in patients with margins between 5 mm and 8 mm.[141] The most commonly used indication for adjuvant vulvar irradiation is close margins; some use <8 mm as the criterion and others <5 mm. Depth of invasion >5 mm or the presence of lymph-vascular space invasion where other risk factors are present such as this may tip the decision in favor of local radiation.

Preoperative Radiation

In the 1960s, Boronow pioneered the use of preoperative RT followed by more conservative surgery in patients with locally advanced or recurrent vulvo-vaginal cancers as an alternative to pelvic exenteration. With a total of 48 treated cases (37 primary cases and 11 cases of recurrent disease) he reported a 72% 5-year survival for all 48 cases treated. One patient required a total pelvic exenteration for local failure, and one had a posterior exenteration for local failure. One bladder and one rectum were lost to permanent diversion because of RT injury. Five of 96 viscera (48 urinary bladders and 48 rectums) were lost and 91 (94.8%) were retained.[180] Three small series totaling 26 patients treated with 30-Gy to 55-Gy preoperative RT reported histologically negative surgical specimens in 13 patients (50%) with only microscopic residual disease in others.[181-183] These series provide further evidence for the radiation sensitivity of vulvar cancer.

Preoperative Chemoradiation

Several single-institution studies reported encouraging results employing preoperative chemoradiation before conservative resection in locally advanced or locally recurrent vulvar cancer.[162,163] These reports, along with reported treatment successes using chemoradiation for patients with anal and esophageal cancer, provided much of the foundation for protocol work commencing in 1989 in the GOG.

GOG Protocol 101 used planned preoperative chemoradiation (chemoRT) consisting of 47.6 Gy in once or twice daily fractions of 1.7 Gy synchronously with two courses of infusional 5-fluorouracil (5-FU) and cisplatin as initial therapy for 71 evaluable patients with extensive squamous cancer of the vulva, 1969 FIGO stages III and IV judged not resectable by radical vulvectomy, followed by surgical excision of residual primary tumor plus bilateral inguinofemoral lymph node dissection.[184] The dose-fractionation schedule for chemoradiation employed in GOG 101 is schematically depicted in Figure 60-4 and the target volumes depicted in Figure 60-5. The planned 1.5- to 2.5-week treatment interruption was intended to mitigate the severity of acute RT dermatitis that can progress to confluent moist desquamation, as well as to permit hematologic recovery. Twice daily RT was employed to optimize the RT and drug synergism. Following chemoRT, 33 of 71 (46.5%) patients had no visible vulvar cancer at the time of planned surgery and 38 of 71 (53.5%) had gross residual cancer at the time of operation. Five of the 38 had positive resection margins and underwent either further RT to the vulva (3 patients), wide local excision and vaginectomy necessitating colostomy (1 patient) or no further therapy (1 patient). Only 2 of 71 (2.8%)

had residual unresectable disease. In only three patients was it not possible to preserve urinary or fecal continence. The authors concluded that preoperative chemoRT is feasible and may reduce the need for more radical surgery including primary pelvic exenteration.

In parallel with the study of preoperative chemoRT for patients with locally advanced primary vulvar cancer, the GOG studied patients presenting with advanced disease in the inguinofemoral nodes, 1969 nodal classification N2/N3, including some patients with matted, fixed, or ulcerated groin nodes not judged resectable by initial surgery and any extent of vulvar disease. The identical preoperative chemoRT schedule was employed to treat 46 patients except the treatment volume was increased to encompass the groins and caudal pelvic nodes (see Figure 60-2). Three patients expired during treatment and one refused to complete the therapy. Four patients who completed chemoRT did not undergo planned surgery, 2 patients dying of causes not related to cancer and 2 patients remaining unresectable. Following preoperative chemoRT, the disease in the lymph nodes was judged resectable in 38 of 40 patients. Two patients who completed chemoRT did not undergo surgery because of pulmonary metastasis. One underwent radical vulvectomy and unilateral node dissection and the other radical vulvectomy only. The operative lymph node specimen was histologically negative in 15 of 37 patients. Nineteen patients developed recurrent or metastatic disease. Local control of the disease in the lymph nodes was achieved in 36 of 37 and in the primary area in 29 of 38 of the patients. Two patients died of treatment-related complications. The authors concluded that resectability and local control of advanced nodal disease may be obtained with a high probability following preoperative chemoRT in patients with carcinoma of the vulva with extensive groin adenopathy even with this modest dose of radiation (47.6 Gy).[154]

Acute toxicity in GOG 101 was primarily in the irradiated skin, with moist desquamation reported in many patients. Major hematologic toxicity was rare, presumably because the volume of irradiated bone marrow was small in patients with clinically negative groins who received radiation only to the vulva and immediately adjacent tissues. When initial RT target volume includes the groins and pelvic nodes (Figure 60-5) because of confirmed node metastasis, hematologic and gastrointestinal toxicities can be expected to be significantly more severe.

Because vulvar cancer and level-one evidence to support optimal treatment approaches are both rare, there is a large variation in management strategies. At Massachusetts General Hospital (MGH) the initial RT volume electively encompasses

the groin nodes bilaterally in all patients with locally extensive primary cancers selected for preoperative or definitive chemoRT, regardless of whether groin node metastases have been histologically verified. Evaluation for potential surgical resection of residual disease is carried out 2 weeks to 3 weeks following completion of preoperative chemoRT. If resection can be carried out without compromising functionally important midline structures, this is considered preferred management to avoid the chronic sequelae of high-dose RT on the vulva and perineum. Reduced volume boost treatment is administered to gross residual primary disease that has not become resectable by conservative excision. Often this is accomplished through the use of an en-face shaped perineal port employing electron beam or low-energy photons to minimize the volume of tissue carried to high dose (eFigure 60-10). To assure accurate perineal port placement and reproducible inclusion of residual disease with narrow (approximately 10 mm) margins, each treatment is done under direct supervision of the responsible physician. In patients with initially negative groin nodes (palpably and by diagnostic imaging assessment), electively irradiated groin nodes are not subsequently routinely dissected.

In some patients, a complete clinical response may be seen after moderate dose preoperative radiation. In GOG Protocol 101 preoperative chemoRT resulted in a complete clinical response in 34 of 71 patients evaluable for therapeutic efficacy (48%) and a pathologic complete response in 70% (22 of 31) of the 34 complete responders undergoing surgery.[184] Possible options for further management of patients with a clinical complete response to preoperative chemoRT include generous biopsy to confirm pathologic complete response (eFigure 60-11, *A* and *B*), conservative surgery to remove palpable scar tissue and the tumor bed, or a modest dose of radiation consolidation (8.5 Gy to 9 Gy in 5 fractions over 1 week).

In GOG Protocol 205 (successor study to GOG 101) with similar patient eligibility requirements, 5-FU was dropped and the more commonly used regimen of concurrent weekly cisplatin at 40 mg/m^2 was adopted. RT was administered once daily in 32 fractions of 1.8 Gy to a total dose of 57.6 Gy, escalating the physical dose 21% from the 47.6 Gy administered in fractions of 1.7 Gy in GOG Protocol 101, while dropping the twice daily fractionation schedule employed on 8 of the 20 treatment days in the previous study. Primary endpoints were clinical and pathologic complete response.[186] Because of these substantial differences in total dose, dose per fraction, and drug regimen, it is difficult to discern which of these factors may have contributed to the higher rates of complete clinical and pathologic response than was observed in GOG 101 (Table 60-6).

Additionally, prechemoRT groin dissections were done in 34 patients entered on GOG 205 of whom 19 (56%) had positive nodes, 12 (35%) had negative nodes, and 3 (9%) had unknown nodal status. Pathologic complete response at the primary site was observed in 8 of 19 (42%) patients with node-positive disease but 9 of 12 (75%) patients with node-negative disease, suggesting the possibility that nodal status and the efficacy of chemoRT at the primary site may be interrelated clinical factors. Pretreatment histologic groin status was not reported for patients treated on GOG 101, although 23 patients were reported to have FIGO 1969 N2/N3 clinical groin assessment. The comparability of patients entered on these sequential trials is not clear.

TABLE 60-6 Outcomes with Different Chemoradiation Schedules in GOG Protocols 101 and 205

	GOG 101*	GOG 205†

Pathological Complete response	22 (31%)	29 (50%)

**47.6 Gy in 1.7 Gy fractions (twice daily days 8 to 20) 5 d/wk plus concurrent 5-flourouracil.*
†57.6 Gy in 1.8 Gy fractions (once daily), 5 d/wk plus concurrent 5-weekly cisplatin.

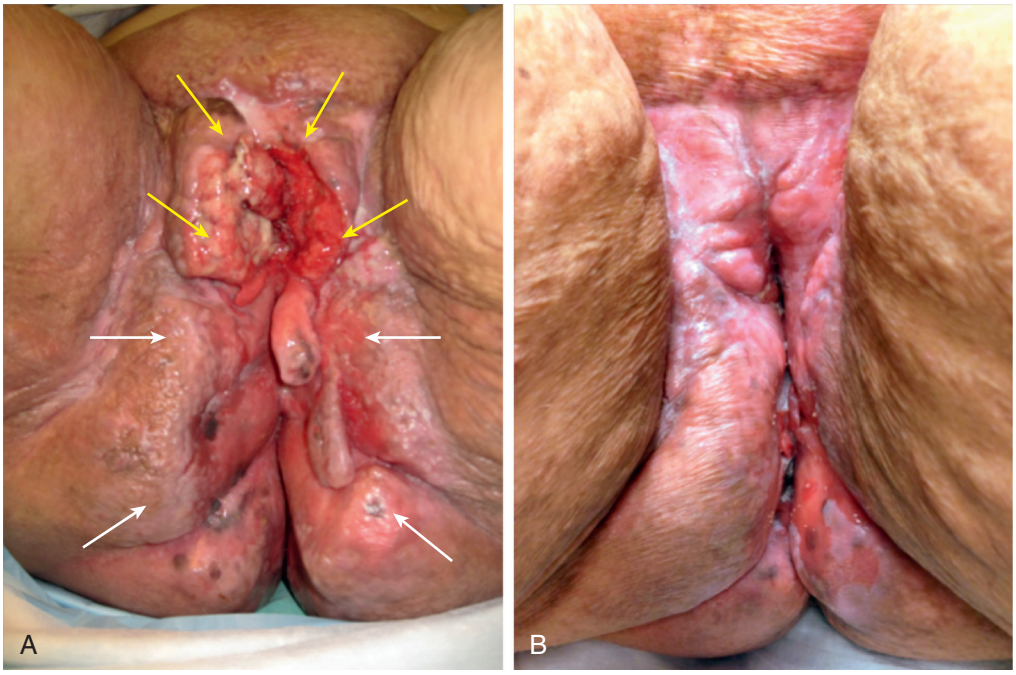
Primary Radiation or Chemoradiation

Treatment of Primary Lesions

Given the complexity of treatment decision making and the many possible ways of integrating surgery, RT and chemotherapy, all patients should be managed by an experienced multidisciplinary team.

Whether high-dose radiation, alone or combined with concurrent chemotherapy, can or should replace radical surgery for all patients with vulvar cancer is unclear. Reports of RT using contemporary techniques and dose-fractionation schedules used as monotherapy after biopsy are uncommon. Consequent to probable selection biases in choosing patients for such treatment, it is impossible to meaningfully compare outcomes to alternative treatment strategies. It can only be concluded that some patients enjoy local-regional control and prolonged DFS when managed employing radiation or chemoradiation alone.[175,191]

Increasingly, the trend is to employ RT and synchronous radiopotentiating chemotherapy as definitive therapy for patients with disease judged too extensive for functionally conservative surgery.[112,162-175,184,186,192-195] Unfortunately, the heterogeneity of the small numbers of patients selected for this approach, using variable selection criteria, diverse drug programs, and a spectrum of RT doses and fractionation schemes conspire to defy identification of an optimal regimen. However, as experience continues to accumulate and observational data become more mature, it seems probable that definitive chemoRT will emerge as a viable treatment plan for patients either with unresectable disease by virtue of disease extent, or medically inoperable because of comorbidities and for midline lesions for which surgery would impair cosmesis or function.



The optimal choice of cytotoxic drugs to administer in conjunction with RT remains unknown. Although Bleomycin is no longer used in this context, whether 5-FU alone or combined with cisplatin or mitomycin-C is more or less effective than weekly cisplatin remains unclear. In a nonrandomized, retrospective outcomes comparison of two different chemoRT approaches used contemporaneously in the treatment of advanced vulvar cancer at two Harvard Medical School affiliated radiation oncology departments in Boston (MGH and Brigham and Women's Hospital/Dana-Farber Cancer Center) there were no clear differences in the apparent efficacy of these two different concurrent chemoRT approaches.[196] In circumstances in which cisplatin is contraindicated it is reasonable to use infusional 5FU.

The currently active study (Figure 60-6) of the GOG (GOG 279) builds on prior efforts by escalating primary RT dose to 64 Gy for patients with locally advanced vulvar cancer unresectable by initial radical vulvectomy and augmenting the radiation potentiating effects of weekly cisplatin 40 mg/m^2 by the addition of weekly gemcitabine 50 mg/m^2, a second drug with known radiosensitization effect. This represents an extrapolation from the proven benefit of the two-drug regimen demonstrated in a prospective randomized trial of

eFigure 60-10 Shaped, en-face perineal port treated with electron beam or low-energy photons. The patient's legs are supported and immobilized by plastic operating room boots or stirrups attached to the treatment couch. To assure reproducible and accurate tumor coverage, it is suggested that each fraction be administered after direct visualization of the light field on the patient by a physician.

In other centers (Sunnybrook Odette Cancer Center) where chemoRT is chosen for the vulvar disease, the groin node status will be confirmed histologically so that patients with negative groins may be spared unnecessary groin irradiation.

eFigure 60-11 **A,** Pretreatment photograph of a young woman with locally extensive T3Nx squamous cancer of the vulva with involvement of the distal urethra and vagina arising in chronic dermatitis of the vulva, anus, and perineum associated with severe inflammatory bowel disease (Crohn's colitis). Yellow arrows delineate gross tumor. White arrows indicate areas of markedly abnormal and inflamed skin without clinical involvement of malignancy. Following diverting colotomy this patient was treated with preoperative chemoradiation delivering 47.6 Gy with two cycles of synchronous 5-flourouracil/cisplatin employing a dose and fractionation schedule modified from GOG Protocol 101 (see Figure 60-4). Target volumes included the primary and both groins using the modified segmental boost technique.[185] Three weeks following completion of chemoradiation an examination under anesthesia suggested complete clinical involution. Seven negative deep circumferential biopsies were obtained from the periphery of the original tumor volume and no further treatment was employed. **B,** Photograph of this patient 4.5 years after completion of treatment. There has been no evidence of recurrence.

Preoperative neoadjuvant chemotherapy (without radiation) has been used in the treatment of locally advanced vulvar cancer.[187-190] Response rates have been quite variable, and although complete clinical or pathologic responses have been recorded, these are rare. This approach has not gained broad acceptance, presumably because response to combined chemoRT is predictable.

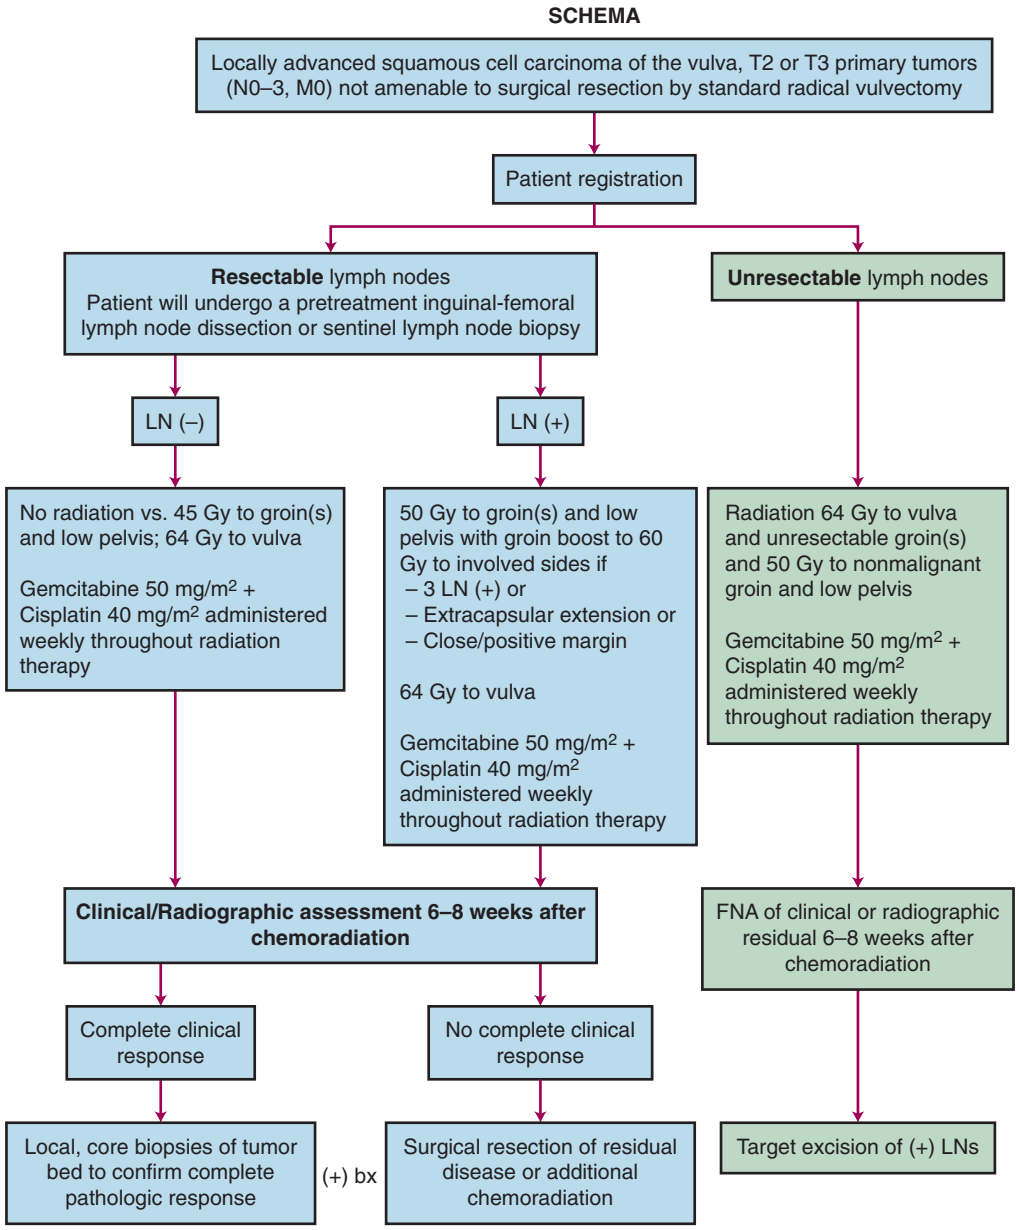


Figure 60-6 Protocol schema for GOG 279.

preoperative treatment of locally advanced cervical cancer conducted in Mexico City.[197] In that study 83 patients with FIGO IB2/IIA/IIB were randomized between 50 Gy in 25 fractions plus weekly cisplatin at 40 mg/m^2 versus 50 Gy in 25 fractions plus weekly cisplatin 40 mg/m^2 and weekly gemcitabine 125 mg/m^2. Although both acute gastrointestinal and hematologic toxicities were greater with the two-drug regimen, 77.5% of subsequent radical hysterectomy specimens were negative for residual cancer in patients treated with both drugs compared to 55% in patients treated with weekly cisplatin alone. Because RT target volumes for patients with vulva cancer treated on GOG Protocol 279 will include less bowel and less bone marrow than conventionally irradiated volumes used in the treatment of cervical cancer, it is hoped that the two-drug regimen will be tolerated in this mainly elderly population. All RT is to be administered by intensity-modulated radiation therapy (IMRT). The primary study endpoint is pathologic complete response at the primary site.

Treatment of Inguinal Nodes

It is unclear whether primary RT or chemoRT can replace primary surgery as definitive therapy for the inguinal regions. A randomized study conducted by the GOG compared primary inguinal dissection with primary groin irradiation to control the inguinal-femoral nodes in conjunction with radical vulvectomy in patients with squamous cancer of the vulva and clinically nonsuspicious groins.[198] This study was terminated before completion of accrual when interim monitoring revealed an excess of nodal relapse and death among patients treated with nodal irradiation. RT consisted of 50 Gy in daily fractions of 2 Gy fractions administered to a depth of 3 cm below the anterior skin surface. On the groin dissection arm, there were 5 of 25 (20.0%) patients with positive groin nodes. Those patients with node-positive disease received postoperative radiation. There were five groin relapses among the 27 (18.5%) patients randomized to receive the groin radiation

regimen, and none among patients treated with initial groin dissection. Patients who underwent an initial groin dissection had significantly better progression-free interval (PFS; $p = 0.03$) and OS ($p = 0.04$). Although resistance of the inguinal node metastases to radiation is one possible reason for the unacceptable groin failures in patients treated without groin dissection, a subsequent analysis of that study indicated that the groin RT technique employed was inadequate.[134] It was based on the assumption that the inguinal lymph nodes lay 3 cm to 4 cm below the surface, and a substantial percentage of treatment was delivered using electrons of energy (12 MeV or 13 MeV) appropriate to that depth. Koh's study illustrated that the median depth of lymph nodes in the groin was 6 cm from the surface but could be as deep as 17 cm in large patients. Kalidas obtained measurements of the inguinal node depths of 31 patients with cervical, vaginal, or vulvar malignancies from their planning CT scans. Twenty-four of 81 superficial inguinal node depth measurements were greater than 3 cm, and all of 84 deep inguinal (femoral) node measurements were beyond the 3 cm range.[133] The RT technique used in the GOG study almost certainly resulted in significant RT underdose of the nodal bed. In planning radiation-based therapy to the groins, there can be no substitute for direct measurement of groin node depth by CT or US. Depth of the deep femoral lymphatics, for radiation prescription purposes, is now usually specified as the depth of the femoral artery because it passes beneath the inguinal ligament.

A review of primarily observational studies[66,180,198-204] indicates that the risk of groin node failure after RT alone in the patient with clinically negative groin nodes is approximately 10% (Table 60-7). These studies did not always report the expected incidence of nodal disease in the patients irradiated, so the efficacy of RT is uncertain. However, approximately 20% of patients with clinically nonsuspicious groin nodes are expected to have subclinical metastases if complete nodal dissection is performed (see Table 60-1). This would suggest that RT alone in the doses applied sterilizes occult groin metastases in only 50% of patients. The results appear somewhat better when synchronous chemotherapy is administered; however, only 36 total patients have been reported treated in this manner[111,112] (Table 60-7).

Patients with FIGO 1969 $N_{0,1}$ negative groin nodes by clinical evaluation.

Two of the articles provide indirect evidence that RT without surgery can eradicate microscopic disease in clinically negative groin nodes in some patients. Frankendal et al[200] performed radical vulvectomy without inguinal node dissection in 29 patients with clinically negative groin nodes. Twelve patients received elective inguinal nodal irradiation; RT dose ranged from 30 Gy to 60 Gy in 15 days to 55 days. There were no nodal recurrences. Seventeen patients received no RT and 3 experienced inguinal failure. Manavi reported on 135 patients who underwent simple vulvectomy for T1 cancers without groin dissection.[204] Sixty-five patients underwent elective groin irradiation. Those patients had, on average, less favorable primary tumors than the 70 patients who had no treatment to their groins. There were three groin recurrences in the irradiated patients (4.6%) and seven groin recurrences in the unirradiated patients (10%).

Treatment Algorithms and Approaches

The initial management decision for vulvar cancer is based on clinical features including the extent of the primary, presence or absence of detectable node metastases, as well as the age, comorbidities, and preferences of the patient. The need for adjunctive therapies is determined by histopathologic findings. Management of the nodes and the primary tumor is based on the potential contributions of each treatment modality.

Because there are no precise definitions of what constitutes "favorable" or "early" disease compared to locally advanced disease, clinical definitions are provided to outline the principles that guide therapeutic choices.

Early, Favorable, or Low-Risk Disease

A practical definition of early, favorable disease (low risk) is disease that can be reasonably expected to be curatively managed by conservative surgery alone. The extent and location of the primary tumor are amenable to radical excision without sacrificing the function of the urethra, the anorectum, the clitoris, and vagina. Generally this will include patients without palpable or imaging evidence of inguinal node metastasis. For low-risk cancers that are unifocal and well-lateralized, radical wide local excision of the primary lesion in the vulva is recommended for most patients. The reported results from observational studies of radical wide local excision for T1 or T2 tumors suggest an average OS of approximately 90%. The criteria proposed for the initial selection of patients for such conservative surgical resection vary but in general include patients with tumors less than 2 cm in diameter.[65,84,86,140,205] Groin assessment, either by sentinel node biopsy or groin dissection, can be limited to the ipsilateral groin in patients with well-lateralized tumors ≤4 cm in diameter. However, when the depth of invasion increases to >5 mm or the ipsilateral groin is involved, contralateral groin metastases are more likely and the contralateral groin should be assessed.[206]

The role and indications for postoperative adjuvant vulvar irradiation are ill defined. Although data have clearly demonstrated that surgical margins less than 8 mm, increasing depth of invasion, presence of capillary lymphatic space involvement, and increasing size of primary cancer portend increased risk for vulvar recurrence after excision of any extent, it is still unclear to what extent postoperative adjuvant irradiation can overcome these risks.

Although wider reexcision, if feasible, may decrease or eliminate the risk of close or involved margins, it may not be feasible or advisable for medial or deep margins and may not overcome other risk factors. Residual cancer in the reexcision specimen is rare except when cancer is present at the original margin (33%), and reexcision is associated with a 23% rate of

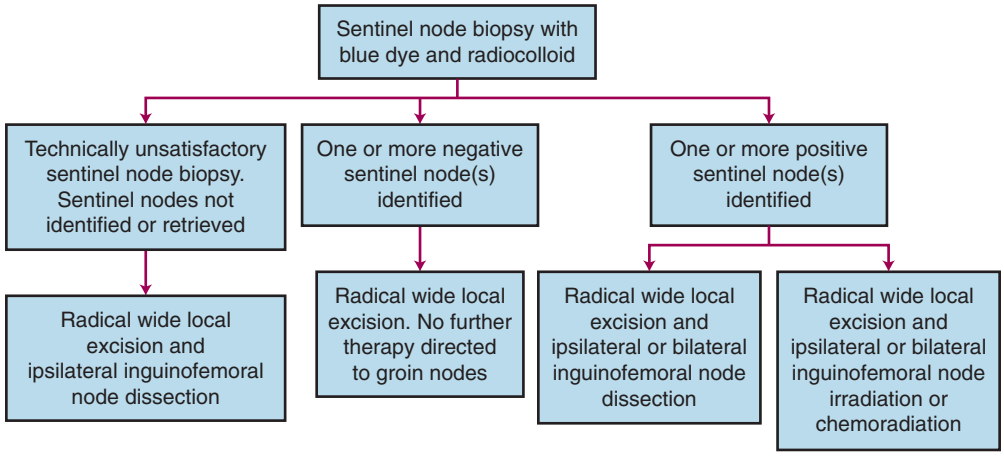

Figure 60-7 Treatment algorithm. Limited, unifocal vulvar cancer <4 cm without encroachment on clitoris, vagina, urethra, or anus. Groins clinically uninvolved. Experienced sentinel node team available.

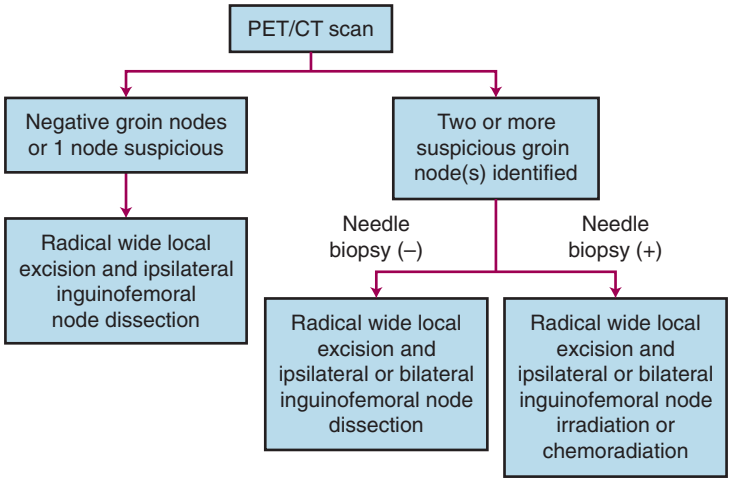
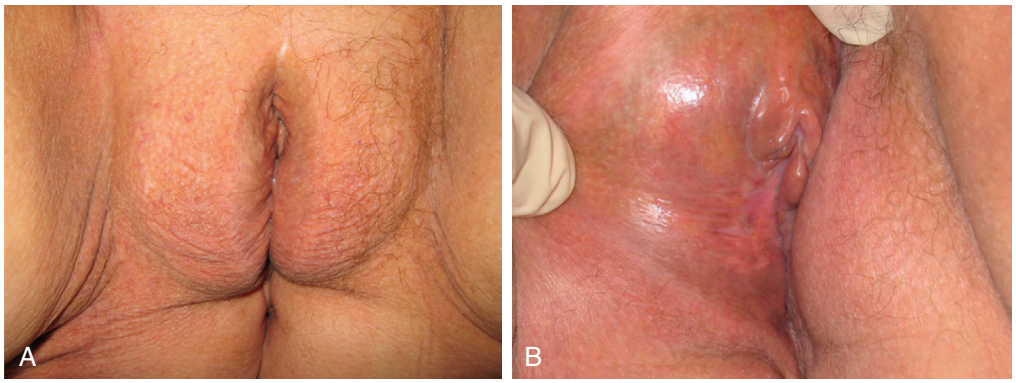


wound breakdown.[207] Reexcision may be easier for the patient if it results in sparing the patient adjuvant local radiation. If primary tumor risk factors (size, depth of invasion, lymphvascular space invasion) suggest adjuvant RT independent of margin width, it is difficult to justify the morbidity and delay incurred by reexcision. One retrospective series of 62 patients with positive or close (<8 mm) margins showed, on multivariate analysis, that adjuvant irradiation significantly reduced local recurrence rates and significantly improved survival rates for the positive-margin group.[141] If adjuvant RT is to be administered for positive or close margins <10 mm, a dose ≥56 Gy is recommended.[208] The role of adjuvant RT after radical wide local excision of vulvar cancer was being explored in a GOG randomized clinical trial, but the trial had to be abandoned as a result of lack of accrual.

Historically, standard management of the inguinal regions for all patients with invasive disease of larger than 2 cm or greater than 1 mm depth of invasion (FIGO stage IA) has been groin dissection. Results from the GROINSS-V study suggest that in selected patients with unifocal primaries <4 cm without encroachment on the urethra, vagina, or anus and successful and retrieval of sentinel node(s) that are negative by pathologic ultrastaging, the acute and chronic morbidities of groin dissection may be avoided with subsequent careful observation. The risk of subsequent groin relapse is low and its consequence may be less ominous than groin recurrence in a previously treated groin because salvage therapy at the time of nodal relapse, in an undissected groin, may be more successful. Postoperative RT to the inguinal and pelvic nodes is recommended for patients with involvement of two or more nodes and for those with a single node with macroscopic metastasis (>5 mm) or extranodal extension. In patients with diagnostic imaging that shows no evidence of pelvic adenopathy, it is unlikely that extending the superior border of the treatment volume more cephalad than the middle of the sacroiliac joints is useful. Limiting the superior extent reduces acute and chronic enteric morbidity. The randomized study (GOG 37) from which these recommendations are largely drawn gave prophylactic adjuvant irradiation to both groins even when involvement was unilateral only.[92,209] The contribution of adjuvant RT to the contralateral negative groin is uncertain and is now largely omitted. Two issues remain controversial. Whether it is beneficial to include the tumor bed or residual vulva routinely in the treatment volume when groins and pelvic nodes require irradiation remains unclear; histopathologic risk features in the primary may suggest that this may be prudent in many, if not all patients. Whether concurrent chemotherapy should be administered with purely adjuvant treatment to further enhance the regional efficacy of RT is also the substance of conjecture and debate. Hypothetically, the increase in acute toxicity could be offset by improved regional control, possibly with a reduced dose of RT that might translate into diminished late RT effects. The therapeutic ratio of this strategy is unlikely to be rigorously defined in studies. Algorithms for management of patients with early, lateralized disease are found in Figure 60-7 and eFigure 60-12 premised on the presence of a team skilled in the performance of sentinel node biopsies or the availability of PET/CT. Absent either capability, radical wide local excision and at least ipsilateral inguinofemoral lymphadenectomy is recommended. Predicated on histopathologic findings, subsequent management is suggested by the algorithm in Figure 60-8.



Small Primary Tumors Encroaching on Midline Structures

Although surgical excision remains the historical standard treatment for patients with small, midline primary tumors, it is not unreasonable to consider treating a primary midline lesion, regardless of size, with a localized field of primary RT or chemoRT if surgical excision would result in predictable loss of cosmesis or function. Although such patients can be cured with surgery as monotherapy, the functional and cosmetic impairments can be psychologically devastating. In many patients, clinical shrinkage after a modest dose (45 Gy to 54 Gy) of RT or chemoRT will permit conservative excision of residual tumor with excellent preservation of function and cosmesis (eFigure 60-13, *A* and *B*).

This recommendation remains controversial, not because of a lack of efficacy for RT (which has been proven effective in more locally advanced disease) but rather because no systematic studies of subsequent sexual function and morbidity have been performed. Anecdotally, clitoral function can be preserved in some sexually active patients following 45 Gy combined with 5-FU–based chemotherapy supplemented by clitoris-sparing local excision. Some such patients, sexually active and orgasmic before treatment, are sexually active and orgasmic 12 or more months following completion of treatment, and subjectively report intact sensation and vascular engorgement and erectile clitoral function. Whether functionality is preserved after higher doses of radiation is unknown.

eFigure 60-12 Treatment algorithm. Limited, unifocal vulvar cancer <4 cm without encroachment on clitoris, vagina, urethra, or anus. Groins clinically uninvolved. Experienced positron emission tomography/computed tomography (PET/CT) diagnostic imaging available.

eFigure 60-13 Clinical results after combined modality therapy for a small T2 N0 anterior right labia minora primary invading clitoris. Images obtained at follow-up 18 months following treatment that consisted of 45 Gy in 25 fractions to a volume encompassing the primary and electively including the groin nodes bilaterally with two courses of concurrent infusional 5-fluorouracil and bolus cisplatin. Conservative excision of residual tissue followed that spared the clitoris and most of the vulva. Images obtained with labia apposed **(A)** and with right labia majora retracted revealing excision scar **(B)**.

LOCALLY ADVANCED DISEASE AND PALLIATION

Patients may be considered to have locally advanced disease if the location and extent of the primary lesion in the vulva is such that radical excision would require functional compromise or sacrifice of functionally important midline structures. Patients with clinically involved groin nodes, particularly matted, ulcerated, or fixed, are also considered to have locally advanced disease. Such patients are predictably inadequately treated by surgery as monotherapy, and combined-modality therapy (chemoRT alone or coordinated with conservative surgery) should be considered by multidisciplinary consultation before initiation of any therapeutic intervention.

Historically, adequate surgical clearance of large primary tumors that involve the anus, rectum, rectovaginal septum, or proximal urethra would usually include radical vulvectomy plus some type of pelvic exenteration. Five-year OS with primary surgery for locally advanced disease range up to 50%.[210] However, physical and psychological morbidity from such surgical procedures is high.

Boronow et al, in a landmark study, explored the use of preoperative RT in locally advanced disease with the intent to reduce the scope of subsequent surgery. Thirty-seven patients with locally advanced vulvar cancer were treated with variable doses of RT (median, 48 Gy) followed by surgery. The 5-year OS was 75.6%, and approximately 40% of patients had no residual disease in the operative specimen.[180]

Subsequently, multiple investigators reported favorable results in observational studies of patients with locally advanced disease treated with chemoRT employed preoperatively if shrinkage permitted nonexenterative surgery. Consequent to these studies as well as the results of GOG 101, there is a growing acceptance by gynecologic oncologists that concurrent chemoRT constitutes the initial treatment of choice for primary management of patients with locally advanced disease.

Randomized trials for vulvar cancer have not been performed to test whether concurrent chemotherapy confers additional benefit to RT alone, but Phase III trials have shown benefit for chemoRT compare with RT alone in both anal and cervix cancer.[160,161] The drugs regimens commonly used with vulvar cancer include 5-FU, alone or in combination with cisplatin or mitomycin-C, or weekly cisplatin alone. Results with Bleomycin have been found unsatisfactory either as a result of gross tumor persistence or a high local relapse rate after initial favorable response.[168,193]

An algorithm for the management of patients with locally advanced primary cancer, with or without locally extensive groin metastases, is depicted in Figure 60-9. The rationale for interval evaluation after a preoperative dose of chemoRT inherent in the management algorithms for both limited and advanced disease depicted in Figures 60-8 and 60-9 is to assess the efficacy of the initial management strategy to determine whether to continue with it or change to a possibly more effective one. Ideally these reassessments should include both the

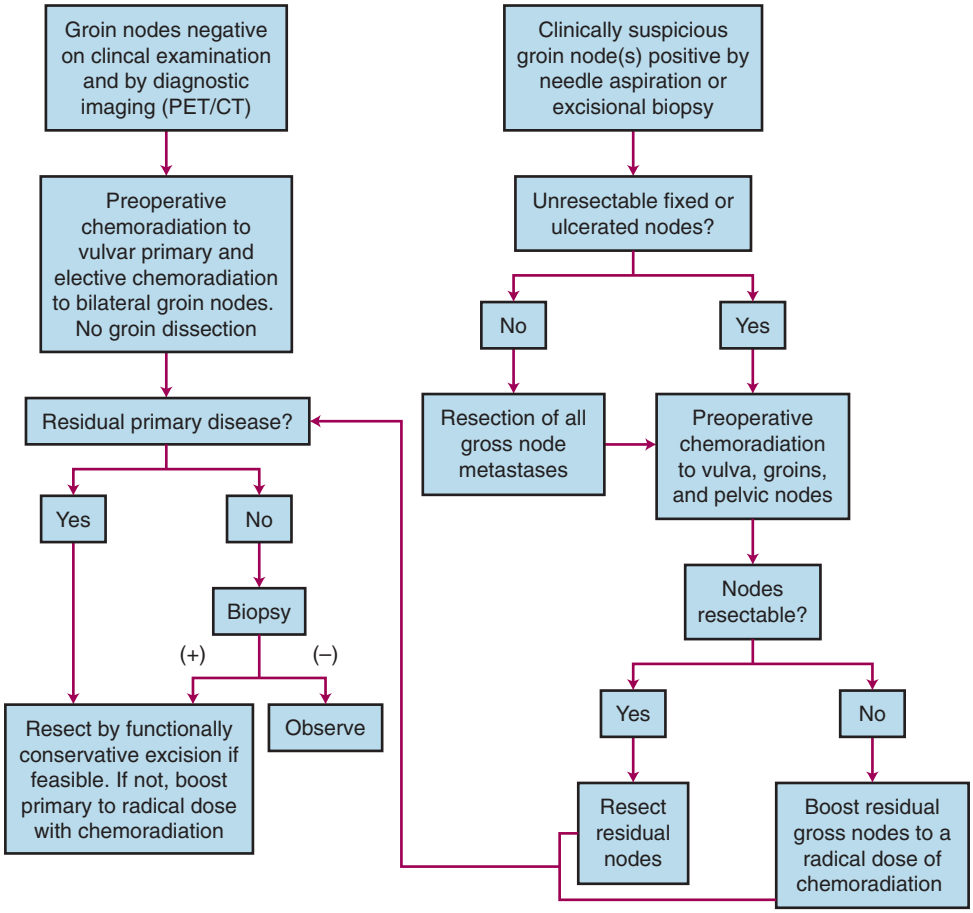

Figure 60-9 Treatment algorithm for extensive primary lesion encroaching on or invading functionally important midline structures (clitoris, urethra, vagina, anorectum) that cannot be surgically resected without potential compromise to the functional integrity of those structures. *PET-CT*, Positron emission tomography/computed tomography.

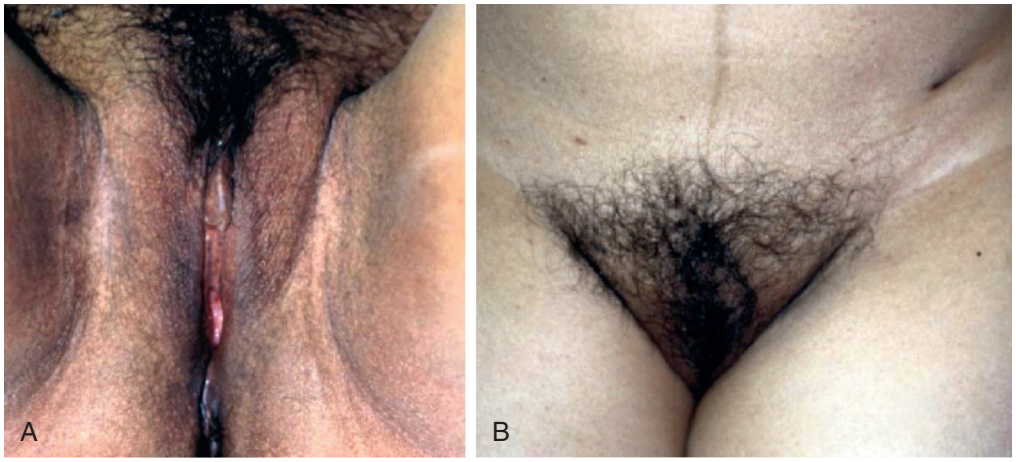

radiation oncologist and the gynecologic oncologist to determine the optimal integration of the modalities.

Locally Advanced Nodal Disease

When groin nodes are ulcerating or fixed, initial treatment of the inguinal regions consists of primary RT or chemoRT. Because it is unclear whether chemoRT in tolerable doses can reliably eradicate bulky nodal disease, if there is substantial regression of nodal disease after modest dose irradiation it is reasonable to subsequently operate to remove residual adenopathy rather than incur the possible attendant morbidity of completing radiation to a radical dose.

Patients with bulky involved nodes that are initially resectable may undergo either initial surgical removal of the bulky nodes followed by postoperative RT or chemoRT, or initial RT or chemoRT followed by operative removal of any residuum. The optimal sequencing of therapies remains controversial because surgery and its possible complications of problems with delayed wound healing or infection will delay initiation of RT, whereas preoperative RT or chemoRT may compromise wound healing. Commonly, patients with bulky inguinal nodes will also have locally advanced primary tumors, in which case initial RT or chemoRT is a logical sequence choice. Conversely, initial gross adenopathy may be difficult to reliably identify and excise after preoperative chemoRT, and a good case can be made for initial surgical removal if negative margins of resection can be achieved by R0 resection. If there is clinical uncertainty whether all gross adenopathy can be removed from the groins, imaging with US, CT, or MRI may aid in elucidating the spatial relationships between blood vessels, nerves, bone, and metastatic adenopathy. These imaging modalities may be particularly useful in defining disease extent in large patients in whom the femoral nodes lie deeper than can be realistically assessed by clinical palpation.

When combined therapy is used, regardless of the sequencing of therapies, to minimize complications, groin surgery should be limited to removal of gross nodes rather than an en bloc removal of all groin lymphatic tissue. It should be accomplished through the smallest feasible incision to accomplish this objective. The intent of such surgery is to reduce groin cancer volume to a microscopic, occult burden that can be controlled by modest doses of fractionated RT, or preferably chemoRT. Conversely, RT dose or chemoRT administered either before or after surgical cytoreduction should generally be restricted to an effective dose for controlling microscopic or occult disease (i.e., 45 Gy to 50 Gy in 1.8-Gy to 2-Gy fractions). By limiting the extent of groin dissection in anticipation of subsequent RT, and by limiting RT dose in anticipation of surgical removal of residual, bulky disease, some acute complications (wound dehiscence, infection) and late sequelae (lymphedema, femoral fracture, arterial occlusion) might be reduced in severity or avoided altogether (eFigure 60-14, *A* and *B*). At MGH, for patients with residual, unresectable node metastases after moderate dose neoadjuvant chemoRT (45 Gy to 50 Gy), limited volume boost radiation (plus concurrent chemo) is used to carry grossly involved nodes to 65 Gy.

eFigure 60-14 Clinical photographs obtained 10 years after completion of all treatment for a primary squamous cancer of the Bartholin's complex presenting with gross left inguinal adenopathy. Appreciating that postoperative radiation would be administered for multiple positive groin nodes as well as inadequate margins on the primary, initial surgery was limited to gross total local excision of the primary and ipsilateral groin dissection limited to removal of all enlarged nodes. Postoperative chemoradiation was administered with to a volume encompassing the residual vulva, the involved groin, next echelon nodes in the left pelvis, as well as contralateral groin nodes over and medial to the right femoral vessels. Radiation dose was limited to 45 Gy in 25 fractions of 1.8 Gy with two cycles of concurrent 5-fluorouracil and mitomycin-C. The patient remains cancer-free, continent of urine and feces, sexually active, and free of lymphedema.

Locally Recurrent or Metastatic Cancer

The outcome for patients who experience relapse of vulvar cancer after primary therapy is markedly dependent on the site of relapse. For the rare situation of distant metastases, chemotherapy with agents active against squamous cancer particularly as concurrent to radiation such as (5-FU, cisplatin, mitomycin-C) is often offered, but response rates and response durations are generally poor.[6,103,211-221] At this time, treatment with targeted agents remains investigational[222] (eFigure 60-15).

Although inguinal recurrences may be amenable to local management with RT or chemoRT, only occasional patients survive long term.[68,103,105,147,148] Several reports have suggested that up to 75% of patients with vulvar recurrence of cancer may be cured, with surgical reexcision.[68,223] Boronow et al reported a 5-year OS of 63% with modest-dose RT.[180] However, Faul et al reported only a 25% 2-year OS after vulvar recurrence.[141] The discrepancy in reported outcomes may relate to the site and extent of recurrence and what prior treatments have been given. RT or chemoRT for local recurrence is an option, particularly when the lesion is not amenable to repeat resection without predictably inadequate surgical margins or compromise of functionally important midline structures.[163,166,224]

IRRADIATION TECHNIQUES AND TOLERANCE

Groin and Nodal Irradiation

GOG 37, which established the usefulness of postoperative adjuvant groin and pelvic irradiation in patients with metastases to inguinofemoral nodes, used external beam radiation therapy (EBRT) bilaterally to the inguinal and femoral dissection beds and pelvic nodes even when node involvement was unilateral.[92] The specific radiation doses in the study—45 Gy to 50 Gy in 1.8-Gy to 2.0-Gy fractions—are commonly those prescribed to control of microscopic disease. The technique used was an anterior and posterior (AP) parallel, opposed pair of fields, a technique rarely appropriate now when more conformal techniques are available. The GOG study used a superior border somewhat arbitrarily placed at the L5-S1 interspace, although the value of extending the field to this level superiorly is uncertain as the observed survival gains appear to be related to improved control of the inguinal regions and not to improved control of the pelvic nodes. Treating this volume with this technique necessarily limits the radiation dose 45 Gy to 50 Gy because of normal tissue dose limitations (bowel, femoral necks, pelvic girdle).

Involved nodes located high in the pelvis or in the common iliac region connote a high probability of extrapelvic failure, and it is unclear that irradiation of the entire pelvic volume contributes to cancer control or survival. In the interest of reducing morbidity, it seems sensible to define nodal target volumes based on the principle of electively irradiating the next echelon of lymph nodes proximal to the lymph node group that is clinically involved. For patients with unilateral node metastases to inguinofemoral nodes without clinical or radiographic evidence of pelvic node metastases, the CTV can sensibly be limited to obturator and external iliac node groups on the affected (ipsilateral) side. Irradiation of hypogastric nodes and the contralateral external and obturator areas will rarely be indicated unless there is significant extension of the primary cancer proximal to the hymenal ring in the vagina or invasion of the urethra or rectum. The patient can be treated in the supine position with the feet apart or in the "frog-leg" position with leg supports to minimize skin reaction in the medial thigh. The central residual vulvar tissue may or may not be included depending on risk factors associated with the primary tumor and institutional philosophy. Each groin should be evaluated where bilateral spread is possible (midline lesions or involved ipsilateral nodes) and radiation directed to each side when there is an indication to do so (any involvement greater than a microscopic focus in a single node). The nodal volume is determined using CT planning. The necessity for specifically encompassing the inguinal lymphadenectomy scar is unclear because the incidence of scar recurrence is unknown. Depending on beam energies and technique employed, the tumor dose may be brought out to the skin. Generally, if a midline block is used because risk factors for local recurrence are minimal, it should be no wider than the distance between the pubic tubercles because it is intended only to reduce dose to midline structures (distal urethra, vagina, and anorectum) and residual vulva.

For patients with clinically and radiographically negative groin nodes in whom elective nodal irradiation or chemoRT is to be used without subsequent surgical dissection, the techniques and volume of RT are similar to those described for adjuvant therapy except that the superior border of the treatment volume may usually extend to midpelvis. Generally this will be done when preoperative RT or chemoRT is needed for a locally advanced vulvar primary and both groins should be included. The nodal bed including the deep femoral node depth should be confirmed by CT or US, particularly if techniques more sophisticated than parallel opposed AP photon fields are to be used. Conventionally, the CTV should be defined on the planning CT. The dose delivered must be substantially increased for patients with fixed or ulcerating (unresectable) lymph nodes. Although the optimal dose is not defined, a dose of 64 Gy to 67 Gy, usually in combination with multiple cycles of concurrent chemotherapy, may be necessary to provide the highest probability of locoregional control while remaining within the tolerance of adjacent normal tissues.

Several techniques have been used to minimize femoral neck dose (and risk of subsequent femoral neck fracture) include partial central transmission block technique; in dose to the deep groin nodes is prescribed through a large anterior photon field employing low-energy photons of 4 MV to 6 MV. Dose to deeper pelvic nodes and the vulva is calculated and supplemented by a smaller, opposed posterior pelvic field using photons of higher energy. A central partial transmission block is placed over the anterior field corresponding to the narrower posterior field that attenuates the contribution of the anterior field to the deep pelvic nodes and vulva, allowing better dose homogeneity. If the CTV is more superficial, dose may be further supplemented by administering a portion of the treatment with high-energy electrons. When abutting photon or photon and electron fields to encompass nodal tissue overlying the femoral necks, there is considerable potential for "hot" and "cold" spots. Hot spots may injure the femoral arteries as well as the femurs, and cold spots hazard disease recurrence within the CTV. Moving the field abutments once or twice during a course of treatment will serve to minimize these hazards.

Another technique used is the *modified segmental boost technique*. Right and left anterior oblique, partially beam-split photon fields are used to supplement groin node dose and is a technique suitable for any department with an isocentric linear accelerator with appropriate beam energies.[185,225] With this technique, the oblique fields are angled so the medial border of each anterior oblique field corresponds to the beam divergence of the lateral border of the posterior field, minimizing the potential for hot and cold spots. The tumor dose must be brought to the skin surface if there is evidence of cutaneous involvement. Bolus material may be required (Figure 60-10).

eFigure 60-15 A patient with regionally advanced squamous cancer of the vulva with necrotic (gauze packed) groin nodes ulcerating through skin. Concurrent 5-fluorouracil–based chemotherapy administration with radiation produced both rapid tumor involution at the primary site and groin nodes as well as accelerated reaction in surrounding skin. During treatment (electron boost therapy) previously unsuspected but subsequently biopsy confirmed discontiguous skin metastases *(white arrows)* were appreciated in skin of lower abdominal wall and upper lateral thigh documenting cancer progression while receiving chemotherapy in areas outside the irradiated volume.

Because vulvar neoplasia is often a field defect, second tumors may develop but are often labeled vulvar recurrences. New primary cancers often develop in sites remote from the initial tumor.[38] It is important, if possible, to differentiate a new occurrence of cancer from a recurrence because the latter would attribute a treatment failure to the original treatment modalities used and lead to an underestimate of the efficacy of the original therapy. Management of the groins is complex when a new cancer is detected and must depend on prior groin management.

Axial dose profiles employing various techniques are depicted in Figure 60-11, illustrating the magnitude of hot spots at the boundaries of treatment fields.

Depending on equipment availability, preferable technical alternatives include the use of IMRT. It is extremely important that the quality assurance measures are rigorous and oncologist technical expertise is satisfactory if IMRT is used. Patients appropriate for the substantially more conformal dose distributions that can be achieved with these alternatives should preferably be cooperative, thin, and amenable to precise and

eFigure 60-16 Dose distributions with intensity-modulated radiation therapy (IMRT) and intensity-modulated proton therapy therapy (IMPT) for 45 Gy to a clinical target volume (CTV) encompassing a recurrent squamous carcinoma of the vulva after wide local excision with a 7-mm surgical margin and a negative sentinel node biopsy. Recurrence was observed at 5 weeks following surgery with clinically rapid progression both in residual vulva and left groin. The advantage of IMPT is seen in reduced dose administered to femoral necks, ischial rami, and acetabular bone in anticipation of an ultimate requirement for high dose to be administered to both the left groin and the vulva. Comparative sparing of the boney structures underlying the left groin mass permits greater flexibility in administering boost radiation to this volume, which can also be carried out with proton beam. The IMRT plan was created using a seven-field (100 segments) beam arrangement with multicriteria optimization and collapsed cone algorithm. The proton beam scanning plan was generated using Astroid, an in-house treatment planning system at Massachusetts General Hospital. Protons in thousands of magnetically steered pencil beams are separately adjustable and optimized to achieve the prescribed dose. *Blue*, 20 Gy; *dark green,* 30 Gy; *grey,* 40 Gy; *light green,* 42 Gy; *orange,* 45 Gy (prescription dose); *red,* 47 Gy. Dose distributions courtesy of Peter Paetzold and Judith Adams, Division of Medical Physics, Department of Radiation Oncology, Massachusetts General Hospital, Boston, MA. **A,** IMRT dose distribution at the center of the groin mass and at the level of the distal vagina, inferior ischial rami, and lesser trochanters of the femurs. **B,** IMPT dose distribution at the center of the groin mass and at the level of the distal vagina, inferior ischial rami, and lesser trochanters of the femurs. **C,** IMRT dose distribution at the cephalad portion of the groin mass, femoral heads and acetabular regions with inguinal CTVs encompassing bilateral groins with generous margins. **D,** IMPT dose distribution at the cephalad portion of the groin mass *(red line)* with inguinal CTVs encompassing bilateral groins with generous margins *(pink lines)*.

reproducible daily setup because the potential for marginal miss is amplified by the tight tolerances used by these techniques. It is important that marginal miss is minimized by ensuring adequate planning target volume (PTV), even if doses to small volumes of normal structures approach those experienced with the old technique of a parallel pair. With IMRT, a somewhat greater degree of dose inhomogeneity within the target volumes is part of the price paid for more conformal therapy, which is more than offset by substantially reduced dose to tissues and structures not part of the target volumes.

A conformal dose distribution achievable with IMRT technique is seen in Figure 60-12. It is easily appreciated that the extra time and effort expended in planning and carrying out such treatment substantially reduces the dose to adjacent normal tissue, which are not included in the target volume. Arguably, absent the capacity or experience in sophisticated RT of this nature, facilities in the United States should refer patients for RT to suitably equipped and experienced tertiary centers capable of employing these more advanced techniques.

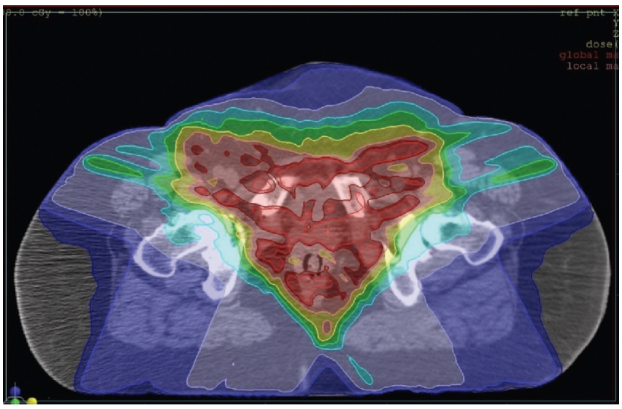

Figure 60-12 Intensity-modulated radiation therapy (IMRT) dose distribution for a patient with a posterior vulvovaginal cancer encroaching on the anal sphincter for whom the target volume included elective treatment of clinically and radiographically uninvolved inguinofemoral nodes. A small portion of the femoral heads receive up to 80% of the prescription dose. The femoral necks receive 70% to 25% of the prescription dose with a steep dose gradient between the subcapital proximal femoral neck and the femoral metaphysis. Coupled with the diminished impact of reduced total dose and dose per fraction, this technique is unlikely to result in radiation induced femoral insufficiency fractures. *Aqua,* 70% of prescribed dose; *blue,* 25%; *dark red,* 105%; *green,* 80%; *orange*, 100%; *purple,* 50%; *red,* 107%; *yellow*, 90%.

Under special circumstances, use of intensity-modulated proton beam (IMPT) can provide more conformal dose distribution than can be achieved by photon IMRT, which may be clinically advantageous when high-dose RT is required for tumors in close proximity to normal structures and surgery is not feasible (eFigure 60-16, *A-D*).

Guidelines for the treatment of primary vulvar cancers and regional nodes by IMRT are codified in GOG Protocol 279 and presented in abbreviated form in Tables 60-8 and 60-9.

It should be understood that selection of target volumes, choice of treatment technique, and prescription of RT dose and fractionation should be individualized based on tumor factors, patient comorbidities, availability of equipment, and sophistication of medical dosimetry support. Reference guidelines with respect to target volumes, dose, and dose limitations to volumes of organs at risk must be interpreted in the light of individual patient and tumor factors and should not be applied with uncritical rigidity. There can be no substitute for thoughtful consideration of all relevant clinical parameters and prudent deviation from guidelines when circumstances dictate this to be in the patient's best interest.

Adjuvant Postoperative Irradiation of the Vulva

When adjuvant irradiation to the vulva is indicated because of risk for local recurrence, an appositional perineal portal may be used with the patient in dorsal lithotomy position. Although often requiring daily physician verification of treatment setup, this permits precisely tailored volumes to be treated reproducibly. Just as surgical concepts are changing to limit radical excision to the site of the primary cancer rather than extirpation of the entire vulva, radiation volumes are also being modified. A localized field of radiation may be used to encompass the vulvar scar with an appropriate margin. This allows maximal sparing of uninvolved vulvar tissues from

TABLE 60-8 Target Volume Definitions from GOG Protocol 279

Vulvar Gross Tumor Volume (GTV)	Gross tumor as seen on radiographic imaging or as visible on clinical examination and delineated with surface markers on planning computed tomography
Inguinal Gross Tumor Volume (GTV)	Unresected or residual gross disease in the inguinalfemoral region as defined on any radiographic imaging
Vulvar Clinical Tumor Volume (CTV)	Vulvar GTV with 2-cm margin including skin and subcutaneous tissues but excluding bone unless bone involvement documented. When vulvar GTV involves vagina, a minimum of 2 cm of normal vagina to be included in CTV. When the vulvar GTV involves or extends to within 1 cm of the anal verge a minimum of 2 cm of anorectum to be included in CTV. When the vulvar GTV involves the urethra or periurethral tissue a minimum of 2 cm of urethra to be included in the CTV
Inguinal Clinical Tumor Volume (CTV)	In the absence of an inguinal GTV the CTV will extend 2.5 cm lateral and 3 cm medial to the nearest inguinal vessel as well as 2 cm anterior and 1 cm posterior to the vessels. The cephalad border is at the top of superior pubic rami. The caudal extent is the bottom of the lesser trochanter. Any postoperative changes from prior dissection should be included in the CTV. In the presence of inguinal GTV the CTV must include the GTV with a minimal expansion of 7 mm
Pelvic Nodal Clinical Tumor Volume (CTV)	Pelvic nodal CTV (when indicated) shall include bilateral external iliac, obturator, and internal iliac nodes defined by the vasculature of each region with a minimum 7-mm expansion
Planning Tumor Volume (PTV)	7-mm to 10-mm margin in all directions around vulvar, inguinal, and pelvic CTVs with bolus as needed to assure adequate skin dose

TABLE 60-9	Dose Constraints for Organs at Risk GOG Protocol 279
Small Bowel	<30% to receive 40 Gy or more Dmax 51 Gy or less
Anorectum	<80% to receive 40 Gy or more Dmax <65 Gy. This constraint should exclude any PTV that overlaps this volume
Bladder	<50% to receive 45 Gy or more Dmax 65 Gy or less
Femoral head/ neck	<50% to receive 45 Gy or more Dmax 55 Gy or less

Dose constraints are guidelines but cognizant of the fact that if following constraints rigidly tumor may be underdosed in which case adequate tumor dose is more important. In this circumstance the patient should be informed of increased risk of complications.

acute and late radiation reactions. This is in contradistinction to "guidelines" developed by the NRG, when RT to the entire vulva is suggested. When therapy is adjuvant, RT alone employing dose ≥56 Gy is recommended, depending in part on whether a margin is narrow or grossly contaminated, as well as on the health of the surrounding tissues. The role of concurrent chemoRT in this adjuvant setting is not established. The beam energy should be tailored to the estimated depth or thickness of the original lesion from the vulvar surface, with appropriate use of bolus to deliver the prescribed tumor dose to the skin of the vulva. Electron beam or a low-energy photon beam is employed.

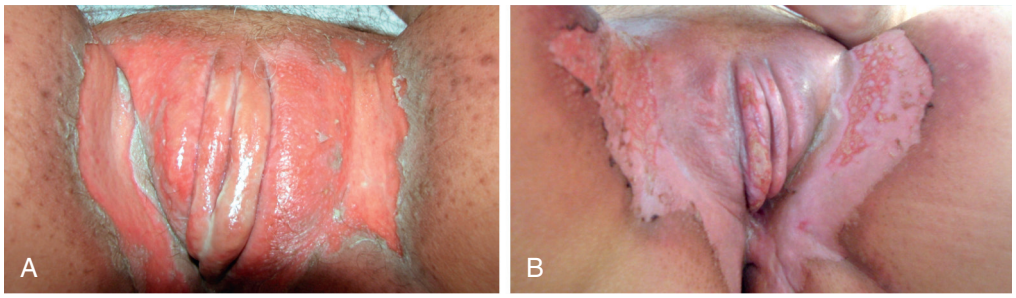
Preoperative or Definitive Vulvar Irradiation

When initial RT is selected for primary management of a small or early midline vulvar primary, a technique of irradiation may be used similar to that described for adjuvant treatment (i.e., a perineal portal tailored to the depth and thickness and size of the lesion) if the groin nodes will not be treated. Alternatively, a small volume may be irradiated with IMRT technique. More commonly, the target volume will include the groin nodes bilaterally. The majority of vulvar cancers are radioresponsive, and visible response to RT is often apparent after a tumor dose of 30 Gy to 36 Gy in factions of 1.8 Gy to 2.0 Gy. Because available dose-control data for vulvar cancer are scant and seldom correlated with the volume of disease treated, and because it is unknown to what extent the addition of concurrent chemotherapy will modify the total dose required to sterilize disease, dosage guidelines are imprecise. In general, concurrent chemotherapy (weekly cisplatin or infusional 5-FU with or without cisplatin or mitomycin C) is recommended for definitive treatment. If primary tumors shrink and become resectable, a preoperative dose of 45 Gy to 57.6 Gy should suffice. For medically inoperable patients or primary tumors which remain unresectable by conservative surgery, tumor doses should be escalated up to as high as 67 Gy. Total dose will be contingent on the fractionation employed, the elapsed time to complete treatment, and whether or not concurrent chemotherapy is employed. As the dose is increased, the risk of skin atrophy, fibrosis, and bone insufficiency fractures increases, complications that can be debilitating.

Because of the complexity of the three-dimensional contours of the vulva, perineum, and groins, thermoluminescent dosimeters placed on the tumor and in the cleft between the labia are a simple mechanism to confirm actual absorbed dose at the vulva. This permits tailoring compensatory measures should the dose inhomogeneity be excessive.

Because of the exquisite radiosensitivity of most vulvar cancers, the potential negative impact of protracted overall treatment time may be less than for other tumors. Data from GOG 101 with a planned split course of RT with a 2-week break and overall dose of only 47.6 Gy still revealed an approximate 30% complete pathologic response in advanced disease. Although planned split-course irradiation is believed to be undesirable, most patients develop confluent moist desquamation and require a short rest to allow epithelial regeneration before completing a planned definitive course of chemoRT to the vulva. Use of twice daily fractionation schemes may reduce overall elapsed treatment time while maximizing radiation-drug synergism. Twice-daily fractionation during reduced volume boost radiation to gross disease or a concomitant small-volume boost may also reduce overall duration of treatment. Because volumes are small, this can be accomplished without unacceptable acute RT toxicity.

Interstitial RT implants have been used by some, particularly for boosting bulky disease or boosting vaginal extension.[226,227] No randomized data are available to evaluate the relative benefits and toxicities of interstitial versus external boost irradiation. Potential pitfalls of interstitial techniques include difficulty in achieving dose homogeneity, potential increased late effects consequent to the unavoidable hot spots in tissues in direct contact with interstitial sources, and variability in intersource separations with patient movement and leg positioning. An illustration of adverse late sequelae in a patient with vulvar cancer treated with interstitial technique is seen in eFigure 60-17.



Radiation Tolerance and Treatment Sequelae

When vulvar radiation is used either as an adjuvant treatment to wide local excision or as definitive treatment, full tumor dose needs to be delivered to the skin and mucosal surfaces. Even when doses of 45 Gy to 54 Gy are given in the adjuvant setting, it is expected that almost all patients will experience some degree of desquamation. This may vary from patchy, moist desquamation to confluent, moist desquamation over the entire treatment volume. Generally, this reaction heals in the 2 weeks to 3 weeks after completion of RT. Because of the accelerated repopulation of normal squamous cells in the epidermis, healing of moist desquamation can be quite rapid (eFigure 60-18, *A* and *B*). The acute reaction is usually managed with symptomatic measures, including frequent sitz baths, exposure to air, application of topical ointments such as those used to treat superficial burns, and pain medication. In some situations, particularly in elderly, frail patients, hospitalization for skin care may be required. Many patients find sitz baths in reconstituted salt solutions of seawater particularly soothing. Irritation from passage of urine over the irradiated vulva can be avoided by voiding into water in a sitz bath. Depending on the volume treated, acute effects may include urethritis, cystitis, and proctitis. Watery diarrhea is unusual unless a full pelvic volume is irradiated, which is rarely appropriate.

The late effects of RT may include skin changes of atrophy or telangiectasis, which, in small volumes, are not usually functionally distressing. Some patients may experience more extensive skin atrophy and dense subcutaneous fibrosis (eFigure 60-5, *B*) depending on the volume necessarily carried to high dose. The development of mucosal or perineal ulcers is rare. Late effects on the vulva appear to be minimized by limiting the radiation fraction size to 1.6 Gy to 1.8 Gy and the volume of reduced target boost therapy. Inclusion of anorectum in boost volume treatment may result in chronic rectal bleeding (radiation proctitis) or fibrosis and stricture of the anal canal.

eFigure 60-17 Severe late radiation toxicity in a patient treated for locally advanced vulvar cancer with high-dose external and interstitial radiation exceeding 70 Gy. Although cancer was controlled, the patient required both urinary and fecal diversions for bladder and anorectal injury, and became narcotic dependent for control of perineal pain.

eFigure 60-18 **A,** Confluent moist desquamation in a patient whose treated volume encompassed the entire vulva. Photograph was taken 9 days after 47.6 Gy chemoradiation (5-fluorouracil/cisplatin regimen similar to GOG Protocol 101) when tiny islands of regenerating squamous epithelium are just beginning to appear. **B,** Six days later the desquamated area has largely reepithelialized. Of note, this patient was treated to a target volume (CTV) that would be considered excessive in the modern area, employing much less sophisticated techniques than are currently available (i.e., intensity-modulated radiation therapy).

Irradiation of the node-bearing areas may result in similar acute effects if full doses are required at the skin because of skin infiltration or ulceration, or when superficial groin nodes lie only millimeters below the skin in thin patients. Acute effects may vary from erythema to moist desquamation, particularly in intertriginous areas and along skinfolds.

The contribution of RT to the problem of leg edema induced by groin surgery is unknown. One series suggested that, after concurrent chemoRT, 4 of 14 surviving patients treated for advanced primary or recurrent disease experienced leg edema. In 2 patients this edema was minimal, not requiring treatment. Two patients did require treatment with compression and diuretics. Both had an inguinal lymphadenectomy before chemoRT.[166] Clearly the magnitude of the surgical intervention in the groins (sentinel node biopsy versus complete groin dissection) has major impact on the risk of lymphedema, with a 1.9% risk in patients undergoing only sentinel node biopsy compared to 25.2% in patients undergoing therapeutic inguinofemoral lymphadenectomy.[151] In a retrospective outcomes analysis, the extent of lymphadenectomy (gross total removal versus en bloc complete lymphadenectomy) did not appear to have a major impact on either disease control in the groin or survival when coupled with groin RT.[228] In the interests of minimizing the risk and severity of subsequent lymphedema and cellulitis, it seems prudent to limit groin dissection to removal of only grossly contaminated nodes when planned RT or chemoRT will follow.

RT to the groins may induce femoral neck fracture.[66,153] The risk of hip fracture may not correlate well with the dose delivered to the hips and may be more frequent in frail, elderly women with underlying osteoporosis.[229] Based on the anatomical study of sentinel node location by Rob et al,[122] a potential way to minimize the risk of this complication is to limit the groin target volumes laterally and use the planning CT to define the volume extending medially to the pubic tubercles when elective groin RT is performed in patients with clinically and radiographically negative groins. By excluding the lateral inguinal nodes as defined by Rob, the substantial majority of the femoral neck and metaphysis can be excluded from direct RT in most patients, when IMRT is not available to accomplish that objective.

Rarely, groin RT may induce hemodynamically significant femoral artery stenosis.[230] Fractures through the ischial rami may occasionally be seen in patients carried to higher RT dose for unresectable primary disease. RT insufficiency fractures are seen in eFigure 60-19.

Acute complications from chemoRT can be severe. Reviewing 5-FU with mitomycin-C or mitomycin-C alone used as concurrent radio-potentiators in the treatment of 17 patients with vulvar cancer, 35% developed grade-4 neutropenia and half of them developed neutropenic sepsis following their second cycle of chemotherapy.[231] About one quarter could not receive the second cycle of chemotherapy. Severe enterocolitis was a direct contributing cause of death in 2 patients. Skin toxicity necessitated treatment interruption in half of the patients at a median dose of 32.4 Gy (range 16.2 Gy to 48 Gy) and half required more than 9 weeks to complete therapy.[231] Because patients are often elderly, chemotherapy dose reductions should be considered for some.[232] Commonly most generally used concurrent chemotherapy is the familiar weekly cisplatin or 5-FU and cisplatin. Mitomycin-C has been associated with significant bowel toxicity and is rarely used.[224] Reduced bowel toxicity could be anticipated by the use of more conformal, contemporary RT techniques. Treatment interruption necessitated by severe acute RT dermatitis may delay treatment longer than the 7 days to 10 days generally needed. Usually chemoRT can be restarted when punctate epithelial islands are seen in areas of moist desquamation.

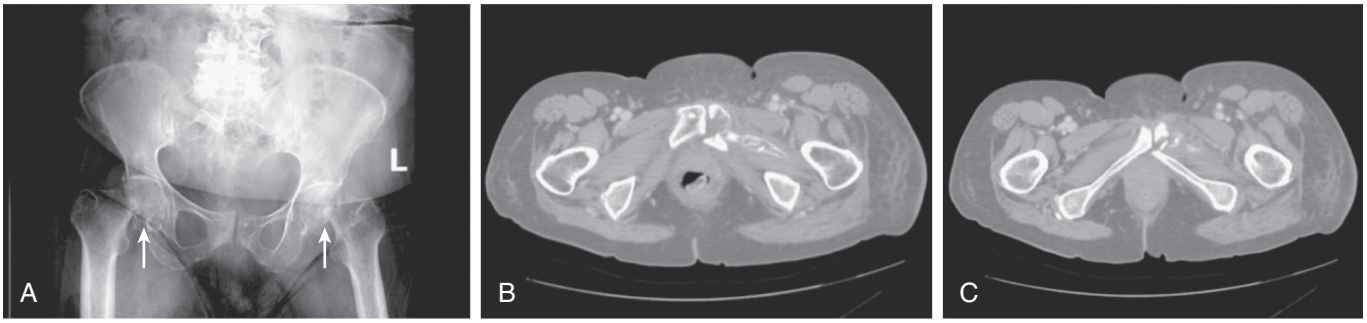
CHALLENGES, CONTROVERSIES, AND FUTURE POSSIBILITIES

Because of the diversity of clinical presentations, the relative rarity of the disease, and the availability of multiple effective treatment strategies, the systematic exploration of treatment options in Phase III clinical trials is difficult. For many questions, observational studies of outcomes after standardized therapy may be the best information available to guide future therapeutic choices. Several important questions remain to be addressed:

1. For resectable primary cancers involving the clitoris, lower urethra, or vaginal introitus, will primary surgery or primary chemoRT provide the best therapeutic ratio? Of particular relevance to this question would be a prospective comparison of both local cancer control as well as psychosexual and overall quality of life.
2. In advanced vulvar cancer, when chemoRT is selected for initial therapy, is it better to try to increase the RT dose sufficiently to eradicate disease, or is there less morbidity with a lower RT dose combined with planned conservative surgical removal of residual disease?
3. Does concurrent chemotherapy allow for the use of a decreased total RT dose or decreased RT dose per fraction with decreased late RT sequelae?
4. If concurrent chemotherapy is used, what agent(s) or combination of agents will provide the most effective radiosensitization with the least risk of serious acute toxicity?
5. Can appropriately planned chemoirradiation be used without compromising outcomes instead of complete inguinofemoral node dissection for patients with clinically and radiographically negative groin nodes or patients with microscopic nodal metastases detected by sentinel node biopsy?
6. When adjuvant groin and pelvic nodal irradiation is used, is it necessary to treat bilaterally if positive nodes are only unilateral?

An understanding of the answers to these questions will come from carefully documented reporting from centers where sufficient patients are treated in a uniform fashion and where techniques and doses of RT and the use of concomitant chemotherapy are carefully documented with respect to the site and extent of disease treated and the sites of cancer recurrence.

MISCELLANEOUS VULVAR MALIGNANCIES



Verrucous Carcinoma

Verrucous carcinoma of the vulva represents a variant of squamous cell carcinoma. These lesions were originally described as occurring in the oral cavity but have also been described involving the vagina, cervix, and vulva.

Metastases to regional lymph nodes are rare and radical local excision is the standard treatment.[46-49] Fine-needle aspiration or excisional biopsy should be carried out if there are suspicious groin nodes. Usually enlarged nodes will be caused by inflammation, but groin node dissections are indicated if metastases are detected. Verrucous carcinoma has a reputation of being radioresistant, and reports of favorable outcomes after RT are uncommon. Surgery remains the treatment of choice whenever feasible, with the use of RT limited to circumstances in which potentially curative surgery cannot be performed.[233]

Melanoma of the Vulva

Melanomas of the vulva are rare and constitute about 10% of all vulvar malignancies but account for more than half of

eFigure 60-19 **A,** Bilateral subcapital femoral fractures *(white arrows)* following elective groin irradiation employing technique that did not use intensity-modulated radiation therapy, delivering excessive, avoidable dose to femoral necks. **B,** Displaced left superior pubus radiation insufficiency fracture. **C,** Radiation-induced insufficiency fracture through inferior ischial ramus and pubic symphysis.

Lesions may grossly resemble cauliflower (eFigure 60-20). Generally large, pearly gray to white in color, this cancer characteristically invades with a sharply circumscribed pushing margin. Clinically, these tumors are usually slow growing.

Melanocytes arise from the neural crest in embryonic life and migrate to a variety of sites including skin, mucosal membranes of the oral cavity nasal and paranasal sinuses, larynx, esophagus, large bowel, anus, leptomeninges, vulva, vagina, and the eyes. Mucosal or mucocutaneous melanomas comprise less than 2% of all melanomas in the United States.[234]

eFigure 60-20 Locally recurrent verrucous carcinoma following radical vulvectomy.

mucosal melanomas in women. Even large, tertiary cancer referral centers will treat only one or two such patients annually.[55,235,236]

Three basic histologic types exist: (1) superficial spreading melanoma is most common and tends to remain superficial in its early course; (2) lentigo malignant melanoma is a "flat freckle" that has a tendency to remain superficial; and (3) nodular melanoma is the most aggressive variety, carries the worst prognosis, and tends to invade deeply early.[235] Prognosis and staging are based on measurements of tumor depth of penetration as described by the melanoma staging systems of Clark, Breslow, and Chung.[53-55] In a study of 71 surgically treated patients with primary malignant melanoma of the vulva, the AJCC 1992 TNM clinical stage was the factor with the highest significant correlation with relapse-free interval. Absent AJCC staging, Breslow's depth of invasion was the most prognostically important factor (Phillips GT 1994).[74]

Treatment

Surgery is the most important management for vulvar melanoma. It has become more conservative as the scope of surgery has minimal, if any, impact on prognosis providing complete excision can be achieved.[237,240] Surgical management is being individualized to take into account identification of the depth of tumor invasion as well as tumor size and location. Wide local excision of vulvar melanoma is used increasingly.[241,242] PET/CT and sentinel node groin biopsies may be tools to aid in tailoring the extent of regional surgery. Systemic therapies for vulvar melanoma parallel systemic strategies for cutaneous melanomas arising at other primary sites. However, the presence of KIT mutations in some patients with mucosal melanomas has led to clinical trials of tyrosine kinase inhibitors that have shown clinically significant response rates including anecdotal durable responses in patients with measurable metastatic disease.[243-245]

Common sites of relapse include the groin, perineum, and vaginal urethral margin, which often predate the clinical appearance of hematogenous metastases.[55,235,246-248] However, in contrast to patients with squamous cancers of the vulva, patients who die of melanoma usually have widespread metastases to parenchymal organs.

At present, RT has no established role in the routine management of vulvar melanomas, although anecdotal information suggests that melanoma arising in this location may be more radiosensitive than melanoma from other cutaneous sites.[249] Given the high local-regional recurrence rate following surgery (often extensive, sometimes mutilating), prospective investigation of adjuvant regional RT or chemoRT, either preoperatively or postoperatively, is warranted. RT may be used for palliation of symptomatic recurrent disease and for patients initially unresectable or those declining surgery.

Although 5-year OS as high as 50% have been reported, most series report 5-year OS of 15% to 30% except for patients with stage I disease.[236] Patients with nodal spread are uncommonly cured.[55] The 5-year OS with negative and positive nodes is 38% and 13%, respectively.[250]

As with melanoma arising at other sites, the spectrum of biologic virulence is broad. Recurrence or metastasis 10 years or more after initial treatment is not uncommon.[55,235,246,247]

Sarcomas

Primary sarcomas of the vagina are extremely rare in adults. Characteristically, these will arise subcutaneously and involve overlying skin secondarily (eFigure 60-21). Often, because primary tumors are bulky, treatment by conservative primary excision is not feasible. Preoperative RT or chemoRT is favored to permit ultimate surgical treatment with less than conventional margins employed for sarcomas in other anatomical locations.

Bartholin's Complex Carcinoma

The Bartholin's complex comprises a duct that is lined by squamous epithelium as it enters the vaginal vestibule. The more proximal portions of the ductal system are lined by transitional epithelium and may be lined by columnar epithelium before branching into secretory glandular elements. Squamous carcinoma (arising in ductal epithelium) constitutes approximately 35% to 50% of cases of Bartholin's complex carcinomas; adenocarcinoma is slightly less common.[251-255] Adenosquamous carcinomas and transitional cell carcinomas make up a small minority of cases. Adenoid cystic carcinoma[56] represents a distinct subset thought to be less likely to spread to regional nodes and associated with a long natural history and late local or hematogenous relapse.[57] Perineural invasion is a characteristic histologic feature of these tumors, and their appearance and behavior closely resembles that of morphologically similar tumors arising in salivary glands.

Because of anatomic proximity of the complex to both the inferior ischial ramus and the anorectum, adequate surgical margins are rarely obtained and management frequently entails combinations of conservative surgery and RT or primary therapy with chemoRT.[256] Recurrences in the contralateral groin have been recorded in patients with negative ipsilateral groin nodes, suggesting that both groins be treated even for a lateralized primary cancer.[82]

Malignant melanoma of the vulva occurs predominantly in postmenopausal Caucasian women, with a peak incidence between the sixth and seventh decades; however, the ratio of white-to-black incidence in the United States is dramatically lower than for cutaneous melanoma and the pathogenesis is presumed to be unrelated to ultraviolet light exposure.[234] These lesions may arise de novo or from preexisting junctional or compound nevi.

Reinforcing the concept that mucocutaneous melanomas should be evaluated and potentially treated differently than cutaneous melanomas are the observations of different rates of driver mutations detected in these entities. BRAF (serine/threonine kinase) mutations are common in cutaneous melanoma but rare in mucosal melanoma. KIT (receptor tyrosine kinase) are significantly more common in mucosal melanoma than cutaneous melanoma.[237]

The AJCC 2009 cutaneous melanoma TNM staging formalism is depicted in eTable 60-1. As a rough approximation, prognosis of melanoma of the vulva parallels prognosis by stage of cutaneous melanomas, but overall prognosis is worse because of characteristically advanced stage at the time of diagnosis.[238]

Because of the clinical radioresistance of melanoma and the poor tolerance of the vulva and perineal skin to high-dose radiation, the addition of synchronous radio-potentiating chemotherapy to conventionally fractionated radiation would seem to merit investigation.

eTABLE 60-1 American Joint Commission on Cancer 2009 Cutaneous Melanoma[239]

Classification	Thickness (mm)	Ulceration Status/Mitoses
T		
Tis	NA	NA
T1	≤1.00	a: Without ulceration and mitosis <1/mm^2 b: With ulceration or mitoses ≥1/mm^2
T2	1.01-2.00	a: Without ulceration b: With ulceration
T3	2.01-4.00	a: Without ulceration b: With ulceration
T4	>4.00	a: Without ulceration b: With ulceration
N	No. of Metastatic Nodes	Nodal Metastatic Burden
N0	0	NA
N1	1	a: Micrometastasis* b: Macrometastasis†
N2	2-3	a: Micrometastasis* b: Macrometastasis† c: In transit metastases/satellites without metastatic nodes
N3	4 + metastatic nodes, or matted nodes, or in transit metastases/satellites with metastatic nodes	
M	Site	Serum LDH
MO	No distant metastases	NA
M1a	Distant skin, subcutaneous or nodal metastases	Normal
M1b	Lung metastases	Normal
M1c	All other visceral metastases Any distant metastasis	Normal Elevated

*Micrometastases are diagnosed after sentinel lymph node biopsy.
†Macrometastases are defined as clinically detectable node metastases confirmed pathologically.

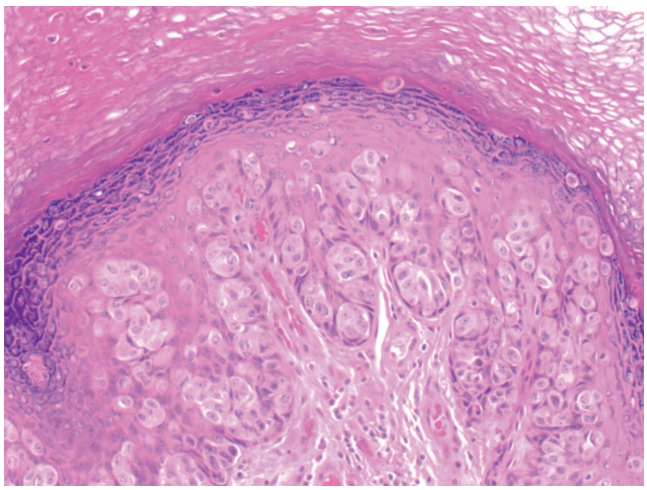
**Clinical staging includes microstaging of the primary melanoma and clinical/radiologic evaluation for metastases. By convention, it should be used after complete excision of the primary melanoma with clinical assessment for regional and distant metastases.*

†Pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes after partial (i.e., sentinel node biopsy) or complete lymphadenectomy. Patients with pathologic stage 0 or stage IA disease are the exception; they do not require pathologic evaluation of their lymph nodes.



eFigure 60-21 Primary vulvar sarcoma. Epithelioid sarcoma of the vulva in a young woman arising subcutaneously in the right labia with secondary invasion and satellite lesions in skin. Prominent engorged tumor blood vessels can be seen through overlying skin. Successful local management was accomplished with preoperative chemoradiation and conservative surgery with extensive plastic reconstruction including rectus abdominis muscle flap.

Other than the special problems associated with treating tumors in proximity to multiple functionally important structures, there is nothing that distinguishes treatment of vulvar sarcomas from the treatment of soft tissue sarcomas at other sites.

Delay in diagnosis is common as Bartholin's complex cancers often present without as a mass without clinical involvement of the overlying vulvar skin and may initially be misdiagnosed as a Bartholin's gland cyst or abcess. Bleeding is usually a late symptom when cancer protrudes from the duct orifice in the vaginal vestibule.

Paget's Disease

Paget's disease of the vulva is a cutaneous change morphologically similar to Paget's disease of the breast (nipple) characterized histologically by large, vacuolated pathognomonic Paget's cells with bluish cytoplasm located in the basal layer of the vulvar epithelium (eFigure 60-22). Paget's disease often presents as an eczematoid "weeping" lesion that may be intensely pruritic. Paget's disease of the vulva is associated with an underlying in situ or invasive neoplasm in approximately 10% of cases. These include adnexal apocrine skin carcinomas, carcinomas of Bartholin's complex, and cancers of the urethra, bladder, vagina, cervix, endometrium, and rectum. Treatment is surgical, with cutaneous recurrences common. Negative surgical margins are difficult to obtain because "pagetoid" changes may extend microscopically in the epidermis well beyond the margins of what can be appreciated on clinical examination. Negative surgical margins have only limited correlation with freedom from local relapse. Micrographic (Mohs's) surgical technique has been advocated for Paget's disease as a means to achieve negative margins with less extensive surgical extirpation; however, this technique has not been proven to yield superior results.[257] Rarely, Paget's disease may become invasive, and metastases to groin nodes have been reported.[258-266] Management including RT has been reported with anecdotal favorable outcomes both in patients with invasive and noninvasive Paget's disease.[267-270] We recommend employing RT doses of 40 Gy to 56 Gy when surgery is medically unfeasible or could be functionally mutilating consequent to the location of the disease.

CARCINOMA OF THE VAGINA

INCIDENCE

Vaginal cancer will account for about 4070 new cancer cases and 910 cancer deaths in the United States in 2015, comprising approximately 0.35% of all cancers in women, 3.1% of gynecologic malignancies, 0.31% of cancer deaths in women, and 3.0% of gynecologic cancer deaths. Seventy percent of patients are age 60 or older.

PATHOLOGY AND BIOLOGIC CHARACTERISTICS

The majority of lesions (80%) are squamous cell carcinoma. The second-most common type is melanoma. Sarcomas and lymphomas may be primary in the vagina. Adenocarcinomas are commonly metastatic from other primary sites (uterus, colon, ovary, kidney, breast) with the exception of primary clear cell cancers. True primary adenocarcinomas of the vagina are extremely rare.

STAGING EVALUATION

FIGO staging includes clinical assessment of the pelvis, chest radiograph, and renal evaluation. Depending on the clinical situation, CT, MRI, and PET/CT may be used to assess local and nodal extent of disease, but findings do not alter FIGO stage. Cystoscopy and proctoscopy may be appropriate when primary disease is extensive and involves the anterior vagina or rectovaginal septum. Patients with vaginal adenocarcinoma should be assessed for potential primaries arising in other organs. Patients with melanoma require systemic evaluation.

PRIMARY THERAPY

Patients with vaginal intraepithelial neoplasia (VAIN) may be treated with local excision, laser ablation, topical 5-FU, or RT.

Primary therapy for invasive disease usually consists of external and intracavitary or interstitial RT, except in highly selected early cases that may be treated surgically with local excision or with brachytherapy alone. Frequently, concurrent chemotherapy is administered, extrapolating from the beneficial results proven for patients with cancers of the cervix and anus.

Radical surgery, intended as monotherapy, may entail partial or total pelvic exenteration, and as such is generally reserved for salvage of isolated pelvic recurrence after RT and as primary therapy for patients with vesico-vaginal or recto-vaginal fistulas at diagnosis.

Five-year actuarial cancer-free survival in patients treated with RT alone or chemoRT with outcomes are similar stage for stage with those for cervical cancer; approaches 100% in stage 0, 85% in stage I, and 75% in stage II, but only 30% to 50% in stage III disease. Long-term cancer-free survival is rare for patients with stage IVA disease is anecdotal and generally less than 20%.

Patients who experience relapse usually do so within 2 years. Most patients will manifest local-regional persistence or recurrence as a component of the pattern of failure. Distant failure alone without antecedent local-regional failure is seen in less than 30% of relapsing patients.

ADJUVANT THERAPY

Concurrent chemotherapy with RT has been reported with favorable results in a small number of patients, paralleling similar treatment for anal, cervical, and vulvar cancers. Randomized, controlled trials comparing chemoradiation to radiation alone have not been performed.

SALVAGE

Radical surgery, usually exenterative, may be appropriate for persistent or locally recurrent disease, but the likelihood of salvage is low.

PALLIATION

Individualized irradiation may be effective to reduce local symptoms. Chemotherapy as with cervical cancer is generally minimally effective for disseminated disease.

Primary invasive cancer of the vagina is rare. According to the FIGO staging formalism, a cancer of the vagina that involves either the cervical os or the vulva must be classified as arising from that structure, even if the tumor epicenter appears to be in the vagina. Only if involvement of these adjacent organs can be excluded can an invasive cancer of the vagina be classified as primary. Because of the infrequency with which the disease occurs, standardized therapeutic approaches have not evolved, and few centers have extensive experience with these tumors.

Approximately 80% of vaginal malignancies are squamous cancers,[271] and the following discussion refers to squamous disease of the vagina except when otherwise stated.

ETIOLOGY AND EPIDEMIOLOGY

Approximately 70% of primary vaginal malignancies are detected in women 60 years of age or older and approximately 60% in patients older than 70 years of age.[271,272]

In a population-based case-control study of 156 women with VAIN or invasive vaginal cancer, number of lifetime sexual partners (>5), early onset of intercourse (age <17), and current smoking were identified as lifestyle risk factors. Antibodies to HPV 16 were much more common in VAIN and cancer patients than controls. Approximately 30% of patients had a history of treatment for a prior anogenital in situ or invasive malignancy, most commonly of the cervix.[273] Early hysterectomy appears to be a risk factor in some studies, but only if done for malignant or premalignant disease.[273,274]

In a review of recently published data, HPV DNA is detected in 64% to 91% of invasive vaginal cancers and 82% to 100% of VAIN grade 3.[275] HPV 16 serotype is the most common, detected in 55.4% of invasive cancers and 65.8% of VAIN grades 2 and 3.[276] Detection of HPV in invasive cancer has been reported to be associated in better DFS and OS independent of age and stage in patients with stages I and II disease.[277]

The criteria for considering a vaginal squamous carcinoma as primary include vaginal location (it should not involve the external cervical os or vulva) and a specified length of time. Approximately 5 years should have elapsed from a previous diagnosis of cervical or vulvar cancer.

Immunosuppression (e.g., among organ transplant patients) predisposes to lower genital tract intraepithelial neoplasia, including VAIN, although a higher incidence of invasive vaginal cancer has not been demonstrated. Previous ionizing radiation for prior malignancy may also predispose to VAIN or vaginal cancer, usually after a latent period of many years,[278] suggesting that RT may a contributing factor in some patients. Given the similarly increased incidence of

vaginal cancer after surgical treatment of cervical malignancy, multiple factors may contribute.

The natural history of VAIN is not precisely known and its potential to progress to invasive squamous malignancy is not known with precision. In most VAIN series there is a clinically significant incidence of subsequent invasive vaginal cancer. The congruence of risk factors for VAIN and invasive disease[273] and the younger average age of patients with VAIN in comparison to patients with invasive disease, gives credence to the theory that VAIN is a precursor lesion in some, if not all, patients with invasive disease.

Aho et al identified 23 patients with VAIN followed for at least 3 years without treatment.[279] The mean age was 41. Half of the VAIN lesions were multifocal and half were associated with either CIN or vulvar dysplasia. The spontaneous regression rate of VAIN was high (78%) including 4 of 5 VAIN grade 3 patients, but two cases (9%) progressed to invasive cancer. Three studies have shown that only 2% to 5% of patients with VAIN treated with various methods progress to having invasive vaginal carcinoma.[278-280]

The normal vagina does not contain glandular elements, thus primary adenocarcinomas of the vagina are rare. Most commonly, adenocarcinomas involving the vagina are metastases from other organs. Common primary sites include the uterine corpus, ovaries, kidneys, breast, colon, and rectum.[281] Direct extension from primary adenocarcinomas in the cervix, Bartholin's glands, or paraurethral Skene's glands may involve the vagina but should be clinically apparent on physical examination.

The clear cell variant of vaginal adenocarcinoma (CCAC) has been linked to in utero exposure to the synthetic estrogen diethylstilbestrol (DES) that was used in the late 1940s, 1950s, and 1960s to support high-risk pregnancies and prevent threatened spontaneous abortion.[282] Despite minimal evidence of efficacy, use was continued until it was banned for use in pregnancy in 1975. Vaginal adenosis, morphologically identical to rare cases of vaginal adenosis in women born before the DES era, has been detected in approximately one third of patients with in utero DES exposure. Three patterns of adenosis have been described: mucinous (resembling endocervical glands), tubo-endometrial, and embryonic.[283,284] Clear cell cancer of the vagina is associated with vaginal adenosis in as many as 95% of cases, most commonly the tubo-endometrial morphology, implicating adenosis as the cell-line of origin.[285,286] The Registry for Research on Hormonal Transplacental Carcinogenesis accessioned more than 580 cases of clear cell carcinoma of the vagina and cervix. In utero exposure to synthetic estrogens accounted for approximately two thirds of reported cases, leaving a significant number of cases unexplained. Work in the United States and the Netherlands suggested that the age distribution for clear cell adenocarcinoma of the vagina has two separate peaks.[287-289] The first peak contained women with a mean age of 26, and the second peak contained women with a mean age of 71 years.[289] The first peak contained all DES daughters, and the second peak contained women born well before 1950 and thus not exposed to DES. However, even when the DES daughters were excluded, a bimodal pattern was observed. The age range of DES-related clear cell adenocarcinoma is 7 years to 42 years. As gestational DES use was discontinued in 1975, it is probable that this peak in younger women will largely disappear. The actual risk of DES-exposed women developing clear cell adenocarcinoma is estimated at only 1 in 1000, with the highest risk in those women exposed before 12 weeks' gestation.[290] Rare patients with endometriotic implants in the vagina (seen after obstetrical or other injury, in an episiotomy scar, or in the vaginal apex scar after hysterectomy) may also develop clear cell cancer or other adenocarcinomas arising within the endometriosis.

PREVENTION AND EARLY DETECTION

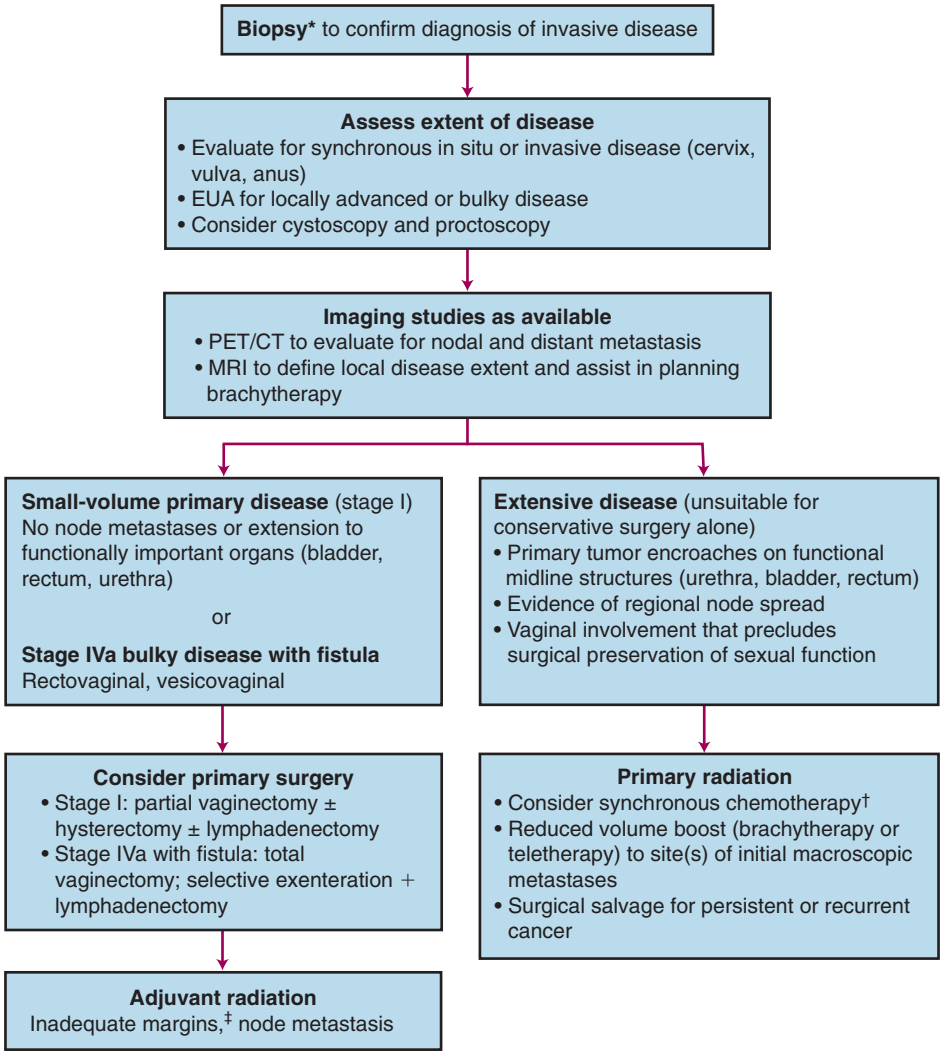
Because of the strong evidence implicating HPV in the pathogenesis of most squamous cancers of the vagina and the predominance of the HPV 16 serotype, encouraging results from Phase III trials of HPV vaccines suggest that substantial reductions can be expected in the incidence of VAIN and in invasive vaginal malignancies if prophylactic immunization is widely implemented.[40]

Although many cases of VAIN spontaneously involute without therapeutic intervention, some do not. A policy of longitudinal surveillance and effective treatment for patients with persistent VAIN will likely reduce the risk of development of invasive cancer in those individuals in whom high-grade VAIN is a precursor lesion.

There is no consensus regarding the utility of routine vaginal vault screening after hysterectomy. Although early detection clearly benefits the woman in whom vaginal cancer is destined to develop, based on the low frequency of the disease and the limited apparent effectiveness of vaginal cytology to make the diagnosis, "there is insufficient evidence to recommend routine vaginal smear screening in women after total hysterectomy for benign disease."[291,292]

If a vaginal smear is done, the histologic and cytologic criteria for VAIN and invasive vaginal cancer parallel those for cervical lesions. In postmenopausal women or women with a history of vaginal RT related to prior treatment of cervical cancer, distinguishing dysplasia from inflammatory or post-RT changes can be difficult because atrophy and radiation effects can mimic the features seen in neoplasia. Topical estrogen therapy before sampling of the vagina may minimize atrophic and inflammatory changes and may facilitate more accurate assessment of specimens.

PATHOLOGY AND PATHWAYS OF SPREAD



The majority of lesions (80%) are squamous cell carcinoma. The second-most common histology is melanoma. Sarcomas and lymphomas may be primary in the vagina. Adenocarcinomas are commonly metastatic from other primary sites (uterus, colon, ovary, kidney, breast) with the exception of primary clear cell cancers. True primary adenocarcinomas of the vagina are rare.

Most vaginal cancers involve the upper two thirds of the vagina where direct extension can involve the adjacent parametria, paracolpos, bladder, or rectum. Normal lymphatic drainage of the proximal third to one half of the vagina parallels that of the cervix: via the obturator nodes to the external iliac, internal iliac (hypogastric), and common iliac nodes. Lesions of the lower third of the vagina may follow vulvar lymphatic drainage patterns to the inguinal-femoral nodes and subsequently to the pelvic nodes. Lesions infiltrating the rectovaginal septum may spread to pararectal and presacral nodes. Interconnections between lymphatic channels do exist. Pathways of potential lymphatic metastases, however, may have been altered by prior surgery (e.g., hysterectomy with or without pelvic lymphadenectomy).

Hematogenous dissemination is rare at diagnosis except in patients with far advanced, neglected lesions.

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Presenting symptoms of early disease include bleeding including contact bleeding, discharge, pruritus, and dyspareunia. Pain and alterations of urinary bladder or anorectal function are associated with locally advanced disease.

*Wide excisional biopsy: appropriate in small stage I lesions if not functionally deforming.
†Value of synchronous chemoradiation unproven for vaginal cancer at this time.
‡Margins ≤5 mm (arbitrary).

Figure 60-13 Diagnostic and therapeutic algorithm for invasive squamous cell cancer of the vagina. An *asterisk* indicates wide excisional biopsy that is appropriate for small stage I lesions if it is not functionally deforming; a *dagger* indicates that the value of synchronous chemotherapy (chemoradiation) is unproved for vaginal cancer; and the *double dagger* indicates margins of less than 5 mm (arbitrary measure). *CT,* Computed tomography; *EUA,* examination under anesthesia; *MRI,* magnetic resonance imaging; *PET,* positron emission tomography.

A diagnostic algorithm for invasive cancer of the vagina is depicted in Figure 60-13. Confirmation of invasive disease should be obtained by biopsy. In selected patients in whom excisional biopsy can be accomplished without functional compromise, wide local excision may be diagnostic and therapeutic in limited disease without risk factors.

Critical in planning therapy is definition of disease extent. Staging includes careful clinical examination of the vagina and pelvis, possibly under anesthesia, with careful examination of the cervix and vulva to exclude involvement of those sites. Colposcopy, cystourethroscopy, anoscopy, and proctoscopy will aid in the evaluation of primary disease extent and in screening for synchronous primaries of the cervix, vulva, and anus. Cystoscopy and proctosigmoidoscopy should be considered in women with locally advanced disease or with bladder or bowel symptoms.

Assessment of the pelvic and groin nodes by CT, MRI, or PET/CT is advisable to plan treatment in most cases of invasive disease, although results do not affect assignment of FIGO clinical stage. MRI may supplement physical examination in assessing primary disease extent and is superior to CT in distinguishing soft-tissue tumor extensions. Effective use of MRI requires contrast administration (gadolinium) and selection of the correct pulse sequences optimized for visualization of pelvic soft tissues. MRI findings may helpful in planning radiation dose distributions, particularly for brachytherapy techniques and in the design of reduced boost volumes for EBRT. Although the value of PET has not been investigated extensively in vaginal cancer,[293] its use to evaluate regional node metastasis and distant metastasis is rational, similar to that in cervical cancer. PET/CT is preferred to PET alone because of improved spatial resolution and ability to distinguish pelvic lymph node involvement from nonspecific fluorodeoxyglucose (FDG) activity in bowel. None of these imaging technologies will alter assignment of FIGO clinical stage. However, results of imaging may importantly

impact on selection, sequencing, and intensity of treatment modalities.

Patients are staged using the AJCC TNM formalism or, more commonly, the FIGO formalism (Table 60-10).

PRIMARY THERAPY

VAIN

VAIN may be multifocal in the vagina in up to 60% of patients,[296] and is best localized by colposcopy and iodine staining, with careful attention being paid to the vaginal vault angles, which are commonly distorted by previous hysterectomy. Among low-grade lesions, there appears to be significant spontaneous regression.

Treatments with surgical excision, laser vaporization, and intravaginal topical 5-FU have proven partially effective.[278,280,297] Local excision, when feasible without functional compromise, is the treatment associated with lowest risk of recurrence, but it is limited in applicability because the disease is so frequently multifocal. Recurrence following laser vaporization has been reported in 38% of cases, and recurrence after topical vaginal 5-FU in 59%.[296]

For selected cases, intracavitary brachytherapy alone may be employed,[280,298-301] but in general it should not be selected as first-line therapy because of the risks of long-term radiation effects including secondary carcinogenesis, particularly if considered for young patients. Usually RT is reserved for patients relapsing after conservative therapies. Control of VAIN by intracavitary brachytherapy alone approaches 100%, although late recurrences are occasionally observed.[301] Prospective data are not available regarding alterations in vaginal depth and diameter, elasticity, sexual function, and quality of life following vaginal brachytherapy.

Invasive Cancer

Primary vaginal malignancies are rare. Single-institution treatment outcome reports retrospectively analyze limited numbers of patients often spanning multiple decades during which diagnostic techniques and management philosophies have evolved rather than remaining static. Because of the correlation of prognosis with stage and tumor size and the fact that treatments feasible for earlier stage, smaller primaries without nodal spread may be quite different than management strategies for patients with more extensive disease, it is difficult to compare outcomes reflecting different therapeutic techniques and modalities. Treatment is often individualized using general principles of oncologic management with chemoRT or RT and tailored on the basis of tumor location and extent and the constraining comorbidities of an individual patient.

Rationale and General Principles

Radical irradiation constitutes the treatment of choice for most patients with vaginal cancer. Primary surgery is appropriate in the earliest of invasive lesions when curative or potentially curative resection can be achieved without exenteration or functionally morbid surgery. Generally this is feasible only for stage 1 lesions at or near the vaginal apex or well-laterized lesions in the distal vagina. Primary surgery may be appropriate for rare patients who present with primary disease–related fistulae that require surgery for restoration of continence. The magnitude of surgical intervention may be quite variable as reported from a single institution with a strong surgical bias[302] (Table 60-11).

Primary surgery may also be used in patients previously irradiated for other malignancies because further radical radiation is only rarely an option. Given the intimate proximity of bowel and bladder to the vagina, exenterative surgery is usually necessary to achieve clear margins and to promote postsurgical healing.

Tjalma et al[302] reported surgical results in 37 patients (26 stage I, 6 stage II, 2 stage III, and 3 stage IV) employing the surgical procedures detailed in Table 60-11. Seven patients received postoperative RT for incomplete excision or node metastasis. Five-year and 10-year OS were 92% and 74%, respectively, for patients managed with surgery alone, and 5-year OS was 71% for patients undergoing combined-modality therapy. Five of 37 patients (14%) in this surgical series were treated with exenterative procedures and may have

TABLE 60-11 Range of Surgical Treatments Used According to FIGO Stage[302]

FIGO Stage	Surgical Treatment
I	Partial or total vaginectomy Radical hystero/vaginectomy, ± pelvic ± paraaortic node dissection; inguinal node dissection for lower third of vagina
II	Partial or total vaginectomy + parametrectectomy + paracolpectomy + Pelvic ± paraaortic node dissection
III	Radical hystero/vaginectomy, + parametrectomy + pelvic/inguinal node, ± paraaortic node dissection
IV	Exenterative surgery, usually total with formation of urinary and bowel bypass

n.s., *percentage not stated.*

been amenable to organ-conserving therapy with RT-based treatment with surgery reserved for salvage of persistent or recurrent disease. Three additional patients with stage IV disease had exenterative procedures.[302]

Eighteen patients in the series reported by Tjalma et al were managed with primary radiotherapy (1 stage I, 6 stage II, 4 stage III, and 7 stage IV) with 44% alive at 5 years and 35% alive at 10 years. These observational data do not permit comparison of the relative efficacy and morbidity of treatment modalities employed. Pelvic exenteration was employed to treat 2 patients with stage I disease and 1 patient with stage III disease in this series. Anterior exenteration was employed to treat 2 patients with stage II disease.

No widely accepted standardized treatment technique has been developed for RT treatment of vaginal cancer. Generally, brachytherapy may be employed alone in highly selected cases where the thickness and extent of disease may be encompassed by adequate tumoricidal dose; EBRT is often used in conjunction with a brachytherapy boost depending on the local and regional extent of disease. EBRT or concurrent chemoRT alone is employed for patients with locally extensive or bulky disease. Brachytherapy may include intravaginal sources such as a symmetrical cylinder or "Miami type" applicator or interstitial needle implants done freehand or with custom templates. Custom molds or partially shielded intravaginal cylinders can be used to selectively administer higher dose radiation to only a portion of the length and diameter of the vagina. Generally patients with early disease receive a higher proportion of their dose from brachytherapy, whereas those with more advanced pelvic disease receive a greater component of their dose from EBRT. Where the tumor volume cannot be encompassed with a brachytherapy boost a small volume IMRT field may be used to boost gross disease.

The principles of RT include treating the draining regional lymph nodes when there is a risk of nodal involvement. Because lesions of the lower third of the vagina have the potential to metastasize to inguinal lymph nodes, it is usual in this situation to electively include the medial inguinal lymph nodes in the RT volume. Relapse in nodes lateral to the femoral vessels is extremely rare. However, when groin nodes are involved, the entire inguinofemoral group of nodes may be irradiated employing techniques similar to those employed for groin irradiation in patients with primary vulvar cancers.

Usually 40 Gy to 50 Gy is delivered using EBRT to the whole pelvis, and intracavitary or interstitial irradiation is used to bring the primary tumor dose up to between 65 Gy to 75 Gy. A broad range of tumor doses are quoted in the literature, but it is important to understand which point or volume received the stated dose because there is a rapid fall-off in dose from intracavitary sources. For example, the brachytherapy dose at 5 mm depth may be 75% or less of the vaginal mucosal dose, accounting for at least some of the width of the spectrum of quoted radiation dose employed in patients treated for cure. Doses in excess of 80 Gy have been employed in some patients with increased risk of late complications, and a total dose between 70 Gy and 80 Gy has been recommended when radiation alone is employed, although obviously some tumor volumes are too large to encompass with more than 65 Gy to 75 Gy.[304]

Results

Series from single institutions often span multiple decades during which diagnostic assessments of tumor extent have changed, treatment strategies and techniques have changed and there is heterogeneity of cell type and tumor extent with some having prior treatment for other primary pelvic cancers. Outcomes analyses are thus challenging to interpret. Because treatment techniques (brachytherapy alone, EBRT alone, combinations of EBRT and intracavitary or interstitial brachytherapy) and total radiation dose appropriately vary with stage, disease distribution, and tumor size, it is difficult to make any statement regarding comparative efficacy of radiotherapeutic modalities, techniques, or doses.

In a series of 26 cases of non-diethylstilbestrol related adenocarcinomas of the vagina treated with radiation at the MDACC, Frank et al[305] reported statistically significantly lower rates of pelvic control (31% versus 81%) and OS (34% versus 58%) and higher rates of distant metastatic spread at 5 years (39% versus 15%) than in patients with primary squamous cancers treated at the same institution. Similarly, melanoma of the vagina is associated with a grim prognosis, and should not be pooled with squamous cancers in analyzing treatment efficacy and survival.[246,306,307]

Mature outcomes from an unusually large series of 193 patients with primary squamous cancers of the vagina spanning 30 years at the MDACC were reported with regard to pelvic control and DSS at 5 years (Table 60-12). This series consisted exclusively of previously untreated patients treated wholly, or predominantly, with RT.[308]

Neoadjuvant chemotherapy followed by surgery has been reported in a limited number of patients with stage II disease. Three cycles of paclitaxel and cisplatin given every 3 weeks were administered preoperatively to 11 patients with stage II disease before radical hysterectomy and vaginectomy.[303] Three patients achieved complete clinical response and 7 achieved partial response. Two patients subsequently relapsed. This approach has not been broadly adopted.

For squamous cancer, tumor stage is generally found to be the most important prognostic variable for local control and survival after treatment with irradiation. Tumor size (smaller or larger than 4 cm) and histologic grade may be influential,[304,309,310] as well as the presence of metastases in regional nodes. None of these factors is reflected directly in FIGO staging.

According to numerous analyses, almost all failures will occur within the first 5 years.[308-313] It is not currently feasible to distinguish potential second primary cancer in the vagina from possible marginal recurrence. Rare late failures in the vagina may reflect an underlying field defect rather than inadequate initial therapy.

Relapse is more likely to be pelvic than systemic. In the series from MDACC, 21 of 31 patients (68%) with stages I to II disease who relapsed had failure in the vagina or pelvis as all, or a component, of their relapse pattern, whereas 10 of 31 (32%) failed distantly only. Among patients with stages III to IV, 15 of 18 who relapsed (83%) had pelvic or vaginal recurrence as all, or a component, of their pattern of initial relapse. Three of 18 patients (17%) who relapsed had distant metastases only.[308] Rare relapse in inguinal nodes is seen in patients whose primary initially involved the distal one third of the vagina and in whom the inguinal nodes either were not included in the treatment volume or were grossly contaminated with metastatic disease at the time of diagnosis.[308,314] Patterns of relapse support more frequent use of concurrent chemoRT because only 17% of patients received combined-modality treatment during the 30-year span of the series.

Except for isolated vaginal recurrence in patients with VAIN or stage I disease, salvage therapy is generally ineffective. Surgical salvage implies partial or total exenteration in virtually all previously irradiated patients.

LOCALLY ADVANCED DISEASE AND PALLIATION

Because combined-modality treatment with concurrent chemoRT demonstrates improved outcomes in squamous cancers of the cervix, anus, and other sites, it is not unreasonable to extrapolate the use of synchronous treatment with concurrent chemoRT to similar patients with locally advanced vaginal cancer. This approach can be most easily justified for patients with stages III and IVA and bulky disease where results with RT alone are associated with substantial risk of local failure.[304,308,315] Consequent to the overall rarity of this disease, only limited numbers of patients have been reported using this approach.[194,304,308,309,316-321] It is unlikely that a prospective comparison of chemoRT and RT alone will be practically feasible. However, multivariate analysis of outcomes within a single institution comparing RT alone with chemoRT for vaginal cancer suggests that concurrent chemoRT confers an independent DFS advantage compared to RT alone.[321] This advantage may not be observed in institutions where chemoRT was preferentially administered to patients with multiple adverse prognostic factors.[304]

Analogous to the evolution of chemoRT in the treatment of cancer of the vulva, chemoRT for vaginal cancer may become more widespread. Drug regimens are similar to those used for vulvar and cervical cancers. No data are available to state which regimen is most effective. Assumptions about the preferential therapeutic ratio in vaginal and vulvar cancers associated with the use of chemoRT over RT alone are extrapolated from data on cervical and anal cancers.

Although anal canal cancers are amenable to cure with high-dose RT alone,[322] better local cancer control is achieved with chemoRT.[160,161] In addition, long-term complications are generally lower and functional results more satisfactory consequent to use of lower total doses of RT using fewer conventional fractions rather than reduced dose per fraction. Reduction in total RT dose from 65 Gy to 70 Gy to approximately 54 Gy has reduced the need for diverting colostomy or abdominoperineal resection for radiation complications in cured patients.

Concurrent chemoRT appears to significantly enhance RT effects on cancer and cycling epithelial cells but does not appear to proportionately increase late effects in normal tissues. Late complications in patients treated for cervical cancer with chemoRT are not dramatically different from those seen in patients treated with RT alone using comparable RT dose and fractionation regimens.[152,323,324] Concurrent chemoRT may increase acute toxicity, but late complications may be reduced if the total RT dose is reduced analogous to the anal canal cancers.

Most publications reporting treatment outcomes for patients with vaginal cancer report late bowel and urinary bladder complications, but few even comment on vaginal depth, diameter, elasticity, sexual function, and quality of life. No prospective evaluation of the impact of radical RT administered to the vagina has been undertaken. A potential benefit from integrating concurrent chemotherapy and implementing RT dose reduction to levels conventionally considered subtherapeutic (median cumulative dose of 63 Gy) may be in improved long-term vaginal function with reduced risk of severe atrophy or vaginal stenosis and fibrosis and reduced risk of severe complications including fistulae and radiation insufficiency fractures.[318] It seems appropriate to use concurrent chemoRT for tumors whose extent is more than superficial mucosal.

In the unusual setting of patients presenting with distant dissemination, local RT limited to areas of gross disease may palliate symptoms of discharge, bleeding, and pain. Systemic chemotherapy alone is minimally effective and characterized by a low probability of complete response and short duration of partial response. Results broadly parallel those for disseminated cervical cancer.

IRRADIATION TECHNIQUES AND TOLERANCE

Brachytherapy

Brachytherapy as monotherapy is appropriate for patients with VAIN, which has persisted despite less potentially damaging interventions, and for highly selected patients with small-volume, minimally invasive disease confined to the vaginal wall whose tumor volume can be encompassed without delivering unacceptable dose to the vaginal mucosal surface. Occasional patients treated thus may relapse in pelvic sites remote from the vagina.

More commonly, brachytherapy is used to supplement EBRT dose given to a large volume encompassing the primary disease, potential subclinical extensions of the primary cancer, and lymph node volumes at risk. Following 45 Gy to 50 Gy of conventionally fractionated EBRT, brachytherapy is employed to "boost" cumulative dose (EBRT plus low-dose rate brachytherapy dose) so that the gross tumor volume (GTV) is approximately 65 Gy to 75 Gy although in smaller tumors doses of 70 Gy to 82 Gy have been achieved when RT is employed as the sole modality of therapy.[304,308,321] The extrapolation of such high doses comes from the high "point A" dose prescription in cervical cancer, but it is important to realize that the entire cervical cancer does not usually receive the "point A" dose. Dose selection for vaginal cancers must include the entire

tumor volume and is therefore usually less than the quoted dose of 75 Gy.

Intravaginal irradiation is often accomplished using some form of vaginal cylinder. The largest possible diameter of cylinder is used to improve the ratio of dose to the tumor surface to dose at maximal tumor depth. Because of the rapid fall-off in dose with distance from intravaginal sources, it is inappropriate to use intracavitary brachytherapy to treat primary cancers that are more than 5-mm thick at the completion of EBRT.

When conventional low-dose rate intravaginal brachytherapy is employed, the labia may be sutured closed, securing the implant in place. When high-dose rate brachytherapy delivers treatment over a few minutes, fixation of the cylinder to a locking base-plate assures rigid immobility of the system. The cylinder should protrude beyond the labia to prevent dose build-up on the inner labial surface where the cylinder is loaded close to the introitus. With high-dose rate it is feasible to employ differential inclusion of the vaginal circumference with a Miami applicator or partial shielding with reproducible treatment of smaller lengths of the vagina. This may contribute to improvement in functional outcomes. Daily high-dose rate treatments may employ fractions as small as 3 Gy at a depth of 5 mm or less to a cumulative brachytherapy dose of 27 Gy to 30 Gy to supplement the EBRT dose of 45 Gy to 50.4 Gy.

For disease involving the upper vagina or vaginal fornices, an intrauterine tandem may be placed to function as an anchor for vaginal cylinders or spacers, while ensuring adequate dose at the proximal end of the vagina. Individual, custom vaginal moulds have been used to treat vaginal cancer.[325]

For cancers with more than 5 mm of thickness, deep paravaginal invasion, or parametrial extension, brachytherapy boosts may be delivered using isotopes such as iridium-192 in interstitial implants. Interstitial implants may be performed "free-hand" or through a template sutured to the perineum.[300,326-329] In patients with cancers involving a vaginal fornix or extending into the parametrium, interstitial needles will commonly penetrate into the peritoneal cavity. Particularly in the common setting of prior hysterectomy, loops of bowel may be adjacent to or adherent to the vaginal apex. Under these circumstances, needle placement may be safer with simultaneous laparoscopy or laparotomy to reduce risk of perforation of abdominal viscera and to assure accurate needle placement.[330,331]

Real-time image guidance (when available) by CT, MRI, or transrectal US may assist in accurate needle placement. Because of the rarity of these tumors and the high degree of technical skill and experience required to conduct interstitial brachytherapy, referral to a high-volume tertiary treatment facility with specialized clinical and medical dosimetry staff would seem prudent.

In the era when brachytherapy is increasingly administered with high-dose rate technique, integration of a variety of high-dose rate dose-fractionation schedules with EBRT is complex and a variety of regimens have been employed. Proposed dose schedules published by the American Brachytherapy Society (ABS) are a useful set of guidelines that can be applied to the care of an individual patient[329] (Table 60-13).

TABLE 60-13 Proposed Dose Schedules for HDR Interstitial Brachytherapy in Combination with EBRT

Dose of EBRT	HDR Dose to CTV (Gy)	EQD2 to CTV	D2 mL per fx to Rectum to Limit EQD2 to ≤70 Gy
36 Gy/18 fx*	5 × 6	72.9	≤4.1
	5.5 × 6	78.0	≤4.1
39.6 Gy/22 fx*	5 × 6	76.4	≤3.8
	5.5 × 6	8l.5	≤3.8
45 Gy/25 fx	3 × 9	73.6	≤3.55
	3 × 10	76.8	≤2.38
	4.5 × 5	71.5	≤3.75
	5 × 5	75.5	≤3.75
	5.5 × 5	79.8	≤3.75
	7 × 3	74.1	≤5.2
50.4 Gy/28 fx	4.0 × 5	72.9	≤3.25
	4.5 × 5	76.8	≤3.25
	5 × 5	80.9	≤3.25
	7 × 3	79.4	≤4.55

CTV, *Clinical target volume;* EBRT, *external beam radiation therapy;* EQD2, *equivalent dose in 2 Gy fractions;* fx, *fractions;* HDR, *high-dose rate.*
**Total pelvic: dose to 50.4 Gy with midline block after 36 Gy to 39.6 Gy.*

External Beam Radiation

External beam irradiation is similar to that given for carcinoma of the cervix with the exception that usually the full length of the vagina is included in the initial EBRT volume. Rare exceptions may include patients with unifocal disease less than 2 cm in length confined to either the vaginal fornices or the distal vagina. Parallel opposed AP and posterior-anterior (PA) pelvic portals rather than a four-field box technique may be employed for slender patients and when medial inguinal nodes are included for patients with involvement of the caudal third of the vagina. For larger patients, a four-field technique may be used in an effort to reduce total dose and dose per fraction to the bladder dome and anterior small bowel. Medial groin nodes may be treated with this technique by expanding the anterior-inferior portion of the lateral fields, provided that the dose to the proximal femurs is kept less than 45 Gy by excluding these structures to the maximal extent feasible on the anterior and posterior fields. Rarely, when inguinal nodes are involved at the time of diagnosis, techniques that are used to encompass the entire inguinofemoral node volumes in patients with cancer of the vulva may be successfully deployed for patients with vaginal cancer.

IMRT may be employed with beneficial dose reduction to adjacent organs at risk and has been reported to result in excellent local control.[304] However, enthusiasm for the use of increasingly conformal dose distributions must be tempered with the understanding that the upper vagina is a mobile structure whose position will vary daily with different degrees of urinary bladder and rectal distension. CT-based treatment planning can account for extremes of potential motion by scanning with bladder and rectum distended and undistended through the use of temporary bladder catheterization and rectal balloon placement at the time of simulation along with intravaginal contrast material so that delineation of target volumes can be designed accordingly.

It should be emphasized that the initial target volume should be influenced by the results of diagnostic imaging studies and that extended volumes may be appropriate for patients with pelvic nodal metastases. Conventionally, the superior extent of the EBRT volume has been at the L5-S1 interspace when there is no evidence of pelvic node metastases. This assures coverage of retroperitoneal nodes caudal to the bifurcations of the common iliac arteries in almost all patients and will include some distal common iliac nodes.[332,333] However analysis of sites of relapse in one clinical series suggested that this volume might be excessive for most patients, contributing to avoidable acute and delayed toxicities of

treatment.[314] As initial failures are predominantly in the vagina, paracolpos, and parametria, expanded volumes to electively encompass larger nodal volumes may not be routinely useful. In patients with negative imaging assessment (PET/CT or diffusion-weighted MRI) of regional nodes, a reduced volume with superior border 1 cephalad to the inferior margin of the sacroiliac joints may be sufficient to encompass obturator nodes and first echelon (distal) external and internal iliac nodes. Target volume for initial EBRT treatment remains controversial. In patients with documented node metastases, extension of the treatment volume to encompass the next echelon of clinically uninvolved nodes seems reasonable. As the accuracy of imaging technology improves, smaller EBRT volumes may be used safely.

For patients with bulky disease including patients with gross lymph node metastasis, boost therapy by intracavitary or interstitial brachytherapy techniques may not be useful. EBRT boost volumes should be based on clinical findings and results from diagnostic imaging studies. Tailored volumes may be treated to a cumulative dose between 65 Gy and 70 Gy using EBRT alone. Higher doses carry substantial risk of late RT complications in adjacent vulnerable normal tissues including urethra, bladder, rectum, and small bowel. Administration of concurrent chemotherapy may be particularly indicated when the EBRT dose is limited by the RT volume required. Rapid clinical tumor shrinkage, often seen in the setting of concurrent chemotherapy administration, may suggest the wisdom of repeat CT simulation before planning reduced volume EBRT boost treatment.

Treatment Tolerance and Complications

Acute effects in patients undergoing EBRT as all, or a major component of their treatment, may include radiation urethritis/cystitis with frequency, urgency, and dysuria. Oral anticholinergic and antispasmodic medications may be beneficial for patients in whom these symptoms are more than a temporary irritant, as well as a urinary tract analgesic.

Depending on the volume of small bowel included in the irradiated volume, most patients will experience some degree of erratic bowel function that will usually include more frequent and often unformed bowel movements that may progress to watery diarrhea. Dietary modification and medications such as loperamide hydrochloride or atropine with diphenoxylate hydrochloride (Imodium, Lomotil) are usually beneficial.

Acute effects on the anorectum may cause tenesmus and small volume blood loss. Topical medications such as those employed for the treatment of hemorrhoids can be beneficial to some patients and may be applied directly to the anal area externally or to the anorectum by suppository.

Vaginal effects may include serous discharge and pruritus, for which oral antihistamines and topical vaginal moisturizing agents (Replens) may provide some symptomatic relief.

Acute RT dermatitis may progress to moist desquamation on the vulva and portions of the perineum when the primary lesion involves the distal vagina. Soaks, air exposure, and topical balms and creams that may or may not include antibiotics such as 1% silver sulfadiazine cream may ameliorate symptoms. Occlusive dressings may be temporarily required for severe cases. Therapy generally parallels skin treatment for thermal burns.

Because of the paucity of large data sets reporting treatment outcomes and the variability in disease extent and the equipment, techniques, and doses of RT, it is difficult to predict the risk of serious late complications for an individual patient.

Complications of treatment have been reviewed in various publications. In a historic series, Dancuart et al treated a group of patients between 1955 and 1982. Reported late effects included vaginal fibrosis (10%) and cystitis, proctitis, or vaginal necrosis (12%). A further 5% of patients experienced rectal or sigmoid stenosis, hemorrhage, or multiple fistulas.[312] Over a similar time period in which patients were treated with radical irradiation from 1953 to 1991 Perez et al[313] reported late complications in 205 patients from an initial population of 212 patients with VAIN (20 patients) or invasive carcinomas of the vagina (192 patients). Twenty-five major local complications (12% crude rate) attributable, all or in part, to RT injury were observed, including six rectovaginal fistulae, three vesicovaginal fistulae, four bladder neck contractures or urethral strictures, two rectal strictures, two proctitis, and one instance each of rectal ulcer, vaginal necrosis, small bowel obstruction, cystitis, leg edema, neuritis, severe vaginal stenosis, and diverticulitis. Tewari et al[327] reported on complications in a series of 71 patients treated between 1976 and 1997 with interstitial brachytherapy alone (10 patients) or in combination with EBRT (61 patients) to a cumulative dose of 80 Gy. Nine patients had major complications including four necroses, four fistulae, and one small bowel obstruction, for a crude rate of 13%. Chyle et al at MDACC found that transperitoneal staging pelvic lymphadenectomy before RT contributed significantly to complications of therapy.[310] Imaging has largely replaced surgical staging for cervical and vaginal cancers.

A retrospective series from MDACC analyzed complication rates for 193 patients treated between 1970 and 2000 using the NCI Common Terminology Criteria for Adverse Events.[308] The cumulative rate of grade-3 or grade-4 complications was 10% at 5 years and 17% at 10 years. Twenty patients had a total of 25 major complications, 19 of which involved the gastrointestinal tract including proctitis requiring transfusion (7 patients), fistulae (5 patients), small bowel obstruction (4 patients), and large bowel obstruction, rectal ulceration, and fecal incontinence (1 patient each). Eight of 11 patients with major rectal complications had primary tumors involving the posterior vaginal wall. Genitourinary complications included vesicovaginal fistulae (2 patients), hemorrhagic cystitis (3 patients), and urethral stricture (1 patient). All major urinary tract complications were seen in patients with primary cancers involving the anterior wall of the vagina. With univariate analysis, the incidence of complications correlated with primary tumor stage and smoking history. Current smokers had a 25% incidence of complications, compared to 18% in former smokers who quit 6 months or longer before RT and 5% in patients who had never smoked.[308]

Vaginal fibrosis and stenosis with shortening and narrowing is probably the complication that occurs with greatest frequency but is underreported. The average age of this population, many of whom may not regularly have vaginal intercourse, probably both increases the likelihood of significant stenosis and decreases reporting of this functionally limiting complication. The morbidity of vaginal stenosis may be limited to difficulty and discomfort with subsequent vaginal examinations in patients who are not active sexually. Stenosis may compromise the early diagnosis and subsequent salvage of local relapse as well as prevent surveillance of the cervix in patients who have not had prior hysterectomy. Vaginal stenosis can be prevented with variable success with the use of vaginal dilators and topical intravaginal estrogen on a chronic basis. This is effective for vaginal mucosal atrophy and should be used in addition to systemic hormone replacement in younger patients in whom RT has ablated ovarian function. When the uterus remains intact, hormone replacement should be combined estrogen and progesterone to protect the hormonally responsive endometrium, which might result in hematometra or hematocolpos in the setting of vaginal stenosis. Because some intravaginal estrogen will be absorbed

systemically, the precise balance of oral or transdermal hormone replacement with vaginal estrogen administration will vary from patient to patient.

TREATMENT ALGORITHM AND FUTURE POSSIBILITIES

A treatment algorithm for invasive cancer of the vagina is depicted in Figure 60-13.

Patients with small-volume primary tumors confined to the vaginal wall that do not encroach on functionally important midline structures (urethra, bladder, rectum) may be treated with primary surgical excision if the surgery would not compromise sexual function. Adjuvant RT may be subsequently indicated. Rarely are patients with more extensive disease suitable for initial surgery. An exception relates to patients with stage IVA bulky central disease and fistula formation (vesicovaginal or rectovaginal fistulae). Total vaginectomy with selective or total exenteration may be necessary initial treatment for hygienic reasons. However, fistula formation is not the inevitable consequence of radiotherapeutic management of patients with stage IVA disease. Anecdotally, some patients presenting with small vesicovaginal fistulae will have urinary continence restored if the vaginal walls fuse after radical RT, effectively sealing the fistula. If that is the intent, use of a vaginal dilator after RT will be counterproductive.

Use of concurrent chemoRT is not of proven value for patients with vaginal cancer, but its use is rational given utility in primary cancers of the anus, cervix, and vulva. As in cervical cancer tumors of diameter >4 cm (IB2) may benefit from additional chemo. It is reasonable to consider in patients whose tumor volume is unlikely to be cured with RT alone in a tolerable dose. Because of the rarity of vaginal cancer, prospective, randomized clinical trials are unlikely in the context of decentralized cancer care. Progress in improving local and regional control may come from more precise definition of disease extent using sophisticated spatial and metabolic imaging modalities. With better knowledge of dose-control probabilities and more powerful treatment planning capabilities rendering tighter, elegant RT dose distributions, the therapeutic ratio should improve. Concurrent chemoRT should also improve outcomes.

NONSQUAMOUS VAGINAL MALIGNANCIES

Vaginal Melanoma

Melanoma accounts for approximately 3% of vaginal malignancies and is the second-most common histologic type of primary vaginal cancer. Bleeding or protrusion of a mass from the vagina is the most common presentation. Data regarding stage distribution are limited, but advanced stage appears common.[306]

Primary treatment includes radical surgery, radical RT, or combinations of RT and surgery. Modality of treatment does not appreciably affect survival.[306] The prognosis is grim. In a series of 37 stage 1 primary vaginal melanomas treated between 1980 and 2009 at MDACC employing a variety of therapeutic strategies, 5-year DFS was 9.5% and median time to recurrence was 17.4 months.[334] The majority of relapses are local or regional, often with distant metastases. The lung and liver are the most common remote organs affected.

The rate of survival is much lower than that for cutaneous melanomas but is consistent with survival at other mucosal sites and the generally large tumor burden at diagnosis. Because inadequate surgical margins are highly predictive of local relapse and salvage after relapse is unlikely, patients treated with primary surgery have sometimes undergone partial or total pelvic exenteration. Given the poor survival and the high morbidity of such procedures, thorough preoperative assessment for disease spread beyond the boundaries of surgical resection should be undertaken in each patient for whom such surgery is contemplated. Investigations may include whole-body CT, PET/CT, and possibly MRI of the brain. Surgical therapy must also be individualized in the context of patient comorbidities and the patient's willingness to undergo procedures that imply profound changes in quality of life in exchange for a slender prospect of cure.

Although melanomas have traditionally been considered radioresistant, there are a few long term who have been treated with RT. Local RT may provide palliation and growth restraint in patients with proven metastatic deposits and primaries for whom exenterative surgery is not appropriate. Adjuvant systemic therapy and treatment of disseminated melanoma parallels the treatment of melanoma of the vulva and melanoma arising in other mucosal sites.

Sarcomas

Vaginal sarcomas comprise 3% of primary vaginal malignancies. The majority of cases are leiomyosarcoma.[335,336] Other reported sarcomas include endometrial stromal sarcoma, malignant mixed müllerian tumor/carcinosarcoma, and rhabdomyosarcoma, among others. Surgical resection is the treatment of choice. RT may be employed preoperatively or postoperatively for inadequate surgical margins or regional spread in analogy to the treatment of extremity and truncal sarcomas although its value and that of chemotherapy is not precisely known.

Embryonal rhabdomyosarcoma is a highly malignant, rapidly growing sarcoma that occurs predominantly in children although sporadic case reports involve adults. The most common site in the pediatric age group is the vagina. This tumor generally presents as soft nodules that fill and protrude from the vagina or as abnormal bleeding. The prognosis for patients with this malignancy has improved dramatically with the use of multimodality therapy including surgery, polyagent chemotherapy, and radiation.[337]

Clear Cell Adenocarcinoma (CCAC) of the Vagina

Prognostic factors for all clear cell carcinomas of the vagina include stage at diagnosis, tumor size, and grade of the lesion, including architecture and nuclear grade, and appear to pertain equally to patients both DES-exposed and DES-unexposed. Among patients who were DES-exposed, young age was also found to be a poor prognostic factor. It appears from the Netherlands registry that DES-exposed vaginal CCAC cases were diagnosed after shorter durations of symptoms.[289] Possibly because of early occurrence of abnormal bleeding, the majority of cases were stage I or stage II at diagnosis.

Both surgery and RT/chemoRT have been used as primary treatment options. Approximately half of all patients with vaginal CCAC in the U.S. Registry for Research on Hormonal Transplacental Carcinogenesis were treated initially with radical surgery alone.[338] Radical RT is offered as primary therapy for patients with locally advanced disease and those who are not surgical candidates or decline radical surgery. RT may be given as adjuvant therapy for patients at high risk for pelvic relapse. RT may be used alone or in combination with surgical resection to treat locally recurrent disease. Optimal treatment of recurrent disease is not clear; in 1979 Herbst reported a 5-year OS after pelvic relapse of 40%.[339]

Of all melanomas in women, less than 1% arise in the vagina. Most of the literature consists of case reports or small case series. The incidence of vaginal melanoma from population-based data is 0.026 to 0.030 per 100,000 women per year. Its etiology unlike cutaneous melanoma is unclear. Melanomas arising are thought to originate from in situ melanocytes in areas of melanosis or atypical melanocytic hyperplasia. Incidence does increase with age. The population-based median age is approximately 70 years.[307] Approximately 20% are multifocal within the vagina. In contrast to squamous cancers, most (65%) arise in the distal third of the vagina.[306,334]

Most relapses are local or locoregional, although the incidence of distant relapse in CCAC is higher than in squamous vaginal cancers. In Waggoner et al's study, 9% of all patients with DES-exposed CCAC presented with lung or distant nodal metastases.[338] Among patients who were DES-unexposed, the rate of distant disease was 24%. Although most relapses occur within 3 years of treatment, later relapses, have been reported.[340]

CHAPTER

61 Ovarian Cancer

Danielle Vicus, William Small, Jr., and Allan Covens

INCIDENCE AND ETIOLOGY

Ovarian cancer constitutes 3% of all cancer diagnosed in women and 5% of all cancer-related deaths. In 2015 the estimated incidence of ovarian cancer in the United States was 21,290 cases with an estimated 14,180 deaths. The lifetime risk in the general population is 1.4%. The molecular events involved in the carcinogenesis of ovarian cancer are still unclear; however, environmental, hormonal, and genetic risk factors have been identified through epidemiologic studies.

PREVENTION AND EARLY DETECTION

The focus of ovarian cancer screening is to attempt to identify women with early-stage disease. The most common techniques used in screening are serum CA-125 and ultrasonography. Multiple trials have shown a low positive predictive value (PPV) of screening the general population and an expected higher PPV when screening high-risk populations. Until further evidence of the utility of screening is available it is not recommended for the general population.

Most hereditary ovarian cancer is associated with a germline mutation in the *BRCA1* or *BRCA2* gene. For patients with an identified *BRCA1* and *BRCA2* mutation, screening has been recommended, despite its unproven value. Prophylactic salpingo-oophorectomy at the completion of childbearing is recommended.

BIOLOGIC CHARACTERISTICS

Epithelial ovarian cancer comprises approximately 90% of all ovarian cancers, 75% of which are of serous histology. In the first two decades of life, ovarian germ cell tumors (GCTs) constitute almost 70% of all ovarian tumors, a third of which are malignant. Sex cord and stromal tumors are rare, although they account for 90% of all hormone-producing tumors.

STAGING EVALUATION

Ovarian cancer is staged surgically according to the International Federation of Gynecology and Obstetrics (FIGO) staging system based on the patterns of spread. In early-stage disease, comprehensive surgical staging is pertinent because the extent of disease determines indications for subsequent treatment. Advanced stage disease (III/IV) exists in 70% of patients at diagnosis.

PRIMARY THERAPY

The primary treatment for ovarian cancer is surgical. In early-stage disease a comprehensive surgical staging procedure is completed. In patients with epithelial stage IA or GCTs, fertility-sparing surgery may be performed. For patients with advanced stage, cytoreductive surgery is performed with the purpose of removing all macroscopic disease if feasible.

ADJUVANT THERAPY

Patients with early-stage, low-grade epithelial ovarian cancer do not benefit from adjuvant therapy. The current recommendation for all other patients is adjuvant combination chemotherapy (chemo) with carboplatinum and paclitaxel. Certain histologies such as clear cell may benefit from adjuvant radiation therapy (RT).

Patients with GCTs (other than stage I dysgerminoma and stage IA grades 1 and 2 immature teratoma) are commonly treated with bleomycin, etoposide, and a platinum-based regimen or with etoposide and a platinum-based regimen.

The benefit of adjuvant chemo for sex-cord and stromal tumors has not been proven.

ADVANCED DISEASE

Advanced ovarian cancer is treated with cytoreductive surgery and postoperative combination chemo. The most commonly used regimen is six cycles of carboplatin and paclitaxel. Intraperitoneal chemo (cisplatin with or without paclitaxel) and intravenous (IV) paclitaxel improves survival and should be considered in optimally debulked patients (<1 cm gross residual tumor), although the regimen for optimal therapeutic ratio is not defined. Maintenance chemo has not been shown to be beneficial and cannot be recommended. Maintenance bevacizumab has demonstrated a modest increase in progression-free survival (PFS) and no difference in overall survival (OS) or quality of life.

The majority of patients with ovarian cancer enter a state of remission on completion of surgery and postoperative chemo, but about 85% experience relapse and die of disease.

RADIATION THERAPY

Abdominopelvic RT is an effective adjuvant treatment for some well-defined patient groups with ovarian cancer, although platinum-based chemo has become the preferred modality. The role of RT in advanced stage disease as consolidation therapy sequential to surgery and chemo is controversial. Certain patients with early-stage disease and specific histologies may benefit from adjuvant RT. RT for palliation is effective and should be recommended in patients with localized symptoms.

PALLIATION

Because disease relapse is usually incurable, the principal aim is to prolong symptom-free survival and palliate symptoms. The benefit of second-line chemo is dependent on the disease-free interval from completion of treatment to relapse. Patients who experience relapse early, less than 6 months from completion of treatment, are "platinum resistant," and their response rates are low, whereas those who experience relapse with a longer treatment-free interval are "platinum sensitive" and have a higher response rate.

Secondary debulking, which is surgery performed to remove tumor relapse, is considered in patients with late relapse and resectable tumor. RT for palliation is an effective modality in patients with symptoms related to localized disease. Patients should be considered for clinical trials or symptomatic measures when a low probability of response to therapy is expected.

Ovarian cancer is the fifth-most common cause of cancer death among women, and the leading cause of gynecologic cancer-related death in the United States.[1] The incidence of ovarian cancer for 2015 in the United States was projected to be 21,290 cases, thus constituting 3% of all cancer diagnosed in women. The lifetime risk in the general population is 1.4%. In 2014 the expected number of deaths attributed to ovarian cancer was projected to be 14,180, accounting for 5% of all cancer-related deaths.[2]

Ovarian cancer is one of the most clinically challenging cancers to treat. Cure rates are low as symptoms are nonspecific and diagnosis is usually late in the disease course. It primarily spreads throughout the peritoneal cavity, and maximal cytoreduction, of proven benefit, often requires complex surgical procedures. The majority of patients experience relapse and will succumb to their disease, making ovarian cancer a psychologically and physically challenging disease for patients and their caregivers.

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

Ovarian cancer is infrequent before the age of 40, with a median age at diagnosis of 63 years. The age-specific incidence increases with age, reaching its peak in the eighth decade, with an incidence of 57 per 100,000 in the 70- to 74-year age group[3] (Figure 61-1). Incidence rates and the number of cancer-related deaths have been relatively stable over the past three decades.

Five-year OS is the typically reported end point for epithelial ovarian cancer and is approximately 45%. The survival is significantly better for the 30% of patients with localized disease, with 5-year OS of 93%. However, approximately 70% of women are diagnosed when disease has spread, with expected 5-year OS of 20% to 30%.[1,4-6] Women diagnosed younger than age 65 have higher 5-year OS (65.8%) in comparison to those older than age 65 (32.9%).

Etiology

The molecular events involved in the carcinogenesis of ovarian cancer are still unclear. However, environmental, hormonal, and genetic risk factors have been identified through epidemiologic studies.

Environmental Risk Factors

Country of residence and race has been associated with an increased risk of ovarian cancer. Women living in North America and in northern Europe have the highest risk. The incidence is highest among white women, is intermediate among black women, whereas Hispanic, Asian, and American Indian women have the lowest reported risk.[7] Many dietary factors have been evaluated in regard to the risk of ovarian cancer, including a diet high in meat and calories, antioxidant intake (e.g., vitamins A, C, and E), and lactose or coffee consumption, although none has consistently been shown to significantly alter the risk.[7-10]

Hormonal Factors

Hormonal factors including increased parity, age at first birth before age 25 years, history of breast-feeding, oral contraceptive use, and tubal ligation have been shown in multiple epidemiologic studies to decrease the risk of developing ovarian cancer by 25% to 60%.[11-13] Hormone-replacement therapy has been shown in the Million Women Study and in a more recent Danish cohort study to be a risk factor for ovarian cancer.[14,15] Both studies demonstrated a 1.5- to 2-fold increased risk of developing ovarian cancer in current users of hormone-replacement therapy. The protective effects of parity, multiple births, oral contraceptive use, and breast-feeding support the "incessant ovulation" theory, in which each ovulatory cycle causes damage to the ovarian epithelium and then the process of aberrant repair becomes an initial step in carcinogenesis.[16] Therefore, the more ovulatory cycles a woman has in her lifetime, the higher her risk of developing ovarian cancer. A second hypothesis attributes an increased risk to excessive

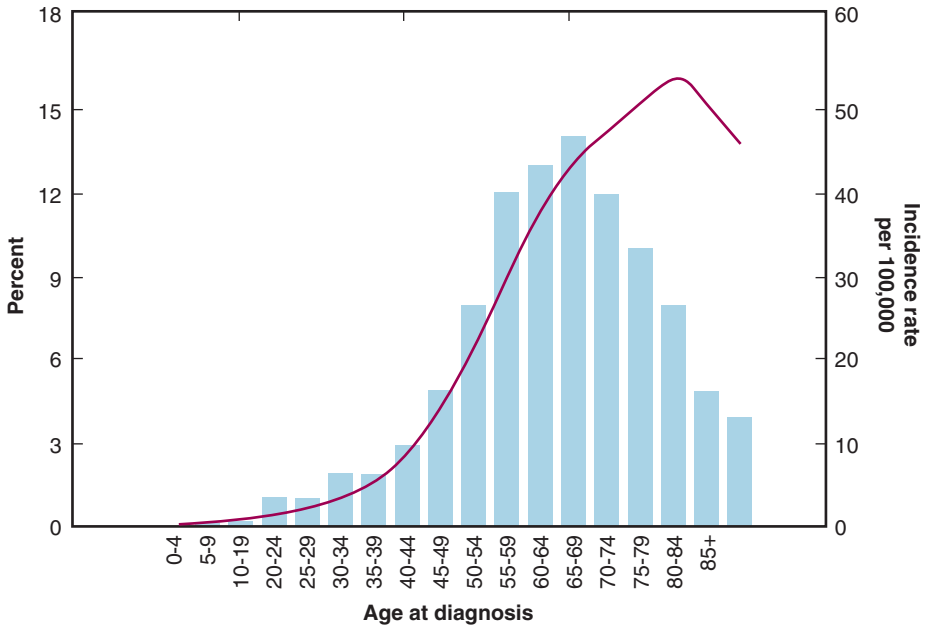

Figure 61-1 Incidence rates by age for ovarian cancer.
Data from Yancik R, Ries LG, Yates JW: Ovarian cancer in the elderly. An analysis of Surveillance, Epidemiology, and End Results Program data. Am J Obstet Gynecol 154:639–647, 1986.

gonadotropin secretion.[17] Because of the high concentration of gonadotropins, estrogenic stimulation occurs, leading to the entrapment of epithelial cells in inclusion cysts, which further leads to cell proliferation and malignant transformation.[17,18] Oral contraceptive use and pregnancy, in addition to stopping ovulation, lower gonadotropin levels; therefore, both traditional risk reducers are in concordance with both theories. Hence, patients treated for infertility with ovarian stimulation would be expected to have an increased risk of ovarian cancer. Although an increased risk of predominantly borderline tumors was reported in a cohort of women treated for infertility with prolonged use of the ovulation stimulator, clomiphene citrate, the data have not been consistent. Both a large Danish population-based cohort study and a retrospective cohort study of almost 10,000 U.S. women treated with a spectrum of infertility medications did not support the correlation between infertility medication and ovarian cancer.[19,20]

Genetic Factors

Only 15% of all ovarian cancers are attributable to known genetic mutations, that is, 13% to the hereditary breast and ovarian cancer syndrome (*BRCA1* and *BRCA2* germline mutations) and 2% to the hereditary nonpolyposis colon cancer syndrome (*MLH1, MSH2,* and *MSH6* mutations).[19,21,22] Women with hereditary nonpolyposis colon cancer (HNPCC) syndrome have an increased risk of developing multiple types of cancer, including colon, endometrial, and ovarian cancer. The lifetime risk of women with HNPCC of developing ovarian cancer is 15% to 25%.[23] The frequency of *BRCA* mutations differs among ethnic groups. Founder (recurrent) mutations have been identified in specific ethnic groups; for example, up to 40% of all women who are of Ashkenazi Jewish descent with ovarian cancer carry one of three founder mutations.[24] Additional founder mutations have been found among women who are Polish and French-Canadian.[25,26] Women who harbor a *BRCA1* mutation have a lifetime risk of 30% to 40% for developing ovarian cancer. Women with a *BRCA2* mutation have a 15% to 25% lifetime risk of developing ovarian cancer, depending on the location of the mutation in the genes; a higher risk is correlated with a mutation in the ovarian cancer cluster region.[27] Women with a *BRCA1* or *BRCA2* mutation also have an increased risk of fallopian tube cancer. The lifetime risk of breast cancer for carriers of *BRCA1* and *BRCA2* mutations is 50% to 85%.

PREVENTION AND EARLY DETECTION

Screening and Prophylactic Surgery

The majority of women with ovarian cancer presents with advanced disease and therefore has a poor long-term prognosis. In contrast, those patients who are diagnosed when the cancer is limited to the ovaries have a good prognosis, with a 5-year OS of 80% to 90%.[28] Unlike cervical cancer, it is unclear that there is an orderly progression from limited to extensive disease. Nevertheless, the focus of ovarian cancer screening is to identify women with early-stage disease. The most common screening techniques used to date are ultrasonography and serum CA 125. The latter is an antigenic serum tumor marker detected by radioimmunoassay that is elevated in 80% of epithelial ovarian cancers.

Two large randomized trials have addressed the question of the yield of screening for ovarian cancer: the U.S. National Institutes of Health (NIH) Prostate Lung Colorectal and Ovary Study (PLCO) and the U.K. Collaborative Trial of Ovarian Cancer Screening (UKCTOCS).[29,30] UKCTOCS randomly assigned 202,638 women who were postmenopausal to a control group (no screening) versus two different arms of screening (annual transvaginal ultrasonography or annual CA 125 screening and further transvaginal ultrasonography if results were elevated). To date only the prevalence data of UKCTOCS has been reported showing that the majority of cases diagnosed were at advanced stage. PLCO randomly assigned 39,115 women to screening (annual CA 125 and transvaginal ultrasonography) versus usual care (i.e., no screening). In 2011, the results of PLCO were published; 118 deaths caused by ovarian cancer were found in the intervention group and 100 deaths in the usual care group (relative risk [RR], 1.18; 95% confidence interval [CI], 0.82 to 1.71).[31] They found that 15% of women with false-positive results who underwent surgery experienced at least one serious complication and therefore concluded that this screening in the general population did not reduce ovarian cancer mortality and was associated with surgical complications. Although there are minor differences in trial design between the two aforementioned studies (including a stricter screening protocol, higher quality control, and the use of a trend in CA125 and not an absolute number in the UKCTOCS trial), at this point in time there is no proven survival benefit for screening the general population and it is not recommended.

Multiple trials have shown the expected higher PPV when screening high-risk populations.[32-37] For patients with an identified *BRCA* mutation, screening has been recommended at the NIH Consensus Conference on Ovarian Cancer despite the absence of proven survival benefit.[38]

New directions examining potential novel serum markers using proteomics and genomics are being explored.[39-41] The majority of studies are evaluating the sensitivity and specificity of combinations of markers. Visintin et al,[40] from Yale University, studied concentrations of a combination of six proteins, including leptin, prolactin, osteopontin, insulin-like growth factor 2, macrophage inhibitory factor, and CA 125 in 156 patients with newly diagnosed ovarian cancer and 362 healthy controls. They reported a sensitivity of 95.3% and a specificity of 99.4% for the detection of ovarian cancer. These promising results require additional validation studies.

The value of genetic counseling for patients with an identified *BRCA* mutation or HNPCC has been established because the management decision making is complex. Individualized recommendations are made based on the specific risk, patient age, and her reproductive goals. Prophylactic salpingo-oophorectomy in women with a *BRCA* mutation reduces the risk of gynecologic cancer (ovarian and fallopian tube) by 85% to 96%.[42-45] There remains an approximately 1% risk of primary peritoneal cancer.[42-44] In addition, the risk of developing subsequent breast cancer was reduced by 50% to 60%.[46] The NIH consensus panel in 1995 recommended prophylactic oophorectomy for women at high-risk at age 35 or after the completion of childbearing.[38] Because of the emerging evidence supporting the hypothesis that ovarian cancer originates in the fimbriated end of the fallopian tube, there is growing acceptance to perform bilateral salpingectomies at time of hysterectomy if oophorectomy is not indicated to potentially lower the risk of ovarian cancer. However, more data is needed before guideline recommendations can be made.

BIOLOGIC CHARACTERISTICS AND PROGNOSTIC FACTORS

Currently prognostic clinicopathologic and biologic variables are used to predict survival probability. It is hoped that molecular markers will soon be identified that better define risk.

Clinicopathologic Factors

The surgically determined stage of disease is directly correlated with survival. The Surveillance, Epidemiology and End Results (SEER) database, for patients diagnosed between 2006 and 2009, reported a 5-year OS of 44.2% for all stages; 91.9% for stage I, 72.0% for stage II, and 27.3% for combined stages III and IV.[47]

Histologic grade, based in the FIGO system on architectural features, that is, the ratio of glandular or papillary structures versus solid tumor growth within a tumor, is an important prognostic factor in epithelial ovarian cancer.[48-50] Patients with high-grade (poorly differentiated) tumors have worse outcomes than those with low-grade (well-differentiated) tumors. In patients with early-stage (IA to IB) low-grade tumors, a 94% 5-year OS has been reported with surgery alone.[51]

The effect of histologic cell type has generally been of less important prognostic significance than other factors although the stage distribution at presentation and response to chemotherapy differ markedly. However, it has been suggested that early-stage endometrioid and mucinous cell types have a better prognosis than serous and clear cell adenocarcinoma, but when grade and cell type are evaluated, histologic cell type has not been found to be an independent factor.[52,53]

In patients with advanced-stage disease, chemotherapy sensitivity is an important prognostic factor. Therefore, patients with serous histology have a better prognosis than those with the more chemoresistant tumors (e.g., mucinous and clear cell).[54]

Patient age at diagnosis and performance status are independent prognostic factors.[55,56] However, tumor size and bilaterality are not prognostic.

The volume of residual tumor at the completion of a cytoreductive surgery for advanced ovarian cancer is directly correlated with survival.[55] Chi et al[57] from Memorial Sloan Kettering Cancer Center have shown that an aggressive primary cytoreduction, including extensive upper abdominal procedures, resulted in increased optimal cytoreduction rates and significantly improved progression-free survival (PFS) and OS in patients with advanced ovarian carcinomas. However, it remains controversial whether it is primarily the aggressiveness of the surgery, the biology of the tumor, or both that contribute to prognosis.

Elevated preoperative and postoperative CA 125 levels, a reflection of volume of disease, and the time frame over which the level declines during chemotherapy have been shown to correlate with prognosis.[58]

Biologic Factors

The cellular DNA content, as determined by flow-cytometric analysis, is an independent prognostic factor. Aneuploid (versus diploid) DNA content in ovarian tumors is correlated with more aggressive biologic behavior and a worse clinical course.[59,60]

Molecular markers, including both abnormalities in oncogene products (e.g., ERBB2 [HER2/neu], ERBB3 [HER3]), and suppressor gene products (e.g., TP53) correlate with prognosis.[61,62] Many additional biologic markers, including markers of proliferation and of DNA repair, together with newer studies on loss of human leukocyte antigen class I, KLK6, and KLK13, have been reported,[63,64] although their significance has not yet been established.

PATHOLOGY AND PATHWAYS OF SPREAD

Pathogenesis

Ovarian cancers are classified by their histology. The largest categories are epithelial (approximately 80% of all ovarian cancers), germ cell, and sex cord and stromal. The traditional view of the pathogenesis of epithelial ovarian cancer asserts that all tumor subtypes share a common origin in the surface epithelium of the ovary, which is repeatedly disrupted by ovulation and consequent release of inflammatory cytokines, capable of damaging DNA.[65,66] This increases the susceptibility to malignant transformation. Moreover, numerous invaginations into the stroma develop as the ovary ages and these invaginations further form cortical inclusion cysts.[67] Epithelial cells in the cysts are exposed to high hormone levels that induce proliferation and are susceptible to malignant transformation if there has been previous DNA damage.

This putative mechanism of carcinogenesis has not been supported by identification of a precursor lesion in the ovary. Prophylactic surgery in patients with a genetic predisposition to breast and ovarian cancer has led to pathological evaluation of removed ovaries and fallopian tubes for the presence of early cancers or noninvasive lesions. Isolated foci of cancer have been seen in the fallopian tube but rarely have small isolated cancers been found confined to the ovary.[68-70] These observations led many authors to conclude that the fallopian tube may be the primary site of cancers, which if diagnosed later in the course of disease would have been classified as a primary ovarian cancer.[70-72]

Pathways of Spread

Epithelial ovarian cancer spreads through four mechanisms: (1) direct contiguous spread to adjacent organs, (2) transcoelomic in the peritoneal cavity, (3) lymphatic, and (4) hematogenous (rare).

Transcoelomic: The most common pattern of spread is through exfoliation of cancer cells into the peritoneal cavity. The cells move with the peritoneal fluid circulation from the pelvis into the right paracolic gutter to the upper abdomen and return to the pelvis through the left abdomen. The cells attach to the surface of intraabdominal organs and grow into masses. They uncommonly invade intraabdominal organs (e.g., the bowel, liver, or spleen).

Lymphatic: Lymphatic spread of cancer cells to the pelvic and paraaortic lymph nodes is common. Spread above the diaphragm to the supraclavicular nodes occurs through retroperitoneal dissemination.

Hematogenous: Hematogenous spread of ovarian cancer to the parenchyma of vital organs (e.g., liver or lungs) is rare at diagnosis, occurring in less than 5% of all cases. Systemic metastases can be seen at time of relapse, when disease is widespread throughout the pelvis and abdomen.

Direct spread: Ovarian cancer cells can spread through direct extension from the ovary to adjacent organs; the most common site being the fallopian tube.

Histologic Classification

Epithelial ovarian carcinomas are subclassified based on histologic cell type: serous, mucinous, endometrioid, clear cell, and transitional. They are also divided into borderline (also called tumors of low malignant potential) and invasive. Borderline tumors of the ovary are defined as those with epithelial atypia without stromal invasion. They generally are associated with an excellent prognosis, with a nearly 100% 5-year OS when diagnosed at stage I.[73] Borderline tumors occur primarily in women of a younger age in comparison with invasive cancer.

Serous carcinoma is the most common histologic subtype of epithelial ovarian cancer.[74] It is characterized histologically by broad, branching papillae covered with stratified epithelial

cells. High-grade serous carcinoma contains large pleomorphic nuclei with many mitoses. Papillary fenestrations with slit-like fenestrations are common, there may be large areas of necrosis, and psammoma bodies may be present.

Low-grade serous ovarian carcinomas (micropapillary carcinomas) are tumors with grade-1 nuclear atypia, low-grade architecture, and low mitotic activity.[75] They are associated with extensive papillary architecture and often contain an abundance of psammoma bodies. Low-grade serous carcinomas may arise in association with borderline tumors and are distinct from high-grade serous tumors because they do not behave aggressively. The low-grade and borderline serous tumors frequently have mutations in BRAF and KRAS and lack TP53 mutations. Borderline serous ovarian tumors clinically behave in an intermediate manner between benign and malignant; that is, there may be peritoneal implants but most are noninvasive. The 5-year OS of stage III borderline serous tumors is approximately 85%, whereas that of stage III invasive serous cancer is only 20% to 30%.[6,76] Long-term follow-up of 276 patients with ovarian serous tumors of low malignant potential identified unresectable disease and invasive implants as significantly associated with decreased survival ($p < 0.001$).[77]

Mucinous cyst adenocarcinomas are diagnosed when the majority of the epithelial cells contain mucin and comprise approximately 15% of ovarian tumors. The majority are benign (80%), approximately 10% are borderline, and 10% are invasive. Microscopically, the malignant areas show back-to-back glands with malignant cells and little or no stroma. The epithelial cells are columnar or polygonal with eosinophilic or mucinous cytoplasm. Goblet cells and signet ring cells may be present, although if they are abundant a metastasis from a gastrointestinal origin should be considered. Invasive mucinous carcinoma of ovarian origin is rare and is usually diagnosed at an early stage.[78] Molecular studies have shown a link between borderline and invasive mucinous tumors.[79] Unlike serous ovarian cancers, individual tumors frequently show heterogeneity with benign, borderline, and invasive areas. On gross examination they are the largest of all ovarian tumors, are commonly unilateral, have a smooth surface, and are multilocular.

Endometrioid carcinomas comprise approximately 10% of all epithelial ovarian cancers and commonly arise in extrauterine endometrial tissue. Approximately one third of the cases are associated with endometriosis.[80] Adenocarcinomas associated with endometriosis may develop in association with proliferative adenofibromas and frequently occur after de novo malignant transformation of the endometrial epithelium. They are composed of epithelial cells and patterns similar to endometrial hyperplasia and neoplastic changes of the endometrium. Early-stage endometrioid carcinomas are bilateral in approximately 15% of cases. They are both cystic and solid and often are seen near foci of endometriosis. The grading is identical to that of primary carcinomas of the endometrium. Endometrioid tumors of the ovary carry genetic alterations in the phosphatase and tensin homolog (PTEN) similar to those in the endometrium.

Clear cell carcinomas of the ovary are adenocarcinomas in which most of their epithelial cells have clear cytoplasm, predominantly owing to glycogen, although part may be from mucin. They are easily recognizable under low power because of their unique architecture. They primarily have a papillary pattern with hyalinized stroma, although they can also have a more cystic, glandular, or solid pattern. Clear cell carcinomas are uncommon, comprising approximately 5% of all epithelial ovarian tumors in North America, and almost half are associated with endometriosis. Unlike serous cancers, patients predominantly present with stage I disease (50% to 60%), and when compared stage for stage to serous ovarian cancer, the prognosis seems to be worse.[81,82] However, in Japan, clear cell carcinoma of the ovary represents more than 20% of all epithelial ovarian cancer.[83] The prognosis of stage I clear cell carcinoma in Japan has been shown to be superior to that of serous ovarian cancer. Ovarian clear cell and endometrioid cancers have been shown clinically to be associated with endometriosis; however, the molecular events associated with this transformation have only recently been identified by Gilks et al with regard to ARID1A mutations.[84] They identified ARID1A mutations in 55 of 119 ovarian clear-cell carcinomas (46%), 10 of 33 endometrioid carcinomas (30%), and none of the 76 high-grade serous ovarian carcinomas. They further saw that ARID1A mutations and loss of BAF250a expression was found in tumors and atypical endometriosis but not in endometriotic lesions. These data implicate ARID1A as a tumor-suppressor gene disrupted in endometriosis associated carcinomas and can potentially be an early event in the transformation of endometriosis into cancer.

Transitional cell ovarian carcinomas have epithelial cells that resemble transitional cells of the urinary tract. They include both Brenner tumors (benign, borderline, or malignant) and transitional cell carcinomas. They may be pure or a component of a mixed epithelial tumor. Brenner tumors are mostly arranged in a trabecular pattern, with lipid-rich cells in the stroma. The epithelial cells have a pale, oval nucleus with a longitudinal groove ("coffee bean" nucleus). They are high-grade epithelial tumors that, by definition, do not include the elements of Brenner tumors. The tumor resembles transitional cell tumors originating in the bladder with broad papillae containing highly stratified, crowded cells. The cells have eosinophilic or clear cytoplasm, and the degree of nuclear atypia varies. Transitional cell carcinomas are bilateral in up to 20% of cases.

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Clinical Manifestations

More than 75% of epithelial ovarian cancers are diagnosed when disease has spread throughout the abdominal cavity. The most common presenting symptoms are abdominal discomfort, pain, or distension because of the presence of malignant masses or ascites throughout the peritoneal cavity. Gastrointestinal symptoms (e.g., nausea, early satiety, change in bowel habit/constipation, bloating) are also frequent at the time of diagnosis. Additional symptoms that may occur include fatigue, dysuria, and vaginal bleeding.

In patients with early-stage disease, symptoms are rare. Therefore, the diagnosis is predominantly made incidentally at the time of evaluation for nonrelated gynecologic complaints or by palpation of an asymptomatic ovarian mass. The majority of palpable ovarian masses in women who are premenopausal are benign. In contrast, any palpable mass in a woman who are postmenopausal has a high probability of being malignant.

Patient Evaluation and Diagnosis

Although the diagnosis of ovarian cancer is made at the time of surgery or by biopsy, benign diseases of the female genital tract such as functional cysts, endometriosis, and uterine myomas must be differentiated from ovarian cancer; therefore, patients who present with an adnexal mass must undergo a full evaluation, including history and physical examination. Pelvic ultrasonography and determination of CA 125 level are also used to assist in evaluating the malignant potential of the adnexal mass. A complex mass evident on ultrasound

evaluation containing irregular borders, solid elements with papillary projections, multiple irregular septa, and bilateral tumors is suggestive of malignancy. The use of additional abdominal and extra-abdominal imaging is dependent on the patient's specific complaints and the physical examination.

Serum CA 125 is elevated in 80% of women with epithelial ovarian cancer and is predominantly associated with serous ovarian cancer. It is seldom elevated in the mucinous subtype. In women who are postmenopausal aCA 125 higher than 65 U/mL was found to have a PPV of 98% and a negative predictive value (NPV) of 72%.[85]

Jacobs et al[86] proposed the "Risk of Malignancy Index" in 1990, estimating the risk of an adnexal mass being malignant in a specific patient. It has since been validated in many studies. The Risk of Malignancy Index incorporates the serum CA 125 level, ultrasound scan result (0, 1, or 3), and the menopausal state (0, premenopausal, 3, postmenopausal). These researchers defined a cutoff of 200 in which a sensitivity of 85% and a specificity of 97% for predicting malignancy were found.

Women who present with apparent advanced disease seen on ultrasonography or computed tomography (CT) need a full evaluation before deciding on optimal management. This includes a full personal and family history, physical examination, and assessment of surgical risk, which is pertinent to confirm the likely origin and probable extent of disease. Because most of the symptoms of advanced-stage ovarian cancer are nonspecific it is essential to confirm that the primary tumor is ovarian. Confusion with metastatic gastrointestinal tract malignancy can occur. Additional tests that may be required include serum CA 125 determination, imaging (e.g., chest radiography, CT, magnetic resonance imaging [MRI], barium enema), and upper or lower gastrointestinal endoscopies. Extensive disease may be judged initially unresectable and therefore indicate consideration of neoadjuvant chemotherapy rather than initial surgery.

Surgical Staging

Ovarian cancer is staged surgically according to the FIGO staging system, which was last revised in 1995. The patterns of spread and natural history of ovarian cancer form the basis of the system[28,87] (Table 61-1). The stage can be determined only after an exploration of the abdomen and pelvis, apart from the rare occasion in which stage IV disease may be documented by cytology positive pleural effusion, fine-needle aspiration of a supraclavicular node, or a liver metastasis. Comprehensive surgical staging is mandatory to determine subsequent treatment. When there is no macroscopic disease outside the ovary, an evaluation for microscopic disease must be performed. On entering the abdominal cavity, aspiration of ascites or peritoneal washings should be performed. The abdomen and pelvis should be thoroughly examined and palpated; any suspicious lesions should be sampled. The tumor should be removed intact if possible because spillage of malignant cells is suggested to worsen the prognosis.[88] The remaining ovary, uterus, and fallopian tubes should be removed unless fertility sparing is appropriate (premenopausal patient with a low-grade or borderline ovarian cancer). Pelvic and paraaortic lymph nodes should be systematically removed, an omentectomy performed, and random peritoneal biopsy specimens taken. Carnino et al showed that the detection of positive lymph nodes correlated with the number of lymph nodes removed (odds ratio [OR], 3.9 for more than 10 lymph nodes in comparison to 1 to 5; 95% CI, 1.0 to 15.4), therefore emphasizing the importance of systematic lymph node dissection.[89] Patients initially thought to have early-stage disease that undergo subsequent comprehensive surgical staging may be upstaged in up to 30% of the cases.[90]

TABLE 61-1 FIGO Staging for Carcinoma of the Ovary

Stage	Description
I	Growth limited to the ovaries
IA	Growth limited to one ovary; no ascites containing malignant cells. No tumor on the external surface; capsule intact
IB	Growth limited to both ovaries; no ascites containing malignant cells. No tumor on the external surface; capsule intact
IC	Tumor either stage IA or IB but with tumor on the surface of one or both of the ovaries; or with capsule(s) ruptured; or with ascites present containing malignant cells or with positive peritoneal washings
II	Growth involving one or both ovaries with pelvic extension
IIA	Extension or metastases to the uterus or fallopian tubes
IIB	Extension to other pelvic tissues
IIC	Tumor either stage IIA or IIB but with tumor on the surface of one or both of the ovaries; or with capsule(s) ruptured; or with ascites present containing malignant cells or with positive peritoneal washings
III	Tumor involving one or both ovaries with peritoneal implants outside the pelvis or positive retroperitoneal or inguinal nodes. Superficial liver metastases equals stage III. Tumor is limited to the true pelvis, but with histologically proven malignant extension to small bowel or omentum
IIIA	Tumor grossly limited to the true pelvis with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces
IIIB	Tumor of one or both ovaries with histologically confirmed implants of abdominal peritoneal surfaces, none > 2 cm in diameter. Nodes negative
IIIC	Abdominal implants > 2 cm in diameter or positive retroperitoneal or inguinal lymph nodes or both
IV	Growth involving one or both ovaries with distant metastases. If pleural effusion is present, there must be positive cytologic test results to allot a case to stage IV. Parenchymal liver metastasis equals stage IV

It has also been shown that it is important that a gynecologic oncologist perform the operation. The percent of properly staged women varies by type of surgical qualification and is 97%, 52%, and 35% when the staging was performed by a gynecologic oncologist, obstetrician/gynecologist, or general surgeon, respectively.[91]

PRIMARY TREATMENT OF OVARIAN EPITHELIAL CANCER

The selection of treatment for each individual patient presenting with epithelial ovarian cancer should be based on the extent of disease, performance status, and individual patient characteristics. Therapeutic options include surgery, chemotherapy, radiation, or a combination of modalities. The identification of biomarkers and subsequent exploration of novel targeting molecular therapies constitute an important direction of research and potential therapeutic opportunity.

Early-Stage Disease: Surgery and Chemotherapy

There is consensus that all patients should undergo comprehensive surgical staging as their primary treatment. Approximately one third of patients with epithelial ovarian cancer present with apparent localized disease confined to the ovaries or to the pelvis. When all patients undergo surgical staging, however, this number decreases to 10% to 15%. Because the percentage of patients with early-stage disease is small and their prognosis is good, it is difficult to conduct studies evaluating the yield of adjuvant treatment for this group of patients.

Two randomized trials—International Collaborative Ovarian Neoplasm Trial 1 (ICON1) and Adjuvant ChemoTherapy In Ovarian Neoplasm Trial (ACTION)[92,93]—addressed the question of the efficacy of adjuvant chemo to improve survival in women with early-stage disease. Both trials randomized patients with early-stage disease to adjuvant platinum-based chemotherapy or no adjuvant treatment. The analysis of the combined trials showed an 8% difference in OS in favor of the adjuvant chemo arm (82% versus 74%, $p = 0.008$). Relapse-free survival (RFS) was also significantly better in the chemo arm of the trials (76% versus 65%, $p = 0.001$).

When the trials were analyzed separately, OS for all patients treated with chemo in comparison to those who did not receive adjuvant chemo in the ACTION trial was not found to be significantly better (hazard ratio [HR], 0.69; 95% CI, 0.44 to 1.08). On subgroup analyses, those whose disease was not surgically staged were found to significantly benefit from adjuvant chemo (OS HR, 1.75; 95% CI, 1.04 to 2.95). However in those optimally staged without evidence of metastatic disease, there was no benefit. This study was not powered to further analyze the influence of histology. Therefore, patients who do not have an optimal staging procedure should receive adjuvant chemotherapy. The benefit of adjuvant chemo in high-grade surgical stage I disease is unclear.

A literature review analyzed the results of 22 prospective randomized trials on the topic of benefit of adjuvant chemo in patients with early disease who had optimal surgical staging.[94] They concluded that adjuvant therapy is not advocated for patients with stage IA grade-1 tumors as their prognosis is excellent.[95] For patients with low-grade disease who did not have a comprehensive staging procedure, it is reasonable to offer completion of a staging procedure to avoid chemo in the proportion of patients shown to have no extra-ovarian disease. The alternative to avoid additional surgery is to give adjuvant chemo on the assumption that further disease is present in some patients.

Consideration of the prognostic factors (i.e., grade, stage, DNA ploidy, and CA 125 levels) may aid in assessing the probability of occult disease. For the clear cell subtype the acknowledged relative chemoresistance may suggest limited benefit from adjuvant chemotherapy.

Fertility-Sparing Therapy

Epithelial ovarian cancer occurs infrequently in women of childbearing age, with an estimated 8% of all malignant stage I epithelial cancers diagnosed in women younger than the age of 35.[96] Although there is relative consensus in regard to conservative surgical treatment (i.e., adnexectomy with comprehensive surgical staging), for patients with early-stage tumors of low malignant potential the literature is limited in regard to young patients with invasive epithelial tumors. Schilder et al[97,98] published a multiinstitutional study in 2002 on 52 women with stage IA ($n = 42$) or stage IC ($n = 10$) patients treated with fertility-sparing surgery and full surgical staging. Although all histologic cell types and grades were included, the majority of cases were mucinous ($n = 25$) and grade 1 ($n = 38$), and only 10 were of the serous cell type. Twenty patients received adjuvant chemo including all with stage IC grade 2 to grade 3. Five patients experienced relapse, and 2 died of their disease. The estimated 5-year OS was 98%, and the 10-year OS was 93%. Twenty-four patients, 6 who had received adjuvant chemo, attempted to conceive and 17 succeeded (71%). In a recent systematic review by Zapardiel et al, a total of 793 cases were reviewed and found to have a 5-year OS of 91%.[99] They further address the consensus in regard to fertility sparing in cases of stage I grade-1 and grade-2 ovarian cancer and the lack of consensus in regard to high-grade ovarian cancers. A study by Fruscio et al of 240 cases who underwent conservative treatment noted that although the tumor grade was the only independent predictor of poor prognosis the PFS and OS rates in the high-grade population is comparable to that shown in ICON1/ACTION trial where conservative treatment was not performed and therefore they conclude that conservative management does not seem to worsen prognosis.[100]

Young patients with stage IA disease can undergo fertility-sparing surgery and close follow-up without the need for adjuvant treatment. Patients with stage IC grade-2 to grade-3 disease can be managed with conservative surgery, but adjuvant chemo should be considered.

Radiation Therapy

Epithelial ovarian cancer is known to be a radiosensitive tumor. The benefit of adjuvant RT in patients with early-stage epithelial ovarian cancer has been evaluated in a series of studies.[101-103] Both intraperitoneal (IP) radioactive chromic phosphate suspension (^{32}P) and whole-abdomen irradiation (WAI) with a boost to the pelvis have been evaluated. Studies have suggested that the addition of RT to chemo for subsets of patients may have an expanding indication.[104-106]

Intraperitoneal Radioactive Chromic Phosphate Suspension (^{32}P)

Intraperitoneal instillation of radioisotopes, such as gold (^{198}Au) and chromic phosphate (^{32}P), have been studied in patients with ovarian cancer. It is now rarely used. Although the initial studies were performed using ^{198}Au, ^{32}P became the preferred isotope because of ease of handling, lack of gamma radiation, and a relatively low complication rate.[107] ^{32}P is a high-energy pure beta-particle emitter with a maximum energy of 1.71 MeV, a maximum penetration of 8 mm (average, 1 mm to 4 mm), and a half-life of 14.3 days. It can be used for intracavitary instillation at a dose of 10 mCi to 20 mCi. The majority of the ^{32}P is absorbed by the peritoneal surface via macrophages and then excreted through the lymphatic channels of the abdomen, that is, the thoracic lymphatics, and from there into the systemic vasculature where it is cleared by the liver. The retroperitoneal pelvic and paraaortic lymph nodes receive low doses of radiation. Because the main pattern of spread of ovarian cancer is transcoelomic, the IP instillation of radiocolloids, which deliver high doses of radiation to the peritoneal surfaces while minimizing systemic effect, would seem theoretically ideal. Gamma camera imaging of the abdomen has shown that the administration procedure including mobilization of the patients in the first 6 hours is critical for homogeneous dispersion of the radiocolloids on the serosal surfaces.[108] Dose calculations gave an estimated tissue surface dose of 30 Gy per 370 MBq of ^{32}P administered. The amount of ^{32}P in peripheral blood increased for 7 days after administration and was then followed by a continuous decrease. The estimated peripheral blood dose is 0.012 Gy, and the maximum bone marrow dose is 0.06 Gy.

TABLE 61-2 Early-Stage Ovarian Cancer: Randomized Trials of Whole-Abdomen Irradiation or ^{32}P

Trial/Author	Year	Stage	Study Design	No. Patients	5-Year Overall Survival (%)	Comments
NCIC/Klaassen[110]	1988	I, II	Pelvic RT + melphalan	106	61	^{32}P arm accrual closed early because of toxicity
			Pelvic RT + WAI	107	62	
			Pelvic RT + ^{32}P	44	66	
MDACC/Smith[103]	1975	I-III	WAI	51	71	<2 cm residual disease
			Melphalan	57	72	
PMH/Dembo[113]	1979	IB, II, III asymptomatic	WAI	76	64 (10-year)	$p = 0.007$
			Pelvic RT ± chlorambucil	71	40 (10-year)	
DACOVA/Sell[114]	1990	IB-IC, II	WAI	60	63 (4-year)	
			Pelvic RT + cyclophosphamide	58	65 (4-year)	
GOG 95/Young[51]	1990	IA-IBG3, IC, II	^{32}P	73	78	6% bowel obstruction in ^{32}P
			Melphalan	68	81	
NRH/Vergote[111]	1992	I-III	^{32}P or WAI	169	83	28 in ^{32}P arm treated with WAI
			Cisplatin	171	81	
GICOG/Bolis[112]	1995	IA-IB, IC	^{32}P	75	79	^{32}P not given in 20% of patients
			Cisplatin	77	81	
GOG 7602/Young[109]	2003	IA-IBG3, IC, II	^{32}P	110	78	3% bowel perforation in ^{32}P
			Cyclophosphamide + cisplatin	119	81	

Several randomized studies evaluating the efficacy of ^{32}P in early-stage ovarian cancer have been published[51,109-112] (Table 61-2). The earliest of the randomized trials was published in 1988 by the National Cancer Institute of Canada (NCIC).[110] Two hundred fifty-seven women with stages I to IIA high-risk ovarian cancer or with stage II disease were randomized to one of three trial arms: arm A, WAI (22.5 Gy in 20 fractions); arm B, melphalan; or arm C, ^{32}P. Surgical staging was not mandatory, and most patients' disease was not thoroughly staged. All patients were initially treated with pelvic RT (arm A: 22.5 Gy in 10 fractions; arms B and C: 45 Gy in 20 fractions). The ^{32}P trial arm was discontinued early because of increased bowel toxicity. No significant difference in survival was found.

In 1990 the Gynecologic Oncology Group (GOG) published a randomized controlled trial including 141 patients with stage I, grade-3 or stage II epithelial ovarian cancer randomly assigned to melphalan or a single dose of ^{32}P at the time of surgery.[51] With a median follow-up of more than 6 years the outcomes for the two treatment groups were similar with respect to 5-year disease-free survival (DFS) (80% in both groups) and 5-year OS (81% with melphalan versus 78% with ^{32}P; $p = 0.48$). They concluded that either treatment was a reasonable option.

In 1992, Vergote et al[111] published a randomized trial of 347 patients, stages I to III (no gross residual tumor), who were allocated to cisplatin (50 mg/m^2) every 3 weeks for six cycles or ^{32}P. Patients with intraabdominal adhesions allocated to IP administration of ^{32}P were treated with WAI (22 Gy to the whole abdomen in 20 fractions) followed by 22 Gy in 11 fractions to the pelvis. Patients did not undergo comprehensive staging because lymph node sampling was not performed. The estimated 5-year OS of patients with stage I disease were 82% for the ^{32}P arm, 94% for the WAI arm, and 79% for the cisplatin arm ($p = 0.79$, $p = 0.44$ compared with the cisplatin arm, respectively). Bowel obstruction occurred more frequently in those treated with ^{32}P (9%, $p = 0.02$) or WAI (21%, $p = 0.001$) in comparison with the cisplatin arm (2%). Because no survival benefit was shown, cisplatin was recommended as the standard treatment.

The Italian Gruppo Interregionale Collaborativo in Ginecologia Oncologica (GICOG) performed a randomized trial[112] of 152 women with stage IA grade 2, IB grade 2, and IC disease, comparing treatment with cisplatin with that with ^{32}P. Patients underwent a surgical procedure that did not include lymph node sampling. In 15 patients randomized to treatment with ^{32}P, the radioisotope was not delivered, owing to the development of abdominal adhesions. An improved 5-year PFS was reported for the cisplatin group in comparison with the ^{32}P group (85% versus 65%, $p = 0.008$) but without an OS difference (81% versus 79%, $p = 0.35$).

The latest randomized study was published by the GOG in 2003. Two hundred twenty-nine women with early-stage ovarian cancer at high risk for relapse (defined as stage IA or IB grade 3, stage IC, or stage II, no macroscopic residual) were assigned to treatment with ^{32}P or with cyclophosphamide and cisplatin.[109] The cumulative incidence of relapse at 10 years was 35% for the ^{32}P arm and 28% for the cyclophosphamide-cisplatin arm. Patients receiving cyclophosphamide-cisplatin had a relapse rate 29% lower than those in the RT arm ($p = 0.15$) and a death rate 17% lower than those in the RT arm ($p = 0.43$). The toxicity profiles of both regimens were reasonably well tolerated, although 3% of the patients receiving ^{32}P suffered perforation of the small bowel during the insertion of the IP catheter and 7% had problems with inadequate distribution. Grade-3 or grade-4 gastrointestinal toxicity was seen in 12% of patients treated with cyclophosphamide and cisplatin. The authors concluded that, although there were no statistically significant differences, the lower relapse rate seen in the chemo arm together with ^{32}P complications make platinum-based chemo the preferred adjuvant therapy.

External Beam Irradiation

WAI has generally been used in patients in whom the tumor was completely resected or in whom macroscopic disease is

<2 cm in diameter and located only in the pelvis. Adjuvant WAI has generally not been used to treat macroscopic extrapelvic residual disease because tolerable doses of radiation are generally insufficient to eradicate more than microscopic residuum except in the pelvis, where higher doses may be administered. Its advantage in comparison to ^{32}P is the ability to deliver a homogeneous dose to all areas of the abdomen and pelvis and the ability to encompass the pelvic and paraaortic lymph nodes. The disadvantage of WAI with conventional techniques is the dose-limiting acute and late toxicity related to the treatment, which is predominantly hematologic and gastrointestinal. The target volume includes the entire peritoneum, with the cephalad border being superior to the diaphragm and the caudal border the pelvic floor, thus encompassing peritoneal surfaces, pelvic and paraaortic lymph nodes, and the organs in the abdomen and pelvis. As the majority of relapses are confined to the abdominal and pelvic cavity, it is reasonable to expect that RT techniques that encompass the entire peritoneal cavity would be more likely to be curative. The total dose to the whole abdomen is limited to 25 Gy to 30 Gy, owing to the dose-limiting organs in the field, although the pelvis is usually given a total dose of 45 Gy.

Multiple randomized trials have been published evaluating the efficacy and toxicity of WAI in patients with early-stage ovarian cancer (see Table 61-2). Early studies established the inadequacy of treating the pelvis alone in patients with no gross residual disease.[113,115,116]

A trial from the Princess Margaret Hospital randomized 147 women with stages I to III disease comparing WAI and pelvic RT to pelvic RT alone or in combination with chlorambucil.[113] After a 7-year follow-up, the 10-year OS difference was significantly higher in the 76 patients treated with pelvic and WAI in comparison to the 71 patients treated with pelvic RT and chlorambucil (46% versus 31%, $p = 0.05$). The survival benefit was present only in patients with no gross residual disease or small volume pelvic residuum (<2 cm).

Hreshchyshyn et al[117] published a randomized trial of 86 patients who were clinical stage I (not surgically staged) randomized to pelvic RT, melphalan, or no additional treatment. They did not find a survival difference between observation and pelvic RT but did find a benefit for melphalan.

Several studies have compared chemo to RT, although only one incorporated a cisplatin-based regimen.[110,114,118,119] As previously noted, the NCIC randomized 257 women with stage I, IIA high-risk ovarian cancer, or stage IIB, and stage III to one of three trial arms: whole-abdomen/pelvic RT, melphalan, or ^{32}P.[110] No significant difference in survival was found. Smith et al[97] randomly assigned 149 patients with early-stage ovarian cancer to postoperative whole-abdomen/pelvic RT or melphalan. No survival difference was found between the groups.

The Northwest Oncologic Cooperative Group of Italy (NOCGI) conducted the only prospective randomized trial[119] in women with high-risk early-stage (stage I or II) ovarian cancer, comparing WAI with a cisplatin-based regimen. It was not completed. They randomized 70 women to cisplatin 50 mg/m^2 and cyclophosphamide 600 mg/m^2 or to WAI in an open technique, consisting of 43.2 Gy/24 fractions to the pelvis and 30.2 Gy to the upper abdomen. The study was closed early owing to multiple protocol violations (63% of patients were treated with chemo) and low accrual. With a median follow-up of 60 months, the 5-year OS was 71% for the cisplatin and cyclophosphamide arm and 53% for the WAI arm ($p = 0.16$). Although toxicity was well tolerated in the chemo arm of the study, in the WAI arm 28% of patients suffered from grade-3 to grade-4 acute diarrhea, two had severe enteritis requiring hospitalization, and one had late bowel obstruction requiring surgery.

In 1996, the GOG initiated a prospective randomized trial comparing WAI with platinum-based chemotherapy. Unfortunately the trial was not completed because of low accrual rates.

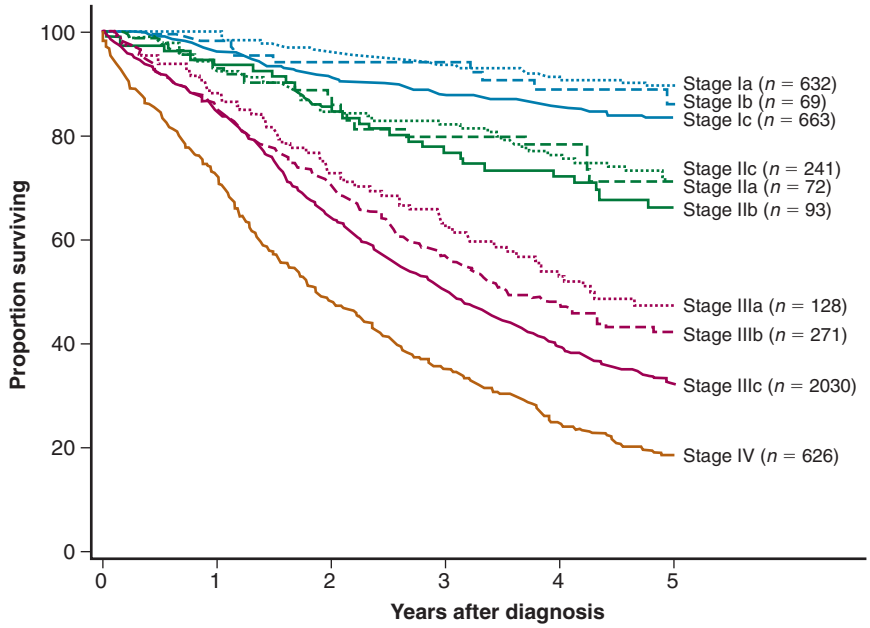
In the majority of studies looking at the efficacy of RT, all epithelial malignancies were included. There is some suggestion that certain histologic subtypes might benefit from the use of RT. Clear cell carcinomas particularly are typically chemotherapy resistant. Small studies have been conducted. Nagai et al[105] compared adjuvant platinum-based chemo to adjuvant WAI alone in 28 women with stages I to III ovarian clear cell carcinoma. Five-year OS and DFS in the RT arm were 81.8% and 81.2% versus 33.3% and 25% in the chemo arm ($p = 0.031$, $p = 0.006$), respectively. Locoregional control was also considerably improved with adjuvant RT. Only 1 of the 16 patients receiving RT had an isolated locoregional recurrence versus 7 who had locoregional recurrences in the 12 patients in the chemo arm. Dinniwell et al[104] performed a prospective, risk-stratified study of 29 patients with stages I to III epithelial ovarian cancer combining surgery, chemo, and adjuvant WAI. The subset of 11 patients with clear cell carcinoma and 5 with endometrioid histologies showed the greatest gains from this aggressive, multimodality approach, with a 4-year DFS of 77% compared with 27% for serous subtypes ($p = 0.01$). Finally, a retrospective but hypothesis generating study by Swenerton et al reported an improved survival in patients with stages I and II clear cell, endometrioid, and mucinous histotypes with the addition of adjuvant WAI to chemotherapy.[106] This group further published in 2012 a study on 241 stages I to II clear cell ovarian cancers comparing two groups; those treated with adjuvant chemo and RT and those treated with chemo only.[120] By physician choice, 211 were treated with chemo alone and 103 had the addition of pelvic and whole abdominal RT in a dose of 22.5 Gy to the pelvis in 10 fractions, followed by 22.5 Gy in 22 fractions to the whole abdomen. Although the groups were not randomly assigned, the stage distribution was comparable between the groups. They found no benefit for radiation in patients with stages IA and IC (rupture alone); however, a PFS benefit of 20% at 5 years in patients with stage IC and stage II was observed. For patients wit stage IC disease (cytology positive or surface involvement) this represents a RR reduction of 49% in those treated with radiation in comparison to those treated with chemo alone. The hypothesis generated from this observation was that improved pelvic control translated into a lower rate of relapse in this patient population. At this point in time there is limited data however. Given that clear cell cancers often are pelvic confined and that they are chemo resistant, an innovative research approach might consider examining a combination of novel targeting agents and pelvic RT in nonserous subtypes.

The trials cited in this section have demonstrated that radiation is an effective adjuvant modality for specific patients with ovarian cancer. However, currently it is used rarely and platinum-based chemo is considered the preferred modality. The role of adjuvant RT in certain early-stage nonserous histologies should be investigated.

LOCALLY ADVANCED DISEASE AND PALLIATION

Advanced-Stage Disease

The majority of cases of epithelial ovarian cancer are diagnosed when the tumor has spread throughout the abdomen and pelvis. Exploratory laparotomy is performed for the purpose of diagnosis, staging, and treatment.

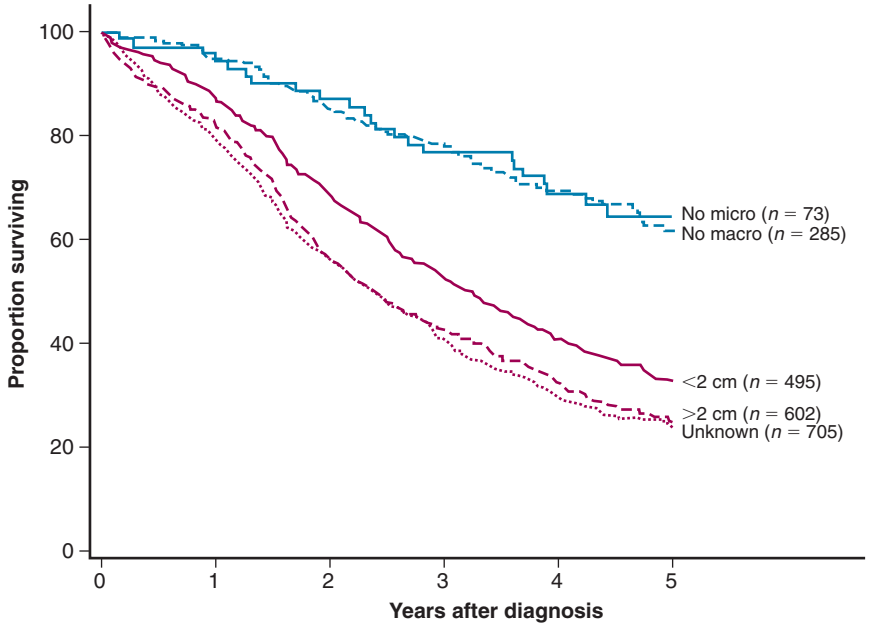


Epithelial ovarian cancer predominantly spreads throughout the peritoneal cavity and multiple masses are regularly

found at time of exploration. For most solid tumors, aggressive surgical resection is justified only if all known tumor can be excised; however, in ovarian cancer this is not the case. Cytoreductive surgery (known also as "debulking") is the standard. Munnell et al[121] were the first to introduce the concept of "maximum surgical effort" for ovarian cancer in 1968. They report on improved survival when patients had a maximum surgical effort in comparison to a biopsy or partial removal. Griffiths[122] was the first to show a significantly improved survival from this strategy in patients with residual disease less than 1.5 cm. Since then, "optimal debulking" has been defined as no tumor masses larger than 1 cm at the completion of surgery; however, the outcome is superior when there is no macroscopic residual.[123]

Hoskins et al reported on the effect of the maximum size of residual disease on the prognosis.[124] They found that among patients with suboptimal debulking (>1 cm residual disease), those with small-diameter residual disease (<2 cm) tended to survive longer than those who had larger residual disease. However, among those with larger residual disease, size did not affect prognosis appreciably. In 2006, Heintz et al[125] published an annual report on ovarian cancer. Five-year OS for the 2160 patients diagnosed with stage IIIC disease was 62.1% for no macroscopic, 32.9% for size less than 2 cm, and 24.8% for size greater than 2 cm. In concordance with the findings of Hoskins et al,[124] the most significant difference is between no macroscopic disease and any macroscopic residual disease (Figures 61-2 and 61-3).

These findings are important to guide management. Therefore, if disease cannot be cytoreduced to less than 2 cm, there is no survival advantage in proceeding with the debulking surgery, which can be a morbid procedure, especially if bowel resections, liver resections, and ostomies are added.



Patients presenting with stage IV disease have been included in most advanced ovarian cancer studies; precise data on their benefit from cytoreductive surgery are limited. Similar to the findings in stage III disease, retrospective studies have shown a statistically significant improvement in survival in cases in which optimal debulking is achieved.[126,127] Bristow et al[126] found optimal surgical debulking and performance status to be important determinants of survival. They showed that even in patients with unresectable liver metastasis,

optimal debulking of extrahepatic disease is associated with a significant survival advantage.

The success rate for optimal debulking varies widely between studies, from 20% to 85%.[128-130] This can be attributed to many factors, including the definition of optimal debulking, the expertise of the surgeon, the patient population (the percent of patients deemed unresectable before a surgical attempt), and probably the biology of the disease.

Because many patients cannot be optimally debulked initially, or the procedure needed to accomplish this is associated with a high risk of significant morbidity, neoadjuvant chemo to accomplish debulking has been introduced and studied. Several retrospective studies have reported survival results of patients treated with neoadjuvant chemo followed by interval debulking to be the same as for patients treated with primary debulking surgery.[131-134]

In the 1980s the European Organization for Research and Treatment of Cancer (EORTC) and the GOG (protocol 152) initiated two randomized trials to investigate the role of interval debulking in cases in which optimal debulking cannot be achieved at primary surgery.[135,136] The EORTC study included 278 women with suboptimally debulked disease (>1 cm residuum, FIGO stages IIB to IV). After completing three cycles of chemo (cisplatin-cyclophosphamide), the patients were randomized to an additional three cycles of chemo or to interval debulking followed by three more cycles of chemotherapy. The 2-year PFS and OS were significantly higher in the interval-debulking arm (OS, 56% versus 46%, $p = 0.01$). The difference in median OS was 6 months. After adjusting for other prognostic factors, interval debulking reduced the risk of death by 33%. GOG protocol 152 randomized 425 suboptimally debulked patients (>1 cm residual disease) who received three cycles of paclitaxel and cisplatin plus interval debulking (followed by three additional cycles of chemo) or three further cycles of chemo without surgery.[136] The median survival and PFS of the two groups was similar (32 versus 33 months and 10.5 versus 10.8 months, respectively). Their conclusion was that women who underwent an initial maximal but suboptimal debulking procedure did not benefit from interval debulking surgery. One of the main differences between the trials was that the initial surgery in protocol 152 was required to be appropriate ovarian cancer surgery (the majority performed by a gynecologic oncologist), whereas in the EORTC trial many of the patients had a minimal surgical effort at primary surgery by a general gynecologist. The majority consensus from these two studies is that debulking surgery should be performed by a gynecologic oncologist.[137]

Bristow and Chi[134] performed a meta-analysis including 22 studies. They concluded that neoadjuvant chemo is correlated with a worse prognosis than primary debulking surgery. The EORTC in collaboration with the NCIC in 2010 published the results of a prospective randomized trial including 718 patients with stages IIIC to IV ovarian cancer randomized to primary debulking surgery and six cycles of postoperative chemo or

to three cycles of neoadjuvant chemo followed by interval debulking and an additional three cycles of chemotherapy.[138] The results show a HR for death (intention-to-treat analysis) of 0.98 (90% CI, 0.84 to 1.13; $p = 0.01$ for noninferiority), and the HR for progressive disease of 1.01 (90% CI, 0.89 to 1.15) with a median PFS of 12 months in both groups. Complete resection of all macroscopic disease at surgery was the strongest independent variable in predicting OS. Importantly significant reduction in surgical complications in the interval debulking arm, including postoperative deaths (2.5% versus 0.7%), was noted. The results of this multiinstitution, multinational trial were not universally accepted. The rate of complete cytoreduction at primary surgery was low (19.4%) and remarkably variable with a range of 3.9% to 62.9%. This suggests a lack of surgical expertise and begs the question of generalizability of the results to centers with high surgical standards. In addition the survival of patients who underwent primary debulking was considered modest in comparison to other previous publications of nonrandomized data. Hence, in advanced stage ovarian cancer the decision between neoadjuvant chemo and interval debulking versus primary debulking surgery is still controversial.

Role of Chemotherapy

Surgery alone is not curative for advanced-stage ovarian cancer as microscopic residual disease is inevitable. Epithelial ovarian cancer is highly chemosensitive; therefore, standard postoperative treatment is combination chemotherapy. Platinum compounds are the most active agents and are the foundation of treatment. Their first use was reported in a small trial in 1982, which suggested a possible benefit to the addition of cisplatin to cyclophosphamide.

In 1986, the GOG published a randomized trial of 440 patients with advanced-stage ovarian cancer, comparing cyclophosphamide and doxorubicin with or without cisplatin.[139] The clinical complete response rate was 26% for cyclophosphamide and doxorubicin and 51% for the combination of cyclophosphamide, doxorubicin, and cisplatin ($p = 0.0001$). A survival benefit was seen for the platinum-based regimen in patients with measurable disease (median OS, 19.7 versus 15.7 months, $p < 0.03$), although not for patients without measurable disease. This and other trials lead to the use of platinum-based combination regimens as the standard of care. One of the important advances made in chemotherapeutic treatment of advanced ovarian cancer is the incorporation of the taxane, paclitaxel, into combination regimens. The GOG performed a randomized trial (protocol 111) comparing therapy with cisplatin and paclitaxel to that with cisplatin and cyclophosphamide.[140] Three hundred eighty-six suboptimally debulked (residual tumor > 1 cm) patients were randomized. Of the 216 with measurable disease, a superior response rate and survival was found for the cisplatin-paclitaxel trial arm (73% versus 60%, $p = 0.01$ and median OS, 38 versus 24 months, $p < 0.001$), respectively. The EORTC-NCIC performed an intergroup trial (OV-10) recruiting 680 women with broader inclusion criteria.[141] They included patients with stages IIB and IIC disease and optimal residuum and allowed for interval debulking. The overall response rate, PFS, and OS were statistically improved in the cisplatin-paclitaxel trial arm with median prolongation in OS of 10 months (35.6 versus 25.8 months, $p = 0.0016$). After the publication of these two Phase III randomized trials, the use of cisplatin-paclitaxel was established as the new standard of care.

Carboplatin, a second-generation platinum-based agent, is less nephrotoxic, neurotoxic, ototoxic, and emetogenic in comparison with cisplatin, although it is associated with a higher degree of myelosuppression, primarily thrombocytopenia.[142-144] Because of its renal excretion, patients with impaired renal function require individualized dose adjustment.[142] Multiple studies have shown equivalent efficacy between cisplatin and carboplatin and less toxicity for the latter. A meta-analysis of 12 randomized trials, including 2219 patients and 1745 deaths, confirmed this whether given as a single-agent or in combination regimens.[143]

The GOG performed a Phase III, noninferiority trial (protocol 158) of 792 women with small-volume stage III disease comparing cisplatin-paclitaxel and carboplatin-paclitaxel.[144] Median OS was 48.7 months for patients receiving cisplatin-paclitaxel arm compared with 57.4 months for those with carboplatin. The RR of death was 0.84 (95% CI = 0.70 to 1.02) for the carboplatin plus paclitaxel group. The GOG concluded that carboplatin plus paclitaxel resulted in less toxicity (gastrointestinal, renal, and grade-4 leukopenia) and was not inferior when compared with cisplatin plus paclitaxel. Combined therapy with carboplatin and paclitaxel is now considered the standard for first-line care of epithelial ovarian cancer.

The Gynecologic Cancer Intergroup (GCIG) evaluated the benefits of incorporating an additional cytotoxic drug or doublet with carboplatin-paclitaxel.[145] Women with stages III and IV epithelial ovarian cancer ($n = 4312$) were randomized to one of five trial arms (incorporating gemcitabine, liposomal doxorubicin, and topotecan) and compared to carboplatin-paclitaxel. There were no improvements in PFS or OS for the experimental regimens. Thus, the addition of these specific third chemotherapeutic drugs to the carboplatin-paclitaxel combination is not indicated.

Dose intensity of platinum regimens has been evaluated in numerous studies of different regimens.[146-148] There appears little evidence to support increased dose intensity of cisplatin and cyclophosphamide in regimens for advanced-stage epithelial ovarian cancer.[146] In 2009 Katsumata et al reported on a Phase III randomized controlled open label trial (JGOG 3016) of 637 patients with stages II to IV ovarian, fallopian tube or primary peritoneal cancer comparing a conventional regimen of six cycles of paclitaxel (180 mg/m^2; 3-hour IV infusion) plus carboplatin (AUC 6), given every 21-days to a dose-dense paclitaxel regimen (80 mg/m^2; 1-hour IV infusion) given on days 1, 8, and 15 plus carboplatin given on day 1 of a 21-day cycle.[149] They demonstrated a statistically significant improvement in median PFS (28 versus 17.2 months; HR, 0.71; 95% CI, 0.58 to 0.88) and 3-year OS (72.1% versus 65.1%; HR, 0.75; 95% CI, 0.57 to 0.98) for those who received the dose-dense regimen. Furthermore, in a subsequent publication looking at long-term results at a median follow-up of 6.5 years they reported a median OS of 100.5 months in the dose-dense treatment group and 62.2 months in the conventional treatment group (HR, 0.79; 95% CI, 0.63 to 0.99; $p = 0.039$).[150] Two large confirmatory trials of dose dense paclitaxel are under way: GOG 262 has completed accrual and results should be available soon and ICON8 completed accrual in the fall of 2014.

IP chemo has been evaluated in three large Phase III randomized trials.[151-153] Alberts et al published in 1996, a Phase III trial of IP cisplatin and IV cyclophosphamide compared with IV cisplatin and IV cyclophosphamide in 546 women with stage III optimally debulked (residual disease <2 cm) ovarian cancer.[152] Outcomes were improved for the IP arm and had less toxicity. However, because cyclophosphamide was no longer a standard regimen, additional studies were required to determine if the advantage was related to the route of administration when regimens incorporating paclitaxel were given.

In 2006, the GOG published a Phase III randomized trial (protocol 172) comparing IP cisplatin and paclitaxel compared with IV cisplatin and paclitaxel.[153] The median OS was found to be 49.7 months in the IV chemo arm and 65.6 months in the IP arm ($p = 0.03$). However, only 42% of patients allocated to

IP chemo completed all six IP cycles (primarily because of catheter-related issues and toxicity), in comparison to 83% allocated to IV chemotherapy. All patients who could not complete treatment in the allocated trial arm were switched to intravenous carboplatin. Quality of life was found to be significantly worse in the IP trial arm up to 6 weeks after treatment but returned to being equivalent to the IV arm 1 year after treatment.[154]

A systemic review of IP chemo identified seven randomized trials: three large Phase III trials and four smaller randomized trials.[155] All three large trials detected a statistically significant benefit in OS with IP cisplatin-based chemotherapy. A pooled analysis of six of the trials confirmed a survival benefit with IP cisplatin-based chemo (RR, 0.88; 95% CI, 0.81 to 0.95). Significant adverse effects including catheter-related complications were more common in the IP group.

In 2006 the U.S. National Cancer Institute (NCI) issued a clinical announcement advocating the use of IP chemo in the treatment of women with optimally debulked ovarian cancer.[156] Although the trials of IP chemo show a survival advantage, the incorporation of IP therapy into general practice is low. The reasons for the reluctance of practitioners include the high level of toxicity associated with the specific regimens showing benefit, the technical difficulties in delivery of the treatment, particularly the necessity for catheter placement and management, and the fact that no trial to date has compared IP chemo with the standard IV carboplatin-paclitaxel. Those using IP chemotherapy usually use lower doses than those reported in the positive trials. The GOG is currently performing trials of IP carboplatin-paclitaxel.

The majority of patients with ovarian cancer enter a state of remission on completion of surgery and postoperative chemotherapy. However, approximately 85% of patients in remission ultimately experience relapse; therefore, maintenance therapy has been proposed and investigated.

A GOG study (GOG 178) evaluated the efficacy of 12 versus 3 cycles of maintenance paclitaxel in patients who achieved a complete response to primary chemotherapy.[157] Because of an improvement in PFS with 12 cycles on an interim analysis (28 months versus 21 months, $p = 0.035$), the trial was closed. It was recommended that all participants then receive 12 cycles of paclitaxel. The difference in PFS did not translate into an OS benefit (median OS 53 versus 48 months for patients who received 12 versus 3 cycles of maintenance paclitaxel [$p = 0.34$]).[158] The proposed explanations behind the improved PFS without an improved OS include the high efficacy of treatment at relapse, crossover into the 12-cycle arm, and an insufficient sample size.

Currently, maintenance therapy with conventional antineoplastic agents is not recommended.

Molecular Targeting Agents

Molecular-targeted therapies have become the frontline of cancer research in many tumor sites and their investigation in ovarian cancer has evolved in the last 5 years. Two Phase III trials (GOG-0218 and ICON7) have evaluated the role of bevacizumab as concomitant and maintenance therapy in first-line therapy for ovarian, fallopian tube, and primary peritoneal cancers following surgical cytoreduction.[159,160] GOG 218, a double-blind, placebo-controlled Phase III randomized trial of 1873 stage III (incompletely resectable) or patients with stage IV ovarian cancer randomized to one of three arms; standard chemotherapy with placebo from cycles 2 through 22, standard chemotherapy with bevacizumab (15 mg/kg of body weight) from cycles 2 through 22 and standard chemotherapy with bevacizumab from cycles 2 through 6 and then placebo during cycles 7 through 22.[159] No difference in PFS was found between the control group and the arm treated with concomitant bevacizumab; however, a statistically significant increase in PFS was found between the control arm and the treatment arm of maintenance bevacizumab (10.3 months versus 14.1 months), with a HR of progression or death of 0.717 (95% CI, 0.625 to 0.824). No OS or quality-of-life differences were found between the three arms. Hypertension grade-2 or greater was more common with bevacizumab than with the placebo in a cost effectiveness evaluation by GOG. Because of the high drug cost, bevacizumab was not cost effective.[161] ICON7, a double-blind, placebo-controlled Phase II study, randomly assigned 1528 women after initial surgery to standard chemotherapy plus placebo or standard chemotherapy and bevacizumab (7.5 mg/kg for 6 cycles), followed by bevacizumab alone for an additional 12 cycles. The patient population in ICON7 differed from GOG 218 and included patients with early (9%) and advanced stage (70% had stage IIIC or IV) disease; 9% of patients had early-stage and 26% had residual tumor larger than 1 cm at completion of surgery. Median PFS was 17.3 months in the control group and 19 months in the group receiving bevacizumab. HR for progression or death in the bevacizumab group was 0.81 (95% CI, 0.70 to 0.94). There were more side effects in the bevacizumab arm including hypertension, thromboembolic events, and gastrointestinal perforations; however, no difference in quality of life was found. Both trials showed a modest increase in PFS with maintenance bevacizumab but no difference in OS or quality of life.

Additional molecular targeted treatments are currently under development for specific populations including a Phase III trial of maintenance poly ADP ribose polymerase (PARP) inhibitor in *BRCA* mutation carriers. The role of various novel molecular-targeted therapies in the adjuvant and the recurrent setting is an important question that needs to be addressed in the next decade. Careful cost-effective and patient-reported outcomes need to be incorporated into trial designs.

Role of Radiation Therapy

The role of "consolidation" RT in ovarian cancer as sequential to surgery and chemotherapy is controversial. Several publications have addressed the benefit of RT in multiple scenarios, although the limitations of the studies have made definitive conclusions difficult. Dembo et al[113] previously showed that WAI is an effective treatment of small residual tumor (<2 cm); therefore it seemed reasonable to suggest that there could be a benefit from administering WAI for consolidative treatment. In 1982 Fuks et al[162] proposed a new paradigm of treatment for stage III ovarian cancer, including initial surgery followed by aggressive combination chemotherapy, second-look laparotomy (to include cytoreduction), followed by WAI.

Several Phase III studies have since evaluated the efficacy of this multimodality treatment paradigm in comparison to postoperative extended chemotherapy (Table 61-3). Bruzzone et al[163] randomized 41 patients with no or minimal disease (<2 cm) at second-look laparotomy to an additional three cycles of platinum-based chemotherapy or WAI (total dose was 43.2 Gy/24 fractions to the pelvis and 30.2 Gy to the upper abdomen). Median survival and PFS were found to be 24 months and 16 months, respectively, in the patients in the RT arm of the study. In the chemotherapy arm, median survival and PFS were not reached at the time of publication. The trial was closed early owing to the superior survival of the patients treated with chemotherapy. In 1993 the North Thames Ovary Group study (NTOG)[164] randomized 117 patients with advanced ovarian cancer (stages IIB to IV) who had received postoperative carboplatin and were found to have minimal residual disease at second-look laparotomy to an additional five courses of carboplatin or WAI (24 Gy). No statistical difference was found in either DFS or OS between the groups.

TABLE 61-3 Randomized Trials of Consolidative WAI or ^{32}P

Trial/Author	Stage	Study Design	No. Patients	5-Year Overall Survival (%)	Bowel Obstruction

PFS, *Progression-free survival;* WAI, *whole abdomen irradiation.*

Additional studies have shown mixed results when estimating a survival benefit for consolidation WAI.[165,170] Thomas[171] published a review in 1993 on the role for consolidation or salvage RT in advanced epithelial ovarian cancer. Twenty-eight studies with 713 patients were included. Overall, the evidence did not support an incremental curative benefit for WAI; however, because of the diverse inclusion criteria and the limited amount of patients in each trial, a decisive conclusion could not be made.

Two randomized trials published subsequent to this review have shown relatively optimistic results.[166,167] Pickel et al[167] performed a randomized study of 64 patients with stages IC to IV disease but without evidence of clinical disease after comprehensive surgical staging and platinum-based chemotherapy comparing WAI versus no further treatment. The 5-year DFS and OS of the patients who received WAI was significantly higher than those who were observed (49% versus 26%, $p = 0.13$, and 59% versus 33%, $p = 0.029$, respectively). This benefit was more obvious in patients with stage III disease (5-year OS, 59% versus 26%, $p = 0.012$). In 2003, group collaboration from Sweden and Norway published a randomized trial comparing consolidation treatment with RT or chemotherapy versus observation in 172 patients with stage III disease who underwent cytoreductive surgery and four cycles of platinum-based chemotherapy followed by second-look surgery.[166] Only patients with no macroscopic disease were included; patients with microscopic disease were randomized to chemotherapy or WAI, and patients with no microscopic disease were randomized to chemotherapy, WAI, or observation. Consolidation RT was a significant ($p = 0.050$) prognostic factor with regard to PFS in the subgroup with complete pathologic remission. In the subgroup with microscopic residual carcinoma, no differential benefit for RT or chemotherapy was observed. Late complications in the RT arm included four cases as grade 1 (diarrhea) and seven cases (10%) as grade 3 (intestinal obstruction).

Consolidative Intraperitoneal Radioactive Chromic Phosphate Suspension (^{32}P)

The role of ^{32}P as consolidative treatment after surgery and chemotherapy in advanced-stage ovarian cancer has been evaluated in several studies (see Table 61-3). The largest retrospective study from the University of North Carolina evaluated ^{32}P in 51 women with stages I to III disease.[172] They treated patients with no evidence of disease on second-look laparotomy with 15 mCi of ^{32}P. These patients were compared with 18 patients who had a negative second-look laparotomy but did not receive ^{32}P because of peritoneal adhesions, other protocols, or physicians' preference; with 15 who did not receive any additional treatment; and with 3 who received additional chemotherapy. After a median follow-up of 58 months, both an improved 5-year PFS (86% versus 67%, $p = 0.05$) and a 5-year OS (90% versus 78%) were noted in the ^{32}P group.

Two randomized trials of ^{32}P have been published.[168,169] The first was performed at the Norwegian Radium Hospital in which 50 patients with stage IA high-grade and stages IB to III disease were randomized after a negative second-look laparotomy to ^{32}P or no further treatment.[168] No significant survival difference was found between the groups; however, ^{32}P was associated with a considerable number of bowel complications. In 2003 the GOG (protocol 93) reported on a prospective randomized trial of 202 patients with stage III disease with a negative second-look laparotomy who were allocated to 15 mCi of ^{32}P or no further treatment.[169] After a median follow-up of 63 months, 5-year OS was 67% and 63% for IP ^{32}P and no further treatment groups, respectively. No significant difference in PFS or OS was found between the study arms. Three patients in the ^{32}P arm required surgery because of bowel obstruction. Thus, the data do not support the use of ^{32}P for consolidative treatment in ovarian cancer.

Recurrent Ovarian Cancer

Approximately 85% of patients with epithelial ovarian cancer will experience relapse. Recurrent or persistent ovarian cancer after first-line therapy is almost always incurable. The majority of the relapses (85%) are in the abdomen alone. Bowel symptoms are common. Treatment is generally aimed at prolonging symptom-free survival and palliating symptoms.

Patients with recurrent ovarian cancer are categorized by their "platinum sensitivity," which is primarily defined by the length of the treatment-free interval. Patients whose disease progresses during therapy or who experience a relapse less than 6 months from the completion of treatment are generally referred to as "platinum resistant," and their response rates and survival tend to be low and short. Patients presenting with early relapse are considered for second-line chemo

regimens or clinical trials. Many second-line chemo agents have been evaluated (liposomal doxorubicin, gemcitabine, topotecan, paclitaxel, and others), with response rates on the order of 10% to 15%.[173-176] In these patients, the median PFS is 3 months to 4 months and the median OS is 9 months to 12 months. Preliminary results of AURELIA, the first Phase III randomized trial of chemo with or without bevacizumab in patients with recurrent platinum-resistant ovarian cancer were presented in 2012.[177] The standard chemo group had an expected 12.6% response rate, whereas the response rate in the bevacizumab arm was significantly improved when measured by CA125 levels or RECIST criteria. Median PFS was 3.4 months in the control arm and 6.7 months in the bevicizumab arm ($p < 0.001$). The final results are pending. Other molecular targeting agents continue to be explored in recurrent, platinum-resistant disease. Because the chance of a meaningful disease-free interval is low, quality of life, treatment-related toxicity, and the patient's wishes are important issues to consider. Palliative RT to localized symptomatic masses produces high response rates even in chemoresistant disease.[178-181]

Patients who experience late relapse (i.e., more than 6 months from the completion of the initial chemo) are referred to as "platinum sensitive," and the probability of having a prolonged progression-free interval is good. The longer the initial treatment-free interval, the higher is the chance of response to second-line chemo, and probability of obtaining a meaningful disease-free interval.[182,183] Second-line chemo is usually retreatment with a platinum-based regimen. The estimated response rate is 30% to 70%.[184-186] Combination second-line chemo versus single-agent platinum has been compared in several studies.[184,185,187] ICON4/AGO-OVAR, a combined analysis of two parallel studies including 804 patients who were platinum-sensitive, compared carboplatin-paclitaxel to "conventional platinum-based chemotherapy" (single-agent carboplatin in the majority).[185] The median OS benefit for the combination was 5 months (29 months versus 24 months). CALYPSO, a randomized Phase III trial comparing pegylated liposomal doxorubicin (PLD) and carboplatin versus paclitaxel and carboplatin in patients who were "platinum-sensitive" with recurrent disease enrolled 976 people.[188] The trial, designed as a noninferiority study found PLD-carboplatin to have a superior PFS (11.3 months versus 9.4 months, HR, 0.821; CI 95%, 0.72 to 0.94) and had a superior toxicity profile including lower rates of severe and long-lasting neuropathy. The final results showed comparable median OS of PLD-carboplatin (30.4 months) and paclitaxel-carboplatin (33 months) (HR, 0.99; 95% CI, 0.85 to 1.16).[188]

Additional studies comparing platinum to platinum and gemcitabine or to platinum and epirubicin have all showed a superior response rate for the combination regimens.[189,190] Thus, the preferred regimen is platinum-based combination chemotherapy with a current recommendation for carboplatin-paclitaxel or PLD-carboplatin.

Molecular-targeting therapies have evolved as an important part of treatment in the recurrent setting. In 2012 the Ovarian Cancer Study Comparing Efficacy and Safety of Chemotherapy and Anti-Angiogenic Therapy in Platinum-Sensitive Recurrent Diseases (OCEANS) trial assessed the role of bevacizumab in the treatment of platinum-sensitive relapses.[191] This placebo-controlled, Phase III trial of chemotherapy (gemcitabine + carboplatin) with or without bevacizumab enrolled 242 patients with recurrent ovarian, primary peritoneal, or fallopian tube cancer. Median PFS was 12.4 months versus 8.4 months respectively in the bevacizumab and control arms. (HR progression, 0.484; 95% CI, 0.388 to 0.605). Bevacizumab-associated toxicities including hypertension were noted, but there were no cases of gastrointestinal perforations.

Additional studies are also exploring PARP inhibition specifically in women with *BRCA* mutations. Final results of a GOG Phase II study are pending (GOG 208). Initial results of 48 patients show 7% had a response; 21 were still receiving study drug.[192] Currently, a Phase III trial assessing the role of PARP inhibitors in *BRCA* carriers in the recurrent setting is open to recruitment.

Patients who do not respond to second-line carboplatin-paclitaxel are considered platinum resistant and have a low probability of responding to alternative regimens. Response rates to third-line chemotherapy including liposomal doxorubicin, topotecan, oral etoposide, and gemcitabine are 15% to 25%.[174,176,193,194]

Salvage WAI for ovarian cancer has also been reported. Sedlacek et al[195] evaluated WAI in 27 patients with recurrent ovarian cancer. Their treatment protocol included 30 Gy to 35 Gy, followed by a pelvic boost. OS at 1 and 5 years was 66% and 15%, respectively.

Secondary Cytoreductive Surgery for Disease Relapse

Technically, secondary debulking can be performed in 25% to 85% of patients.[196-198] It is commonly considered most likely to benefit patients with late relapse and resectable tumor, but the likelihood for and benefits of successful secondary debulking are not understood. Its intent is to remove recurrent tumor and thereby prolong the disease-free interval and survival.

Successful secondary debulking is limited. The Arbeitsgemeinschaft Gynaekologische Onkologie (AGO) DESKTOP OVAR trial is the largest series ($n = 267$ patients) published on the benefit of secondary cytoreductive surgery for recurrent ovarian cancer.[199] Complete resection was associated with significantly longer survival compared with surgery leaving any postoperative residuum (median 45.2 versus 19.7 months; $p < 0.0001$). Variables associated with complete resection were performance status, stage, residual tumor after primary surgery, and absence of ascites of more than 500 mL. An optimal resection was achieved in 79% of patients with all favorable prognostic factors. The EORTC attempted a randomized trial to evaluate the benefit of cytoreductive surgery in recurrent ovarian cancer, but it was closed because of poor accrual. A review of 17 publications of secondary cytoreductive surgery by Hauspy and Covens[200] concluded that patients with favorable characteristic (good performance status, long disease-free interval, and a single or few small intraabdominal sites of relapse) are the ideal candidates that may benefit from secondary cytoreductive surgery.

The most common site of relapse in ovarian cancer is IP with ascites and masses. Bowel complications frequently occur before general deterioration is profound. Comprehensive palliative care is required for all such patients. Partial bowel obstruction is treated conservatively with intestinal decompression and IV hydration. If bowel obstruction is complete or if conservative measures fail, palliative surgery performed to relieve bowel complications may be considered. In patients with an impaired performance status, extensive disease, and limited life expectancy, including multiple levels of obstruction, palliative measures without surgical intervention should be considered.

Intraoperative Irradiation for Locoregional Relapse

In patients with recurrent ovarian cancer localized in the pelvic sidewalls or paraaortic or pelvic lymph nodes, the use of aggressive surgery and intraoperative irradiation (IORT) alone or plus external beam irradiation (EBRT), appears beneficial when compared with "standard" EBRT salvage. Excellent results have been found in IORT series from both Mayo Clinic Rochester[201,202] and Stanford University.[203]

The Mayo Clinic Rochester (MCR) electron beam IORT (IOERT) series of 148 patients with gynecologic cancer included 16 with recurrent ovarian cancer.[201,202] In this highly select group of patients, 2-year OS was 61% and 5-year OS 54%. In an updated MCR analysis,[197] 20 patients with recurrent ovarian cancer received IOERT as a component of treatment and 16 of 20 also received perioperative EBRT (median 50 Gy, range 20 Gy to 54 Gy). With median follow-up of 76 months in surviving patients, 5-year OS was 49%.

Twenty-four patients had maximal resection of recurrent ovarian cancer followed by orthovoltage IORT at Stanford University, and 22 were evaluable for analysis.[203] Most had cytoreductive surgery plus chemotherapy at initial diagnosis; the mean disease-free interval was 48.2 months before resection or IORT. After maximal resection, residual disease was either microscopic (R1) or less than 0.5 cm (R2). The median IORT dose was 12 Gy (range, 9 Gy to 14 Gy). Postoperative EBRT (14 patients) or chemotherapy (6 patients) was given to 20 of 22 patients and was individualized based on sites of relapse and prior therapy (EBRT: abdominal/pelvic, 9; pelvic, 4; inguinal, 1). With median follow-up of 24 months, 5 patients remained free of disease. The 5-year OS was 22%, with a median survival of 26 months from the time of IORT.

Palliative Radiation Therapy

Palliative RT in ovarian cancer is effective in patients with symptoms because of localized disease. It is often a forgotten or ignored modality. In cases of vaginal bleeding, localized pain resulting from masses in the abdomen or retroperitoneum, or disseminated disease (e.g., brain metastases, supraclavicular nodes), RT can induce tumor regression and provide symptomatic relief.[180] Investigators from M. D. Anderson Cancer Center published a 55% response rate for pain palliation and 71% for vaginal bleeding with one to three fractions of 10 Gy.[181] However, 6 of 42 patients developed bowel radiation injury attributed to the large fraction size. A study from Fox Chase Cancer Center[204] reported the use of palliative RT in 33 patients with symptomatic ovarian cancer. Complete palliative response was noted in 51%, and the overall response rate was 79%. Vaginal bleeding and pain were controlled in 90% and 83% of patients, respectively. The median duration of palliation was 4 months, which reflected palliation until death in 90% of cases. In an additional study, from Memorial Sloan Kettering Cancer Center, the median duration of response was 11 months (range, 1 to 86) and closely approximated the survival rate. Additional studies show a similar benefit for palliative RT.[180,181,204,205] Recommendations on the optimal dose for palliation of soft-tissue masses are difficult to make because no comparative trials have been conducted and each center or oncologist uses different doses. No data support the common contention that palliation of symptoms or duration of symptom relief is greater with higher doses of radiation. However, it is obvious from the literature that RT is an effective modality in palliation for ovarian cancer even if the tumor is resistant to multiple lines of chemotherapy.

TREATMENT OF NONEPITHELIAL OVARIAN TUMORS

Ovarian Germ Cell Tumors

GCTs of the ovary are derived from the primordial germ cells of the ovary. They account for less than 5% of all ovarian malignancies and occur predominantly in young patients.[206] In the first two decades of life, GCTs account for two thirds of all ovarian malignancies and are rarely found in women older than the age of 30. The World Health Organization classification of GCTs includes dysgerminoma, yolk sac tumor, embryonal carcinoma, polyembryoma, nongestational choriocarcinoma, immature teratoma, and mixed GCTs. Dysgerminomas are the most common subtype, accounting for 40% to 50% of all GCTs. Immature teratomas and yolk sac tumors each comprise about 20%, and the other subtypes are extremely rare.

GCTs are rapidly growing tumors that frequently present as abdominal pain as a result of capsular distention, torsion, or hemorrhage or to menstrual irregularities. Physical examination and ultrasonography assist in making the diagnosis of an ovarian mass; differentiation between a benign and malignant mass can only be made by histology. Serum markers including β-human chorionic gonadotropin (β-hCG), lactate dehydrogenase (LDH), and α-fetoprotein (AFP) can be useful in helping to identify the presence of a GCT (eTable 61-1). Solid adnexal masses larger than 2 cm in premenarcheal girls or a growing mass with or without elevated tumor markers in menarcheal girls or young women is an indication for exploration. Ovarian GCTs (specifically gonadoblastoma and dysgerminoma) can be associated with dysgenetic gonads. Therefore, in premenarcheal girls with a gonadoblastoma or dysgerminoma, a karyotype should be obtained. Staging of GCTs is per the FIGO staging of epithelial ovarian cancer (see Table 61-1).

Because GCTs predominantly present in young women and are sensitive to postoperative chemo, fertility-sparing surgery is indicated even if the contralateral ovary is involved. The need for a staging procedure is controversial, particularly if adjuvant chemo will be recommended anyway. Many centers do consider careful inspection of the abdomen and pelvis by a trained gynecologic oncologist, with biopsy specimens taken from suspicious areas being adequate. Published recommendations for an appropriate staging procedure for ovarian GCTs[207] include peritoneal washings for cytology, a unilateral salpingo-oophorectomy, and biopsies of the omentum, contralateral ovary, and locoregional lymph nodes.[208] GCTs predominantly spread to retroperitoneal lymph nodes, in contrast to transcoelomic spread of epithelial ovarian cancer. A high proportion of the diagnoses are made after a gynecologist or general surgeon has performed surgery (usually unilateral salpingo-oophorectomy without staging). The value of reoperation is unclear. There is consensus that if observation without adjuvant therapy is adopted there is a need for close surveillance to detect and treat recurrence early. This includes frequent clinic visits and a combination of study of tumor markers and imaging.[208] The exact protocol differs among oncology centers.

Where there is no residual disease, the indication for and use of adjuvant chemo differs among oncology centers. The response to salvage chemo is good and survival rates appear comparable in many cases between those treated with adjuvant therapy versus treatment at the time of relapse. Serum tumor markers can assist in the early detection of recurrence in nondysgerminomas.[209]

Nondysgerminoma

The evolution of chemo for GCTs has been based on the successful treatment of similar histology and, more commonly, testicular GCTs. Initially, patients with advanced ovarian GCTs were treated with surgical debulking, followed by vincristine, dactinomycin, and cyclophosphamide chemotherapy (VAC regimen), with cure rates of approximately 50%.[210,211] As a result of the high cure rates achieved even in advanced testicular GCT using cisplatin, vinblastine, and bleomycin, the GOG evaluated a similar regimen in ovarian GCTs and noted a 70% 4-year OS.[211] Etoposide reduced toxicity and improved cure rates in testicular GCTs. Using three to four cycles of bleomycin, etoposide, and cisplatin (BEP regimen) led to its adoption as the standard regimen for ovarian GCTs, with a 79% to 83% PFS.[212,213] Patients who have no evidence of disease

eTABLE 61-1 Tumor Markers in Malignant Germ Cell Tumors of the Ovary

after surgical staging followed by three cycles of a BEP regimen can expect a 96% to 100% PFS.[208,214]

Most centers treat all tumors except stage IA grade-1 immature teratoma with postoperative chemotherapy. Recently, a large study of observation only for all stage IA GCTs showed a relapse rate of 36% for nondysgerminomatous tumors and 22% for dysgerminomas.[215] Relapse after observation has high salvage rates with the BEP regimen; all but 1 patient who experienced relapse was salvaged. As patients are young, and long-term risks from chemotherapy are relevant, a strong argument can be made for observation.

Disease relapse after primary chemo is treated primarily with second-line agents; infrequently, cure may require ablative regimens and bone marrow transplant. Palliative RT can be used in specific cases after chemo failure.

Dysgerminoma

Dysgerminoma, the most common of germ cell tumors, accounts for approximately 1% of all ovarian cancers. The majority occur between the ages of 10 and 30. Stage IA is the most common stage at diagnosis, representing 75% of all cases.[212] Ten percent may involve both ovaries. It predominantly spreads in an orderly progression to retroperitoneal lymph nodes, in contrast to the transcoelomic spread of epithelial ovarian cancer. LDH is a nonspecific tumor marker and is reported to be elevated in up to 95% of cases[209] β-hCG may be produced in low levels (<200 IU/L).

Young patients found to have stage IA dysgerminoma are usually treated with fertility-sparing surgery without adjuvant chemo or RT. Surveillance for clinical stage IA ovarian dysgerminoma is safe and effective in reducing unnecessary use of chemotherapy, with 10-year OS of 91% in the prechemo era, where relapse was commonly salvaged with RT, to which it is exquisitely sensitive.[216] Relapses usually occur within 2 years of diagnosis, and the relapse rate for stage IA is approximately 20%.[215]

Despite its radiosensitivity, extra-ovarian disease at diagnosis or relapse is usually treated with chemo because of the negative impact of RT on fertility. The BEP regimen and the EP regimen (etoposide/platinum) are the most common combination regimens used because they spare fertility; however, significant side effects do occur.[217,218] As all patients with an ovarian dysgerminoma are young, short- and long-term effects from chemo such as bleomycin-induced lung toxicity and secondary malignancies should be taken into consideration when deciding on treatment.[219-221]

Survival after diagnosis of ovarian dysgerminoma is good even when disseminated disease is found at time of diagnosis. The 5-year OS is higher than 90%.[222,223]

Immature Teratoma

Immature teratomas are composed of tissue that resembles embryonic elements, most commonly nervous system components, bone, cartilage, mucinous fluid, and hair, although any tissue may be seen. Microscopic examination reveals tissue from all three germ layers, with at least some of the components having an immature appearance. The majority of patients do not have an identified serum tumor marker; however, AFP can be elevated in cases with immature gastrointestinal elements.[224]

The treatment recommendation is an initial staging procedure for all patients; however, because most patients are only diagnosed after the final pathologic findings, reports of more limited surgery are common. Treatment decisions are commonly made based on pathology, imaging, and tumor markers.[225-227]

Immature teratomas are graded based on the amount of immature neural tissue they contain, and grade is correlated with prognosis. Norris et al,[228] in 1975, reported the prognosis of 58 patients with a pure immature teratoma treated with surgery: 16 patients were treated with RT or non–platinum-based chemotherapy either after surgery or at time of relapse. Survival of patients with grades 1, 2, and 3 were found to be 81%, 60%, and 30%, respectively. Patients with stage IA, grade-1 tumors can expect an excellent prognosis without the need for adjuvant chemo, and postoperative observation is recommended.

Yolk Sac Tumor (Endodermal Sinus Tumor)

Yolk sac tumors, also called endodermal sinus tumors, are derived from the primitive yolk sac. The majority of tumors secrete AFP, and there is a good correlation between the levels and the extent of disease.[209] Microscopically, Schiller-Duval bodies, a cystic space lined by endothelium with a central vascular area resembling a glomerulus, are characteristic. The median age at diagnosis is 17, with approximately one third of cases diagnosed in premenarcheal girls. Most patients present with stage I disease.[228]

Surgical treatment usually includes unilateral salpingo-oophorectomyas involvement of the contralateral ovary is rare. Although yolk sac tumors present at an early stage, the relapse rate is high. Therefore, some physicians advocate treating all patients with adjuvant chemotherapy.[229] Others believe it is reasonable to observe patients with stage I disease because AFP is elevated in the majority of cases and can be used as a serum tumor marker for early detection of relapse along with imaging. Serial AFP levels are used to monitor response to treatment.

Ovarian Sex Cord and Stromal Tumors

Sex cord and stromal tumors of the ovary account for approximately 5% of all ovarian malignancies. They can occur in patients of all ages, and a significant proportion is diagnosed in patients younger than 40 years old. The cells originate from the sex cords and mesenchyme of the embryonic gonad. Granulosa and Sertoli cells are derived from the sex cord cells; pleuripotential mesenchymal cells are the precursors of Leydig and theca cells, and fibroblasts. The most common type, granulosa cell tumors, constitutes 70% of all sex cord and stromal tumors.

Sex cord and stromal tumors have the ability to produce hormones, especially estrogen or testosterone. They account for 90% of all hormone-producing tumors. The presenting symptoms such as precocious puberty, virilization, or abnormal menstruation in the premenopausal age group or postmenopausal bleeding in the older group are the result of the hormonal elaboration from the tumor itself, or, in the majority of cases, as a result of a nonspecific stromal response in the ovarian tissue. Approximately 60%, of sex cord and stromal tumors, present as stage I.

Granulosa Cell Tumors

Granulosa cell tumors can occur at any age, with a peak in the fifth and sixth decades of life.[230] Two granulosa cell tumors have been separated into the adult type (95%) and juvenile type (5%) based on clinical and histologic characteristics. The main presenting symptoms are abnormal vaginal bleeding, abdominal pain, or distention. Tumors are frequently diagnosed at a large size, more than 10 cm in diameter. Because of the potential estrogen production of granulosa cell tumors, evaluation of the endometrium is important. Endometrial hyperplasia and cancer has been noted in up to 50% and 5% of patients, respectively, at diagnosis.[220] Microscopically, Call-Exner bodies (granulosa cells in rosettes around a central cavity resembling primordial follicles) can be seen. Granulosa

cell tumors spread by transcoelomic, lymphatic, and hematogenous routes, and metastases can develop in parenchymal organs (liver, brain, lungs). Inhibin is a tumor marker that is secreted by some granulosa cell tumors.[231]

The cornerstone of treatment is surgical resection. For women presenting at a young age, fertility-sparing surgery is an option after a negative endometrial biopsy. In a recent retrospective review[232] of 58 patients with sex cord and stromal tumors who underwent lymphadenectomy as part of their initial surgical procedure, none was found to have nodal involvement; thus, lymph node dissection seems unnecessary. Patients with granulosa cell tumors tend to experience relapse years after initial treatment. Because of late relapse, survival declines over decades; there is a significant difference between the 10-year and 20-year OS (90% and 50% to 75%, respectively).[233] In most stage IA cases, surgery alone is curative, although in patients with high-risk factors (large tumor size > 10 cm, tumor rupture, high mitotic index), adjuvant chemo may be considered, although its benefit is unproven.[234,235] Patients with disease spread outside the ovary (stages II to IV) are traditionally treated with postoperative adjuvant chemo, although benefits are unproven. Both chemotherapy and RT produce responses and are used in the recurrent setting.[234]

A Phase II GOG trial evaluated the efficacy of the BEP regimen in completely resected or recurrent sex cord and stromal tumors. Forty-eight of 57 patients had granulosa cell tumors. The response rate for primary disease was 69% (11 of 16), and for recurrent disease it was 51% (21 of 41).[236]

Pankratz et al[237] retrospectively evaluated the prognosis of 61 patients with granulosa cell tumors, 48 of who received postoperative RT. The patients who received postoperative RT had a lower mortality in comparison to those who were not treated with RT even though the stage distribution was in favor of the nonirradiated group. However, the improved OS was not statistically significant and specific data are lacking to make conclusions. Other studies have not shown a benefit of adjuvant RT.[220,234]

Relapses are often isolated intraabdominal or pelvic masses. Accordingly, further surgical resection or localized RT may control disease for protracted periods of years.

IRRADIATION TECHNIQUES

EBRT Technique

When used as a primary or consolidative adjuvant therapy, surgical staging information, as well as analysis of patterns of failure, suggests that to be effective the EBRT volume must include all peritoneal surfaces. Dembo et al[113] emphasized the necessity of covering the diaphragm with adequate margin during all phases of normal respiration.

In general, patients treated with WAI should undergo CT treatment planning in the supine position with arms placed on the chest, or above the head, with appropriate immobilization. Given the importance of treating the entire diaphragm, customized shielding above the diaphragm should allow full irradiation during all cycles of respiration but also attempt to minimize pulmonary and cardiac irradiation. The use of "four-dimensional" CT can allow customized shielding during all phases of quiet respiration. Alternatively, CT at full expiration will have the diaphragm at the most cephalad position, and if shielding is designed at that point in respiration, diaphragmatic coverage can be assured. This technique may result in increased pulmonary and cardiac RT. Coverage of the diaphragm at quiet respiration with four-dimensional CT is preferred.

The inferior edge of the field should be placed below the pelvic floor, generally below the level of the obturator foramen.

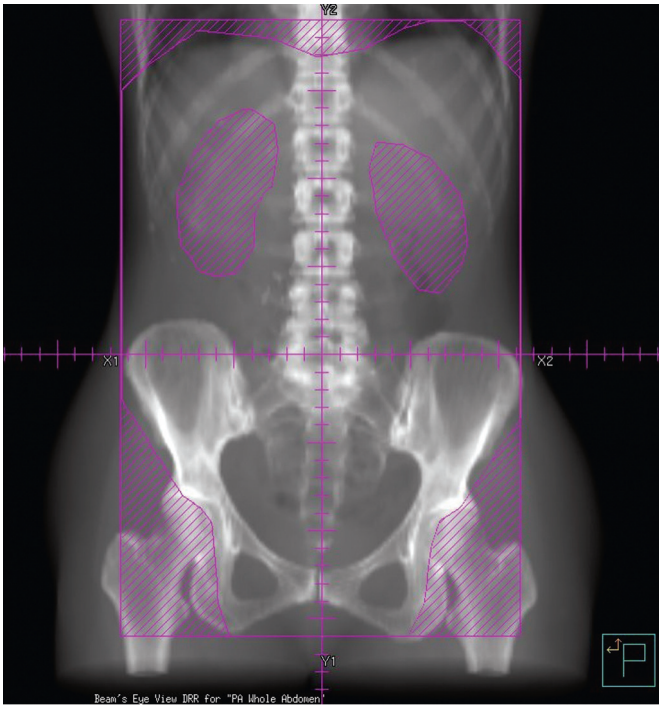

Figure 61-4 A typical whole-abdomen irradiation field.

The lateral edges of the field should be beyond the peritoneal reflection. Current WAI should be performed with an open-field technique, often at an extended source-to-skin distance. Previous use of a moving strip technique has been replaced with an open field technique, given the modern RT machines. The dose to the whole abdomen is generally limited to 22.5 Gy to 30 Gy in 1.0 Gy to 1.5 Gy per fraction. There is no obvious dose response, with a randomized trial noting no benefit to an abdominal dose of 27.5 Gy as compared with 22.5 Gy.[238] That being said, if doses above 25 Gy are used, there should be a consideration for liver shielding to keep the mean liver dose at approximately 25 Gy. In addition, the kidney dose should be limited to approximately 18 Gy. Given the use of the anterior-posterior/posterior-anterior (AP/PA) field, the most common technique is to use the PA shield for most or all of the PA treatments. Further shielding to block the bony pelvis and femoral heads, although delivering the full dose to the entire peritoneum, should be accomplished. Dose-volume histograms (DVH) should be obtained for the liver, kidney, and spinal cord to ensure that these organs are properly shielded. In addition, DVH analysis of the lungs and heart should also be accomplished with dosing to these organs minimized. Figure 61-4 depicts a typical WAI field.

In general, most studies have used a pelvic boost after WAI, for a total pelvic dose of 45 Gy to 50.4 Gy. This should be accomplished with standard pelvic RT techniques rather than IMRT to deliver tumor dose to all peritoneal surfaces. A repeat CT treatment planning session with the patient in a prone position, with a full bladder and possible abdominal compression, should be considered. Paraaortic boost for nodal disease or boost to residual disease should also be considered on an individual basis. If a paraaortic boost is accomplished, the spinal cord dose should be limited to 45 Gy.

Newer WAI treatment techniques have been developed to improve target coverage while reducing radiation to organs at risk, including the bone marrow. This can be particularly important in patients who are receiving chemotherapy and RT. Dosimetric studies have noted improved coverage of the

planning treatment volume and sparing of organs at risk with IMRT.[239] A recent Phase I study noted the feasibility of IMRT WAI as a consolidation after chemotherapy.[240] Helical tomotherapy also has been evaluated with improved dosimetric outcome.[241] All techniques must ensure delivery of tumor dose to the entire peritoneum.

Phosphorus-32

^{32}P is injected into the peritoneal cavity via an intraabdominal port or catheter. This is generally preceded by injection of contrast medium or a technetium-labeled radionuclide, followed by imaging to ensure adequate flow throughout the abdomen, including the cul-de-sacs and infradiaphragmatic region. After adequate flow has been determined, radioactive chromic phosphate ^{32}P (10 mCi to 20 mCi) is injected into the peritoneal cavity along with saline. Patients are then asked to move positions frequently to ensure good distribution through the peritoneal cavity.

TREATMENT ALGORITHMS, CHALLENGES, AND FUTURE POSSIBILITIES

Treatment Algorithm

The treatment of epithelial ovarian cancer is guided by the extent of disease at the time of diagnosis. Patients with disease confined to the ovary undergo a staging procedure to assess extent of microscopic dissemination that necessitates adjuvant chemotherapy. Certain early-stage histologies may benefit from adjuvant RT (clear cell, endometrioid, mucinous). Patients diagnosed with advanced disease undergo either a primary debulking procedure (to remove the maximum amount of macroscopic disease) or neoadjuvant chemo and interval debulking. The treatment algorithm presented in Figure 61-5 represents the current standard of care.

Challenges and Future Possibilities

Epithelial ovarian cancer remains a challenging cancer to treat as the majority of patients are diagnosed with advanced disease; although the response to chemo is high, most patients will eventually succumb to their disease. In the past decade, a modest improvement in survival has been demonstrated with the introduction of intraperitoneal chemotherapy. The specific timing and extent of debulking surgery together with the optimal chemo regimen are still controversial and will remain so until future results of current studies become available and the outcome becomes clearer. As technology improves, consolidative RT may play a role as the toxicity ratio is improved.

The role of RT for both early-stage and locoregional relapse needs to be clarified. Certain early-stage histologies (clear cell, endometrioid, and mucinous carcinomas) may benefit from adjuvant RT, as discussed previously, and this potential indication continues to evolve. The role of irradiation (EBRT, IORT,

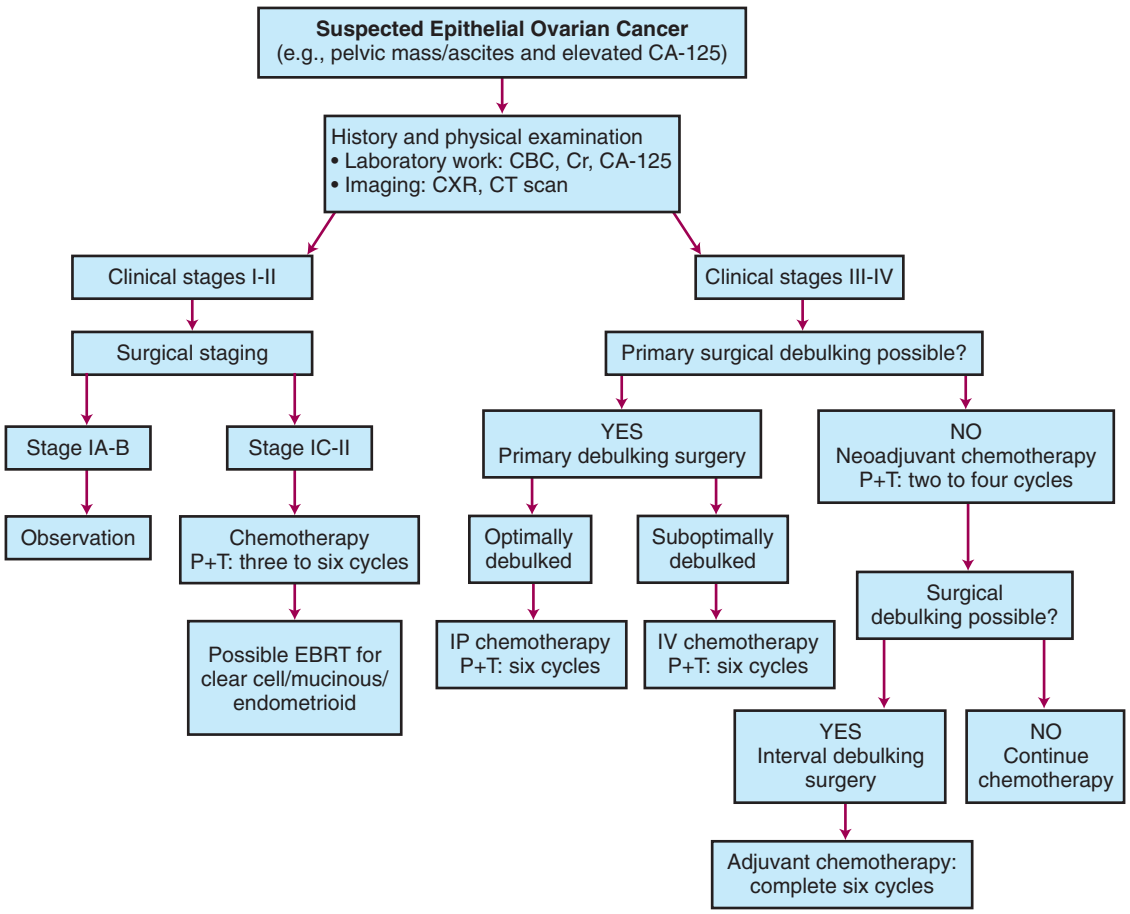

Figure 61-5 Treatment algorithm for epithelial ovarian cancer. *AFP,* α-fetoprotein; *β-hCG,* beta-human chorionic gonadotropin; *CBC,* complete blood count; *Cr,* complete response; *CT*, computed tomograph; *CXR,* chest x-ray; *EBRT,* external beam radiation therapy; *IP,* intraperitoneal; *IV,* intravenous; *P+T,* platinum plus taxane chemotherapy.

and even SBRT for localized masses) as a component of aggressive salvage treatment for select patients with locoregional relapse also needs to continue to be evaluated.

Multiple novel therapies, including PARP inhibitors and antiangiogenic drugs, have also shown promising results. The further understanding of the pathogenesis of ovarian cancer will potentially lead to the exploration and development of additional novel therapies based on the molecular signature of the tumor.

For specific patients who harbor a predisposition to the development of epithelial ovarian cancer, prophylactic surgery has been shown to prevent its development and should be recommended. Early detection has not yet been shown to be effective in high- or low-risk populations and should not be relied on at this time.

Overview

Rashmi K. Murthy, Vicente Valero, and Thomas A. Buchholz

INCIDENCE AND MORTALITY

Breast cancer is the most common cancer in women, and it is estimated that one in eight women in the United States will develop breast cancer in their lifetime. Every year more than 40,000 women die from breast cancer, making it the second-leading cause of cancer-related deaths in women. Historically, the increase in breast cancer incidence was thought to be a reflection of changes in reproductive patterns, such as delayed childbearing and nulliparity, which are recognized as risk factors. Since the early 1980s, the incidence of breast cancer among older women was steadily rising because of improved early detection with the widespread use of mammography. The rates stabilized in the late 1990s and then started to decrease. In contrast the incidence of breast cancer in younger women has remained stable. With a rapidly aging population in the United States, the number of breast cancers is expected to increase over the next 20 years. Fortunately, screening, early detection, and advances in multidisciplinary treatment have led to continuous declines since 1990. Survivorship is a growing issue and research into the late effects of treatment will become even more relevant as the population of breast cancer survivors continues to increase. In this chapter, we will provide an overview and highlight the general considerations necessary in formulating a multimodality treatment plan for the management of a patient with breast cancer.

ETIOLOGY, RISK FACTORS, AND GENETICS

Breast cancer results from a series of genetic and epigenetic events that lead to dysregulation of cell growth, circumvention of apoptosis, and development of the ability to invade. The causes of these events remain largely unknown, although epidemiologic studies have implicated lifestyle, environmental, and germ-line genetic factors in predisposition to this disease.

Accepted risk factors for breast cancer include female sex, increasing age, personal or family history of the disease, exposure to ionizing radiation, nulliparity, hormone replacement therapy, alcohol intake, germ-line mutations in the *BRCA1* gene or *BRCA2* gene, and other more unusual inherited conditions. Up to 10% of breast cancers are caused by germ-line mutations that are passed down in families.

Advances in molecular genetics have identified several genes associated with an inherited susceptibility to breast cancer (i.e., *BRCA1, BRCA2, PTEN, TP53, CDH1*), and identification of a mutation has major implications for prevention, screening, and treatment. Formal risk assessment and genetic counseling takes into account a detailed family pedigree, an evaluation of the patient needs and concerns, past medical and surgical history, and any active cancer diagnoses.

PROGNOSTIC AND PREDICTIVE FACTORS

Several features help to predict the probability of successful outcome after treatment for breast cancer. The most powerful prognostic factor is disease stage at diagnosis, which is determined by the status of regional lymph nodes and the size of the primary tumor. Additional tumor-related prognostic factors include tumor grade, estrogen and progesterone receptor status, HER2/neu (ERBB2) status, and proliferative index. The most important patient-related factor is age, with young patients with breast cancer typically having the worst outcomes.

The genetic heterogeneity of breast cancer is increasingly being appreciated. New molecular tumor assays, including cDNA microarray classifications and molecular-based predictive assays, are enhancing the understanding of tumor biologic characteristics, prognosis, and predictors of treatment response. Several have moved into the marketplace and are used for treatment decisions (i.e., Oncotype-DX, PAM50, Mamaprint). Ultimately, it is hoped that continued research into the molecular biology of breast cancer will continue to identify new therapeutic targets and increase the personalization of breast cancer therapy.

TREATMENT

Breast cancer therapy requires a multidisciplinary team consisting of surgeons, medical oncologists, radiation oncologists, pathologists, radiologists, reconstructive surgeons, and supportive care personnel. Each aspect of multidisciplinary care should occur in a coordinated fashion. Most patients with breast cancer receive surgery, radiation, and systemic treatment. All three therapeutic specialties have seen significant advances, and each component of these treatments has been shown to independently offer survival benefit for selected patients. For patients with early-stage breast cancer, the outcomes associated with breast-conservation surgery, sentinel lymph node dissection, radiation, and systemic treatments are excellent. Treatment advances have also improved the prognosis for patients with more advanced disease at presentation. A particularly exciting advance has been the use of anti-HER2–directed therapies for patients with HER2-positive disease. In the future, additional molecularly targeted treatments are likely to further improve breast cancer outcomes.

INTRODUCTION

Breast cancer is one of the most common cancers seen and treated by radiation oncologists. Radiation plays an important role in the management of breast cancer at all stages, including ductal carcinoma in situ, early-stage disease (as a component of breast conservation), and locally advanced disease (as an adjuvant treatment after mastectomy). Radiation is also a highly effective palliative modality for patients with metastatic disease progressing within a localized area that adversely affects their quality of life.

This section of the textbook consists of this overview introduction, followed by chapters highlighting the role of radiation in ductal carcinoma in situ, early-stage disease, and locally advanced disease. This overview component reviews important aspects of breast cancer anatomy, breast cancer epidemiology and statistics concerning incidence and mortality, risk factors for the disease, screening, staging, prognostic and predictive factors, including the molecular classification of disease, and a summary of the role of surgery, radiation, and systemic therapies for breast cancer.

ANATOMY

A comprehensive understanding of the anatomy of the breast and its regional lymphatics is imperative for radiation oncologists to appropriately design radiation therapy fields that optimally cover targeted areas at risk for disease while sparing uninvolved normal structures. Historically, radiation treatment fields were designed based on standard external landmarks, but such techniques risked inadequate treatment of sites at risk of containing disease. Treatment planning based on computed tomography (CT) imaging has optimized the planning process and heightened the importance of radiation oncologists' familiarity with anatomy, particularly with respect to the breast's lymphatic drainage pathways.

The breast typically extends medially to the midline and laterally to near the midaxillary line. The cranial and caudal borders of the breast are typically the second and sixth anterior ribs, respectively, although the breast may extend higher into the axillary region (known as the *tail of Spence*). Breast parenchymal tissue is supported by fibrous septa (Cooper's suspensory ligaments) and connective tissue that contains blood vessels, nerves, lymphatics, and adipose tissue. The deep boundary of the breast is the fascia of the pectoralis major muscle. The chest wall, which consists of the rib cage and interosseous muscles and fascia, lies underneath the pectoralis major muscle. Microscopically, the breast parenchyma consists of lobules and ducts. The ductal system of the breast is divided into branching segments that converge into major lactiferous ducts near the nipple-areola complex. The interface between the lobules and the ducts, the *terminal ductal-lobular unit*, is the most common location for the development of breast cancer.

The breast has a rich lymphatic plexus that drains to lymph nodes of the axilla, internal mammary chain (IMC), and supraclavicular fossa (Figure G-1). Drainage can also occur to lymph nodes within the breast itself (intramammary nodes) and those between the pectoralis major and minor muscles (interpectoral or Rotter's lymph nodes). Sentinel lymph node surgery has helped to identify the most common drainage pathways of the breast lymphatics. Most individuals have lymphatic drainage to one or more lymph nodes in the low axilla. Axillary lymph nodes are customarily divided into three levels according to their anatomic location relative to the pectoralis minor muscle: level I axillary lymph nodes are located inferolateral to the pectoralis minor muscle; level II lymph nodes are beneath the pectoralis minor muscle; and level III lymph nodes (also called infraclavicular lymph nodes) are those superior and medial to the pectoralis minor muscle but below the clavicle. Figure G-2 shows an axial positron emission tomography (PET) image combined with a CT image of a patient with involvement of level I, II, and III lymph nodes. Patients with advanced disease are also at risk of having involvement of Rotter's nodes, an example of which is shown in Figure G-3.

Breast cancer can also involve lymph nodes within the IMC. Lymphatic channels that drain to internal mammary lymph nodes tend to run close to the pectoralis fascia, and therefore a sentinel lymph node procedure that is done with a superficial or subdermal injection of blue dye or radiocolloid will rarely reveal drainage to the IMC. To demonstrate drainage in such cases, these injections must be done within the tumor bed or deep near the pectoralis muscles. When breast cancer involves lymph nodes in the IMC, the nodes are usually within the first three intercostal spaces. These anatomic areas are easily visualized with CT scans, on which the internal mammary artery and vein are apparent just lateral to the sternum within the thoracic cavity. One study involving lymphoscintigraphy before sentinel lymph node surgery indicated that the frequency of drainage to the IMC was highest for lower inner quadrant tumors (43%), followed by lower outer quadrant tumors (32%) and central tumors (28%).[1] An axial PET/CT slice of a patient who presented with involvement of an internal mammary lymph node and concurrent disease within the ipsilateral breast and level I axilla is shown in Figure G-4. The frequency of internal mammary lymph node involvement depends on the status of the axillary lymph nodes and the anatomic location of the primary tumor. An important study from China reported the rates of IMC involvement in 2269 patients who had had dissection of this region as a component of an extended radical mastectomy.[2] The rates of IMC involvement were highest when axillary disease was also present (Table G-1).

Finally, breast cancer can also spread to the supraclavicular nodes, although this typically occurs only when axillary lymph nodes are also involved. The risk of supraclavicular lymph node involvement depends greatly on the number of positive axillary lymph nodes; clinical outcome data suggest that supraclavicular involvement for patients with one to three positive axillary lymph nodes is rare, but more than 15% of patients with four or more positive axillary lymph nodes

TABLE G-1 Pathologic Rates of Involvement of Internal Mammary Lymph Nodes According to Tumor Location and Pathologic Status of the Axilla

Tumor Location	Axillary Lymph Node (ALN) Status	Rates of Involvement of the Internal Mammary Lymph Node(s)
Medial/central	0 + ALN	6% (27/428)
	1-3 + ALN	26% (41/160)
	4-6 + ALN	43% (21/49)
	≥7 + ALN	40% (44/110)
Lateral	0 + ALN	3% (12/456)
	1-3 + ALN	14% (34/238)
	4-6 + ALN	20% (18/90)
	≥7 + ALN	43% (63/148)

Data from Huang O, Wang L, Shen K, et al: Breast cancer subpopulation with high risk of internal mammary lymph nodes metastasis. Analysis of 2,269 Chinese breast cancer patients treated with extended radical mastectomy. Breast Cancer Res Treat 107(3):379–387, 2008.

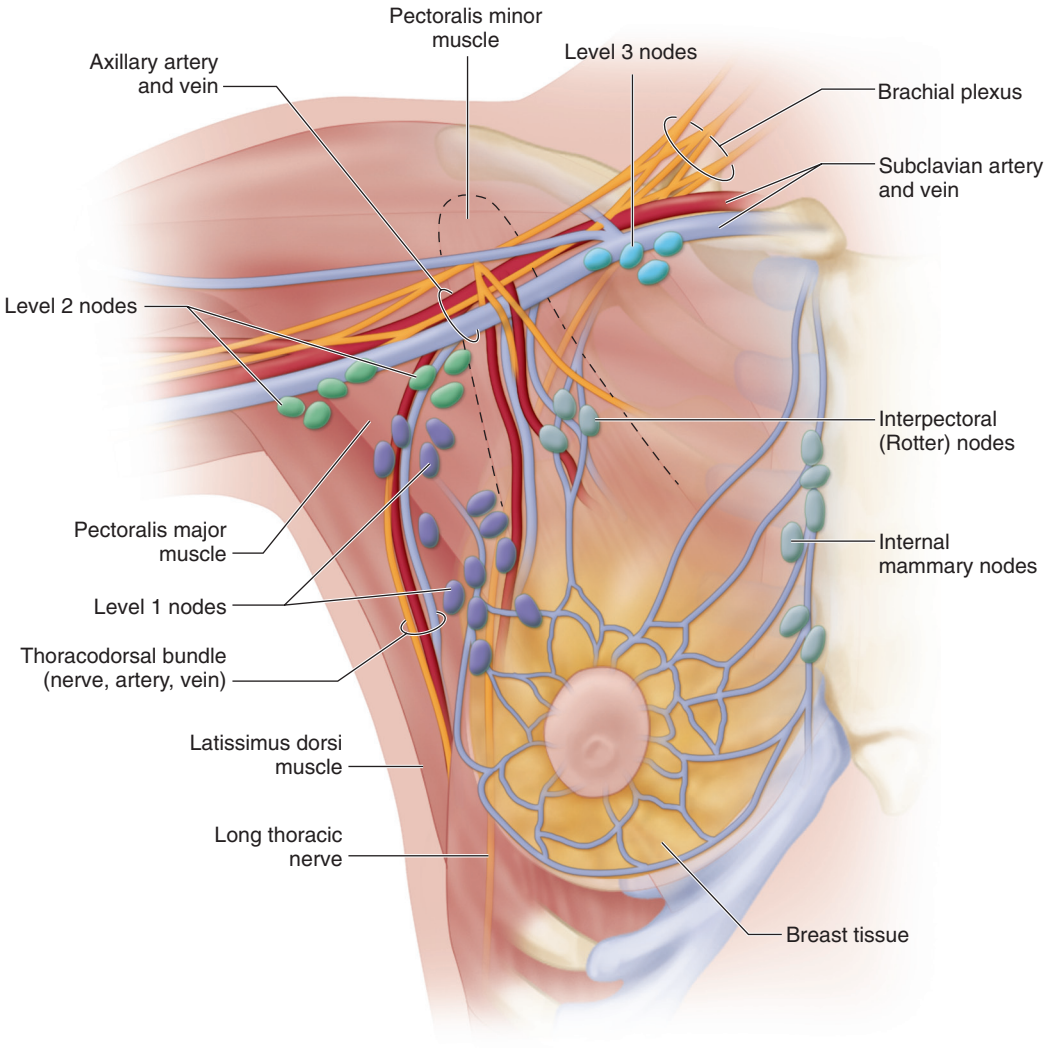

Figure G-1 Pictorial depiction of anatomic landmarks of the axilla and lymphatic drainage of the breast.

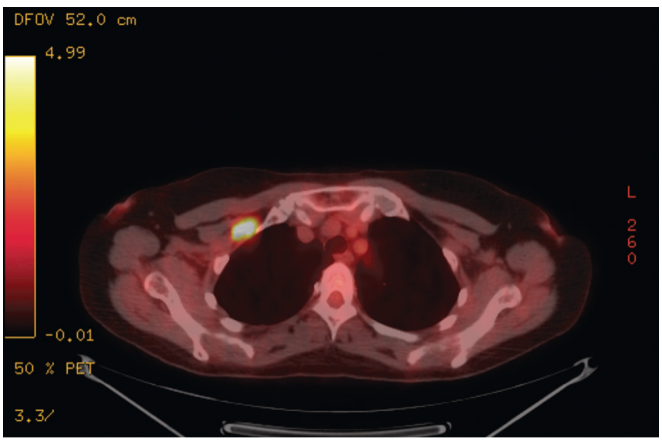

Figure G-2 Axial PET/CT slice of a patient with a right breast cancer that involved the level III axilla and infraclavicular fossa. The involved lymph node is below and medial to the pectoralis minor muscle. *CT,* computed tomography; *PET,* positron emission tomography.

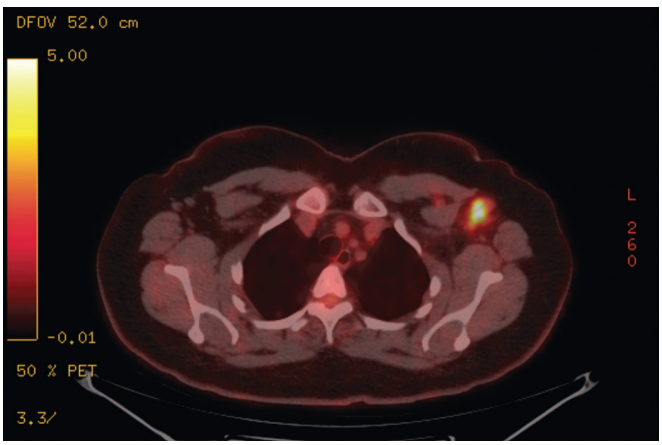

Figure G-3 Axial PET/CT slice of a patient with a left breast cancer that involved the level I axilla and Rotter's lymph nodes. The level I adenopathy is located lateral to the pectoralis minor muscle, and the involved Rotter's lymph nodes are anterior to the pectoralis major muscle. *CT,* computed tomography; *PET,* positron emission tomography.

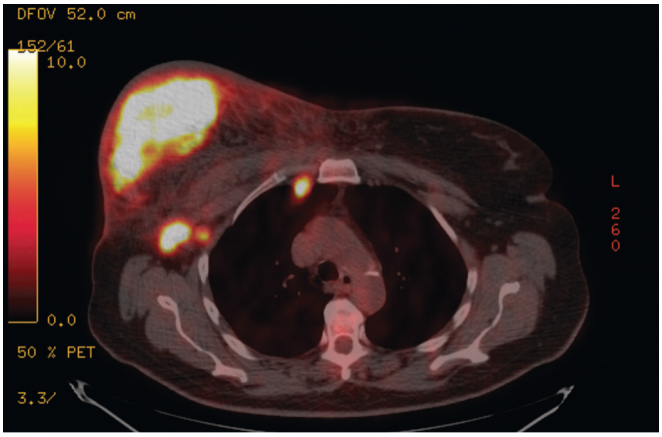

Figure G-4 Axial PET/CT slice of a patient with an inflammatory carcinoma of the right breast showing increased activity diffusely through the breast and involvement of both axillary level I and internal mammary lymph nodes. *CT*, Computed tomography; *PET*, positron emission tomography.

will have recurrence in the supraclavicular fossa if this region is not treated.[3] However, a recent study indicated that specific subsets of patients with one to three positive axillary lymph nodes may be at higher risk of recurrence in the supraclavicular fossa and may therefore benefit from treatment to this region. Those subsets include patients with high-grade disease, estrogen receptor–negative disease, and younger patients.[4] Disease that presents with involvement of supraclavicular lymph nodes at diagnosis has a particularly poor prognosis and represents the highest-risk category of nodal disease.

When designing radiation fields, a comprehensive understanding of anatomic relationships in the area to be targeted is essential for the radiation oncologist. Contouring, the process by which the target is delineated from normal tissue is subject to significant levels of inter- and intraobserver variability in terms of accuracy and reproducibility.[5] Guidelines have been developed for high-risk breast cancer to reduce this variability and to guide the delineation of the primary and lymph node clinical target volumes.[6] A recent advance in radiation treatment planning is the use of automated atlas based segmentation (AABS), a technology that uses CT-based atlases as a template to help delineate target volumes with more consistency.[7-9] This technology allows for increased reproducibility among radiation oncologists in delineating the regions of interest.

EPIDEMIOLOGY AND ETIOLOGY

Incidence and Mortality Rates

The American Cancer Society estimated that in 2013 an estimated 232,340 new cases of invasive breast cancer and 39,620 breast cancer deaths would occur[10] making it the second-leading cause of cancer-related deaths in women, exceeded only by lung cancer. Historically, the increase in breast cancer incidence was thought to be a reflection of changes in reproductive patterns, such as delayed childbearing and giving birth to fewer children, which are recognized as risk factors.

Starting in the early 1980s, the incidence of breast cancer among older women began rising as a result of improved detection with the widespread use of mammography. The rates stabilized in the late 1990s and then started to decrease; it has been hypothesized that the decline occurred because of a reduced use of hormone replacement therapy following the 2002 publication of the Women's Health Initiative randomized trial results.[11,12] In contrast the incidence of breast cancer in younger women has remained stable. Although breast cancer is a rare disease in young women, it is the most common cancer occurring in the age group. When it occurs in women younger than 35, it brings forth unique clinical challenges for the clinician and personal challenges for the patient, especially when associated with pregnancy.[13,14]

With a rapidly aging population in the United States, the number of breast cancers is expected to increase over the next 20 years. Fortunately, breast cancer mortality rates have declined continuously since 1990, probably because of screening leading to early detection and advances in multidisciplinary treatment.[15] Survivorship is a growing issue and research into the late effects of treatment is of relevance given that more than 2.9 million U.S. women with a history of breast cancer are expected to be alive in 2012.[16]

Risk Factors

The average lifetime risk of breast cancer for a woman in the United States has been estimated at 12.3% (1 in 8 women).[10] Table G-2 lists risk factors for developing breast cancer. The strongest risk factor for breast cancer is being female; only about 1% of all new breast cancer cases occur in men.[10] The second-most important risk factor is an individual's age, with 95% of all new breast cancer cases developing in women aged 40 years or older.[10] The annual risk of developing breast cancer increases exponentially from age 40 until menopause, at which time the rate of increase in annual risk slows considerably. After the age of 80, the annual incidence of breast cancer begins to show a slight decline. The risk of developing breast cancer as a function of age for females is shown in Table G-3.

The risk of breast cancer development is influenced by estrogen exposure over the course of one's life. Specifically, risk factors for breast cancer development include young age at menarche, nulliparity or older age at first pregnancy, and older age at menopause. In a large study of Swedish women, the risk of breast cancer increased approximately 13% for every 5-year increase in age at first birth.[17] Postmenopausal estrogen replacement therapy also has been shown to increase the risk of breast cancer. In a meta-analysis of 51 studies that included 52,705 women with breast cancer and 108,411 women without breast cancer, receipt of postmenopausal hormone replacement therapy was found to increase the annual relative risk of developing breast cancer by 2.3% for each year of hormonal therapy.[18] In 2000, a study of 46,000 women reported that the combined use of estrogen and progesterone increased the relative risk of breast cancer by 8% compared with the risk in nonusers, whereas the use of estrogen alone increased the relative risk by only 1%.[19] These data have been confirmed by two large prospective studies conducted through the Women's Health Initiative.[20,21]

Many patients and family members are interested in whether they can modify their risk for developing breast cancer through diet or exercise, or both. Evidence in support of any association between dietary fat content and breast cancer development has been weak and inconsistent.[22,23] Because of conflicting findings, it has been difficult to make strong nutritional recommendations for breast cancer prevention. Use of omega-3 polyunsaturated fatty acid (PUFA) supplements has gained attention in preclinical studies as a potential protectant against breast cancer.[24] In contrast, alcohol intake seems to be more consistently associated with increased breast cancer risk.[25,26] Exercise and body weight have a moderate impact on breast cancer risk. Relatively large studies have demonstrated that daily exercise, particularly early in life, can reduce the risk of breast cancer for both premenopausal and

TABLE G-2 Breast Cancer Risk Factors

Risk Factors Used in the National Cancer Institute Breast Cancer Risk Assessment Tool*	Other Known Risk Factors	Unlikely Risk Factors
Personal history of lobular carcinoma in situ or ductal carcinoma in situ	Female sex	Higher fat intake
Older age	Personal history of breast cancer	Fibrocystic breast disease
Family history of breast cancer and number of first-degree relatives with breast cancer	Germ-line mutation in *BRCA1* gene or *BRCA2* gene	Fibroadenoma
Nulliparity and age at first birth	Higher alcohol consumption	Simple breast cysts
Older age at menarche	Low amounts of exercise	Use of oral contraceptives
History of a breast biopsy and number of breast biopsies	Use of hormone replacement therapy	Use of tobacco
Personal history of atypical ductal hyperplasia	History of radiation treatments to the chest for Hodgkin's disease	
White race	Lack of breast-feeding

TABLE G-3 Risk of Being Diagnosed with Breast Cancer in 10, 20, and 30 Years and in the Remaining Lifetime*

Current Age	+10 yrs	+20 yrs	+30 yrs	Eventually
0	0.00	0.00	0.05	13.39
10	0.00	0.05	0.49	13.54
20	0.05	0.49	1.95	13.57
30	0.44	1.91	4.57	13.59
40	1.49	4.18	7.64	13.31
50	2.79	6.36	9.77	12.21
60	3.83	7.49	9.63	10.11

yrs, *Years.*
**Given cancer-free status at the current age, lifetime risk (%) of being diagnosed with cancer was determined according to 12 Surveillance, Epidemiology, and End Results (SEER) areas; the lifetime risk of dying of cancer was 2.98% (determined for U.S. totals, 1999 to 2001).*

postmenopausal women.[27,28] Some recent evidence suggests that exercise and body weight can influence the outcome after breast cancer treatment as well.[29,30]

Genetic Factors and Breast Cancer Etiology

Breast cancer develops from breast epithelial tissue with abnormalities in several cellular processes as a result of genetic and epigenetic events. Some patients have inherited germ-line genetic conditions, such as a mutation in a relevant tumor suppressor gene, but in most cases the genetic events leading to breast cancer are somatic or sporadic. Approximately 20% to 25% of women diagnosed with breast cancer have a family history of the disease, and approximately 10% of patients have a family history showing an autosomal dominant pattern of breast cancer inheritance.

Epidemiologic studies of families with a history of breast cancer led to the discovery of germ-line mutations in two important tumor suppressor genes, the *BRCA1* and *BRCA2* genes. Individuals who inherit a mutation in the *BRCA1* gene or *BRCA2* gene from one of their parents have a high lifetime risk of developing a breast cancer that is associated with certain aggressive tumor characteristics. Mutation in the *BRCA1* gene is associated with triple negative cancers, medullary cancer, young age at diagnosis, and ovarian cancer.[31] Patients with mutations in the *BRCA2* gene more commonly develop ER-positive breast cancer, and although they are still at increased risk of ovarian cancer relative to the general population, this risk is less than for those with the *BRCA1* gene mutation. The *BRCA2* gene is also associated with male breast cancer.[31] Table G-4 highlights the main features of BRCA-linked tumors and the prevalence of second malignancies in *BRCA1* and *BRCA2* gene mutation carriers.[13,32-35]

The mutations of interest are point mutations that are found during traditional Sanger sequencing of the *BRCA1* and *BRCA2* genes. Large rearrangements in BRCA1 and BRCA2 (BART) occur in a small percentage (<1%) of all patients tested for hereditary breast or ovarian cancer syndrome.[36] Since 2008, BART testing has been included as part of Comprehensive BRCA*analysis* tests for patients with a strong personal and family history of breast and ovarian cancer and in individuals meeting criteria for automatic BART testing, the prevalence of mutations in a high-risk population is higher (7.5%) than in the normal population.[37]

For all patients diagnosed with breast cancer, a preliminary risk assessment should be performed to determine if a more formal evaluation is needed. The degree of risk for a familial syndrome increases with the number of affected family members, the closeness of the relationship, and the younger the age at diagnosis of the affected member.[38] Formal risk assessment and genetic counseling takes into account a detailed family pedigree, an evaluation of the patient needs and concerns, and the past medical and surgical history as well as any active cancer diagnoses.

The National Cancer Center Network (NCCN) panel recommends that patients with a personal history of breast cancer in addition to one or more of the criteria listed in Box G-1 should undergo testing. Furthermore, mutations should be suspected and tested for in cases of male breast cancer at any age, ovarian cancer at any age, and in high-risk ethnic backgrounds (e.g., Ashkenazi Jewish heritage). In addition to hereditary breast and ovarian cancer syndrome (BRCA1/BRCA2), advances in molecular genetics have identified several genes associated with an inherited susceptibility to breast cancer (e.g., *PTEN*, *TP53*, *CDH1*) and identification of a mutation has implications for prevention, screening, and treatment.[39]

New genetic testing panels use next-generation sequencing to detect hereditary breast, ovarian, and other cancer for patients who have tested negative for high penetrance genes such as *BRCA1* and *BRCA2* in light of a suggestive family history. These panels should not be routinely ordered without an expert cancer geneticist consultation as guidelines on risk assessment and management of variant mutations is not clearly defined.

Breast Cancer Screening

Breast cancer screening is performed in asymptomatic women so that disease can be detected earlier. Irrespective of risk level,

TABLE G-4 Features of BRCA-Linked Tumors

	BRCA1	*BRCA2*
Tumor biology	High proliferation rates Low differentiation Increased prevalence of grade-3 tumors Reduced ER/PR expression Increased rate of p53 mutations Higher degree of aneuploidy Reduced Her2/neu expression	Higher frequency of medullary tumor Increased rate of p53 mutation Higher degree of aneuploidy Reduced HER2/neu expression
Estimated lifetime breast cancer risk	47%-66%	40%-57%
Female breast cancer risk according to age	2% by age 30 20% by age 40 37% by age 50 55% by age 60	Same as *BRCA1*
Ovarian cancer risk	21% by age 50 40% by age 60	2% by age 50 6% by age 60

BOX G-1 Hereditary Breast and Ovarian Syndrome Testing Criteria

HEREDITARY BREAST AND OVARIAN SYNDROME TESTING CRITERIA (*BRCA1/BRCA2*)

A personal history of breast cancer plus one or more of the following:

1. Diagnosed at age 45 or younger
2. Having two breast primaries with the first breast cancer diagnosed at younger than age 50
3. Diagnosed at younger than age 50 with one or more close relative with breast cancer at any age.
4. Diagnosed with triple negative breast cancer at younger than age 60
5. Diagnosed at any age with two or more close relatives with breast cancer at any age; diagnosed at any age with one or more close relative with epithelial ovarian cancer diagnosed at any age
6. Diagnosed at any age with 2 or more close relatives with pancreatic or aggressive prostate cancer (Gleason ≥7) at any age

Adapted from Genetic/Familial High-Risk Assessment: Breast and Ovarian. NCCN Guidelines 2014. Accessed on 2/21/14.

a routine physical examination including a clinical breast examination (CBE) should be performed in all women. Following a complete medical history, women may be stratified into two risk groups: those at average risk and those at increased risk to determine further testing. Although controversies are unresolved regarding the timing interval of screening and the benefit of screening in particular age groups (i.e., ages 40 to 49), it is recommended that average risk women age 40 or older should undergo yearly screening bilateral mammogram based on a consensus statement from the American Cancer Society.[40-43] In the guidelines, there is no strict upper age limit for screening. However, if a patient has severe comorbidities that limit her life expectancy and if no intervention will be planned on the basis of the screening findings, then a recommendation should be made against screening in those clinical situations.

Much of the controversy over breast cancer screening stems from the concern that mammography may be overdiagnostic. This term refers to the fact that some cancers detected at screening may grow so slowly or not at all and that they may never result in death even if left undetected and untreated.[44] In these cases, patients are being subjected to unnecessary biopsies, surgeries, radiation therapy, and subsequent systemic treatments. This results in psychosocial and financial costs for patients, families, and society at large.

Table G-5 shows the recognized risk factors that place women at a higher risk of breast cancer and highlights the appropriate screening recommendations for them. The modified Gail model is a risk assessment tool, which calculates the 5-year and lifetime predicted risk of developing invasive breast cancer as a function of several known risk factors.[45,46] However, this risk tool should not be used in women with a predisposing gene mutation, a strong family history, a history of prior thoracic radiation, or for those with lobular carcinoma-in situ (LCIS). Additionally, models that rely on family history (i.e., Claus,[47] Tyrer-Cuzick,[48] and BRCAPRO[49]) can identify women with a greater than 20% lifetime risk of breast cancer based on these models and are instrumental in directing screening and identifying women who are candidates for risk reduction strategies.

The routine use of magnetic resonance imaging (MRI) screening for the general population is not recommended because of the high cost and high false-positive rate associated with MRI. Among the high-risk populations, clear evidence exists to recommend annual MRI screening in addition to mammography for BRCA carriers. In general, screening for hereditary breast cancer begins at age 25 and includes annual mammography, annual breast MRI, and biannual clinical breast exams. Because of the high incidence of "interval" cancers in BRCA carriers, alternating the imaging techniques (mammogram and MRI) every 6 months is suggested to attempt to provide more coverage. Women who received radiation treatment for prior diagnosis of lymphoma are screened similarly with mammography and MRI starting 10 years after completing radiation. Other high-risk characteristics such as a personal previous history of breast cancer, LCIS, or average familial risk do not warrant the adjunct use of MRI.

Breast Cancer Prevention Strategies

Women who are at increased risk of developing breast cancer can reduce this risk through prevention strategies. Specific lifestyle changes with the potential to modify risk include reducing or eliminating alcohol consumption, maintaining ideal weight, and exercising on a regular schedule. All women regardless of age or risk status should be recommended to

TABLE G-5 Breast Cancer Screening: Increased Risk Category

High-Risk Factor	Screening Recommendation
Prior history of breast cancer, Hx of lobular carcinoma in situ (LCIS) or familial risk	Encourage breast awareness, CBE every 6-12 months, annual mammography
≥35 years of age with a 5-year risk of invasive breast carcinoma ≥1.7% by Gail Model*	Encourage breast awareness, CBE every 6-12 months, annual mammography
Lifetime risk of breast cancer >20% based on family history models	Encourage breast awareness beginning at age 30, CBE every 6-12 months, annual mammogram; consider reduction strategies
History of previous therapeutic thoracic radiation (e.g., mantle radiation) between the ages of 10-30 years	Age ≥25: encourage breast awareness, annual mammograms, annual MRI as adjunct to mammograms, to be initiated 8-10 years after radiation exposure or at age 40, whichever comes first Age <25: encourage breast awareness, risk counseling, and annual CBE; annual mammography and MRI to be initiated 8-10 years after radiation exposure
Known genetic predisposition	Encourage breast awareness, CBE every 6-12 months, annual mammography, annual MRI; begin screening at age 25
Family history pedigree suggestive of genetic predisposition	Encourage breast awareness, CBE every 6-12 months, annual mammography, annual MRI; begin screening 10 years earlier than age of youngest woman in family diagnosed with breast cancer, but no later than age 40

maintain a healthy lifestyle. Pharmacologic strategies that affect estrogen and progesterone signaling pathways can also reduce the risk of developing breast cancer. Risk reduction surgeries (i.e., bilateral total mastectomy or bilateral salpingo-oophorectomy) may be beneficial in select high-risk groups.

Risk Reduction Agents

Estrogen and the estrogen receptor (ER) are key regulators in the progression of breast cancer. Drugs that target ER are known as selective estrogen receptor modulators (SERMs) and were first approved as a treatment for metastatic hormone-receptor–positive breast cancer given its antagonistic effects on breast tissue. Tamoxifen is now routinely used to treat all stages of breast cancer. In adjuvant treatment trials, it has been noted that women who have been treated with tamoxifen for primary invasive disease have a lower incidence of ipsilateral and contralateral tumor recurrences.[50,51] This clinical finding as well as preclinical studies showing that tamoxifen has anti-initiator and antipromoter properties served as the basis for exploring the preventative effects of tamoxifen.[52,53]

The National Surgical Adjuvant Breast and Bowel Project (NSABP) P-1 trial was a randomized placebo-controlled study of tamoxifen that enrolled 13,388 women predicted to have a 1.67% or higher risk of developing breast cancer within 5 years. The results showed that tamoxifen reduced the rates of invasive and noninvasive ER-positive breast cancer by 49% and 50%, respectively.[54] In the International Breast Cancer Intervention Study I (IBIS-I) trial, women at high risk were treated with tamoxifen for 5 years and were found to have a reduced incidence in ER-positive breast cancer by 48% with a persistent benefit for at least 10 years after discontinuing therapy.[55,56] Although highly effective for breast cancer prevention, a side effect profile including hot flashes, night sweats, vaginal symptoms, and more serious effects such as endometrial cancer and thromboembolism has been associated with tamoxifen use. The rate of endometrial cancer was higher in women over the age of 50, and the risk for thromboembolism increased with age as well. Because of tamoxifen-related side effects, efforts were undertaken to consider alternative agents. Raloxifene (another SERM) was evaluated and found to reduce the rate of invasive ER-positive breast cancers becoming available as an alternative option in women who are postmenopausal.[57,58] Based on the collective results of the tamoxifen and raloxifene clinical prevention trials, the STAR (P-2) trial, conducted by the NSABP, compared the effectiveness of treatment with tamoxifen or raloxifene for 5 years on reducing breast cancer risk in 19,474 women who were postmenopausal and high risk.[59] The long-term follow-up of the STAR trial showed that although there were fewer cases of thromboembolism and uterine cancers in the raloxifene group, it was ultimately less effective at prevention of invasive breast cancer.[60]

More recently, the portfolio of choices for prevention strategies among patients who are high risk and postmenopausal has been further expanded. Aromatase inhibitors such as letrozole, anastrozole, and exemestane block the biosynthesis of estrogen from androgens by inhibiting the aromatase enzyme, which results in a decrease of circulating estrogen levels in the serum, tissue, and tumor cells.[61] Aromatase inhibitors have been shown to be more effective at preventing breast cancer recurrence and reducing second breast cancers than tamoxifen in the adjuvant setting.[62-64] These data led to the evaluation of aromatase inhibitors in the preventative setting. Two randomized placebo-controlled trials have demonstrated that exemestane (a steroidal aromatase inhibitor) and anastrozole (a nonsteroidal aromatases inhibitor) appear to be more effective than placebo at reducing the incidence of invasive and ductal carcinoma in situ cancers in women who are postmenopausal.[65,66] It is important to note, however, that the effects of tamoxifen have been shown to last for at least 10 years, and further follow-up is needed in the IBIS-II and MAP.3 trials to evaluate whether the effects of exemestane and anastrozole on breast cancer risk reduction will be sustained. At the current time, for women who are older than 35 years of age and who are at increased risk of breast cancer, oncologists may select among the available pharmacological strategies for breast cancer risk reduction based on the patient's hormonal status and the side effect profile of the drug.[67] Table G-6 highlights the available pharmacologic breast cancer risk reduction strategies.

The diagnosis of ductal carcinoma in situ (DCIS) has become a more common entity since the widespread use of screening mammography has been adopted, and it is recognized to be a risk factor for development of invasive breast

TABLE G-6 Highlights from Select Pharmacological Breast Cancer Prevention Trials

Trial	Study Design	Patient Population	Results	Toxicity Pearls
SELECTIVE ESTROGEN RECEPTOR MODULATORS (SERMS)				
Tamoxifen				
NSABP-P-1[54]	Tamoxifen vs. placebo	*N* = 13,388, HR, PPM	49% reduction in all BC	Decreased risk of bone fractures* Increased risk of thromboembolism† Increased risk of uterine cancer†
IBIS-I[55]	Tamoxifen vs. placebo	*N* = 7154, HR, PPM	27% reduction in all BC and 31% reduction in ER+BC	
Raloxifene				
MORE[57]	Raloxifene (60 or 120 mg) vs. placebo	*N* = 7705, NR, PM	65% reduction in all BC and 90% reduction in ER+BC	
CORE[58]	Extension of MORE	*N* = 5213‡	50% reduction in all BC and 66% reduction in ER+BC	
Tamoxifen vs. Raloxfene				
STAR-P-2[60]	Tamoxifen vs. raloxifene	*N* = 19,747, HR, PM	5 years: raloxifene = tamoxifen 81 months: raloxifene is 75% as effective as tamoxifen	Raloxifene: decreased risk of thromboembolism and uterine cancers compared to tamoxifen
AROMATASE INHIBITORS (AIS)				
Exemestane				
MAP3[65]	Exemestane vs. placebo	*N* = 4560, HR, PM	65% reduction in all BC at 3 years follow-up and 75% reduction in ER+BC	Increased risk of bone fractures, skeletal symptoms and vasomotor symptoms with AIs
Anastrazole				
IBIS-II[66]	Anastrazole vs. placebo	*N* = 6000, HR, PM	53% reduction in all BC at 5 years and 58% reduction in ER+BC

cancer. It is unclear, however, which lesions will progress and develop invasive properties and which will not. Currently management of this entity includes a combination of surgical resection, radiation, and tamoxifen. For women with DCIS, the NSABP B-17 study reported a significantly better overall 5-year event-free survival attributed to a lower incidence of invasive and noninvasive ipsilateral breast cancer among women who underwent lumpectomy and radiation therapy compared to lumpectomy alone or lumpectomy and tamoxifen. The NSABP B-24 trial showed that the combination of lumpectomy, radiation, and tamoxifen was more effective in the prevention of invasive cancer in women with DCIS compared to lumpectomy and radiation alone.[68] A retrospective subset analysis of NSABP B-24 showed that women with ER-positive DCIS benefit from intervention with tamoxifen, whereas women with ER-negative disease do not.[69] Therefore, tamoxifen is recommended for women with ER-positive DCIS who have remaining breast tissue following locoregional management. Second-generation trials of endocrine therapy with aromatase inhibitors (NSABP-35 and International Breast Cancer Intervention Study II) have been limited to women with hormone-receptor positive DCIS.

Risk Reduction Surgeries

Bilateral risk-reduction mastectomy has a role in carefully selected patients after an appropriate workup, multidisciplinary consultation, and genetic counseling. Bilateral mastectomy is proven to be an effective risk reduction strategy for women with a germline mutation in the *BRCA1* or *BRCA2* gene.[70-72] When it is performed for the purpose of risk reduction, it should involve removal of all breast tissue. Axillary evaluation is not required unless there is invasive disease identified when the mastectomy specimen is evaluated pathologically.[73] For *BRCA 1* and *BRCA2* gene mutation carriers, prophylactic bilateral salpingo-oophorectomy is recommended after completion of childbearing as a highly effective preventative measure against ovarian cancer risk.[74]

Diagnostic Overview

In most cases, breast cancer is diagnosed after abnormalities are found on screening mammography or after detection of a palpable mass. Some patients may present with an isolated painless lump in the breast. Others may have discharge or bleeding from the nipple. In some, the mass may have gone unnoticed, ignored, or neglected for some time and the presenting signs and symptoms may include nipple retraction, pain, ulceration, inflammation, or malodor with fixation to the skin or chest wall on physical examination. All patients should undergo a careful history with attention given to risk factors and family history. Next, a detailed physical examination should be performed with focus on the involved breast, the opposite breast, all regional lymph node areas, the lungs, bone, and liver. Bilateral diagnostic mammography, including additional views that highlight the noted abnormality should be performed to assess the extent of involvement and to

evaluate for additional ipsilateral or contralateral disease. Most patients should also have diagnostic ultrasonography of the breast and regional lymph nodes to further delineate the locoregional extent of disease.

For patients with a suspicious abnormality on physical examination or on mammography or sonography, tissue from the abnormality should be obtained to rule out cancer. The recommended biopsy procedure is a percutaneous core biopsy usually done under sonographic guidance. For patients who present with suspicious calcifications that cannot be well visualized with sonography, a stereotactic biopsy is recommended. A stereotactic biopsy is done under mammographic localization. In any biopsy procedure, it is important to leave a clip or other marker near the abnormality to help localize the tumor bed for subsequent surgery. Once the diagnosis of breast cancer is established further pathological testing should be done on the tumor tissue to determine important features such as histology, grade, presence of lymphovascular invasion, and receptor status (ER), progesterone receptor [PR], and HER2/neu receptor). Fine-needle aspiration of any suspicious regional lymph nodes can also be valuable for determining the initial extent of disease. When indicated, appropriate staging studies should be performed to rule out the presence of distant metastatic disease. However, most patients with early-stage disease do not require staging studies.

STAGING

Breast cancer is staged according to the size and characteristics of the primary tumor (T), the involvement of regional lymph nodes (N), and the presence of metastatic disease (M).

Table G-7 shows the breast cancer staging system from the seventh (2010) edition of the *American Joint Committee for Cancer (AJCC) Staging Manual*.[75] That system comprises both a clinical staging system, based on physical examination and radiographic studies, and a pathologic staging system, based on examination of surgical specimens. Pathologic staging after initial systemic treatments before surgery should be annotated with a *yp* before the assigned stage. All practitioners involved in breast cancer care should be familiar with the AJCC staging

TABLE G-7 American Joint Committee on Cancer Staging System for Breast Cancer[75]

PRIMARY TUMOR (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Tis (DCIS)	Ductal carcinoma in situ
Tis (LCIS)	Lobular ductal carcinoma in situ
Tis (Paget's)	Paget's disease of the nipple with no tumor[a]
T1	≤2 cm in greatest dimension
T1mi	Microinvasion 0.1 cm or less in greatest dimension
T1a	Tumor >0.1 cm but not >0.5 cm in greatest dimension
T1b	Tumor >0.5 cm but not >1 cm in greatest dimension
T1c	Tumor >1 cm but not >2 cm in greatest dimension
T2	Tumor >2 cm but not >5 cm in greatest dimension
T3	Tumor more than 5 cm in greatest dimension
T4	Tumor of any size with direct extension to (a) chest wall or (b) skin, only as described below
T4a	Extension to the chest wall, not including only pectoralis muscle invasion
T4b	Edema (including peau d'orange) or ulceration of the skin of the breast, or satellite skin modules confined to the same breast
T4c	Both (T4a and T4b)
T4d	Inflammatory carcinoma
REGIONAL LYMPH NODES (N)	
Clinical Disease	
NX	Regional lymph node(s) cannot be assessed (e.g., previously removed)
N0	No regional lymph node metastasis
N1	Metastases to movable ipsilateral level I to II axillary lymph node(s)
N2	Metastases in ipsilateral axillary lymph nodes fixed or matted, or in clinically apparent[b] ipsilateral internal mammary nodes in the absence of clinically evident axillary lymph node metastasis
N2a	Metastases in ipsilateral axillary lymph nodes fixed to one another (matted) or to other structures
N2b	Metastases only in clinically apparent[b] ipsilateral internal mammary lymph nodes and in the absence of clinically evident axillary lymph node metastasis
N3	Metastases in ipsilateral infraclavicular lymph node(s) with or without axillary lymph node involvement, or in clinically apparent[b] ipsilateral internal mammary node(s) and in the presence of clinically evident axillary lymph node metastasis; or metastasis in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
N3a	Metastases in ipsilateral infraclavicular lymph node(s)
N3b	Metastases in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
N3c	Metastases in ipsilateral supraclavicular lymph node(s)

TABLE G-7 American Joint Committee on Cancer Staging System for Breast Cancer—cont'd

Pathologic Disease (pN)[c]			
pNX	Regional lymph nodes cannot be assessed (e.g., previously removed or not removed for pathologic study)		
pN0	No regional lymph node metastasis histologically, no additional examination for isolated tumor cells[d]		
pN0(i–)	No regional lymph node metastasis histologically, negative immunohistochemical staining		
pN0(i+)	Isolated tumor cells identified histologically or by positive immunohistochemical staining, no cluster >0.2 mm		
pN0(mol–)	No regional lymph node metastasis histologically, negative molecular findings (RT-PCR)[e]		
pN0(mol+)	No regional lymph node metastasis histologically or by immunohistochemical staining, positive molecular findings (RT-PCR)e		
pN1	Metastasis in 1 to 3 axillary lymph nodes and/or in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent[f]		
pN1mi	Micrometastasis (>0.2 mm or >200 cells, none >2 mm)		
pN1a	Metastasis in 1 to 3 axillary lymph nodes		
pN1b	Metastasis in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent[f]		
pN1c	Metastasis in 1 to 3 axillary lymph nodes[g] and in internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent[f]		
pN2	Metastasis in 1 to 3 axillary lymph nodes or in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent[f]		
pN2a	Metastasis in 4 to 9 axillary lymph nodes (at least one tumor deposit >2 mm)		
pN2b	Metastasis in clinically apparent internal mammary lymph nodes in the absence of axillary lymph node metastasis		
pN3	Metastases in 10 or more axillary lymph nodes, or in infraclavicular lymph nodes, or in clinically apparent[b] ipsilateral internal mammary lymph nodes in the presence of one or more positive axillary lymph nodes; or in more than 3 axillary lymph nodes with clinically negative microscopic metastasis in internal mammary lymph nodes; or in ipsilateral supraclavicular lymph nodes		
pN3a	Metastasis in 10 or more axillary lymph nodes (at least one tumor deposit >2 mm), or metastasis to the infraclavicular lymph nodes		
pN3b	Metastasis in clinically apparent[b] ipsilateral internal mammary lymph nodes in the presence of one or more positive axillary lymph nodes; or in more than three axillary lymph nodes and in internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent[f]		
pN3c	Metastasis in ipsilateral supraclavicular lymph nodes		
DISTANT METASTASIS (M)			
MX	Distant metastasis cannot be assessed		
M0	No distant metastasis		
cM0(i+)	No clinical or radiographic evidence of distant metastasis but molecular or microscopically detected tumor cells in circulating blood, bone marrow, or other nonregional nodal tissue no larger than 0.2 mm in a patient without symptoms		
M1	Distant metastasis		
STAGE GROUPING			
Stage 0	Tis	N0	M0
Stage I	T1[h]	N0	M0
Stage IIA	T0	N1	M0
	T1[h]	N1	M0
	T2	N0	M0
Stage IIB	T2	N1	M0
	T3	N0	M0
Stage IIIA	T0	N2	M0
	T1[h]	N2	M0
	T2	N2	M0
	T3	N1	M0
	T3	N2	M0
Stage IIIB	T4	N0	M0
	T4	N1	M0
	T4	N2	M0
Stage IIIC	Any T	N3	M0
Stage IV	Any T	Any N	M1

From Edge SB, Byrd DR, Compton CC, et al, eds: AJCC cancer staging manual, ed 3, New York, 2010, Springer, pp 345–376.

[a]*Paget's disease associated with a tumor is classified according to the size of the tumor.*

[b]Clinically apparent disease *is defined as disease detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination or is disease that is grossly visible pathologically.*

[c]*Classification is based on axillary lymph node dissection with or without sentinel lymph node dissection. Classification based solely on sentinel lymph node dissection without subsequent axillary lymph node dissection is designated (sn) for "sentinel node," for example, pN0(i+)(sn).*

[d]*Isolated tumor cells are defined as single tumor cells or small cell clusters ≤0.2 mm, usually detected only by immunohistochemical or molecular methods but which may be verified on hematoxylin and eosin staining. Isolated tumor cells do not usually show evidence of metastatic activity (e.g., proliferation or stromal reaction).*

[e]*Reverse transcriptase-polymerase chain reaction.*

[f]Not clinically apparent disease *is defined as disease not detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination.*

[g]*If associated with more than three positive axillary lymph nodes, the internal mammary nodes are classified as pN3b to reflect increased tumor burden.*

[h]*T1 includes T1mic.*

system, and it is critical that each case be assigned a tumor-nodes-metastasis (TNM) stage before any treatment is begun. For patients with clinical stage I or II disease, the staging workup should include a physical examination, diagnostic mammography, ultrasonography, and routine serum studies. For patients with locally advanced disease, screening tests for metastatic disease should include a bone scan and liver imaging with CT or PET/CT.

The TNM staging of breast cancer has evolved over time. Some of the more important changes in recent staging systems have included:

- Considering the number of positive lymph nodes in assigning the pathologic N stage
- Considering the size of positive lymph node metastasis in assigning the pathological N stage (micrometastasis versus macrometastasis)
- Changing involvement of infraclavicular lymph nodes from N1 to N3 disease
- Changing involvement of supraclavicular lymph nodes from M1 to N3 disease
- Considering isolated tumor cells detected with immunohistochemical staining of sentinel lymph nodes, which is denoted as N0(i+)

Although it is important to establish the clinical stage before breast cancer, this is preliminary and following surgery a more definitive stage will be decided based on pathological examination of the postsurgical specimen. The pathologic stage is important for prognosis, to understand tumor biology, and to direct future systemic therapies. In up to one third of patients who have no clinically evident axillary nodes at diagnosis, histological examination of the nodes after surgery reveals cancer.

BREAST CANCER BIOLOGIC CHARACTERISTICS

Breast cancer is a biologically heterogeneous disease. Recent advances in genomics and molecular biology techniques have permitted more comprehensive assessments of its genetic heterogeneity. DNA microarray expression profiles have led to classification of breast cancer into molecular subtypes that correspond with distinct prognostic groups based on biology and aggressiveness of the disease.[76,77] Interestingly, these molecular classes are strongly influenced by the genes controlling expression of the ER and HER2/neu receptor.

Molecular Classification

The molecular profiles of estrogen-enriched cancers tend to be similar to those of luminal ductal cells, whereas estrogen-negative breast cancers have molecular phenotypes similar to cells in the basal layers of the breast ductal epithelium. Tumors that overexpress HER2/neu have unique signatures. Recent molecular classifications often group diseases into four classes that overlap but are not synonymous with variations in ER, PR, and HER2/neu status: luminal A tumors, which include most ER-positive, PR-positive, HER2-negative tumors; luminal B tumors, which include most ER-positive, PR-positive, HER2-positive tumors; HER2 tumors, which include most ER-negative, PR-negative, HER2-positive tumors; and, finally, basilar cancers, which overlap significantly with triple-negative (ER-negative, PR-negative, HER2-negative) breast cancers.

Luminal A disease expresses more ER-related genes, carries the best prognosis and predicts response to hormonal therapy. Luminal B tumors express more cellular proliferation and HER2-related genes and often have a higher grade and a worse prognosis compared to luminal A. A subgroup (30% to 50%) of basal-type cancer tends to be chemoresponsive but is nevertheless an aggressive molecular subtype with an overall poor prognosis. Finally, the inherent aggressive biology of HER2-positive disease has been transformed with the use of trastuzumab and other HER2-directed therapies—lapatinib, pertuzumab, and recently ado-trastuzumab. Increasing numbers of reports suggest that molecular subtypes and genetic factors can also affect the outcome after radiation and other locoregional treatments. For patients treated with breast conservation, recent studies from Harvard, British Columbia, and the M. D. Anderson Cancer Center suggest that triple-negative or basilar-like cancers are at increased risk of local recurrence after treatment with lumpectomy and whole-breast radiation.[78-80] These findings are consistent with reports from the Danish randomized trials and the M. D. Anderson Cancer Center indicating that triple-negative disease is also associated with locoregional recurrence after postmastectomy radiation.[81,82]

Predictive Markers and Selection of Therapy

In addition to classification, molecular markers are used to select patients for systemic treatment (e.g., chemotherapy, endocrine therapy, and targeted therapy) and to predict those who are most likely to benefit from the therapies. The quintessential example of a predictive marker is ER; since its discovery, all breast tumors are pathologically assessed for ER and patients with ER-positive tumors benefit from antihormonal treatments such as tamoxifen. A second important predictive factor was discovered in 1985 as the HER2 or erbB2 protein and is found to be amplified in 20% of breast cancers leading to protein overexpression.[83,84] HER2/neu is a transmembrane cell surface receptor with an internal domain that activates downstream signaling pathways. Overexpression has been associated with increased proliferative capacity, enhancement of metastatic potential, and increased rate of tumorigenesis. Trastuzumab is a humanized monoclonal antibody against the extracellular domain of the surface receptor and is an effective treatment in HER2–positive breast cancer in both the metastatic and adjuvant settings (adjuvant therapy as discussed later).[85] HER2 testing by immunohistochemistry to measure protein expression or fluorescent in situ hybridization (FISH) to measure HER2 gene copies is standard for all breast tumors and is predictive of response to targeted therapy.[86]

Furthermore, gene products may be combined to provide a picture of the molecular phenotype of the individual's cancer and thereby predict recurrence or response to chemotherapy. The Oncotype DX assay (Genomic Health) is a 21-gene recurrence score assay that was originally designed to predict the recurrence of ER-positive, node-negative breast cancer after treatment with adjuvant endocrine therapy. The test estimates 10-year risk of recurrence using formalin-fixed, paraffin-embedded tumor tissue. The gene expression is analyzed and a risk score (RS) is assigned based on a weighted algorithm. The assay was validated in 668 patient samples from patients treated with ER-positive, node-negative, tamoxifen who were enrolled in the NSABP B-14 clinical trial.[87] It has now been clinically adopted to determine whether women with high-risk, node negative, HER2-negative, ER-positive breast cancer should receive adjuvant chemotherapy in addition to endocrine therapy (see discussion in this chapter) as it is able to predict the magnitude of benefit.[88]

The assay categorizes patients into three risk groups: (1) A low-risk group (RS, 0-18), distant recurrence risk of less than 10%; (2) intermediate-risk group (18 < RS < 31), distant recurrence risk between 10% and 20%; (3) high-risk (RS > 31), distant recurrence risk greater than 20%. Chemotherapy is generally recommended for patients with intermediate and

high risk for recurrence.[89] Other multigene assays have been identified such as Mammaprint and PAM50; however, Oncotype-DX is widely used in the United States because of its practical attributes and ability to predict response to chemotherapy.

The prognostic and predictive capabilities of the Oncotype DX assay are continually being evaluated. In the prospective, randomized TAILORx clinical trial, patients assigned an intermediate RS were randomized to receive either chemotherapy and hormonal therapy or hormonal therapy alone. This trial enrolled more than 11,000 patients and closed to accrual in October 2010. Results are eagerly anticipated and will refine the utility of the test for the intermediate-risk group. A similar trial for patients who are node-positive (RxPONDER; SWOG S1007) is currently enrolling patients to determine whether there is a subset of patients who are node-positive, HER2-negative, hormone receptor–positive who may be spared from chemotherapy. As discussed later in this chapter, according to current guidelines, patients who are node-positive should be offered chemotherapy outside of a clinical trial.[89]

TREATMENT OVERVIEW

For invasive breast cancer in stages I to III, the goals of treatment are curative. Treatment decisions are ultimately made with regard to patient comorbidities, after weighing the potential benefits and harms of therapy, and based on the patient's personal preferences. Often, several extended discussions between the patient and a multidisciplinary team including medical oncology, surgical oncology, plastic surgery, and radiation oncology are needed to determine the best treatment plan. Multimodality therapy (Figure G-5) has had a profound impact on the outcomes of breast cancer because it has allowed for improved disease-free survival and overall survival.

Locoregional Treatments

Surgery and radiation have important roles in the curative management of most breast cancers and greatly determine the level of local control achievable. For patients with early-stage invasive disease, surgery can either be a breast-conserving resection of the primary tumor (e.g., a lumpectomy, segmental mastectomy, wide local excision) or a mastectomy. As highlighted in the subsequent chapter on early-stage breast cancer, numerous randomized prospective clinical trials have indicated that breast-conserving surgery with whole-breast radiation provides long-term outcomes equivalent to those of mastectomy. The goal of breast-conserving surgery should be to remove the primary tumor with surgical margins that are free from either invasive or in situ disease. A secondary goal is to provide the best possible cosmetic outcome, without retraction, nipple displacement, or excess volume loss from the procedure. For some women with larger breasts, several centers are now advocating oncoplastic surgery, in which local tissue rearrangements are performed at the time of surgical resection to maintain optimal breast aesthetics.[90,91]

Breast Surgery

Mastectomy is performed when the tumor is too large or locally advanced to allow breast conservation, although neoadjuvant systemic therapy can sometimes convert a patient into becoming eligible for breast-conserving surgery. Furthermore, mastectomy is indicated if the tumor is multicentric or multifocal, if the patient has a contraindication to radiation therapy, if the lesion is an ipsilateral recurrence in a previously irradiated breast, or if margin-free status cannot be achieved. Mastectomy is also a highly effective local treatment modality for early-stage disease and often precludes the need for radiation if the patient has lymph node-negative disease.

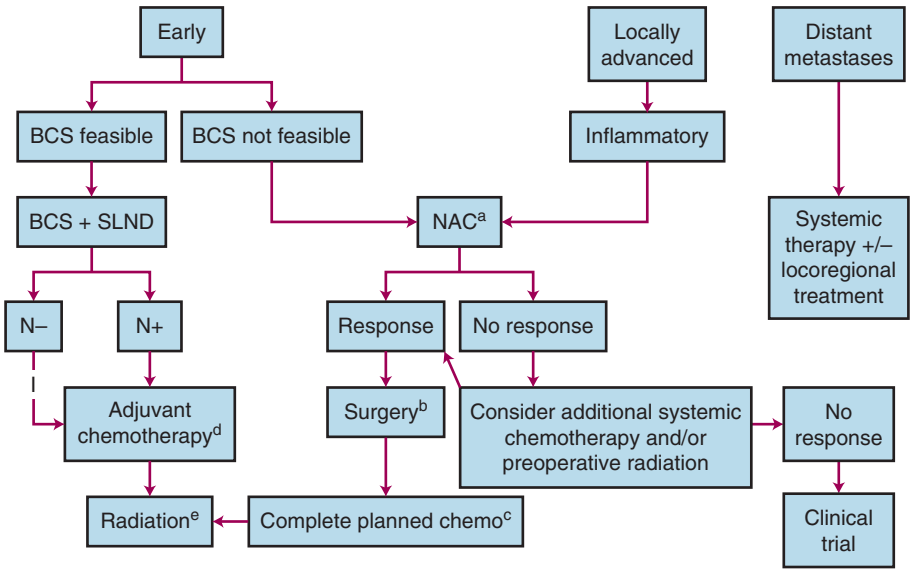

Figure G-5 Overview of multimodality therapy for breast cancer. *ALND,* axillary lymph node dissection; *BCS,* breast-conservation surgery; *ER,* estrogen receptor; *NAC,* neoadjuvant chemotherapy; *PR,* progesterone receptor; *SLND,* sentinel lymph node dissection. [a]Anthracycline- and taxane-based therapy is preferred. For Her2-positive tumor, add dual anti-HER2 blockade to the taxane portion. [b]The extent of surgery is determined by response but always includes an ALND. In inflammatory breast cancer, the surgery is always mastectomy + ALND. [c]Complete planned chemotherapy regimen if not completed preoperatively. Add endocrine treatment if ER-positive or PR-positive. Complete up to 1 year of trastuzumab in HER2-positive disease; may be administered concurrently with radiation therapy and with endocrine therapy if indicated. [d]Adjuvant chemotherapy is indicated in triple negative and HER2-positive tumors >5 mm. In hormone receptor–positive, HER2-negative tumors, chemotherapy is beneficial in patients with a high recurrence score on Oncotype-DX testing and is currently offered as standard of care in patients with intermediate recurrence score. [e]Whole-breast radiation with or without chest wall and lymph node basins as clinically indicated. For inflammatory breast cancer, radiation should include chest wall, level I/II axillary lymph nodes, supraclavicular nodes, and internal mammary lymph nodes if involved.
Adapted from NCCN guidelines and the ASCO-SEP Medical Oncology Self-Evaluation Program.

Skin-sparing mastectomy can preserve significant breast skin, which can allow plastic surgeons to use the breast's natural scaffolding to optimize the cosmetic results of an immediate reconstruction. If the normal inframammary sulcus is maintained, the breast can be reconstructed with excellent symmetry to the contralateral breast. Immediate breast reconstruction can be performed at the time of mastectomy for patients with noninvasive or early-stage disease and can be accomplished with tissue expanders and implants or autologous tissue flaps. Reconstruction may also be delayed for a period of up to 1 to 2 years.

Axillary Management

In addition to treating the primary breast tumor, surgery is important for staging and treatment of the axillary lymph nodes. For patients with invasive disease but no clinical evidence of spread to axillary lymph nodes, sentinel lymph node surgery is the gold standard approach for initial axillary disease staging. Sentinel lymph node biopsy is based on the concept that there is a reproducibly identifiable node (or nodes) that drains the breast and predicts the status of the remaining axillary lymph nodes.[92] This procedure entails injection of azusulfan blue dye or a radiocolloid, or both, into the periareolar or peritumoral subcutaneous tissue. Drainage to the first-echelon lymph nodes in the axilla is then detected by visual inspection of afferent lymphatic channels to a blue node or by use of a handheld gamma probe to detect lymph nodes showing radioactivity. Randomized trials have indicated that sentinel lymph node surgery is highly accurate, with identification and detection rates of 97%, equivalent to those of standard axillary dissection.[93] Axillary recurrence rates are less than 1% after a negative sentinel lymph node biopsy.[94] Currently, sentinel lymph node biopsy is the standard of care for staging the axilla in women with T1-T3, clinically node negative breast cancer.

The sentinel lymph node biopsy procedure represents a significant advance in surgical management that reduces the morbidity of axillary dissection in patients with node-negative disease by reliably differentiating between patients who are node-negative and node-positive disease. One of the main clinical questions after standardization of this approach is to ask whether there is a need for axillary dissection for local control and survival in the era of multimodality therapy. The ACOSOG Z11 trial randomized women with clinically node-negative with cancer <5 cm in size and positive sentinel lymph node(s) (<3 in number) treated with lumpectomy and radiation to completion axillary dissection versus no further surgery. At a median follow-up of 6 years, there were no differences in local control or survival between the groups.[95] Although these results are impressive, much discussion has occurred and the consensus is that further investigation is necessary. A key question is whether whole breast radiation played any role in the low recurrence rates and whether the axilla was actually untreated as all patients in the study received adjuvant breast radiation as a part of their breast-conservation surgery. Furthermore, long-term follow-up is needed as the majority of patients in the Z11 study had ER-positive, HER2/neu–negative postmenopausal disease making them more susceptible to late recurrences. Given that axillary burden is a reflection of tumor biology, these results should be applied within context and carefully to a select group of women who meet the Z11 criteria (Box G-2).[96] In patients who meet the strict criteria for the trial, discussion of these data should ensue with a focus on the questions that remain and the need for long-term follow-up.[97]

Radiation

The role of radiation in the locoregional management of breast cancer is reviewed in the three chapters on ductal carcinoma in situ, early-stage invasive disease, and locally advanced disease. Investigations of the use of radiation for breast cancer date back to some of the first randomized prospective trials in medicine, conducted during the 1950s and 1960s. As such, radiation is one of the most comprehensively investigated aspects of breast cancer care. A unique aspect of these investigations is that the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) in Oxford, England, which has done meta-analyses of the compiled data every 5 years, has centralized all of the data from each randomized trial investigating radiation treatments. Data from the EBCTCG analyses have yielded important and conclusive information about the benefits and risks of radiation treatments for breast cancer. For many decades, radiation was clearly shown to reduce the probability of locoregional recurrence for patients treated with breast-conserving surgery and for patients with positive lymph nodes who underwent mastectomy. The 2005 publication of the EBCTCG meta-analysis, which was able to assess 15-year outcome data, further demonstrated that use of radiation could reduce rates of breast cancer death and improve overall survival rates.[98] Included in that study were individual patient data from 42,080 patients with breast cancer treated in 78 clinical trials that investigated locoregional treatments between 1952 and 1995. Among those patients were 7311 patients treated in 10 trials comparing radiation versus no radiation after breast-conserving surgery and 9933 patients treated in 25 trials comparing radiation versus no radiation after modified radical mastectomy. In the trials that investigated radiation as a component of breast-conservation therapy, radiation was shown to reduce the risk of local recurrence by two thirds and to improve the absolute 15-year overall survival rate by 6% (41% versus 35%). Similarly, for patients with positive lymph nodes treated with modified radical mastectomy, radiation reduced the locoregional recurrence rate by 21% at 15 years (29% versus 8%), which was associated with a 5% decrease in the 15-year breast cancer mortality rate (60% versus 55%). A more recent update of these analyses continues to demonstrate locoregional and survival advantages for radiation therapy.[98]

The time course of the survival advantages from radiation is quite different than that seen from adjuvant systemic treatments. Specifically, survival advantages from systemic treatments tend to become evident within the first 5 years, probably reflecting the eradication of micrometastatic disease present at the time of adjuvant treatment. In contrast, the survival benefits from radiation reflect the eradication of persistent locoregional disease. For persistent locoregional disease to cause death, it must first repopulate and then successfully metastasize, after which the metastases must grow and become life-threatening. This concept is supported by data from the EBCTCG analyses; specifically, the locoregional advantages associated with radiation were found to occur early,

BOX G-2 ACOSOG Z0011 Criteria

"Z11 CRITERIA"[95,96]

Clinical T1 or T2 tumors
Clinically node negative
Breast conserving surgery and whole breast radiation
One or two positive sentinel lymph nodes
The following patients should be excluded:
Mastectomy
Breast conservation surgery with accelerated partial-breast radiation
Neoadjuvant chemotherapy
Three or more positive sentinel lymph nodes

with separation of the radiation versus no radiation curves developing during the first 5 years. However, the survival curves continued to overlap during these first 5 years, separating only later to become clearly evident by 15 years.[98,99]

The EBCTCG data also have been valuable in clarifying potential risks associated with radiation. Long-term outcome data from randomized trials indicate that coincidental radiation of the heart increased the risk of subsequent death from cardiovascular disease.[43] Indeed, in the first generation of randomized radiation trials, the percentage of patients dying from cardiovascular disease was roughly proportional to the decrease in risk of death from breast cancer after radiation therapy. These findings highlighted the importance of developing new radiation techniques to avoid irradiating the heart. Fortunately, with improvements in radiation techniques and improvements in the management of cardiovascular disease, the risk of cardiac toxicity associated with radiation has decreased over time.[100,101]

In general, the survival benefits associated with radiation treatments depend on four factors: (1) the risk of persistent locoregional disease after surgery and adjuvant systemic therapy; (2) the success of radiation in eradicating any persistent locoregional disease; (3) the risk of radiation-related death from normal tissue effects; and (4) the risk of dying of micrometastatic disease present at the time of locoregional treatment and outside of the radiation treatment volume. The success of radiation in eradicating persistent locoregional disease has increased and the risk of radiation-related toxicity has declined with the development of new treatment techniques that more accurately deliver the appropriate radiation doses to intended targets while avoiding radiation of normal tissues. Remarkably, the benefits of radiation have been relatively consistent over time: generally, radiation can reduce the risk of recurrence in all clinical settings by 65% to 75%.[98] In addition, with the advent of modern radiation techniques, the risk of radiation-associated death from normal tissue effects should be quite small.

Clinical research continues in attempts to identify, before treatment if possible, which patients will have clinically relevant persistent locoregional disease after surgery and adjuvant systemic therapy. The current standard is to recommend adjuvant radiation therapy for patients with invasive disease who are treated with breast-conserving surgery with the possible exception of women older than the age of 70 years with stage I ER-positive breast cancer. In addition, women with pathologic stage III breast cancer and some patients with pathologic stage II breast cancer who are treated with systemic therapy and surgery should receive postmastectomy radiation because of the clinically relevant risk of persistent locoregional disease. The risk of persistent disease is also interrelated with the risk of dying from micrometastatic disease that is present at the time of locoregional treatment and is outside of the radiation treatment volume. Specifically, having more than one involved lymph node and having an advanced primary tumor are predictive for both locoregional recurrence and distant metastases. Correspondingly, the probability of achieving a survival advantage with radiation may change over time as new systemic therapies are developed that have a much higher probability of reducing the competing risk of dying from micrometastatic disease.

Systemic Treatments

Systemic treatments are added to the treatment regimen of locally advanced or early-stage breast cancer based on a balance between the risk of distant metastasis and the benefit of therapies to reduce the risk of relapse early in the disease course (within the first 5 years). Data from a meta-analysis of adjuvant chemotherapy trials conducted by the EBCTCG indicate that systemic therapy provides a survival benefit for patients with lymph node-positive disease, those with lymph node-negative disease, and those with ER-positive tumors.[102] As you read further in this section, it will be helpful to refer to Figures G-5 and G-6. With increasing stage of disease, there is an associated increased risk in the development of systemic recurrence. In addition, to the extent of disease present at diagnosis, the underlying biological characteristics of the tumor are vital to determine the risk of recurrence or existence of micrometastatic disease. Age is an independent prognostic feature and younger women are at a higher risk of local and distant recurrence. In the setting of a young patient population, adjuvant systemic therapy is offered at a lower risk-to-benefit threshold. In comparison, for women older than age 70, there are no strict guidelines because few of them are included in clinical trials and decisions to proceed with systemic treatment should consider patient comorbidities and toxicity related to treatments. Treatment for breast cancer with cytotoxic agents may impair fertility and all patients who are premenopausal should be informed of the potential impact of chemotherapy on fertility. It is appropriate to consider fertility preservation before breast cancer treatment in young women who desire to bear children in the future.

Selection of Therapy

To help physicians and patients make treatment decisions and understand prognosis, Adjuvant! (www.adjuvantonline.com) was designed to determine the risk of relapse and death and to estimate the benefit of adjuvant systemic therapy based on patient age, comorbid conditions, tumor grade, ER status, tumor size, and the number of involved lymph nodes.[103] Systemic therapy should be considered for all patients when the tumor size is larger than 0.5 cm regardless of nodal status, or when there is lymph node involvement regardless of tumor size. The only patients who may not be at sufficient risk to warrant systemic treatment are those with small stage I tumors (<6 mm) that do not overexpress HER2/neu (Figure G-6).

The NCCN guidelines recommends consideration of Oncotype DX testing in patients with hormone receptor–positive, HER2/neu–negative, node-negative disease to help identify patients who are predicted to obtain the most benefit from adjuvant hormonal therapy alone and those who may or may not require adjuvant chemotherapy.[89] Tumors larger than 1.0 cm or tumors measuring 6 mm to 1.0 cm with unfavorable features including angiolymphatic invasion, high nuclear grade, or high histological grade, triple receptor negative and HER2/neu–positive should be considered for systemic adjuvant therapy, Tumors with a high RS (>31) have a predicted benefit from chemotherapy in addition to hormonal therapy. Patients in the low risk group (RS, 0-18) with a distant recurrence rate of less than 10% are predicted to have marginal benefit if any from adjuvant chemotherapy and should be offered hormonal therapy alone. Patients who are in the intermediate RS group (19-31) and those who are node positive (1-3) are currently being advised to receive chemotherapy followed by hormonal therapy; the clinical utility of Oncotype-DX test in these groups is being further defined in clinical trials (TAILORx and RxPONDER, respectively).

Cytotoxic Therapies

Several regimens are considered appropriate standard treatment for early and locally advanced disease (Tables G-8 and G-9). In general, a combination of two or more drugs is more effective than single agents. The NSABP B-18 trial showed that the administration of chemotherapy in the neoadjuvant setting did not improve or affect disease-free survival or overall survival in comparison to adjuvant administration.[124] Given that

TABLE G-8 Adjuvant or Neoadjuvant Chemotherapy Options

HER2-Negative Disease[a]	HER2-Positive Disease[c]
Adjuvant or Neoadjuvant	**Adjuvant**
Doxorubicin/cyclophosphamide (AC) × 4 cycles followed by 12 weeks of paclitaxel (p × 12)[b,104]	AC × 4 cycles followed by 12 weeks of paclitaxel and trastuzumab ± pertuzumab (pH ± P)[d] followed by trastuzumab (H) (over a 40-week duration)[114]
Dose-dense doxorubicin/cyclophosphamide (ddAC) × 4 cycles followed by dose-dense paclitaxel (ddp) × 4 cycles[105]	Docetaxel/carboplatin/trastuzumab ± pertuzumab (TCH ± P)[d] × 6 cycles followed by H (over a 34-week duration)[115]
Docetaxel/doxorubicin/cyclophosphamide (TAC) × 6 cycles[106]	Paclitaxel (p) and trastuzumab (H) (pH) × 12[e] followed by trastuzumab (H) (over a 40-week duration)[116]
Doxorubicin/cyclophosphamide (AC) × 4 cycles followed by docetaxel (D) ×4 cycles[107-109]	**Neoadjuvant**[d]
Other:	Non-anthracycline containing:
Docetaxel/cyclophosphamide (TC)[f] × 4 cycles[110]	Docetaxel/trastuzumab/pertuzumab (THP) × 4-6 cycles followed by adjuvant H (over a 40-week duration)[117]
Cyclophosphamide/methotrexate/fluorouracil (CMF)[g] × 6 cycles[111]	Docetaxel/carboplatin/trastuzumab/pertuzumab (TCHP) × 6 cycles followed by adjuvant H (over a 40-week duration).[118]
The following may be substituted for AC in the regimen AC × 4 → p × 12:	Anthracycline containing:
Fluorouracil/Adriamycin/cyclophosphamide (FAC) × 4 cycles[112]	AC/FAC/FEC/EC × 3-4 cycles, followed by preoperative THP × 3-4 cycles followed by adjuvant H (over a 40-week duration).[118,119]
Fluorouracil/epirubicin/cyclophosphamide (FEC) × 4 cycles[113]	

[a]*In Her2-negative disease, adjuvant systemic regimens are equally effective administered as adjuvant or neoadjuvant.*
[b]*The following substitutions may be made for AC: fluorouracil/epirubicin/cyclophosphamide (FEC); fluorouracil/adriamycin/cyclophosphamide (FAC).*
[c]*For patients with Her2-positive and axillary node-positive breast cancer, trastuzumab should be a component of their adjuvant systemic therapy. Trastuzumab should be highly considered for patients with HER2-positive node-negative tumors ≥1 cm. Trastuzumab given in combination with an anthracycline is associated with significant cardiac toxicity. Anti-Her2 therapy should not be given in combination with an anthracycline.*
[d]*A pertuzumab containing regimen should be administered to patients with HER2-positive breast cancer preferably in the neoadjuvant setting for tumors >2 cm that are locally advanced and operable. Patients who have not received a neoadjuvant pertuzumab-containing regimen may receive adjuvant pertuzumab.*
[e]*Paclitaxel with trastuzumab may be considered for patients with low-risk stage I, Her2-positive disease, particularly if not eligible for other standard adjuvant regimens because of comorbidities. Preliminary results from the Adjuvant Paclitaxel and Trastuzumab (APT) study were presented at San Antonio Breast Cancer Symposium 2013.*
[f]*Can be considered in patients who are low-risk and node negative; if node positive, anthracycline-containing regimen is preferred.*
[g]*Can be considered in patients who are low risk, those who have underlying cardiac dysfunction, or those with recurrent breast cancer or new breast primary who have previously received anthracycline-based therapy.*

TABLE G-9 Adjuvant Endocrine Therapy in Hormone Receptor-Positive Disease

Study	Endocrine Therapy/Duration	RR Recurrence	RR Mortality
	Primary Therapy		
EBCTC[120]	Tamoxifen (5 yrs)	0.61 (0.57-0.65)	0.70 (0.64-0.75)
ATAC[121]	Anastrozole vs. tamoxifen (5 yrs)	0.90 (0.82-0.99)	1.00 (0.89-1.12)
BIG 1-98[122]	Letrozole vs. tamoxifen (5 yrs)	0.88 (0.78-0.99)	0.81 (0.69-0.94)
	Sequential Therapy		
BIG 1-98	Tamoxifen/letrozole vs. letrozole Letrozole/tamoxifen vs. letrozole	1.05 (0.84-1.32) 0.96 (0.76-1.21)	1.13 (0.83-1.53) 0.90 (0.65-1.24)
	Extended Therapy

RR, *Relative risk;* yrs, *years.*

there is no efficacy advantage in progression-free or overall survival, systemic therapy regimens may be considered for administration in the adjuvant or neoadjuvant settings.[125] For locally advanced or inflammatory breast cancers, chemotherapy with or without targeted therapy is routinely administered in the neoadjuvant setting. The key advantages of neoadjuvant chemotherapy (NAC) include the ability to enable breast conserving surgery by downstaging tumors before surgery and the ability to assess in vivo response to chemotherapy.[126] In addition to increasing the likelihood of tumor control, more recently, a cited advantage of administering chemotherapy in the neoadjuvant setting has been accelerated drug approval. Pathological complete response has been proposed as a surrogate endpoint predictive of long-term clinical benefit and neoadjuvant trials allow for rapid assessment of drug efficacy.[127,128]

The most widely adopted regimens include combinations of an anthracycline and a taxane (either paclitaxel or docetaxel). This recommendation is based in part on an intergroup trial that randomly assigned patients who had been treated with four cycles of doxorubicin and cyclophosphamide (AC) to receive either four cycles of paclitaxel or no additional chemotherapy. Results of that trial showed a disease-free survival benefit for patients treated with paclitaxel.[129] These results are supported by those of a similar study conducted by the NSABP (the B-28 trial), which also found that patients who received four cycles of AC plus four cycles of paclitaxel had higher disease-free survival rates than those who received four cycles of AC alone.[130] Subsequent chemotherapy trials have investigated various combinations of taxane and anthracycline chemotherapy. An intergroup trial revealed that giving four cycles of AC followed by four cycles of paclitaxel in a dose-dense fashion improved disease-free survival rates relative to the usual 3-week dosing schedule of the same chemotherapy.[131] Finally, the Breast Cancer International Research Group conducted a trial that randomly assigned patients with lymph node-positive breast cancer to receive either six cycles of docetaxel, doxorubicin, and cyclophosphamide (TAC) or six cycles of fluorouracil, doxorubicin, and cyclophosphamide (FAC) and found an improvement in disease-free survival rates among those given TAC.[132] Collectively, these findings suggest that for patients with high-risk disease features (e.g., lymph node-positive disease, and node-negative with unfavorable features including large tumor size, high histological grade, triple receptor negative), any of the following third-generation chemotherapy regimens can be considered acceptable: dose-dense scheduling of AC with paclitaxel, weekly paclitaxel followed by AC, AC followed by docetaxel every 3 weeks, or TAC.[104,107,131,133,134] For patients with lower-risk breast cancer who desire a shorter course of chemotherapy, giving four cycles of docetaxel and cyclophosphamide (TC) has become more common after a recent randomized prospective trial found that this regimen produced better disease-free survival and overall survival rates than did four cycles of AC.[135]

Triple-negative breast cancer (TNBC) lacks expression of ER and PR and lacks overexpression or amplification of HER2 and is worth some focused attention because it is associated with a poor prognosis and poor overall response to standard anthracycline and taxane-based chemotherapy. Standard chemotherapy when administered in a neoadjuvant (NAC) fashion and results in a pathological complete response (pCR) of 20% to 34%.[128,136,137] A pCR is associated with increased survival and those who do not achieve this status are at high risk for disease recurrence.[138] Recent studies have shown that the pCR may be improved in TNBC with the addition of platinum-based NAC; however, this continues to be a topic of debate across TNBC.[139] Continued research efforts are under way to improve local and systemic control in this molecular subtype.

Endocrine Therapies

For most patients with ER-positive or PR-positive disease, hormonal therapy is indicated (Table G-9). Before selection of hormonal therapy, it is important to establish the patient's menopausal status. Premenopausal women whose ovaries continue to function after chemotherapy should receive tamoxifen for 5 years to 10 years as the preferred therapy.[140,141] Cytotoxic therapy may induce menopause; however, for the purpose of adjuvant hormonal therapy selection, the patient's menopausal status at the time of diagnosis is most relevant. Patients who were perimenopausal at the time of diagnosis should receive tamoxifen for 2 years to 3 years and may be switched to an aromatase inhibitor when they achieve menopause. For women who are postmenopausal, the use of an aromatase inhibitor is most effective. There are several options for patients who are postmenopausal, including an aromatase inhibitor for 5 years, initial tamoxifen for 2 years to 3 years followed by an aromatase inhibitor, aromatase inhibitor for 2 years to 3 years followed by tamoxifen for 2 years to 3 years or tamoxifen for 5 years followed by 5 years of an aromatase inhibitor.[142-144] Results of a recent EBCTCG meta-analysis of trials that compared breast cancer outcomes with adjuvant aromatase inhibitors versus tamoxifen for women who are postmenopausal with ER-positive breast cancer demonstrated that the use of aromatase inhibitors was associated with a breast cancer recurrence rate that was 3% lower than that with tamoxifen within 3 years to 5 years of follow-up.[64] A recent consensus statement from the American Society of Clinical Oncology that also reviewed published and ongoing trials of

adjuvant aromatase inhibitors recommends that women who are postmenopausal with ER-positive breast cancer consider incorporating an aromatase inhibitor at some point during adjuvant treatment.[145]

HER2 Targeting

The introduction of trastuzumab (Herceptin) for the adjuvant treatment of tumors with amplification of HER2/neu has been one of the most exciting advances in systemic treatment in the history of breast cancer. Randomized prospective trials demonstrated substantial improvements in disease-free and overall survival rates for patients with HER2/neu-overexpressing tumors when trastuzumab was added to adjuvant chemotherapy.[146-148] Specifically, the combined results from two randomized trials involving 3351 patients (94% of whom had lymph node-positive disease) indicated that four cycles of AC followed by weekly paclitaxel or 3-week paclitaxel with concurrent trastuzumab followed by 1 year of trastuzumab achieved a 52% reduction in the relative risk of recurrence compared with chemotherapy without trastuzumab.[147] The absolute reduction in risk of recurrence at 3 years was 12%. The European Herceptin Adjuvant (HERA) trial randomly assigned 5081 patients who had received at least four cycles of chemotherapy for HER2/neu-positive breast cancer (68% of whom had positive lymph nodes) to receive no further treatment, trastuzumab for 1 year, or trastuzumab for 2 years.[146] Trastuzumab reduced the relative risk of recurrence over chemotherapy alone by 46% (8.4% absolute reduction of the risk at 3 years). Finally, the Breast Cancer International Research Group trial 006 randomly assigned 3174 patients with HER2/neu-positive breast cancer (71% of whom had lymph node-positive disease) to receive chemotherapy with or without trastuzumab. That trial again confirmed that the addition of trastuzumab reduced the relative risk of recurrence or death over chemotherapy alone by 39%.[148] The incorporation of adjuvant trastuzumab based therapy has transformed the natural history of HER2-positive disease.

Neoadjuvant treatment with HER2 blockade has been found to significantly improve the pCR rate for patients treated with chemotherapy plus trastuzumab compared to chemotherapy alone.[149,150] More recently, neoadjuvant dual HER2 blockade has been evaluated.[117,118,151] The NeoSPHERE and NeoALLTO studies demonstrated that double HER2 blockade increased the pCR rate from 29% to 45% with pertuzumab plus trastuzumab and from 29% to 51% with lapatinib plus trastuzumab.[117,151] In NeoSPHERE, patients with hormone receptor–negative disease had a greater benefit when treated in the arm with dual HER2 blockade and chemotherapy. Of note, 17% of patients in the dual HER2 blockade–only arm achieved a pCR. It has recently been shown that achievement of a pCR specifically in the NeoALLTO study translates to an event-free survival and overall survival benefit.[152] In 2014 the results of ALTTO, NeoALTTO's "sister" trial in the adjuvant setting became available showing no additional benefit for the addition of lapatinib to trastuzumab in the adjuvant treatment of HER2 positive breast cancer.[152a]

For HER2-positive tumors that are large (>2 cm), operable, and locally advanced, the preferred treatment approach currently is dual HER2 blockade in the neoadjuvant setting with trastuzumab and pertuzumab in combination with a taxane with or without sequential anthracycline-based therapy.[117,118] Pertuzumab recently gained Food and Drug Administration (FDA) approval in the neoadjuvant setting in October 2013 and is recommended for use in one of the combinations as listed in Table G-8. A trial known as the Adjuvant Pertuzumab and Herceptin in Initial Therapy of Breast Cancer (APHINITY) will provide further data, disease-free survival, and results are eagerly anticipated in 2016. Further clinical investigation will be required to further examine the role of dual HER2 blockade alone and to identify the subset of patients that achieve pCR with a less toxic regimen.[117]

Sequencing of Therapies

The choice of sequence of systemic therapy in relation to surgery and radiation is optimally made by a multidisciplinary team. The decision is based on disease stage, the need for "up front" pathologic staging information, patient eligibility and desire for breast conservation, and coordination of the treating disciplines. Sequences in which chemotherapy is given before surgery (neoadjuvant therapy) are becoming increasingly more common for patients with stage II or III breast cancer. Trials investigating neoadjuvant hormonal therapy and chemotherapy with or without targeted therapy and its use to increase rates of breast conservation are reviewed in an upcoming chapter. For those patients who undergo surgery to be followed by adjuvant chemotherapy and adjuvant radiation, most centers in the United States recommend that the chemotherapy be completed first and then the radiation be given. A randomized prospective trial comparing 12 weeks of adjuvant chemotherapy given either before or after radiation for patients treated with breast-conservation therapy found no significant differences between the two treatment groups in time to any event, distant metastasis, or death.[153] The findings from this trial indicated that plans to delay radiation so that adjuvant chemotherapy could be completed first should be considered only for those patients with negative surgical margins. The sequencing of hormonal therapy and radiation has not been studied in a randomized comparative trial, but retrospective analyses suggest that concurrent and sequential treatments probably provide similar outcomes.[154-156] Finally, concurrent radiation and trastuzumab treatment also seems to be safe, although information on long-term outcome is not yet available. Randomized trials investigating the use of adjuvant trastuzumab have involved giving radiation and trastuzumab concurrently; findings from these trials on normal tissue effects, including short-term cardiac toxicity, suggest that giving trastuzumab concurrently with radiation does not increase the risk of injury.[157,158]

FINAL REMARKS

In the past 20 years, there has been tremendous growth in knowledge regarding the pathogenesis and treatment of breast cancer. Many of these advances have been possible because of collaborative focused efforts among radiologists, pathologists, genetic counselors, radiation oncologists, surgical oncologists, and medical oncologists. In this introductory chapter to the breast cancer section, we provide a broad overview that ranges from incidence and mortality to anatomy, biological characteristics, risk assessment, screening, diagnosis, staging, prognosis, selection of therapies, and multimodality treatment (surgery, radiation, and systemic therapy). We hope to have provided a strong foundation that will help you in your study moving forward. In the chapters to follow, there will be a more detailed discussion of early breast cancer, postmastectomy radiation, and DCIS from a radiation oncology focused perspective.

CHAPTER

62 Noninvasive Breast Cancer

Chirag Shah, Douglas W. Arthur, and Frank A. Vicini

INCIDENCE

Noninvasive breast disease accounts for more than 20% of all breast cancers. Lobular carcinoma in situ (LCIS) represents less than 15% of these noninvasive cancers, whereas ductal carcinoma in situ (DCIS) represents 85% of noninvasive cancers. A third less common form of noninvasive disease, Paget's disease, accounts for 0.5% to 5% of all breast cancers.

BIOLOGIC AND PATHOLOGIC CHARACTERISTICS

LCIS is a noninfiltrating lobular proliferation exemplified by loose discohesive cells filling the acinar space. Lesions are frequently positive for estrogen receptor (ER) and progesterone receptor (PR), and loss of *E-cadherin (CDH1)* gene expression is characteristic. Overexpression of the c-*ERBB2* gene or mutation of the *TP53* gene may occur, but this is rare with the exception of pleomorphic LCIS.

In Paget's disease, Paget's cells are found in the epidermis with underlying malignant tissue found in more than 95% of cases.

DCIS is a noninfiltrating clonal proliferative process confined to the ductal lumens of the breast. DCIS may be a precursor to invasive disease. ER positivity is present in 70% of DCIS lesions; the rate of expression varies according to the grade of the lesion. The rate of expression is 90% in low-grade lesions and 25% in high-grade lesions. About 35% of DCIS lesions exhibit overexpression of the *HER2 (ERBB2)* gene and about 25% exhibit mutation of the *TP53* tumor suppressor gene.

STAGING AND EVALUATION

Staging and evaluation are accomplished with bilateral mammograms and excision with pathologic evaluation, which should determine the size and histologic type of the lesion, the ER and PR status, and the lesion's margin status. MRI is increasingly being used to help identify women with multicentric disease and those ineligible for breast-conserving therapy. In LCIS, the pathologic evaluation is limited to identification of the lesion and ER and PR status.

TREATMENT

For LCIS, treatment usually consists of observation. The rate of in-breast failure at 12 years is less than 15%. LCIS has a minimal impact on survival rates. Alternative approaches for high-risk disease have included tamoxifen versus bilateral mastectomy.

Treatment for Paget's disease usually involves breast-conserving therapy. Excision with negative margins is needed, followed by whole-breast radiotherapy. In-breast control rates are 87% to 95%. Patients with high-risk disease (i.e., diffuse disease with positive margins despite reexcision) should undergo mastectomy.

Breast-conservation therapy is also recommended for DCIS lesions. Excision with negative margins is followed by whole-breast radiation therapy with in-breast control rates of 85% to 95%. For low-risk disease (i.e., grade I lesions of <1 cm and negative margins of >1 cm), excision alone may be chosen. Mastectomy may be used for high-risk disease (i.e., diffuse disease with positive margins despite reexcision). More recently, data supporting the use of shortened radiation schedules as part of breast conservation has emerged in the form of accelerated partial breast irradiation and hypofractionated whole-breast irradiation.

INTRODUCTION

Noninvasive breast cancer is composed of three distinct histologic entities: LCIS, Paget's disease, and DCIS. As a result of the increased quality of and use of mammography, these three histologic types make up a larger percentage of all the breast cancer cases seen today.[1] Historically, mastectomy was frequently used as treatment for noninvasive disease, but with a better understanding of the natural history of these noninvasive disease processes, investigation has led to breast-conserving treatment options with regards to DCIS and Paget's disease and observation or risk-reduction for LCIS. Controversy regarding the optimal treatment approach continues to exist, and as a result, treatment recommendations range from observation to breast-conservation therapy to mastectomy. To appropriately formulate a patient's treatment options, it is important to understand the distinguishing pathologic appearances, biologic characteristics, and natural history of these three noninvasive breast disease entities.

LOBULAR CARCINOMA IN SITU

LCIS was first described as a pathologic entity by Foote and Stewart in 1941.[2] Microscopically, LCIS appears as a noninfiltrating process of lobular proliferation. LCIS has been reported to present with multicentric breast involvement in up to 90% of mastectomy specimens, with bilateral involvement documented in 35% to 59%.[3-6] Histologically, LCIS is characterized by loose discohesive epithelial cells filling the acinar space.[3-6] The degree of lobular involvement ranges from a simple filling of the ductal lumens to moderate distention to overt distention with extension into the adjacent extralobular ducts.[7] As a result of this spectrum of appearances, the lines of histologic delineation can become blurred between atypical ductal hyperplasia, LCIS, and when ductal extension is seen, DCIS. This introduces a source of complexity when comparing publications from varying institutions; even when using a proposed three-tier grading system, controversy still exists.[4-6,8]

Molecular markers have been suggested as a potential method of providing a technique for distinguishing LCIS in problematic cases.[5] LCIS cells are frequently ER-positive cells, and rarely overexpress c-ERBB2 or contain p53 mutations, with the exception of pleomorphic LCIS, which expresses high rates of Ki-67 and p53 positivity.[5,9-12] The loss of *CDH1* gene expression is documented in more than 95% of LCIS cases.[11,13] The *CDH1*gene is a calcium-dependent cellular adhesion molecule that is responsible for epithelial organization, and the absence of this adhesion molecule in LCIS may explain its discohesive morphologic characteristics.[11,13]

Publications on biopsy results report LCIS incidence rates to be 0.5% to 3.6%; these lesions represent less than 15% of all noninvasive lesions recorded, but recent population-based analyses suggest that this rate may be increasing.[6,14,15] Because there are no clinical or mammographic indicators, LCIS without additional histologic findings is typically an incidental finding when biopsy is performed for alternative reasons.[2-5,14] Although mammographically detected calcifications corresponding with LCIS have been reported, the calcifications are more commonly unassociated and are present in the adjacent tissue; therefore, if LCIS is identified on biopsy with a mammogram demonstrating calcification excisional biopsy is warranted.[14,16] In fact, DCIS or invasive disease, or both, is frequently identified in the subsequent lumpectomies performed (22% to 27% of cases) when LCIS is the sole histologic entity seen on core biopsy.[12,17,18] Criteria identifying those patients for whom observation only is sufficient following core biopsy showing LCIS have not yet been clearly specified.

Management considerations for LCIS differ depending on whether it is associated with a diagnosis of DCIS or infiltrative disease or whether LCIS is the sole histologic entity encountered. Only 5% to 12% of early-stage breast cancers have an associated component of LCIS.[19,20] Several institutional experiences have evaluated the potential impact of the presence of LCIS on breast-conserving treatment outcomes.[19-24] The number of patients included in these experiences is relatively small, and there are differences in these cohorts, including pathologic assessment, length of follow-up, and use of tamoxifen (Table 62-1). However, the majority of data suggest that no statistically significant difference exists when comparing rates of in-breast disease control, distant disease-free survival, and overall survival between patients with or without a component of LCIS.[19-24] The presently accepted treatment approach is to manage the breast according to the dominant histologic findings present (DCIS or invasive disease) and disregard the presence of LCIS. Additional surgery is not pursued to obtain LCIS clear margins. The need for the addition of tamoxifen or a more aggressive treatment approach in this group of high-risk patients is uncertain, and further study is necessary with no definitive evidence-based guidelines available.[25]

If LCIS is the sole histologic diagnosis, treatment recommendations range from observation to mastectomy. When first described as a pathologic entity, the significance of LCIS was unknown and mastectomy was consistently pursued.[2] Knowledge of frequent contralateral involvement extended treatment recommendations to random contralateral biopsy and bilateral mastectomy.[2,3] However, observational studies after lumpectomy only have led to a better understanding of the natural history of this disease, and a more conservative approach is now commonly practiced.[6,14] Although studies of *CDH1* and loss of heterozygosity (LOH) suggest that LCIS may be a precursor to invasive disease, LCIS has historically been considered a marker for an increased risk of developing invasive disease (9 to 12 times that of the normal population); this risk requires long-term follow-up exceeding 20 years.[4,26] More recently, population based data has found that 73% of patients undergo excision alone, 16% mastectomy, 10% biopsy, and 1% excision with radiation therapy.[15]

A range of ipsilateral and contralateral breast failure rates are reported following treatment. This variation is the result, in part, of differences in the length of follow-up, the definitions used for histologic classification (atypical lobular hyperplasia versus LCIS), and the extent of excision used in these observational studies.[27,28] In a 12-year follow-up publication on a 182-patient cohort treated with lumpectomy only for LCIS, the National Surgical Adjuvant Breast and Bowel Project (NSABP) reported a 14.4% in-breast tumor recurrence (IBTR) rate, and a 7.8% contralateral breast tumor recurrence (CBTR) rate.[28] Of the IBTRs, nine (34.6%, or 5% of the total cohort) were invasive malignant tumors and 17 (65.4%, or 9% of the total cohort) were noninvasive malignant tumors. Although the frequency of CBTRs was less than that of IBTRs, the frequency of invasive CBTRs (5.6% of the total cohort) was similar to that of invasive IBTRs (5% of the total cohort). All of the IBTRs were documented to be at the site of the index lesion except for one, characterized as pure LCIS, that was found at a remote site. This report continues to support the indolent nature of LCIS and a conservative management approach.

The impact of subsequent development of invasive disease on mortality risk has been estimated in earlier publications to

be 5% to 7% with a population study identifying the risk at 7.1% at 10 years.[14,29] However, with contemporary use of close mammographic and clinical follow-up leading to early detection of subclinical abnormalities, one would expect this mortality risk to be reduced. This reduction is reflected in the lower mortality risk (1%) reported by the NSABP.[28] Further, recent guidelines have not suggested an alteration in subsequent screening in those diagnosed with LCIS further supporting the reduced risk of mortality.[25]

Management options vary depending on individual risk assessment (Figure 62-1). Close observation with regular physical examinations and mammographic surveillance is the accepted management approach.[6,14,25,27,28] At present, there is no role for radiotherapy in the management of LCIS. Knowing that this is a bilateral breast disease process leaves a unilateral treatment approach inadequate (i.e., ipsilateral mastectomy).[25] Bilateral prophylactic mastectomy is thought to be excessive in all patients except those believed to be at higher risk (i.e., young patients, diffuse process, a significant family history of disease) for whom it could be considered.[25] A less radical approach to be considered is the use of tamoxifen. Indeed, a cohort of patients with LCIS was entered into the NSABP P-01 trial, which compared tamoxifen with placebo for breast cancer prevention. The 5-year risk of subsequent disease development was reduced with the use of tamoxifen by 56%, though patients with LCIS represented a small percentage of patients.[30]

Pleomorphic LCIS represents an emerging area of interest based on data demonstrating differences in molecular markers for this variant as well concern for underlying invasive malignancy with further sampling.[12,31] Data from Northwestern University found that variants of LCIS including pleomorphic LCIS were misinterpreted as solid DCIS in up to 15% of cases and that 20% of such cases had underlying lobular carcinoma at the time of surgery, which has been confirmed by other series.[31,32]

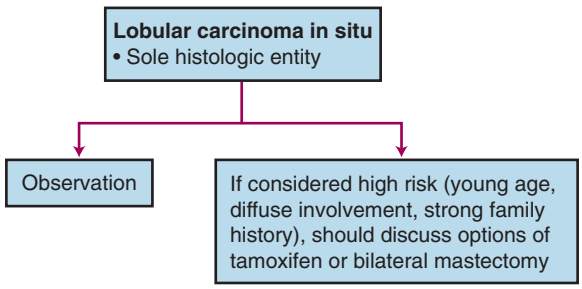

Figure 62-1 Treatment algorithm for lobular carcinoma in situ.

PAGET'S DISEASE

The clinical presentation of crusting, bleeding, and ulceration of the nipple was first described in 1856, but it was not until 1874 that the association with an underlying breast carcinoma was recognized by Sir James Paget.[33] Paget's disease of the nipple is characterized histologically by the presence of unique, clearly identifiable Paget's cells that are described as large, round to oval cells that contain hyperchromatic nuclei and prominent nucleoli with frequent mitoses noted. The Paget's cells occur singly or in clusters and are scattered throughout the epidermis.[34,35]

Reported in 0.5% to 5% of breast cancer patients, Paget's disease is an infrequent diagnosis.[33,36,37] It is most commonly unilateral, but reports of bilateral and male Paget's disease can be found.[38-40] Clinically, women describe itching and burning of the nipple and areola and crusting is often described. There is a slow progression toward an eczematoid appearance, which can extend to the skin. If neglected, bleeding, pain, and ulceration can occur.[37,38] The differential diagnosis includes superficial spreading melanoma, pagetoid squamous cell carcinoma in situ, and clear cells of Toker.[34-37] A palpable mass is detected in about 50% of patients at diagnosis. If there is a palpable mass, more than 90% will be invasive carcinoma. On the other hand, if no palpable mass is detected, 66% to 86% will have an underlying DCIS.[34-37] These adjacent, underlying malignant tumors are usually located centrally; however, they have also been located elsewhere in the breast.[33,37]

The appropriate management of Paget's disease remains unsettled; however, in concordance with physician and patient preference, attempts have been made to investigate the role of breast-conservation therapy. Because mastectomy was initially shown to be effective, the transition to breast-conserving treatment has been done cautiously because of the inability to accumulate a significant number of uniform patients similarly treated.[36,37] Recent data have demonstrated that based on pathological evaluation of mastectomy specimens, that breast-conserving therapy is feasible with appropriate margins and this is echoed in currently published treatment guidelines.[25,41] Limited series have described results with various forms of breast-conserving treatment, including limited surgical resection alone, radiotherapy alone, and limited resection followed by radiotherapy[42-47] (Table 62-2).

The combination of limited surgical resection and postoperative radiotherapy appears to be the most successful breast-conservation approach. Two collaborative studies have shown the successful use of breast-conservation therapy in Paget's disease of the nipple. The European Organization for Research and Treatment of Cancer (EORTC) Study 10873 was a

multiinstitutional registration study reporting a 5-year local recurrence rate of 5.2% for a subset of 61 patients.[45] In this study, a complete excision with tumor-free margins of the nipple-areolar complex and underlying breast tissue was followed by whole-breast radiotherapy to 50 Gy. The median follow-up time was 6.4 years, and the majority of patients were found to have an underlying DCIS without a palpable mass.

The second study, a seven-institution collaborative review of 36 patients, included patients with Paget's disease without a palpable mass or mammographic density.[47] The median follow-up time was 9.4 years, and all had at least 12 months of follow-up. Patients underwent complete (69%) or partial (25%) excision of the nipple-areolar complex and underlying breast tissue, with 6% reported as a biopsy only. The final margin status was documented as negative in 56%, positive in 6%, and unknown in 39%. All received whole-breast irradiation at a median dose of 50 Gy, and the majority received an additional boost dose to the tumor bed. Actuarial rates of local in-breast failure as the only site of first recurrence were 9% at 5 years and 13% at both 10 years and 15 years. Despite the variation of clinical, pathologic, and treatment factors, statistical evaluation did not identify any factors that significantly predicted for risk of local recurrence. The findings from these studies have been confirmed by a large series from Sweden that evaluated 223 patients and found that type of surgery (BCS versus mastectomy) was not associated with breast cancer survival or disease free survival.[48]

On presentation, the workup and evaluation should include a bilateral breast examination, mammography, and full-thickness biopsy to confirm the diagnosis of Paget's disease and fully evaluate the extent of the underlying malignant disease.[25] In individuals with a positive biopsy for Paget's but no underlying mass, consideration for magnetic resonance imaging (MRI) is reasonable.[25] An individual's prognosis is not dependent on the diagnosis of Paget's disease but rather depends on the associated underlying malignant disease. Therefore, local treatment decisions as well as systemic and regional nodal disease risk management should be based on the underlying disease (Figure 62-2).[25] Standard breast-conservation therapy principles governing patient selection, surgical resection, and radiotherapy should be applied. Complete surgical resection of the disease process (i.e., nipple-areolar complex excision in conjunction with any underlying disease) with a negative microscopic surgical margin is then followed by standard whole-breast irradiation.

DUCTAL CARCINOMA IN SITU

Epidemiology

DCIS is represented by a heterogeneous spectrum of histologic appearances that all arise within and are confined to the ductal lumens of the breast. This clonal proliferation does not breach the epithelial basement membrane, and there is no evidence of invasion into the adjacent breast stroma.[49] DCIS lacks the ability to metastasize; the rarely reported axillary nodal metastasis or distant metastasis has been attributed to the probable presence of an undetected component of invasive carcinoma.[49,50]

Before 1980, the incidence of DCIS was low (i.e., only 1.4% of all breast biopsies and only 5% of all breast malignant tumors).[51,52] With the increased use of mammography and as pathologists began to recognize that DCIS was a distinct pathologic entity, the incidence of DCIS dramatically increased.[53] The incidence of DCIS has increased from 4800 cases reported in 1983 to more than 50,000 cases out of the estimated 230,000 new breast cancers diagnosed in 2013.[53] With this increase, there has been a corresponding change in the presentation of DCIS lesions from predominantly palpable to more than 90% of new lesions being nonpalpable.[54] Studies have shown that the rate of DCIS lesions detected by screening increases with age, whereas DCIS accounts for a progressively smaller percentage of the total cancers detected (i.e., invasive cancers plus DCIS).[55,56] The rate of DCIS detection has been shown to increase from 0.56 per 1000 mammograms among women aged 40 years to 49 years to 1.07 per 1000 mammograms among women aged 70 years to 84 years.[56]

Associated risk factors for the development of DCIS are similar to risk factors for invasive disease and include older age, benign breast disease, mammographic density, a family history of breast disease, and reproductive factors, including nulliparity or older age of pregnancy.[49,57-59]

Prevention and Early Detection (MRI)

Although successful treatment options are available, improved outcomes can be realized through both prevention of DCIS development and the early detection of new lesions. The role of tamoxifen in the prevention of disease development has been studied by the NSABP in a protocol that randomized patients at high risk for the development of breast cancer to either tamoxifen or placebo.[30] Patients eligible included those who were either 60 years of age or older, had a history of LCIS, or were between the ages of 35 and 59 years with a

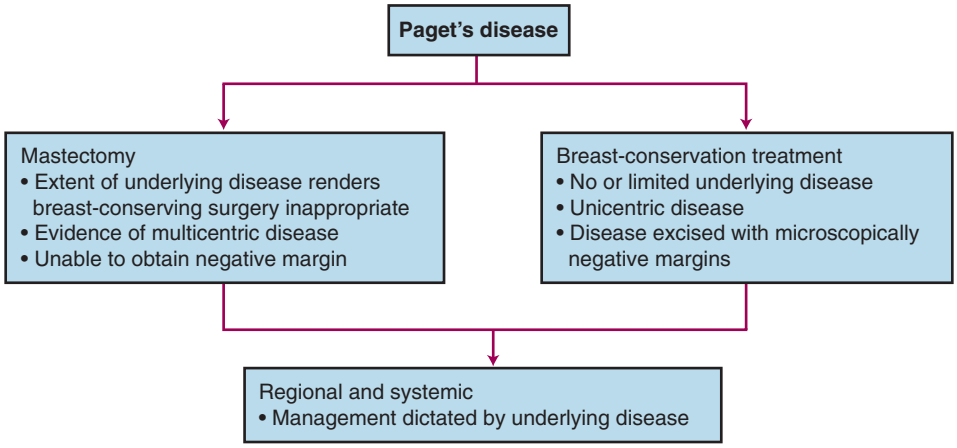

Figure 62-2 Treatment algorithm for Paget's disease.

5-year predicted risk for breast cancer, using the Gail model, of at least 1.66%. The 7-year follow-up data reveal that for noninvasive breast cancer, tamoxifen use was associated with a 37% reduction in risk. A subsequent randomized trial (NSABP P-2) randomized similar patients (woman who were premenopausal excluded) to tamoxifen or raloxifene. At 5 years, raloxifene was found to have a statistically nonsignificant increase in the incidence of noninvasive cancers than tamoxifen (relative risk, 1.40).[60]

Mammography plays an essential role in the early detection of noninvasive lesions, providing an opportunity for intervention early in the course of disease development. The distinctive mammographic feature of DCIS is the presence of microcalcifications, which has been reported in 84% to 98% of cases.[61,62] Seventy-two percent to 76% of DCIS lesions have microcalcifications as the sole mammographic finding, and an additional 12% have microcalcifications in combination with other mammographic abnormalities.[61,62] Beyond detection, several attempts have been made to correlate the mammographic appearance of the lesion with the histologic type, grade, and extent of disease. Linear branching microcalcifications have been reported to be associated with high-grade or comedo-type DCIS. Heterogeneous granular calcification is commonly associated with moderately differentiated DCIS and fine granular microcalcifications more typically with low-grade, non-comedo DCIS.[56,61,62] Although there is a degree of correlation between appearance and histologic type, there is considerable overlap, which limits the use of this information in clinical decision making. Microcalcifications are not always present throughout the histologic abnormality, and the estimated mammographic size and extent of disease frequently underestimate the true pathologic extent of the disease process. Although the mammographic extent can be used to guide the extent of surgical excision, caution should be exercised because the size is typically underestimated by 1 cm to 2 cm.[63,64] In patients presenting with nipple discharge with a negative mammographic evaluation, galactography may be helpful in distinguishing the presence of a papilloma from an underlying DCIS.[65]

More recently, MRI has emerged as another modality to help identify lesions. Its use has been suggested in patients with dense breasts as well as to identify multicentric disease and is increasingly being used in the noninvasive setting.[25] Further, recent studies have found that MRI has increased sensitivity to detect DCIS compared with mammography and can better identify those patients eligible for BCT.[66]

Biologic Characteristics and Molecular Markers

DCIS is a precursor lesion to invasive ductal carcinoma and exists along an evolutionary continuum that starts with benign breast tissue and ends with an invasive breast lesion.[67] This concept has been verified in several ways. For years, pathologists have recognized and documented confirmation of a histologic progression from benign breast cells to invasive breast cancer and realized that this histologic evidence was more commonly present where an invasive lesion was discovered. The evolutionary concept is further supported by the acknowledged association between the presence of DCIS and the subsequent increased risk of developing an invasive breast cancer.[49,68,69] In some series, a 10-fold risk of developing an invasive lesion has been reported. The presence of shared identical genetic abnormalities between DCIS and synchronous invasive breast cancer also suggests a clonal relationship of biologic progression.[49,68-70] This was noted in a recent study that found that the molecular phenotypes of coexisting DCIS within IDC were identical in 100% of cases.[71]

Documented genetic and molecular differences can differentiate DCIS from normal breast tissue. Genetic alterations have been evaluated with an analysis of LOH that has demonstrated gain or loss of multiple loci.[68-70] LOH is not seen in normal breast tissue but is present with an increasing frequency that correlates with histologic progression from benign to malignant tissue. In hyperplasias from noncancerous breasts, LOH is rarely documented; however, it is more commonly present (in 42% to 50% of patients) in atypical ductal hyperplasia. Among specimens harvested from cancerous breasts, 77% of noncomedo and 80% of comedo DCIS lesions share LOH with the synchronous invasive lesion in at least one locus.[70] Molecular markers have been studied and are found to have a heterogeneous distribution of expression.[49] The ER is present in 65% to 80% of DCIS lesions, but the rate of expression is high (90%) in low-grade lesions and is significantly less (25%) in high-grade lesions.[49,72] This trend is reversed with the *HER2/neu* proto-oncogene and the *TP53* tumor suppression gene. About 25% to 50% of DCIS lesions exhibit overexpression of the *HER2/neu*, with the *TP53* tumor suppressor gene mutated in 25% of cases. Both of these molecular markers are noted in less than 20% of low-grade lesions, but they are found in up to two thirds of high-grade lesions.[49,72]

Pathologic Characteristics and Pathways of Spread

The primary goal of pathologic assessment is to differentiate DCIS from invasive cancer because the presence of invasive disease alters the focus of treatment from the breast only to possible regional and distant metastases. Once DCIS has been identified, pathologic classification follows in an attempt to predict the clinical outcome and direct the treatment management. Historically, an architectural classification system has been used, dividing tumors into the five classic subtypes of comedo, solid, cribriform, papillary, and micropapillary cancers.[73-75] Less common subtypes have been described and include apocrine, neuroendocrine, signet-ring cell cystic, and hypersecretory carcinomas and clinging DCIS.[76] The difficulty with an architectural classification method is that there can be a mixture of architectural subtypes identified within the same lesion and that the reproducibility of classification is unreliable because pathologists apply various criteria.[77,78] Additionally, the value of an architectural classification system is questionable because the architectural subtypes do not correlate well with clinical behavior.[79] Although this was not an issue when mastectomy was routinely used, the ability to predict clinical behavior has become important now that breast-conserving approaches represent the standard of care in the management of DCIS.[25]

In an attempt to better predict clinical behavior, several classification systems have been proposed.[80,81] These are based on nuclear grade of the tumor cells and presence of comedo necrosis with and without architectural features. These characteristics appear to correlate with the risk of local recurrence.[79] In 1997, an international consensus conference was convened to discuss several pathologic aspects concerning DCIS, with the goal of reaching a consensus where possible.[82] Conference participants recognized that several classification systems had been proposed, and although a specific system was not endorsed, they recommended that four features be routinely described: nuclear grade, necrosis, polarization, and architectural pattern. They also recommended that several additional features be documented in the pathology report, including the margin status, size of the lesion, location of microcalcification in relationship to the DCIS lesion, and correlation of characteristics of the tissue specimen with radiographic and mammographic findings.[82]

Primary Therapy

Patient evaluation focuses on bilateral mammography, with which the presence of additional breast malignant lesions can be excluded and the extent of the DCIS process defined; MRI may also be useful to determine extent of disease and any multifocality or multicentricity.[25] After it is determined that DCIS is the only disease entity requiring treatment, the primary focus becomes local management of the breast. In concert with the spectrum of clinical presentations encountered with DCIS, there are several treatment approaches. They range from treatment of the whole breast to treatment of a partial breast target. On the one end of this spectrum, when multicentric disease or a diffuse DCIS process is documented, a mastectomy is considered to be the standard of care.[25] If a focal area of DCIS is confronted, then breast-conserving approaches are favored because of improved quality-of-life outcomes. Supported with Phase III trial data, the use of standard breast-conservation therapy with lumpectomy and standard whole-breast radiotherapy is most commonly recommended, and newer partial breast techniques (with and without radiotherapy) are now being offered with increased frequency based on emerging data.

All presentations of DCIS can be successfully managed with total mastectomy. This is supported by reports from mastectomy series showing disease control rates that approach 100% and cancer-specific mortality rates of less than 4%.[83-86] However, it is recognized that the availability of mammographic screening has shifted the most common presentation of DCIS from one of a palpable mass with advanced involvement to one of early-stage and limited-extent of disease for which a total mastectomy would intuitively appear to be excessive.[25,49] To promote mastectomy in the management of noninvasive disease would be in opposition to the increasing use of breast-conservation therapy for invasive disease. Although a Phase III trial comparing total mastectomy with breast-conservation therapy for DCIS has never been done, the psychological benefits of preserving the breast and the acceptable rates of local control achieved with breast-conserving therapy support the use of total mastectomy only when necessary. Total mastectomy is most commonly reserved for patients presenting with multicentric or diffuse disease, for patients in whom the use of radiotherapy is contraindicated, when an unacceptable cosmetic result is anticipated following appropriate surgical excision, or for salvage in the event of in-breast recurrence following standard breast-conservation therapy.[25,87]

Breast-conservation treatment consists of initial surgical excision of the primary lesion with a negative surgical margin followed by whole-breast radiotherapy delivered with standard accepted techniques, such as those used for early-stage invasive breast cancer. Literature supporting this approach is found both in retrospective series as well as in prospective Phase III trials comparing lumpectomy only with lumpectomy followed by whole-breast irradiation.[88-92]

Retrospective analyses of lumpectomy and whole-breast irradiation have reported 5-year cause-specific survival rates that approach 100% and local control rates that range from 85% to 95%.[88,93-98] Prospective randomized trials have been completed evaluating the role of postoperative radiotherapy and tamoxifen in breast-conserving management of DCIS (Tables 62-3 and 62-4). In a Cochrane Database review, postoperative radiotherapy for DCIS focused on four prospective randomized trials[99] (see Table 62-3). This meta-analysis confirmed a statistically significant benefit from the addition of radiotherapy for all ipsilateral breast events (hazard ratio [HR], 0.49; $p < 0.00001$), for DCIS (HR, 0.61; $p = 0.03$), and for invasive recurrence (HR, 0.50; $p = 0.0001$). This benefit was demonstrated in all of the subgroups evaluated, which included patients who underwent complete excision versus those who underwent incomplete excision, patients older than 50 years versus those younger than 50 years, patients with comedo necrosis versus those without comedo necrosis, and patients with lesions of 1 cm or larger versus those with lesions of less than 1 cm; these findings have also been confirmed by the Early Breast Cancer Trialists Group meta-analysis.[100]

The first of these four prospective randomized trials is the National Surgical Adjuvant Breast and Bowel Project (NSABP)

protocol B-17, designed to evaluate the role of postoperative irradiation.[84,89-91] All 814 evaluable patients enrolled were initially diagnosed with DCIS and underwent lumpectomy achieving clear surgical margins (i.e., inked specimen margins that were tumor free on histologic testing). Patients were subsequently randomized to receive postoperative whole-breast radiotherapy or no radiotherapy. The radiotherapy guidelines used consisted of whole-breast tangential fields treated to 50 Gy as per previous NSABP studies; a boost to the surgical bed was not included. With 15 years of follow-up, the rate of in-breast tumor recurrence with lumpectomy only was 35.0%, as compared with 19.8% when irradiation was delivered. Nine pathologic features were evaluated for their ability to predict for in-breast recurrence: comedo necrosis remained as a significant predictor for recurrence.[101]

A second randomized Phase III trial evaluating the role of radiotherapy after complete local excision was completed by the European Organization for Research and Treatment of Cancer (EORTC 10853) enrolling more than 1000 patients.[90,92] All patients had histologically confirmed tumor-free margins, defined as no DCIS at the inked margin, and the prescribed radiotherapy consisted of whole-breast tangential fields treated to 50 Gy in 25 fractions. A boost dose was not advised, and only 5% received a boost to the surgical bed. At a median follow-up interval of 15.8 years, researchers reported a 31% in-breast failure rate with excision only and an 18% in-breast failure rate with excision plus radiotherapy.[90] Risk factors for recurrence were evaluated, and the relative benefit from the addition of radiotherapy was equivalent in all subgroups. It should be noted that there were two groups identified with an exceptionally low risk of recurrence of less than 10%. These groups were defined as those with well-differentiated DCIS with either a clinging or micropapillary growth pattern. The relative benefit of radiotherapy remained consistent in these patient groups, but the absolute benefit was reduced.[90,102]

The United Kingdom Coordinating Committee on Cancer Research (UKCCCR) DCIS Working Group and investigators from Australia and New Zealand have also conducted a randomized trial investigating the role of adjuvant irradiation (Table 62-5).[91] Within a more complex 2 × 2 factorial protocol design, the aim was to compare four treatment regimens: excision alone, excision plus tamoxifen, excision plus radiotherapy, and excision plus radiotherapy and tamoxifen. Tamoxifen was prescribed as 20 mg/day, and radiotherapy was delivered through whole-breast tangential fields to a total dose of 50 Gy. A boost was not recommended. A total of 1030 patients were enrolled in the radiation arm of the trial. With a median follow-up of 12.7 years, radiation therapy was associated with a reduction in ipsilateral invasive (HR 0.32, $p < 0.0001$) and noninvasive recurrences (HR 0.38, $p < 0.0001$). The addition of tamoxifen to radiotherapy offered minimal benefit toward the overall ipsilateral local control rates; however, it did appear to reduce the ipsilateral recurrence rate of DCIS (HR 0.70, $p = 0.03$) and contralateral events (HR 0.44, $p = 0.005$).[91]

The SweDCIS study from the Swedish Breast Cancer Group enrolled 1067 patients from 1987 to 1999, randomizing between lumpectomy followed by radiotherapy and lumpectomy only for treatment of DCIS.[92] Patients underwent a sector resection with the aim of achieving a 1-cm gross surgical margin; microscopic clear resection was not required. The majority of

patients received 50 Gy in 25 fractions to a whole-breast treatment target. A split course of 54 Gy in 2-Gy fractions delivered in two treatment series separated by a 2-week break was allowed. No boost dose was delivered. A recent 20 year update found the absolute difference in local recurrence to be 12% with an absolute reduction of 10% for DCIS recurrences and 2% for invasive recurrences. Subgroup analysis by age, lesion size, focality, completeness of excision, and the presence of a lesion detected by screening confirmed that all groups benefited in risk reduction with the addition of radiotherapy.[92]

In a trial asking a similar question of the role of tamoxifen and building on the results from B-17, the NSABP initiated a trial to determine if the addition of tamoxifen to lumpectomy and postoperative radiotherapy would be more effective than lumpectomy and postoperative radiotherapy alone.[89] All of the 1799 women underwent excision and were randomized to whole-breast irradiation and placebo or whole-breast irradiation followed by tamoxifen. The postoperative radiotherapy was delivered with standard tangential fields to a total dose of 50 Gy. The placebo or tamoxifen (10 mg twice daily) was continued for 5 years. At 15 years, the in-breast failure rate following lumpectomy, radiotherapy, and placebo was 16.6%, and it was reduced to 13.2% when tamoxifen was added to lumpectomy and radiotherapy. The occurrence rate of cancer in the contralateral breast was also reduced with the addition of tamoxifen from 8.1% to 4.9%.[89]

Risk factor assessment has been performed with the goals of determining which patients are ideal for breast-conservation therapy, which patients would be better treated with mastectomy, and which patients could be successfully managed with lumpectomy only. Single-institution studies and randomized studies have identified factors that predict for an increased risk of recurrence. Tumor size, the presence of comedo necrosis, the nuclear grade, young patient age, and the margin status have all been identified as factors associated with a higher risk of in-breast recurrence.[88-92,95,102-107] However, the addition of radiation therapy reduces the risk of recurrence in all cases; only when diffuse disease, signified by mammographic appearance or the inability to achieve clear surgical margins, is encountered is mastectomy the preferred method of surgical management.[25] In the absence of these high-risk factors, the prevalent question is whether a less-comprehensive treatment approach (i.e., wide excision only or lumpectomy and hypofractionated/accelerated partial breast irradiation) is sufficient. Although failure pattern data and retrospective analysis exist to confirm the validity of these more directed treatment approaches, confirmation by an appropriately designed clinical trial is lacking.[26,108]

The Van Nuys Prognostic Index is a proposed method of identifying patients whose risk of in-breast failure following lumpectomy is so low that adjuvant radiotherapy would be of minimal benefit.[108,109] This scoring index is based on tumor grade, tumor size, patient age, and surgical margin width. Achieving a clear margin of more than 1 cm has been determined to be an important predictor of this index. It is important to note that this determination is characterized by a comprehensive, exhaustive pathologic evaluation assuring that a 1-cm clear surgical margin is achieved in all directions. The scoring index was developed and evaluated at a single institution through retrospective analysis and has yet to be consistently independently validated.[110-112]

In a prospective single-arm study at the Dana-Farber/Harvard Cancer Center evaluating wide excision alone, 158 patients with grade I or II DCIS lesions of 2.5 cm or less were treated with wide excision with final surgical margins of 1 cm or more without further treatment.[113] Treatment with tamoxifen was not permitted. Presently accepted standard practice approaches to surgical resection and pathologic assessment were applied. The median follow-up time was 40 months. Accrual was prematurely closed after 13 patients developed local recurrence at an unacceptably high in-breast failure rate corresponding to a 5-year rate of 12%.[113]

The Radiation Therapy Oncology Group (RTOG) initiated a prospective randomized trial evaluating the need for radiotherapy in patients with low-risk DCIS. Following lumpectomy with clear margins of resection of 3 mm or more, patients were stratified according to age (<50 years versus ≥50 years), tumor size (≤1 cm versus >1 cm to 2.5 cm), margin status (negative reexcision versus 3 mm to 9 mm versus ≥10 mm), grade, and use of tamoxifen (at the discretion of the managing physician). After stratification, patients were randomized to whole-breast irradiation versus observation. This trial had a target accrual of 1800 patients but closed because of slow enrollment with 636 patients. At 5 years, the addition of radiation therapy significantly reduced local recurrence rates (0.4% versus 3.2%). Importantly, a patterns of failure analysis found that two thirds of recurrences in the observation-alone arm were true recurrences (in the same quadrant as the initial tumor), whereas none of the recurrences in the RT arm were true recurrences.[114]

In an intergroup trial run by the Eastern Cooperative Oncology Group (ECOG) and North Central Cancer Treatment Group, wide excision only in a population of conservatively selected patients with DCIS was evaluated.[104] Eligible patients included those with low- or intermediate-grade DCIS lesions measuring 2.5 cm or less or high-grade DCIS lesions measuring 1 cm or less. The microscopic margin width was required to be 3 mm or more with no residual calcifications on postoperative mammograms and 30% received tamoxifen. Six hundred and seventy patients were evaluable, and at 5/10 years, the rates of local recurrence were 6.1%/15.4% and 15.3%/15.1%, for the low- and intermediate-grade and high-grade cohorts, respectively.[115]

Alternatives to traditional whole-breast irradiation have emerged as modalities to shorten the duration of adjuvant radiation therapy. Accelerated partial breast irradiation allows for the delivery of treatment in 1 week or less. While waiting for results from NSABP B-39, multiple studies have emerged demonstrating low rates of local recurrence and excellent toxicity profiles in patients with DCIS.[116-118] Evidence-based guidelines allow for the use of partial-breast irradiation in patients with DCIS at this time off-protocol.[116-118] With regard to hypofractionation, increasing data has demonstrated equivalent efficacy to whole-breast irradiation though data is limited in the setting of DCIS.[119-121]

Recently, there has been renewed interest in identifying those patients with DCIS who may not benefit from adjuvant radiation therapy. Although previous approaches and trials used clinical and pathologic criteria, more recently data has emerged on the role of multigene assays in patients with DCIS. Solin et al evaluated 327 patients from the ECOG trial with adequate tissue for multigene assay using three risk categories: low (DCIS score <39), intermediate (39-54), and high risk (≥55). DCIS score, as a continuous variable, was found to be significantly associated with ipsilateral breast tumor recurrence after adjusting for tamoxifen utilization; on multivariate analysis, DCIS score remained significantly associated. By risk group, the 10-year rate of IBTR was 10.6%, 26.7%, and 25.9% for low, intermediate, and high-risk groups, respectively, and for invasive IBTR the rates were 3.7%, 12.3%, and 19.2%, respectively.[115] Further prospective study is required, although these data do suggest the possibility of tumor genetics identifying patients at low risk suitable for treatment with lumpectomy alone. However, there still remain concerns as the low-risk cohort still had a greater than 10% risk of recurrence.

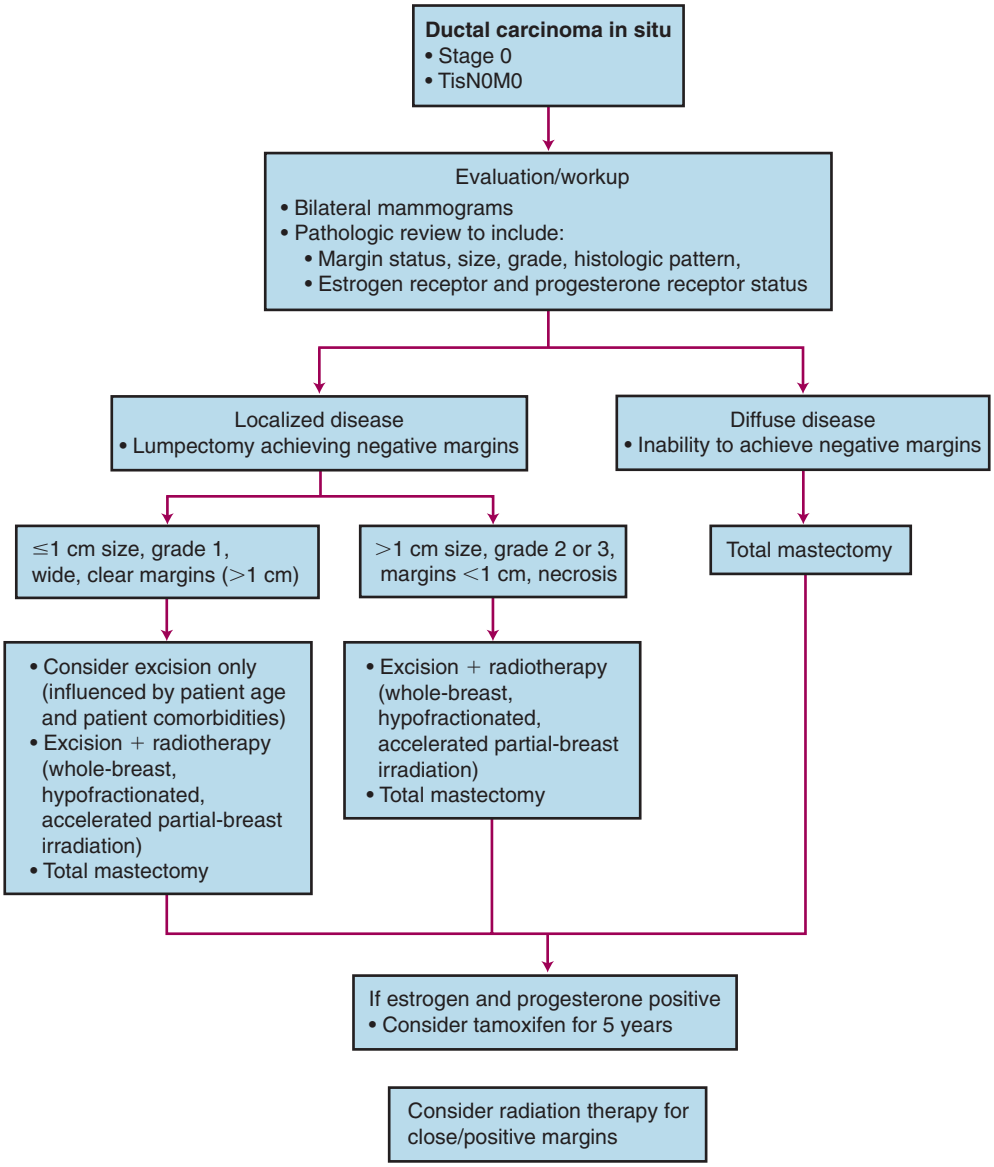

Figure 62-3 Management decision tree for ductal carcinoma in situ.

In summary, DCIS is a noninvasive malignant tumor that is managed successfully with treatment directed toward the breast only (Figure 62-3). Treatment approaches addressing the whole breast are considered the standard of care, although hypofractionated and partial-breast treatment (i.e., wide excision only versus lumpectomy plus partial-breast irradiation) techniques are being evaluated. Although mastectomy can always be considered a treatment option, breast-conservation therapy is the preferred treatment approach. When considering a patient for standard breast-conservation therapy, it is important to first ensure that clinical and mammographic information confirms that the lesion is unicentric. When surgical excision of the lesion is performed, negative pathologic margins should be established and an acceptable cosmetic result achieved. Postoperative irradiation should be delivered with whole-breast tangential fields to a homogeneous dose of 46 Gy to 50 Gy in 1.8 Gy to 2 Gy per fraction. An additional dose to the surgical bed plus the tumor margin (1 cm to 2 cm) typically follows, so that the total cumulative dose to the surgical bed is 60 Gy to 66 Gy.

CHAPTER

63 Breast Cancer: Stages I-II

Abram Recht

PATIENT SELECTION

The majority of individuals with stages I to II invasive breast cancer are candidates for breast-conserving therapy (BCT).

Treatment with conservative surgery (CS) and radiation therapy (RT) is absolutely or relatively contraindicated because of toxicity concerns for only a few patients. In some individuals the anticipated cosmetic results of CS and RT may be so poor that mastectomy with immediate reconstruction is a more appealing alternative.

Proper pretreatment evaluation is a critical aspect of deciding on the most appropriate treatment approach. Careful physical examination should be performed. All patients should have mammograms before biopsy and, in selected patients, after surgery to ensure the completeness of resection. The role of magnetic resonance imaging (MRI) is still unsettled and controversial. Specimen radiography should be performed routinely, including for patients who present with a nonpalpable mass without microcalcifications.

Careful evaluation of the tumor specimen is mandatory, especially with regard to the margins of resection. It is critical for the pathologist to note whether and how far tumor extends beyond the edges of any grossly apparent mass, and whether calcifications are associated with the tumor, benign tissue, or both. Detailed description of the size of the invasive component, histologic type, presence of an extensive intraductal component or lymphovascular invasion, grade, and other features of the lesion should be recorded.

TREATMENT

Some patients have a low risk of local recurrence when treated with CS and endocrine therapy without irradiation. However, there is no consensus on exactly which combination of patient, clinical, and histologic factors permit acceptable results with this approach.

There is no consensus on the minimum microscopic tumor-free margin width needed to offer patients BCT (either with or without RT). Though uninvolved margins are preferred, selected patients with involved margins have excellent local control with RT.

Most patients with uninvolved margins have excellent local control and cosmetic results when given whole-breast doses of approximately 45 Gy to 50 Gy in 2-Gy fractions or its biologic equivalent. Patients younger than age 50 years or those with certain histologic findings may benefit most from the addition of a boost dose to the tumor bed and surrounding area.

Three-dimensional compensation improves the homogeneity of radiation dose distribution within the breast. This results in fewer acute side effects and improved cosmetic outcome for many patients.

Accelerated partial-breast irradiation allows patients to undergo BCT more quickly than with conventional whole-breast irradiation. However, there are substantial uncertainties regarding its long-term efficacy and toxicity, selection of patients for this approach, and its technical details.

The value of RT directed at regional lymph nodes is uncertain. There is no consensus on when (and which) regional nodes should be irradiated.

FOLLOW-UP

The focus of follow-up should be on detecting potentially curable recurrences and new primary tumors in the ipsilateral and contralateral breasts.

The optimal follow-up schedule and testing regimen is unknown. Nonetheless, it is reasonable to perform biannual or annual physical examinations and annual mammograms indefinitely.

THERAPY OF LOCOREGIONAL RECURRENCE

Most patients with a local recurrence who have received prior RT should undergo mastectomy. Selected patients may have acceptable results with further BCT if careful clinical, radiologic, and pathologic evaluation shows the lesion to be limited in extent, and there is no evidence of multicentric disease.

Patients not previously irradiated are usually candidates for further BCT, including RT.

The value of further adjuvant systemic therapy for patients with local recurrence after BCT is uncertain.

INTRODUCTION

Approximately 70% to 80% of patients with stage I or II invasive breast cancers are technically candidates for BCT.[1,2] Six major randomized trials[3-9] using modern RT techniques (eTable 63-1) and a meta-analysis including additional studies[10] found no differences in disease-free survival (DFS) or overall survival (OS) between mastectomy and BCT.

Many questions remain regarding optimal patient evaluation and selection for BCT, RT techniques and doses, factors affecting complications and cosmetic outcome, follow-up, and treatment of locoregional recurrences. Several texts discuss these topics in greater depth.[11-14]

PRETREATMENT EVALUATION

Imaging

Mammography should always be performed, although it does not always accurately delineate the extent of disease. MRI finds additional ipsilateral foci in 5% to 10% of candidates for BCT and unsuspected contralateral disease in 3% to 5%.[15-17] Most abnormal findings near the index lesion are malignant, whereas those further away are likely to be benign.[18] Two randomized trials disagreed on whether preoperative MRI reduced the need for reexcision.[19,20] Two retrospective studies found a lower risk of local failure in patients undergoing

eTABLE 63-1 Randomized Trials Comparing Mastectomy to Breast-Conserving Therapy

MRI,[21,22] but two others did not.[23,24] MRI may be most valuable for patients with tumors larger than 2 cm or infiltrating lobular histology.[25]

Postoperative mammograms only rarely show residual calcifications or additional masses in patients with uninvolved microscopic margins.[26,27] Its use made no difference to the recurrence rate for patients with ductal carcinoma in situ (DCIS) in one series.[28] Postoperative MRI has limited accuracy in detecting residual disease.[29-31]

Pathologic Evaluation

The most common approach for microscopic margin assessment is for the surgeon to remove a single specimen that the pathologist rolls in India ink and sequentially sections perpendicular to its long axis ("bread-loafing"). Some pathologists "shave" each face of a specimen; the margin is considered involved when tumor is seen in one of the shaved margin slides. These approaches may have quite different clinical implications.[32,33] Some surgeons take additional "cavity" specimens after removing the main specimen.[34] The role of intraoperative margin assessment is uncertain.[35]

SURGICAL TECHNIQUES

Breast-Conserving Surgery

Technical aspects of breast surgery are discussed in depth elsewhere.[11,13,14] Patients with large cancers or lesions in areas where resection can cause substantial breast distortion may benefit from "oncoplastic" reconstruction.[36-38] Reduction mammoplasty at the time of excision may reduce the risk of retraction in patients with large breasts.[39]

Axillary Dissection

The classical three anatomic "levels" of the axilla are: level I, lateral and inferior to the border of the pectoralis minor muscle; level II, under the pectoralis minor; and level III (also called the "infraclavicular" nodes), medial and superior to the border of the pectoralis minor.[40] Randomized trials found no differences in axillary failure or survival rates between "limited" dissection (removal of level I or level I and II nodes only) and "complete" dissection (removal of levels I, II, and III), but limited dissection caused less morbidity.[41-43] Axillary failures are rare after technically adequate levels I to II dissection[40,44] unless there is extensive nodal involvement.[45]

Sentinel Node Biopsy

Sentinel node biopsy (SNB) uses injection of a radionuclide tracer or vital dye (or both) in the breast to guide the surgeon to the nodes to remove.[46] Immediate and long-term complications are lower for SNB than for levels I to II axillary dissection (AxD).[47-49] False-negative rates of SNB are 0% to 12% in different series, but the risk of axillary failure after a negative SNB is small.[50-53] OS and distant failure rates are the same after AxD and SNB for patients with clinically negative axillary nodes.[54-56]

BREAST-CONSERVING SURGERY WITH RADIATION THERAPY

The effectiveness and toxicities of BCT are affected by patient, clinical, and pathologic factors and treatment parameters.

Patient Factors

Pregnancy

Unterminated pregnancy is an absolute contraindication to breast RT because of the possible teratogenic and carcinogenic effects of scattered radiation on the fetus.[57]

Prior Treatment with Radiation Therapy

Most physicians recommend mastectomy for patients with prior thoracic irradiation.[58] However, there were no unusual acute or chronic sequelae among several small studies of women treated with CS and RT after RT for Hodgkin's disease or non-Hodgkin's lymphoma.[59-62] One such patient treated at Stanford University did develop severe soft-tissue necrosis.[63] Some individuals have been successfully treated with partial-breast irradiation, albeit with short follow-up.[64,65] Such patients should understand they may be at substantial risk of developing new breast cancers because of their prior exposure, which may affect their decision making.

Rheumatologic Disorders

The use of BCT in patients with rheumatologic disorders has been controversial. Three small studies found no clear increased risk of complications in patients with rheumatologic disorders to a matched "normal" population, except for scleroderma.[66-68]

Breast Size

Women with large breasts have more acute skin reactions and long-term retraction and fibrosis than patients with smaller breasts.[69,70] However, their results can be improved by using higher-energy photons,[71] 1.8-Gy daily fractions, three-dimensional compensation,[69] and treatment in the lateral decubitus or prone positions.

Prior Breast Augmentation

Patients with augmented breasts should have MRI, given the limitations of mammograms in this setting. Capsular fibrosis and other complications after RT occurred in half or more of patients in two series[72,73] but were much less common in several others.[74-76] Thus, it seems reasonable to offer such patients BCT.

Patient Age

Patients younger than 35 years to 40 years old at diagnosis have higher local recurrence rates than older patients in most series.[77,78] However, overall outcome is not superior after mastectomy.[79-83] Some studies have suggested margins smaller than 2 mm or high histologic grade increase young patients' risk of local recurrence,[84-86] but others have not.[87] Systemic therapy substantially reduces their local failure rates.[77,88]

Older patients tolerate RT well and have excellent local control rates.[89,90]

Genetic Factors

A family history of breast cancer by itself does not increase the risk of local failure following BCT (eTable 63-2).[91-95] Most[96-102] but not all[103-105] studies also found modest or no differences between patients with *BRCA1* and *BRCA2* mutations and unaffected patients (eTable 63-2). Recurrence in a different quadrant is more common in *BRCA1* and *BRCA2* mutation carriers than noncarriers, suggesting they have a higher risk of developing new primary cancers.[99] Tamoxifen or oophorectomy may reduce both ipsilateral local failure[99] and contralateral new primary cancers.[99,106]

Most studies do not show that ipsilateral mastectomy with or without contralateral prophylactic mastectomy improves long-term outcome for patients with *BRCA1* and *BRCA2*

mutations or a family history of breast cancer compared to BCT,[97,108-111] though there are exceptions.[112] However, these studies usually contain small numbers of patients, there is considerable selection bias in treatment assignment, and follow-up is too short to detect late differences.

Syndromes associated with impaired radiation damage repair, such as ataxia telangiectasia, result in a substantial risk of complications from RT.[113] However, patients heterozygous for *BRCA1* and *BRCA2* mutations or with a single ATM mutation do not have increased toxicities.[99,114-116] Some studies suggested increased adverse results for patients with more than one ATM mutation,[117] those with particular single ATM mutations,[118,119] and those with polymorphisms of multiple radiation repair genes.[118,120-123]

In-field cancers have been reported to occur within a few years of RT in several patients with TP53 mutations, which causes the Li-Fraumeni syndrome.[124-126] RT does not increase contralateral breast cancer rates in patients with ATM[127-129] or *BRCA1* and *BRCA2* mutations.[111,130]

Clinical Factors

Means of Detection

Local recurrence rates are similar for patients with palpable and nonpalpable cancers.[131] Patients with nipple discharge do not have higher local failure rates than others.[132]

Tumor Size and Location

Tumor size does not influence local recurrence rates.[84] However, it is difficult to achieve both acceptable cosmetic results and negative margins in most patients with tumors larger than 4 cm to 5 cm without using neoadjuvant chemotherapy.

Patients with subareolar or periareolar lesions that do not directly extend to the nipple or areola have high local control rates following excision with negative margins without nipple-areolar resection.[133,134] Even when nipple-areolar resection must be performed, local control is high,[135] the appearance and texture of the remaining breast are at least as good as that following reconstruction procedures, and sensation is preserved.

Bilateral Breast Cancers

Patients with bilateral breast cancer (either synchronous or metachronous) can be treated successfully with BCT without increased complications,[136-138]

Multiple Ipsilateral Primary Cancers

Multiple synchronous ipsilateral breast cancers occur in only 2% to 4% of patients.[139-141] The majority of apparently independent lesions in one recent study were clonal, indicating a single site of origin.[142] Local failure rates are similar to those of patients with a single lesion when negative margins are achieved.[137,143-148]

Pathologic Factors

Margin Status

A "positive" or "involved" margin is defined as invasive cancer or DCIS present at an inked surface when a bread-loafing technique is used or having tumor anywhere in shaved margin specimens. Involved margins are associated with higher local failure rates than uninvolved margins, although the difference is much smaller in recent studies than older ones.[149] Invasive cancer and DCIS involvement have similar implications.[150,151] Studies differ on whether the presence of lobular carcinoma in situ (LCIS) at margins is a risk factor.[152,153]

The extent of margin involvement is important. In one study with a median follow-up time of 127 months, the crude 8-year local failure rate was 14% for 122 patients with focal margin involvement and 27% for 66 patients with extensive involvement.[150] In another study, the risk of local failure was 14% (10 of 70) for patients with a single positive margin, compared to 36% (17 of 47) for patients with multiple involved margins with a median follow-up of 72 months.[154]

TABLE 63-1 Tumor-Free Margin Width and the Risk of Local Failure Following Breast-Conserving Therapy with Radiation Therapy

Investigators often distinguish "negative" from "close" but uninvolved margins based on the tumor-free margin width.[155] However, there is no standard definition of these terms. Only three published studies with long follow-up examined outcome according to sequential margin intervals, rather than a single cut-point (Table 63-1).[85,150,156] They do not show a consistent relation between increasing margin width and lower local failure rates. A study from British Columbia also found a 4% local failure rate in both 170 patients with margins of 0.1 mm and 1 mm and 52 patients with 1.1-mm and 2-mm margins, with median follow-up of 62 months.[149]

Few data exist on other aspects of margins. A study from Scotland found that reexcision performed for an anterior margin of less than 1 mm found residual disease in only 4% of patients who had initial excision in the subcutaneous plane, compared to 24% of patients with a narrow posterior margin (originally taken to the pectoralis fascia) and 33% of those with a narrow circumferential (or radial) margin.[157] Margin direction did not affect local failure for patients with margins of less than 2 mm or those with positive margins in another study.[158] One study found that the volume of disease near uninvolved margins affected the risk of local recurrence.[156]

The number of excisions required to achieve uninvolved margins was not a risk factor for local failure in most,[159,160] but not all,[161] series. Studies also disagree whether finding residual

disease on reexcision modestly increases local failure rates, even with negative margins.[162-164]

Chemotherapy and tamoxifen substantially reduce failure rates in patients with uninvolved margins as a whole.[165,166] This effect may be proportionally greater for patients with margins narrower than 1 mm to 2 mm.[150,167]

Other Histologic Features

An infiltrating ductal carcinoma has an "extensive intraductal component" (EIC) when DCIS both comprises a prominent portion of the area of the primary mass and is present in grossly normal adjacent breast tissue, or when the tumor is predominantly noninvasive.[168] (Other definitions probably describe the same entity.) Tumors with an EIC extend more widely within the breast.[169] Its impact on local failure is uncertain when margin status is accounted for.[84,150,170] Patients with microinvasive cancers have the same risk of local failure as those with larger areas of invasion.[171]

The terms *multicentric* and *multifocal* are not standardized but commonly refer to the presence of cancer in more than one quadrant or in multiple areas within a single quadrant, respectively. Such findings do not affect the risk of local relapse.[172,173]

Lymphovascular invasion is an independent but small risk factor for local recurrence in most,[174-177] though not all,[91] studies.

Patients with infiltrating lobular carcinomas or mixed ductal and lobular features[178-182] or rarer histologic subtypes[181,183-187] have comparable local recurrence rates to patients with infiltrating ductal carcinomas.

One study found a substantial risk of residual DCIS or invasive disease on reexcision when atypical ductal hyperplasia was at or near the margins.[188] However, benign proliferative diseases do not appear to affect the risk of local failure.[189-191]

Studies conflict on whether the presence of LCIS does[192-194] or does not[153,195-197] increase local failure rates.

Biologic Markers of Tumor Behavior

Patients with tumors that express the estrogen receptor (ER) have modestly lower local recurrence rates than patients with ER-negative tumors when systemic therapy is not used.[198] Appropriate systemic therapy reduces this difference substantially.

Breast cancers can be grouped into "intrinsic subtypes" according to patterns of gene expression.[199] Most studies classify cancers with immunohistochemical assays of critical cell signaling receptors, rather than direct analysis of gene copy numbers. Subtypes are associated with marked differences in age at presentation, tumor size, histologic features, and the extent of lymph node involvement.[200,201] Patients with luminal A subtypes (ER-positive, progesterone receptor, or PR, positive, and c-*erb*B-2/neu, or HER2, negative) uniformly appear to have 10-year local relapse rates of 5% to 8% after BCT. Patients with basal (or "triple-negative") subtypes have similar local failure rates to patients with other combinations of ER, PR, and HER2 status in some studies[202-208] or modestly higher rates in others.[209-213] Local failure rates increased with HER2 overexpression in some series[201,209,212,214] but not others.[207,215] Trastuzumab may reduce this risk.[216]

Other gene expression profiles may also affect local control, but differences in outcome are small.[207,217,218] Intratumor heterogeneity must also be considered when using such panels for clinical decision making.[219]

Prognostic Indices

Several investigators have proposed using prognostic indices that combine patient-, clinical-, and tumor-related features to more accurately determine the risk of local failure after BCT.[220-222] Their ultimate role is not yet clear.

Conclusions

There are only a few patients for whom RT is absolutely or relatively contraindicated because of toxicity concerns. The anticipated cosmetic results may be so poor for some individuals that mastectomy with immediate reconstruction may be a more appealing alternative. Margin status is the most important determinant of local control, but other factors interact with it and each other in complex and poorly-understood ways. An uninvolved margin is sufficient to obtain excellent local control rates in the great majority of patients. Wider tumor-free margin widths might benefit certain patient subgroups (e.g., those younger than age 35 to 40, those with an EIC, or patients receiving RT after a long delay from surgery as a result of chemotherapy), but data are limited and contradictory. If margins are still involved microscopically after reexcision, then the patient should understand that she is at higher risk of local recurrence, although this may be reduced somewhat by systemic therapy.

BREAST-CONSERVING SURGERY WITHOUT RADIATION THERAPY

Results of Conservative Surgery with or without Radiation Therapy

eTable 63-3 summarizes the largest randomized trials comparing CS alone to CS with RT for relatively unselected patients, with respective local recurrence rates of about 15% to 40% and 3% to 20%, respectively.[5,223-228] However, more recent trials with more restrictive patient selection which routinely used endocrine therapy have considerably lower failure rates without RT (Table 63-2).[165,229-238] For example, in the NSABP B-21 trial, the local failure rate was 10% (19 of 197 patients) at median follow-up of 89 months for patients with a tumor 1 cm or smaller with known positive ER treated with tamoxifen without RT.[165,229] Giving RT changed rates of distant metastasis, breast cancer-specific mortality, or OS in the former studies but not the latter ones.

The use of RT improved recurrence-free, breast cancer-specific survival, and OS in both patients with negative and positive axillary nodes in the most recent meta-analysis of the Early Breast Cancer Trialists' Collaborative Group, which included trials begun before 2000.[241] The proportional reductions were greatest in patients with positive axillary nodes. The benefits of RT with respect to these endpoints were much more variable in patients with negative nodes in relation to patient age at diagnosis, tumor size tumor grade, ER status, and the use of systemic therapy. The investigators therefore created a model to further investigate the impact of RT on breast cancer-specific mortality for patients with pathologically uninvolved nodes. This resulted in three groups, based on how much RT would reduce the predicted 10-year risk of any recurrence: large (20% or more); intermediate (10% to 19%); and low (less than 10%). Ten-year risks of locoregional failure were reduced by RT by 24%, 13%, and 9%, respectively, and 15-year breast cancer death rates by 7.8%, 1.1%, and 0.1%, respectively (Figure 63-1).

Correlates of Local Recurrence in Patients Treated with Conservative Surgery and Endocrine Therapy without Radiation Therapy

Endocrine therapy seems needed to obtain acceptably low failure rates without RT.[230,234,242] There was no difference in

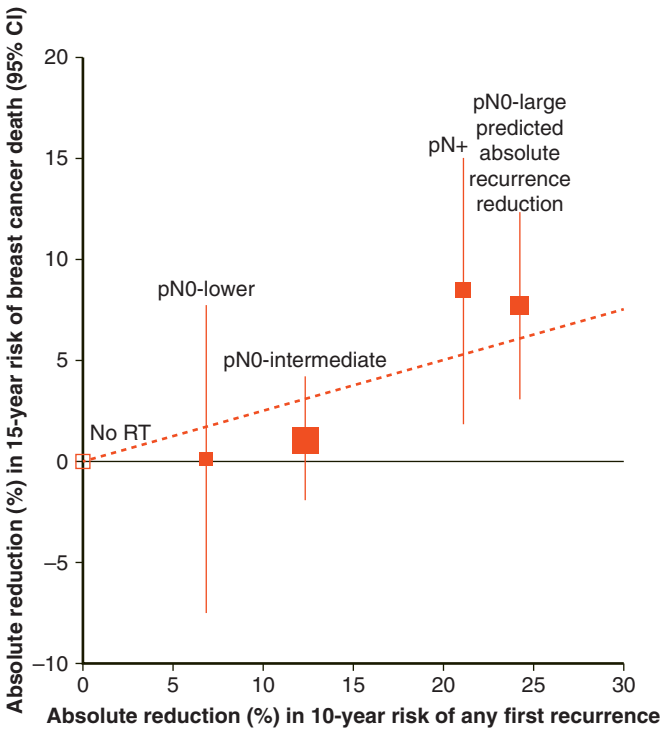

Figure 63-1 Relation between the absolute reduction in 10-year overall recurrence risk and reduction in 15-year breast cancer mortality.

From: Early Breast Cancer Trialists' Collaborative Group: Effect of radiotherapy after breast-conserving surgery on 10-year recurrence and 15-year breast cancer death: meta-analysis of individual patient data for 10 801 women in 17 randomised trials. Lancet 378:771–784, 2011; with permission of the publisher.

local failure rates between patients ages 50 and 60 years, ages 60 and 70 years, or older than 70 years in a retrospective study in London employing tamoxifen[243] or between those ages 55 and 64 years and 65 and 75 years in a prospective randomized trial from Italy.[238] Age older than 65 years,[228] the absence of comedo or lobular features,[223] and low histologic grade[244] were associated with reduced failure rates in series not employing systemic therapy. In a study from Milan, patients with infiltrating lobular carcinomas had a slightly higher local failure rate (12%, or 9 of 72 patients) compared to patients with infiltrating ductal histology (8%, or 18 of 231 patients).[245] A study from Guy's Hospital, London of patients age 70 and older found that lymphovascular invasion and ER-negative status were associated with higher risks of locoregional recurrence.[246] Patients with grade 1 or 2 luminal A tumors demonstrated no difference in the 10-year local failure rates with or without RT in the Ontario-British Columbia trial (both 5%); patients with other subtypes had substantially higher local failure rates when RT was omitted.[247] In a retrospective study of patients older than 70 years treated in Nottingham, England, with median follow-up of 37.5 months local failure rates were 33% (4 of 12) for margin widths less than 1 mm, 12% (2 of 17) for margins of 1 mm to 5 mm, and 2% (1 of 54) for margins wider than 5 mm, respectively.[248]

Combinations may be more important than individual features in predicting local failure. In the Ontario-British Columbia trial, the actuarial 8-year local recurrence rate for 237 patients age 60 years or older with tumors 2 cm or smaller and positive ER or PR was 7% when treated with tamoxifen alone at a median follow-up of 94 months.[233]

Conclusions

There is no consensus on which patients are appropriate candidates for CS without RT. I feel it reasonable to offer such

treatment to those with all of the following characteristics: age 60 years or older (though many American radiation oncologists prefer a minimum age of 70 years); 2-cm or smaller ER-positive grade 1 or 2 tumor without an EIC or lymphovascular invasion; microscopic margins 5 mm or wider; pathologically negative axillary nodes (or clinically negative nodes for those age 70 or older); and willingness to take endocrine therapy. However, the effect of RT on patients' quality of life is brief and limited,[249] serious complications are rare, and some patients may prefer to reduce their risk of local failure yet further by being irradiated.[250,251] Decision aids may help patients make this choice.[252]

WHEN TO USE NODAL IRRADIATION

Axillary Irradiation

Some patients with clinically uninvolved (cN0) axillary nodes have a low risk of regional nodal failure without any axillary treatment.[233,236,245,253,254] Many studies using breast RT alone without axillary surgery also found a low risk[245,255-261] but others had much higher rates.[257,262] A trial at the National Cancer Institute of Milan randomly assigned 517 evaluable patients age 18 years to 65 years with clinical T1N0 cancers to breast irradiation plus axillary dissection (AxD) or breast RT alone.[262] The incidence of nodal involvement in the AxD group was 29%, with the latter group having an axillary failure rate of 9% (21 of 243 patients) with median follow-up of 10.6 years. However, the axillary failure rate was only 4% (4 of 110 patients) in an otherwise identical trial they performed for patients ages 65 years to 80 years.[263] Axillary plus breast RT results in failure rates of 1% to 3%.[258,264-266] Such treatment resulted in 1% to 2% lower failure rates than breast RT alone in two Italian trials.[267,268] Axillary RT is not as effective for patients with clinically suspicious (cN1) nodes,[40] who should undergo AxD.

Axillary failure rates after a positive levels I to II AxD are generally low if a minimum of 6 to 10 nodes are removed.[45,269] Failure rates may be 7% to 10% or higher in unirradiated patients with 8 or more positive nodes or T2-3 tumors with 4 or more positive nodes[45] or when a substantial proportion of removed nodes are involved.[270] In one series there were no axillary failures in patients with 10 or more positive nodes who received only supraclavicular irradiation after a complete axillary dissection.[271] Extracapsular tumor extension does not increase the risk of axillary failure.[269,272]

Three trials have compared AxD to breast RT only after a positive SNB. The American College of Surgeons Oncology Group Trial Z0011, conducted from 1999 to 2005, randomly assigned 891 patients with T1-2 tumors and one to two positive sentinel nodes. With median follow-up of 6.3 years, the crude risks of regional nodal failure in the AxD and SNB arms were 0.5% and 1%, respectively.[273] However, 20% of patients were lost to follow-up.[274] The International Breast Cancer Study Group 23-01 trial, conducted from 2001 to 2010, included 931 patients with micrometastases (0.2 mm to 2 mm). With a median follow-up of 60 months, crude axillary recurrence rates were 0.2% and 0.8% in the two arms, respectively.[275] A similar Spanish trial found an axillary recurrence rate of 1% (1 of 113 patients) in patients treated with BCT without AxD, with median follow-up time of 62 months.[276] Finally, the European Organization for Research and Treatment of Cancer (EORTC) AMAROS trial, conducted from 2001 to 2010, randomly assigned patients with a positive SLN to either AxD or breast plus axillary RT. With a median follow-up of 6.1 years, axillary failure rates in the two arms were 0.5% (4 of 744 patients) and 1% (7 of 681 patients), respectively.[277]

It is not known whether breast plus axillary RT is better than breast RT alone for certain patients with positive SLN(s). In a nonrandomized Dutch study of patients with sentinel node micrometastases, the 5-year axillary failure rate was 4% among 93 patients treated with CS and RT to the breast only,[278] compared to no failures in 94 patients treated with breast plus axillary RT.[279]

Supraclavicular Nodal Irradiation

Supraclavicular recurrences are often grouped with axillary apical or infraclavicular recurrences. They occur in only a few percent of patients with uninvolved or one to three positive axillary nodes.[44,45,280,281] Such failures occurred in 7% to 10% or more of patients with four or more positive axillary nodes in older studies,[45,269,282,283] but only 3% to 5% of patients in several recent studies.[284-286] Patients with a high proportion of involved nodes may also be at increased risk.[270]

The impact of other factors on supraclavicular relapse rates is uncertain. Some studies suggest that lymphovascular invasion increases the risk,[269,280,285] though others do not.[272,281] A study from Taiwan found that high tumor grade, having four or more positive nodes, and having positive nodes in axillary level II or III were associated with increased supraclavicular failure rates.[287] A study from Seoul, South Korea, found lymphovascular invasion, having two to three positive nodes, extracapsular extension, and involved nodes at level II or III to be independent risk factors. The 79 patients with two or more risk factors had a 5-year supraclavicular failure rate of 27%, compared to 3% for the 369 patients with one or no risk factor.[288] A study from London used tumor grade and the number of involved nodes to create three risk groups, with 10-year supraclavicular-infraclavicular failure rates of 1%, 10%, and 21%.[289] The British Columbia Cancer Agency found that patients with two or more of the findings of histologic grade 3, lymphovascular invasion, an ER-negative tumor, or three positive nodes had a 10-year regional nodal failure rate of 12%.[290] However, failure rates at specific nodal sites were not reported.

The impact of supraclavicular RT on overall outcome has never been examined in any randomized trial separately from internal mammary nodal irradiation.

Internal Mammary Nodal Irradiation

Internal mammary node (IMN) metastases occur in 5% or fewer of patients with pathologically negative axillary nodes and in 20% to 50% with positive nodes.[291,292] Tumor size and the number of involved nodes influence this risk.[44] Results of the largest such study are shown in eTable 63-4.[293] The location of the primary tumor has only a minor impact on this incidence when tumor size and axillary nodal status are accounted for.[293,294] It is common to see drainage to the IMNs when lymphoscintigraphy is performed for SNB,[294] but only 10% to 25% of such "hot spots" are involved pathologically.[295-298] Despite their frequent involvement, clinical IMN recurrence occurs in 1% or fewer patients in nearly all studies and is rare even when the nodes are shown to be involved by biopsy.[299]

The value of treating the IMNs prophylactically has thus been controversial for decades.[300] A trial conducted in France from 1991 to 1997 randomly allocated 1334 evaluable patients with positive axillary nodes or medial or central tumors with negative nodes after mastectomy and AxD to either chest wall and supraclavicular RT or the same plus IMN irradiation.[301] There was no significant difference between the two arms in 10-year DFS (50% and 53%, respectively) or OS rates (59% and 63%) at a median follow-up of 8.6 years. OS was worse in the IMN irradiation arm for patients with medial or central tumors

Data from: Huang O, Wang L, Shen K, et al: Breast cancer subpopulation with high risk of internal mammary lymph nodes metastasis: Analysis of 2,269 Chinese breast cancer patients treated with extended radical mastectomy. Breast Cancer Res Treat 107:379–387, 2008.

with negative axillary nodes (25% of the study population); the opposite trend was found for patients with positive axillary nodes. The MA.20 trial performed in Canada from 2000 to 2007 enrolled 1832 patients undergoing BCT with positive nodes (85% of the study population) or "high-risk" node-negative tumors to undergo either breast RT only or breast plus supraclavicular and IMN RT.[302] With a median follow-up of 62 months, there were statistically significant improvements in 5-year rates of locoregional failure (5% and 3% in the two arms, respectively), distant DFS (87% and 92%), and DFS (84% and 90%). The EORTC trial, conducted from 1996 to 2004, accrued 4004 patients treated either with BCT or mastectomy with either involved axillary nodes or medial or central tumors with negative nodes.[303,304] With a median follow-up of 10.9 years, the 10-year OS rate in patients receiving breast or chest-wall RT only was 80.7%, compared to 82.3% in patients also receiving supraclavicular plus IMN RT ($p = 0.056$); their respective 10-year rates of freedom from distant metastases were 75% and 78% ($p = 0.02$), and DFS were 69.1% and 72.1%.[305] Nodal irradiation had a greater effect on OS for patients with negative nodes (hazard ratio [HR], 0.79, with 95% confidence interval [CI] 0.61 to 1.02) than for patients with 1-3 positive nodes (HR 0.89; CI 0.73 to 1.09), 4-9 positive nodes (HR 0.85; CI 0.61 to 1.18), or 10 or more positive nodes (HR 1.0; CI 0.59 to 1.71).

Conclusions

There is no consensus on when axillary or supraclavicular RT should be given following levels I to II AxD when zero to three nodes are positive. I will generally add a supraclavicular field for patients with one to three positive nodes when there is LVI or a large primary. A supraclavicular field seems adequate for most patients with four or more involved nodes; a full axillary field may be useful for patients with extensive nodal involvement or a more limited dissection. Most patients with a positive SNB have a low risk of regional nodal failure when treated with breast RT only. It is not yet clear which patients have meaningfully improved results with AxD or breast plus axillary RT. The role of prophylactic IMN RT is still uncertain. Two of the three randomized trials on this topic were designed in a way that the impact of IMN RT could not be separated from that of supraclavicular irradiation. Subgroup analyses suggest that subtle differences of treatment technique and patient characteristics may determine whether individual patients benefit or not. Because IMN RT increases the irradiated volumes of lung or heart, in my view it is currently acceptable but not mandatory to give IMN RT to patients with positive axillary nodes.

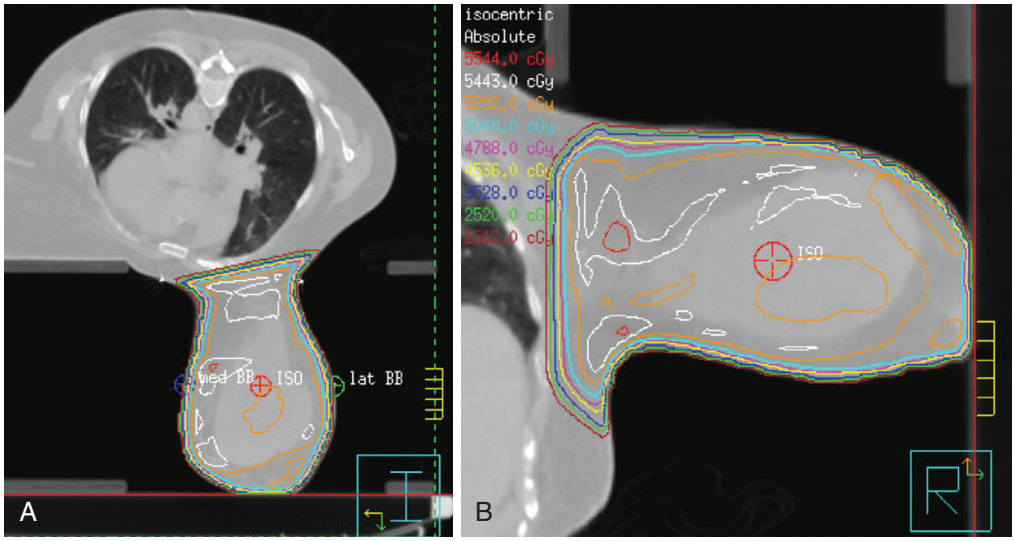
TREATMENT TECHNIQUES

Patient Position and Immobilization

Patients are traditionally irradiated in the supine position. The lateral decubitus[306] and prone positions[307-309] may be especially useful for patients with large breasts because acute reactions are reduced by opening skin folds and long-term fibrosis lessened by decreasing separation (eFigure 63-1). The prone position results in anterior displacement of the heart,[310] which sometimes increases the irradiated heart volume,[311] though heart exposure is decreased for the majority of patients.[312] Some patients are unable to tolerate these positions.[308,313]

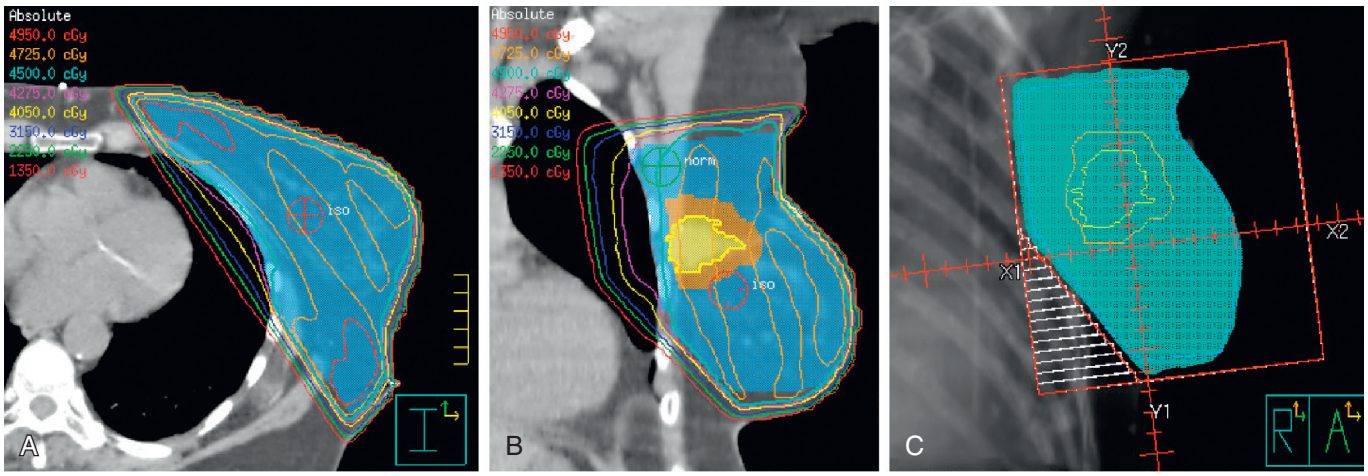
Immobilization techniques using specialized breast boards, custom-made foam cradles, and other approaches can achieve daily patient position reproducibility within 5 mm.[314-316] Set-up errors with prone positioning are comparable to supine treatment.[317,318] However, there is no fully satisfactory way to immobilize the breast itself, especially for large-breasted women. Netting is useful to move the breast tissue medially, and careful taping can help open skin folds. Using a bra increases skin reactions, though this may allow a reduction in intrathoracic normal-tissue exposure.[319]

Whole-Breast Irradiation



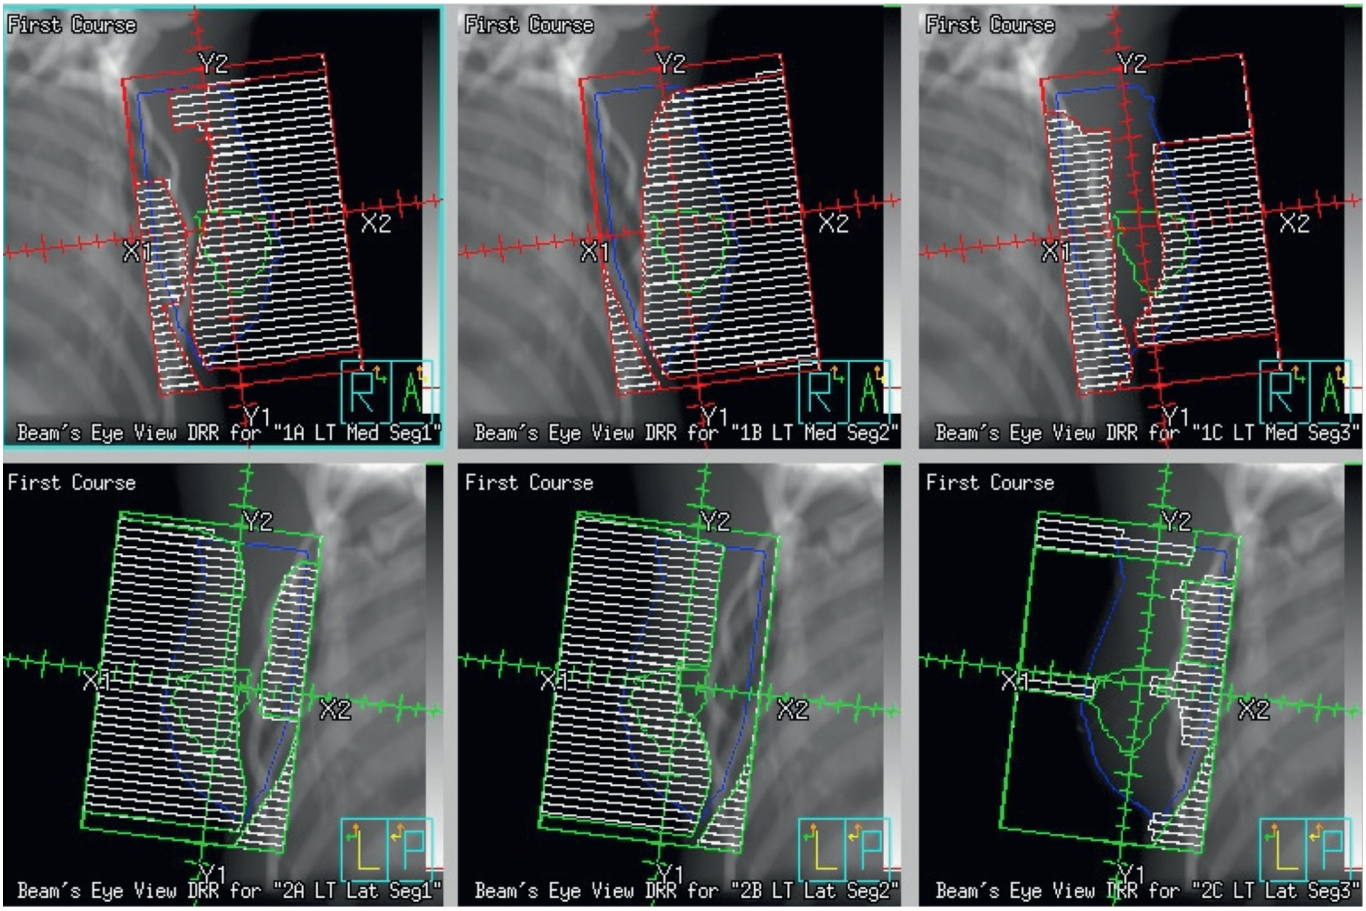
Traditional tangential field borders, created in the era of fluoroscopic simulation based predominantly on surface anatomy, include nearly the entire volume of the breast with adequate margin for daily set-up error (Box 63-1 and Figure 63-2). Three-dimensional CT-guided simulation has replaced fluoroscopic simulation. However, there is substantial interphysician variation in delineating the breast on CT.[320-322] Although interobserver variation may be reduced by the use of "standard" templates or atlases,[323,324] it seems unlikely such variations are of substantial clinical importance because the risk of local recurrence is quite low for patients planned based on surface anatomy. One advantage of CT-guided simulation is to allow greater accuracy in localizing the excision site. Because most recurrences occur at or near this area, deviating from the classical field borders for selected patients is likely to reduce toxicity without increasing local failure rates (e.g., moving the medial tangent entrance to left of midline laterally and using cardiac blocking in a patient with a small left upper outer quadrant lesion) (eFigure 63-2). Blocking or gantry rotation should be used to make the posterior tangent field edges coplanar to reduce normal-tissue exposure.

Most patients are best treated with 6-MV photons. It is preferable to use 10 MV or higher energies alone or in combination with 6-MV photons for patients with large breasts or medial-to-lateral separations (more than 22 cm to 24 cm) to keep the maximum inhomogeneity less than 110%. Skin failures are rare, regardless of treatment energy,[71] and bolus or a beam-spoiler should not be used routinely.



The breast-chest wall volume varies substantially in shape and transverse dimensions superiorly to inferiorly. Physical wedges generally result in satisfactory dose homogeneity in the central-axis plane, but there are often large and intense hot spots in the more superior and inferior planes. Inverse-planned intensity-modulated radiation therapy (IMRT)[325,326] with or without treatment of regional lymph nodes,[327-333] results in much more homogeneous dose distributions throughout the entire treatment volume. Several randomized[334-336] and retrospective and prospective studies[69,337-339] of three-dimensionally compensated breast RT found it reduces acute and chronic toxicities. These studies used simple forward-planned IMRT techniques with only a few additional segments (Figure 63-3 and eFigure 63-3). This approach produces nearly identical results to inverse-planned IMRT for the great majority of patients.[340-343] Elimination of a physical medial wedge also reduces scattered radiation exposure of the contralateral breast and other areas.[344,345] Hence, CT-guided simulation and three-dimensional treatment planning and compensation should be routinely used.

Respiratory excursion of the breast is 2 mm to 6 mm in different directions.[346] Daily set-up variation and respiratory motions have only a small impact on the cumulative dose distribution within the breast or near the excision cavity.[346-351] However, these can have a substantial effect on the IMN dose.[346,352]



Respiratory gating or breath-holding during deep inspiration reduces the amount of heart irradiated.[315,346,352-358] Both deep-inspiration breath-holding and judicious cardiac blocking may be needed (eFigure 63-4). The left anterior descending coronary artery may move more than other portions of the heart, and therefore keeping the heart 5 mm or more from

BOX 63-1 Traditional Field Borders and Blocks

TANGENTS

Inferior: 1-cm margin inferiorly to the inframammary fold.

Superior: The margin of the breast is determined by palpation and is given a 1-cm margin. When a three-field technique is used, the placement of the match-line will depend on the location of the primary tumor as well as the breast tissue; ordinarily, the match-line will be at the second intercostal space or the second rib (radiographically, usually at the inferior edge of the sternoclavicular junction).

Lateral: Include all breast tissue with a 1-cm margin; this usually places this border at the posterior to midaxillary line.

Medial: At the midline in most patients. When the internal mammary nodes are to be included, then the medial border is best determined with the aid of lymphoscintigraphy or computed tomography; otherwise, the medial border is arbitrarily placed 3 cm across the midline. When the contralateral breast has been previously treated, or when both breasts are to be treated simultaneously, care should be taken to ensure that treatment fields do not overlap. A gap of 0.5 cm on skin between the medial borders of the two pairs of fields is adequate.

Anterior: 2-cm margin of light is given above the highest point of the breast.

Posterior: The deep edges of the tangents should be coincident; the medial and lateral borders determine their exact position.

Blocks: When the "corner-block" three-field technique is used, then a block is drawn along the hanging wire that defines the match-line at the superior border with the en face supraclavicular/axillary field. If a single-isocenter three-field technique or the primary collimators are used to match the superior border of the tangents to the nodal field, then blocking is used to define the posterior field borders of the tangents. Heart blocks may be used if needed for some patients with left upper-quadrant or central primaries.

BOOST

Include the breast tissue from approximately skin surface to anterior chest wall, with 1 cm to 2 cm around the excision cavity, as the planning target volume.

SUPRACLAVICULAR AND AXILLARY FIELD:

This field is angled approximately 5 degrees to 10 degrees from the vertical toward the medial side to avoid treating the cervical spinal cord.

Borders:

Inferior: Determined by the match-line with the tangential fields. With the Joint Center for Radiation Therapy (JCRT) technique, the central-axis plane is located here.

Superior: Radiologically, usually the superior-most portion of the first rib. Except in unusual situations, it is preferable not to clear skin (or "flash") in the supraclavicular region.

Lateral: Usually two thirds of the medial-to-lateral distance through the humeral head. In some patients with extensive axillary disease, it may be necessary to clear skin laterally.

Medial: Set up to the center of the suprasternal notch (midline), then angle the gantry.

Blocks: The inferior border is defined by a block through the central axis. In most patients the lateral third of the humeral head should be blocked; in some patients with extensive axillary disease, this may not be possible.

SUPRACLAVICULAR FIELD

Same borders as the full axillary and supraclavicular field, except the lateral field border is at the coracoid process.

EN FACE AXILLARY BOOST (EAB)

The couch, gantry, and collimator are angled to direct the beam from the axilla toward the supraclavicular nodes by aiming toward the suprasternal notch. The isocenter is placed at a point 3 cm to 4 cm lateral to the head of the clavicle, in the supraclavicular fossa. The field size will vary with the patient's body size, but will usually be on the order of 6 cm × 8 cm. The anterior border is set to run posteriorly to the anterior edge of the pectoralis major muscle, as determined visually and by palpation. The other borders are determined by the desired volume of treatment.

POSTERIOR AXILLARY BOOST (PAB)

Inferior: Block the field to match the superior border of the tangential fields.

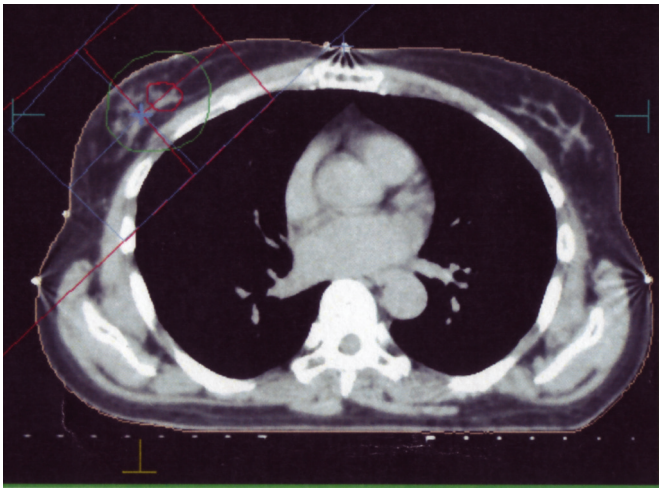
Superior: Parallel the clavicle.

Medial: 2 cm into the lung tissue medial to the chest wall.

Lateral: At the middle of the humeral head.

EN FACE INTERNAL MAMMARY FIELD

Use computed tomography simulation to plan depth and width. Blocking is needed to avoid overlap with the tangential fields used to treat the breast and lateral chest wall.



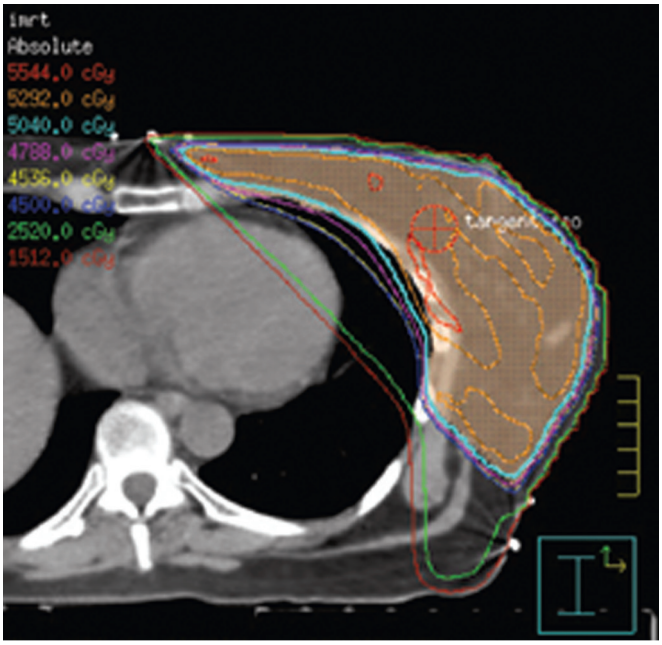


Figure 63-2 Transverse view of tangential fields without nodal irradiation. Gantry rotation is used to make the posterior field edges coplanar. (Excision cavity outlined in red, with green circle representing a 2-cm circumferential expansion.)

the field edge or block may be prudent.[359] However, patients cannot always comply with breath-holding, it does not always provide much heart sparing, or blocking cannot be used because of the location of the primary. Using additional gantry angles or helical tomotherapy may reduce heart dose (eFigure 63-5) but at the price of decreased coverage of the breast volume[360] or increased exposure of other normal tissues.[328,332,333,361,362]

Breast Boost Volume and Techniques

The optimal boost volume is unknown. In most institutions, the breast boost clinical target volume is defined by adding a 1-cm to 2-cm circumferential margins around the tumor bed, with the anterior boundary extending just below the skin and the posterior boundary at the anterior chest wall or pectoralis major muscle. The volume of the excision cavity decreases particularly within the first 1 month to 2 months after surgery and often further during RT.[363-370] There are no data whether local control or cosmetic results are changed if the boost is planned soon after surgery or just before the boost is to be given. Surgical clips help delineate the excision site compared to CT images

eFigure 63-5 Transverse dose distribution for a multiple-gantry angle intensity-modulated radiation therapy (IMRT) plan, used to reduce the heat dose. The prescribed dose was 5040 cGy in 28 fractions. Note how the 50% isodose line (2520 cGy) extends posteriorly, reflecting the use of a posterior field including the lateral portion of the breast.

alone,[371] but the volume defined by CT is generally larger than that defined solely by surgical clips.[372-374] It can be difficult to delineate the extent of the cavity on CT,[375-378] and there is no agreement on exactly what features should be included in the target volume. Variation between radiation oncologists in defining the lumpectomy site can be reduced by establishing common guidelines and training.[379,380] Nonetheless, small differences in the size or placement of the boost volume seem unlikely to have a major impact on the risk of recurrence.[381,382]

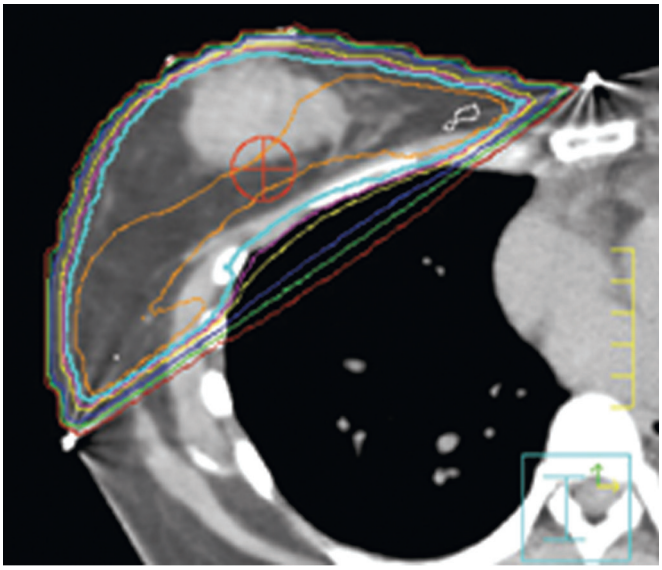

Figure 63-3 Dose distribution of tangential fields created using lung inhomogeneity corrections and forward planning, with additional medial and lateral segments added to improved homogeneity. The prescribed dose was 4500 cGy. Isodose color key: red, 30%; green, 50%; dark blue, 70%; yellow, 90%; magenta, 95%; light blue, 100%; orange, 105%; white, 109%.

Local control rates are similar with interstitial implantation, photons, or electrons, though there are conflicting data on whether their cosmetic results differ (eFigures 63-6 to 63-8).[383-388] Intraoperative photon and electron beams have also been used for this purpose.[389-392]

Supraclavicular and Axillary Nodal Irradiation

A slightly oblique anterior "third field" is generally used to treat the upper axillary and supraclavicular nodes, which are not adequately included in breast tangential fields.[393-396] Both multiple isocenter[397-401] and single isocenter[402,403] approaches have been employed to match this field to the tangents. The former use combinations of table, gantry, and collimator rotation and blocking to avoid hot spots because of field overlap or underdosing as a result of fields being too far apart (Figure 63-4). Nodal irradiation can also be given in the prone position.[404,405]

Nodal fields borders are often different at different institutions, though confusingly the same terms are used from one center to another. A *supraclavicular field* includes the level III axillary nodes, as well as the true supraclavicular nodes more medially. The inferior border is generally placed at the inferior edge of the clavicular head.[406] In most centers its lateral border is at the coracoid process or the medial border of the humeral head. A *full axillary field* (also called a *supraclavicular/axillary field*) extends the lateral border of the supraclavicular field to split the humeral head or, at some institutions, to extend laterally beyond the axillary soft tissue entirely. The superior border of these fields also varies between institutions, from the top of the first rib radiographically, to the top of the shoulder, to the superior border of the thyroid cartilage. The subclavian and axillary vessels are used as surrogates for the position of the axillary nodes in CT simulation, and the sternocleidomastoid, pectoralis minor and major, and anterior scalene muscles and the clavicle used to define the infraclavicular and supraclavicular nodal regions.[407] A block is usually placed along the transverse spinous pedicles to protect the spinal cord, larynx,

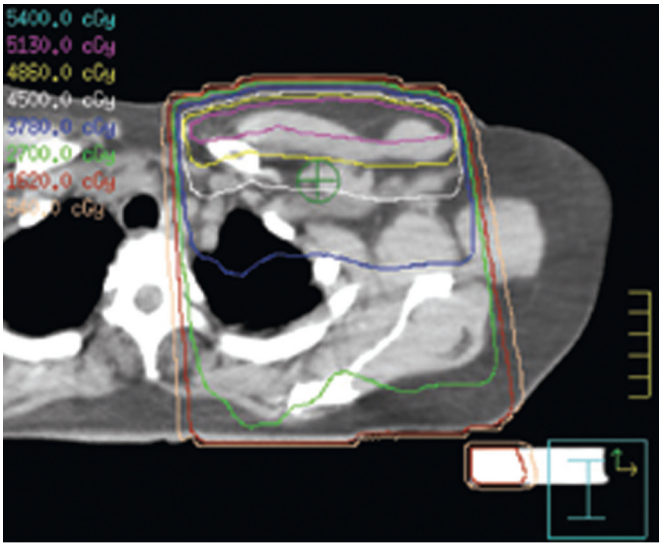

Figure 63-5 Dose distribution in a supraclavicular-axillary field, prescribed to 4500 cGy at a depth of 5 cm.

and esophagus, though some supraclavicular recurrences are close to the medial field border.[408]

Supraclavicular and full axillary field doses were traditionally prescribed to an arbitrary depth below the skin surface (3 cm and 5 cm, respectively). However, nodal depths vary substantially,[407,409-411] and CT should be used to define the prescription depth when possible (Figure 63-5). A single anterior oblique field is effective and safe for most situations. Opposed fields or three-dimensional conformal techniques may improve nodal coverage with acceptable inhomogeneity for patients with deep nodes or situations calling for doses above 45 Gy to 50 Gy.[412,413]

Internal Mammary Nodal Irradiation

The majority of IMNs lies in the first three intercostal spaces between the posterior edge of the sternum and the parietal pleura but may be as inferior as the sixth intercostal space.[414,415] The nodes themselves cannot be seen unless pathologically enlarged.[416] Their depth and location from the midline vary substantially.[411] Half to three quarters of nodes in the upper two to three intercostal spaces are located medial to the internal mammary vessels (usually visible at the sternal-pleural junction). Most (but not all) nodes in more inferior levels are lateral to the vessels.[415] However, the maximum distance of the IMNs from the vessels has not been described; hence the optimal expansions to define the clinical target volume are not known.

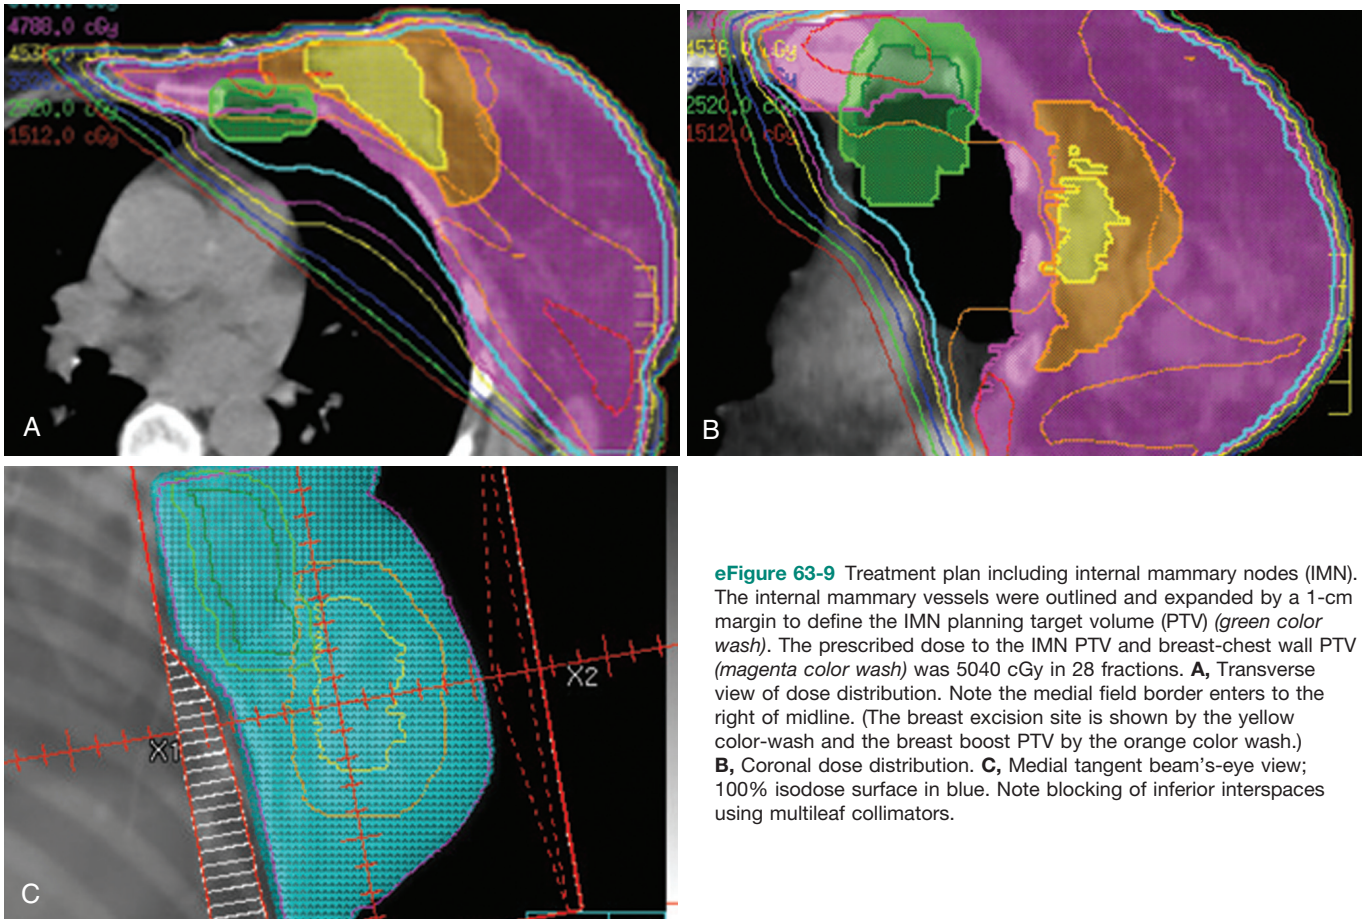
Anterior photon fields commonly used to treat the IMNs in the past increased the risk of late cardiac deaths.[417] Electron or mixed-beam direct internal-mammary fields reduce heart exposure,[418-420] but this approach requires substantial care to achieve an acceptable junction with the tangential fields. The "partially-wide tangent" technique includes the IMNs in the third interspace and above in tangential fields that cross the midline, with the inferior portions blocked posteriorly to reduce the irradiated volumes of lung and heart (eFigure 63-9).[421] However, such blocking may increase the risk of local failure for patients with inferiorly located tumors.[422] Coverage of the IMNs may be improved and normal-tissue doses reduced with IMRT.[412,423] Using protons may reduce cardiac and lung exposure even further,[424,425] but this modality is not widely available.

RADIOTHERAPY DOSE AND SCHEDULE PARAMETERS

Interval between Surgery and the Start of Radiation Therapy

Local failure rates do not increase when RT starts up to 4 months to 5 months after the last breast surgery in most,[426-432] but not all studies.[433] Prolonging the start of RT beyond this time increased failure rates for patients with close margins (1 mm or less) in one randomized trial of the sequencing of chemotherapy and RT.[434,435] The effect of the tumor-free margin width was not reported in other such randomized trials.[436-438]

Whole-Breast Fractionation



Conventions for prescribing dose to the breast or boost have varied substantially from one institution to another both in the "two-dimensional" era[439,440] and now. Hence, data on the dose-response must be interpreted with caution.

Most centers in the United States and Western Europe traditionally gave whole breast doses of 45 Gy to 50 Gy in 1.8-Gy to 2-Gy daily fractions given five times weekly.[441] Centers in the United Kingdom and Canada routinely used schemes with higher daily fraction sizes but lower total doses (for example, 40 Gy in 15 or 16 fractions over about 3 weeks). Several randomized clinical trials have compared these and other fractionation schemes.[442-450] Two are particularly important. A trial conducted from 1993 to 1996 in Canada assigned 1234 women to receive either 50 Gy in 25 fractions or 42.5 Gy in 16 fractions.[444,445,448] A boost was not given. With a median follow-up of 12 years, 10-year rates of local recurrence in the two arms were 6.7% and 6.2%, respectively. Seventy percent of patients in each arm had excellent or good global cosmetic outcome, with no difference in complication rates. The "START B" trial, conducted in the United Kingdom between 1999 and 2002, compared 50 Gy in 25 fractions to 40 Gy in 15 fractions in 2215 patients.[446,450] A boost of 10 Gy in 5 fractions was given to 43% of patients. With a median follow-up of 9.9 years, 10-year actuarial locoregional failure rates were 5.5% and 4.3% in the two arms, respectively. Cosmetic results were slightly better in the 40 Gy arm, with no difference in complication rates.[446,451] The Canadian trial found a higher local failure rate for patients with grade-3 tumors in the hypofractionated treatment arm than the prolonged arm,[448] but this was not seen in the START trials[452] or a retrospective study from British Columbia.[453] Subsequent central review of the pathology slides of patients in the Canadian trial also found grade no longer to be a factor in outcome.[453a]

Some groups have given RT once or twice weekly.[447,454-462] However, there are only limited long-term data on this approach.

Total Dose to the Primary Tumor Site and Overall Treatment Time

Four randomized trials have compared whole-breast RT alone to whole-breast RT plus a boost for patients with uninvolved margins.[463-468] Absolute differences in local control between the arms were only 2% to 3%. The largest trial, conducted by the EORTC, initially defined margin status only in relationship to the invasive component of the tumor.[466,468] A central pathology review including about one third of the entered patients (which did evaluate the margins for DCIS) found a boost benefited significantly only patients with margins wider than 2 mm, reducing the 10-year failure rate from approximately 14% to 7% when the distance to invasive disease was assessed and from about 17% to 5% when the distance to DCIS was assessed.[469] The boost also decreased local failure rates

eFigure 63-9 Treatment plan including internal mammary nodes (IMN). The internal mammary vessels were outlined and expanded by a 1-cm margin to define the IMN planning target volume (PTV) *(green color wash)*. The prescribed dose to the IMN PTV and breast-chest wall PTV *(magenta color wash)* was 5040 cGy in 28 fractions. **A,** Transverse view of dose distribution. Note the medial field border enters to the right of midline. (The breast excision site is shown by the yellow color-wash and the breast boost PTV by the orange color wash.) **B,** Coronal dose distribution. **C,** Medial tangent beam's-eye view; 100% isodose surface in blue. Note blocking of inferior interspaces using multileaf collimators.

significantly for patients with high-grade cancers or age younger than 50, but results were not described according to margin status and use of the boost simultaneously.

The EORTC trial also randomly allocated patients with positive margins to receive a boost to either 60 Gy or 76 Gy. Their 10-year local recurrence rates were 17.5% and 10.8%, respectively.[470] Thirteen percent of patients in the high-dose arm developed severe fibrosis in the boost region, compared to 3% of the control group.

A retrospective study from Istanbul, Turkey, suggested that treatment interruptions or breaks of 8 days or more significantly increased the risk of local recurrence in patients treated with whole-breast RT plus a boost.[471]

Many institutions have investigated "concurrent boost" techniques, in which IMRT is used to give a higher daily dose to the boost volume with either hypofractionated or 1.8-Gy to 2-Gy daily whole-breast doses.[472-479] Although well tolerated acutely, data on long-term efficacy and complications are limited. This approach is being evaluated by randomized trials in North America and Europe.[480,481]

Nodal Irradiation Doses

Doses of 45 Gy to 50 Gy or their hypofractionated equivalent result in a low incidence of nodal failure in patients with clinically uninvolved nodes or involved nodes following axillary dissection.[40,446,450,482,483] The dose-response relationship for control of suspiciously enlarged nodes or gross residual disease is unknown.

Conclusions

Whole-breast and nodal doses of 45 Gy to 50 Gy in 25 fractions or 40 Gy to 42 Gy in 15 to 16 fractions appear equally effective and safe for most patients, though it is not known whether some subgroups would have better results with one scheme or another. A boost dose to the excision cavity and its environs increases the local control rate modestly for patient populations as a whole. There is not consensus on which patient subgroups are most likely to benefit from a boost. When a boost is used, the total dose to the primary tumor site should be approximately 60 Gy to 65 Gy in 1.8-Gy to 2-Gy fractions or its biologic equivalent for patients with uninvolved margins. Higher doses may be appropriate for patients with involved margins, but the risk of toxicity is increased.

ACCELERATED PARTIAL-BREAST IRRADIATION

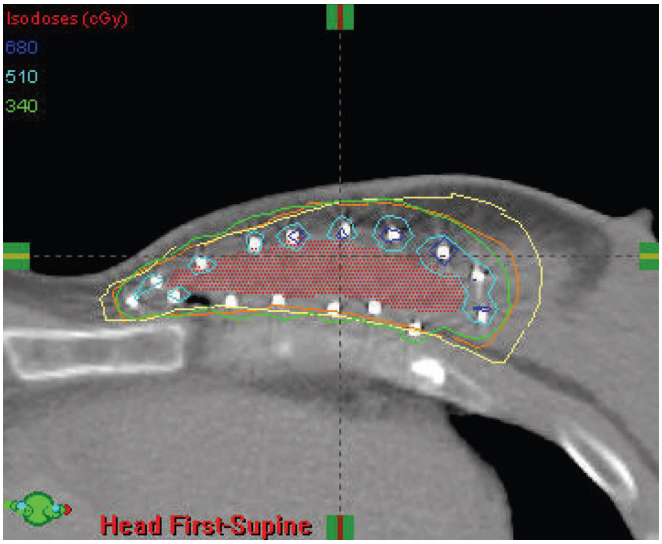
Introduction

As noted previously, occult synchronous primary cancers are rare in patients with clinically unicentric cancers. Most residual tumor cells are located within a few centimeters of the excision cavity[169] and within only 10 mm to 15 mm for those with small cancers with 1 mm to 2 mm microscopic margins.[484,485] Two thirds or more of local recurrences are at or near the site of the primary tumor, whether RT is used or not.[486] Hence, treatment of only a limited volume surrounding the tumor might be as effective as whole-breast irradiation (WBI) for many patients. This approach might reduce complications and allow treatment to be completed more quickly.[487] Techniques for "accelerated partial breast irradiation" (APBI) include: low- or high-dose rate interstitial implantation[488] (eFigure 63-10); high-dose rate brachytherapy using a balloon catheter with one or more source channels[489,490] (eFigure 63-11); permanent interstitial implantation of radioactive seeds[491] (eFigure 63-12); single-fraction intraoperative irradiation using 50 kV photons[492] (eFigure 63-13), high-energy electrons[493] (eFigure 63-14), or brachytherapy[494]; and three-dimensional conformal external-beam irradiation using photons,[495-497] mixed photons and electrons[498] (eFigure 63-15), or protons.[499,500]

Randomized Trials Comparing Whole-Breast and Accelerated Partial-Breast Irradiation

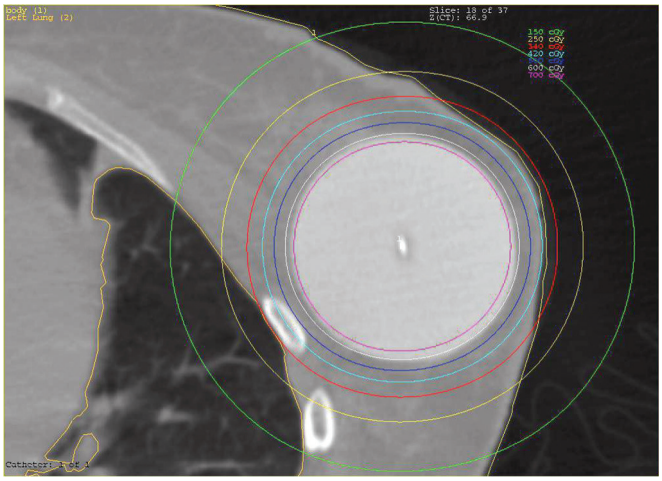
eTable 63-5 lists randomized trials comparing APBI to WBI.[501-511] Two trials did not assess microscopic margin status and used obsolete treatment techniques.[502,503] Efficacy results from three of the more recent trials have been published.

The National Institute of Oncology in Budapest, Hungary, conducted a trial from 1998 to 2004 that included 258 patients, all except one with microscopic margins 2 mm or wider.[504,505] Patients in the WBI arm received 50 Gy in 25 fractions without a boost, whereas patients in the APBI arm received either high-dose rate implantation (36.4 Gy in 7 fractions over 1.5 weeks) or (if technically unsuited for an implant) electrons (50 Gy in 25 fractions over 5 weeks). With a median follow-up of 10.2 years, the 10-year actuarial local failure rates in the two arms were 5% and 6%, respectively, with excellent or good cosmetic results in 63% and 81%, respectively.[505]



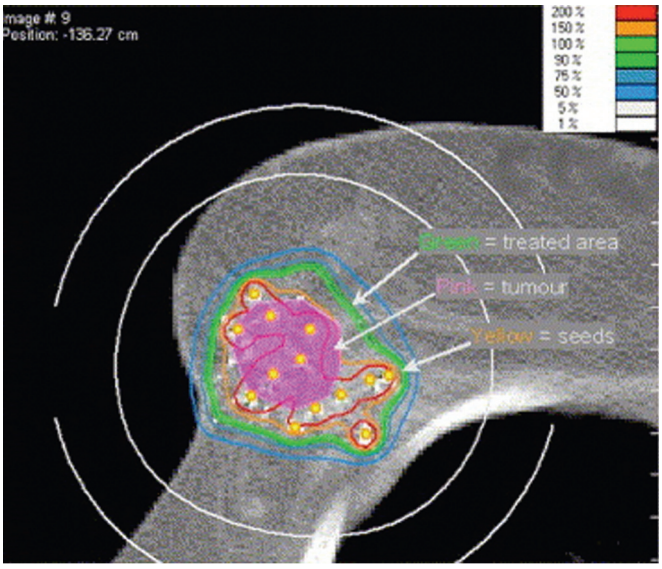
The international TARGIT-A trial randomly allocated 3451 patients from 2000 to 2012 to receive either WBI or a single dose of intraoperative radiotherapy (IORT) using an orthovoltage device delivering a dose of about 20 Gy immediately at the surface of the applicator and about 5 Gy at 1 cm.[507,508] Their 5-year local failure rates were 1.3% and 3.3%, respectively, with a median follow-up of 29 months. However, 14% of patients in the IORT arm received whole-breast irradiation because of histologic features following surgery or other reasons. Failure rates in the IORT arm were lower in patients having surgery simultaneously with IORT (2.1% at 5 years) than those having surgery, then IORT at a later date (5.4%).

The ELIOT trial, performed at the European Institute of Oncology in Milan, Italy, from 2000 to 2007, randomly allocated 1305 patients to receive WBI plus a boost or IORT using megavoltage electrons to give 21 Gy to the tumor bed. Their 5-year breast recurrence rates were 0.4% and 4.4%, respectively, with median follow-up of 5.8 years.[506] Patients with tumors larger than 2 cm, four or more positive nodes, ER-negative tumors, and triple-negative tumors had local failure rates of more than 10% after IORT.



None of these trials showed differences between the arms in OS or breast cancer-specific mortality. However, cosmetic results were worse with external-beam APBI than for WBI in the Canadian RAPID trial[512] but better in the IORT arm of the TARGIT-A trials.[508] Most toxicities were lower in the IORT arm of the ELIOT trial than in the conventional arm, but the rate of fat necrosis was higher.[506]

Results of Nonrandomized Studies and Correlates of Local Recurrence



Local failure rates in most nonrandomized studies of APBI with median follow-up of 5 years or more were comparable to those achieved with WBI (eTable 63-6).[513-529] Several early series had much higher failure rates,[513,514,517] likely as of the result of different patient selection criteria and treatment technique. Several studies had higher local failure rates for women younger than age 50 than for older patients.[524,530,531] Patients with infiltrating ductal carcinomas and infiltrating lobular tumors had the same recurrence rates in the German-Austrian trial.[524] Several[528,529] but not all studies[532] found having a triple-negative or an ER-negative tumor was a significant risk factor. A tumor-free margin width of less than 2 mm appears

associated with a high risk of local failure.[528,533-535] The Radiation Therapy Oncology Group (RTOG) 96-17 trial found a local failure rate of 14% (4 of 29) among patients not receiving systemic therapy, compared to 3% (2 of 70) among those who did.[522]

It is likely that combinations of features will predict more for local failure than any single factor. However, one scheme created by a consensus panel[536] has not generally been found to predict strongly for relapse.[527,531,537,538]

Conclusions

The optimal pretreatment evaluation, selection criteria, technical parameters, and choice between different modalities for APBI are not known. At present, I limit such treatment to patients age 50 or older with 2-cm or smaller grade-1 to grade-2 ER-positive invasive cancers or DCIS with microscopic margins 2 mm or wider, with negative axillary nodes if invasive.

ACUTE AND CHRONIC COMPLICATIONS AND COSMETIC RESULTS

Acute Reactions and Their Management

Two randomized trials found washing with soap and water reduced the severity of skin reactions, compared to not washing or using water alone.[539,540] Several trials showed no differences in reactions between patients using different skin care products compared to each other or when no products were applied.[541-545] One double-blinded trial suggested a cream containing hyaluronic acid was more effective in preventing severe skin reactions than one containing only the base.[546] Several trials found that applying a potent steroid cream from the beginning of treatment decreased the intensity of acute skin reactions.[547-549] However, there were no data whether this increased the risk of folliculitis or caused long-term skin changes. A randomized trial showed no difference in skin reactions whether aluminum-based antiperspirants were used during treatment or not.[550]

Moisturizers can substantially reduce itching and irritation once they occur. Applying these before RT does not appreciably increase the skin dose[551]; hence, patients may use such products whenever and as often as needed. Folliculitis can be treated successfully with chlorhexidine gluconate or other antibacterial soaps.

About 10% to 15% of patients develop moist desquamation (usually in the axilla or inframammary fold) during or shortly after completion of RT[434]; the rate may be 50% or higher for patients receiving concurrent chemoradiotherapy.[552] Such reactions are more common in large-breasted women, even with three-dimensional compensation.[69,553] Patients with only limited areas of moist desquamation can often continue RT without interruption; if necessary, treatment can often temporarily switch from tangential fields to the boost field. Reepithelialization need not be complete for RT to resume; hence, treatment breaks of more than 1 week are rarely necessary. Antibacterial soaps, moisturizers, and nonadherent dressings are helpful in reducing symptoms. In a randomized trial performed in Scotland, patients with moist desquamation took longer to heal when a hydrogel dressing was used than when a dry dressing was applied.[544]

Mild fatigue is common during RT. A prospective study in Munich, Germany, did not find any factors correlated with its development or severity.[554] A study in Newcastle, Australia, found that a higher baseline fatigue level and higher baseline neutrophil and red cell counts were predisposing factors.[555] Although fatigue usually resolves within 2 months following completion of RT, a prospective study in Caen, France, found some patients still reported fatigue 1 year later, which correlated with being depressed at initial evaluation.[556]

Myelosuppression of clinical significance is extremely unusual, and hence blood counts do not need to be routinely checked.

Postoperative cellulitis or abscess should be dealt with before RT is started if possible. If RT has started, antibiotics or surgical consultation should be initiated promptly, but it is probably not necessary to interrupt RT unless abscess drainage is required.

Subacute and Chronic Complications

Skin, Soft Tissue, and Bone

Skin thickening is common after BCT.[557] Hyperpigmentation may persist in some patients, particularly darker-skinned ones. Patients may develop telangiectasias years later. Rarely, patients develop postirradiation morphea or circumscribed scleroderma weeks to years following RT,[558-560] with patches of white or yellowish well-circumscribed sclerosis and induration (sometimes surrounded by a more highly pigmented, bruise-like area or preceded by erythema). Patients may develop a skin "radiation recall" reaction when chemotherapy (particularly doxorubicin) is given following RT (Figure 63-6). However, this is rare when chemotherapy begins more than 2 weeks after the completion of RT.[552]

Breast abscesses or cellulitis develop in 5% to 10% of patients at any time after surgery.[561,562] Cellulitis may be more frequent in patients with hematomas or seromas requiring drainage, large volumes of resected breast tissue, or breast edema.[563,564] Sometimes cellulitis or abscesses mimics an inflammatory-type recurrence,[561,565] although the presence of pain, possible systemic symptoms of infection, and the time-course of development usually make the distinction clear. Removing large volumes of breast tissue following RT is associated with a high risk of complications.[566]

Breast fibrosis can evolve over 5 years or more after treatment.[388,448,450] It is generally mild, but when severe can impair the cosmetic results. Some patients with severe fibrosis respond to treatment with pentoxifylline alone or in combination with vitamin E.[567,568] Other therapies, such as hyperbaric oxygen, have been inadequately tested.[569]

Soft-tissue necrosis is quite rare, even with outmoded RT techniques.[570] Some individuals develop fat necrosis, which typically causes a painful or painless mass, sometimes accompanied by thickening or retraction or dimpling of the overlying skin.[571,572] Mammography usually reveals a spiculated,

Figure 63-6 Moist desquamation in electron boost field after completion of radiotherapy. Such reactions are uncomfortable but rarely become infected.

often poorly defined mass that may contain punctate or large, irregular calcifications. Cystic degeneration may eventually result in a cavity that contains oily fluid or necrotic fat.

Milk production is substantially reduced after irradiation.[573,574] Nonetheless, a few patients have reported breastfeeding to a limited extent from the treated side.

Patients commonly have intermittent transient breast pain even decades after treatment, which can be sharp and shooting or dull and aching, usually lasting a few seconds or minutes though rarely longer. Younger patients seem more likely to experience pain than older individuals.[575,576] Patients treated with RT had more breast discomfort initially than those allocated not to receive RT in a randomized trial, but with further follow-up the degree of discomfort became equal in both groups.[577] Pain is generally mild or moderate, but for some it is sufficiently bothersome to require medication.[575]

The risk of rib fractures is related to the treatment energy and the total dose.[570] Its incidence should be less than 1% with current techniques.[578]

Arm Edema and Shoulder and Arm Function

Arm edema usually develops in the first 3 years after treatment.[579,580] About half of patients with mild edema will develop greater edema with time.[581] Symptomatic edema occurs in about 5% to 10% of patients treated with either SNB, levels I to II AxD, or RT alone; these cases are usually mild.[582] The incidence and severity of arm edema are substantially increased following a complete AxD,[42] especially when full axillary RT is also given.[583-585] However, full axillary RT does not increase the risk of arm edema for patients having limited surgery.[583-586] Arm edema rates were not increased in most retrospective studies by supraclavicular RT, even for patients having complete AxD,[587-590] though in other studies it has.[591-593] In the randomized MA.20 trial, supraclavicular RT increased the 5-year incidence of grade-2 or higher lymphedema from 4% to 7%.[302] A posterior axillary boost increases the risk of arm edema.[590,592,594-596]

Arm edema may cause psychological and functional morbidity, as well as predisposing patients to cellulitis. The risk of arm edema does not seem to be reduced by prophylactic manual lymphatic massage.[597] There is no agreement on a threshold to start treatment.[598] A meta-analysis of randomized trials suggested that manual lymphatic massage has some benefit in addition to compression bandaging.[599]

Axillary RT may cause changes in shoulder mobility or arm functioning.[600] These are rare in patients treated with doses of 50 Gy or less in 1.8-Gy to 2-Gy fractions or its equivalent.

Neurologic Injuries

The intercostal brachial nerve syndrome is characterized by fairly constant paresthesias and dull, aching, or burning pain of the upper arm, shoulder, and axilla, and occasionally of the more anterior chest wall. This syndrome may be permanent. Occasional patients respond to nerve blocks or topical measures.[601,602] Injury of the thoraco-dorsal, long thoracic, and pectoral nerves resulting in motor weakness is rare now.

Classic RT brachial plexopathy is a chronic, progressive syndrome whose onset can occur from as soon as 3 months to as long as 26 years after RT.[603] Patients usually present with sensory or motor symptoms in the ipsilateral limb. Pain can occur but is generally not prominent. A second, rarer type of radiation plexopathy appears more rapidly and usually resolves spontaneously.[604] The incidence of brachial plexopathy is 0% to 5% in patients receiving doses to the plexus of 50 Gy to 54 Gy in 1.8-Gy to 2-Gy fractions or 40 Gy to 45 Gy in fractions of 2.5 Gy to 3 Gy.[603] A pilot study combining pentoxifylline, vitamin E, and clodronate showed promise in treating patients with RT-induced lumbosacral radiculopathy.[605]

The presence of severe pain and an enhancing mass on MRI are the most helpful findings in distinguishing between radiation-induced and malignant brachial plexopathy.[606-609] Abnormal uptake of 18-fluorodeoxyglucose on positron emission tomography generally indicates malignancy.[610]

Pulmonary Effects

Radiographic infiltrates and localized interstitial fibrosis are common after RT.[611] These generally stabilize by 12 months after treatment, although some may resolve, and some may progress for 5 years or longer.[612,613] Patients' exercise tolerance or ability to engage in activities is very rarely affected.

Clinical radiation pneumonitis is characterized by nonproductive cough, fever, and nonspecific infiltrates inside the treatment fields.[611] It generally appears from 4 months to 9 months after completion of RT. Rarely, RT appears to precipitate a more generalized syndrome, bronchiolitis obliterans organizing pneumonia.[614,615] Either type of pneumonitis is rare in patients treated to the breast alone.[616-618] It occurs in fewer than 5% of patients treated with a third nodal field when the average lung distance is 3 cm or less.[618] Radiation pneumonitis has also been reported following external-beam APBI, which exposed large volumes of the ipsilateral lung to relatively low doses.[619] There are conflicting data on whether the risk of pneumonitis is increased by chemotherapy (particularly when given concurrently with RT)[552] or tamoxifen.[167,620] Prolonged courses of steroids are often needed to treat pneumonitis when symptoms are severe.

Cardiovascular Complications

RT may cause heart damage.[621-624] Acute and subacute complications, such as pericarditis, are rare.[570] The exact degree of long-term cardiac risk is uncertain. Such toxicity appears mainly as a result of coronary artery disease[625] and may have a latency period of 10 years or more. Early development of perfusion abnormalities on radionuclide imaging has not yet been shown to predict the long-term risk of clinical heart disease.[626] Meta-analyses and registry-based studies, which included patients treated mainly with outmoded techniques of RT or large daily fraction sizes, found increased mortality rates.[417,627-629] One such study suggested the risk was related to the estimated mean heart dose.[630] Other registry studies did not find such an effect or found substantial effects only for patients irradiated before about 1980 to 1985.[631-633] Several single-institution studies using modern RT techniques did not show increased cardiac morbidity or mortality at median follow-up times of 10 years to 20 years after RT,[634-638] although others have.[639,640]

Risk factors for cardiac complications of RT are not well understood. Preexisting ischemic heart disease was a risk factor in a study from Sweden and Denmark.[629] A study from the University of Pennsylvania found a statistically significant interaction between hypertension and left-breast irradiation in the development of coronary artery disease.[639] However, a study from Amsterdam and Rotterdam found that smoking was the only significant factor.[641] Of note, excess cardiac events in this study occurred in patients treated with postmastectomy RT (which generally included the IMNs) but not patients treated with BCT (which included only the breast). The volume of heart irradiated in the tangential fields was not a risk factor in another study from the Netherlands, with median follow-up 16 years.[640] Cardiac risk is similar between regimens using fraction sizes of 1.8 Gy to 2 Gy and those using fractions of 2.5 Gy to 3 Gy[642] but may be increased with fractions larger than 3 Gy.[643]

Anthracycline cardiac toxicity after commonly used drug doses is not increased by RT.[578,644-647] There is no evidence yet for a deleterious cardiac interaction between breast RT and

trastuzumab, but follow-up of these patients is still short.[648,649] It is uncertain whether irradiating the IMNs will increase this risk.[650,651]

Giving prophylactic RT to the supraclavicular nodes does not appear to increase the risk of stroke.[642,652-654]

Carcinogenesis

Patients age 40 years to 45 years or younger at initial diagnosis have a small increased risk of developing new contralateral primary cancers as a result of RT.[655-657] The relative risk was 1.21 at a dose of 1 Gy in a study using the Connecticut Tumor Registry.[655] Modern techniques result in contralateral breast doses of 0.5 Gy or less when physical wedges are not used.[658]

Most cancers developing within the RT fields are soft-tissue sarcomas or angiosarcomas. These may appear as soon as 1 year to 2 years after treatment but tend to occur after 8 years to 10 years or longer.[659-661] The excess incidence of soft-tissue sarcomas is 9 cases to 14 cases per 100,000 patient-years observation.[662-665] The excess incidence of angiosarcomas in patients treated with BCT is 5 cases to 13 cases per 10,000 treated patients.[659,665-667] Treatment outcomes are poor.[665,668-671]

Lung cancers following RT given for breast cancer are almost entirely limited to current or former smokers.[672-674] Postmastectomy RT was associated with an estimated excess of 7 to 8 cases per 10,000 women who survived more than 10 years from diagnosis in one study,[675] but studies following BCT found no increased risk,[676,677] perhaps because of the smaller irradiated lung volume. Esophageal cancer rates increased after RT in some studies,[678,679] which likely reflect direct exposure from en face supraclavicular and IMN fields.[680]

Radiation-induced leukemia is rare in patients not receiving chemotherapy.[578] Leukemia risk may be increased by 0.3% to 0.5% by RT in patients who receive standard-dose chemotherapy.[681,682]

Lymphangiosarcoma of the arm (or Stewart-Treves syndrome) is an extremely rare complication in patients developing arm edema.[683]

Cosmetic Results

Cosmetic results may evolve for more than 5 years from treatment.[388,448,450] Outcomes have improved over time as a result of changes in surgical and RT techniques (Figure 63-7). The great majority of patients treated now have acceptable results. There is no "standard" for describing cosmesis. Schemes for objectively measuring changes in breast size, shape, fibrosis, or contour have been devised,[388,684-686] but these are not widely used. They also may not capture skin changes and other significant sequelae. Patients tend to have more favorable views of cosmetic outcome than do physicians.[687,688]

Surgery is the most important factor affecting cosmetic outcome.[383,387] Radiation-induced fibrosis can lead to breast retraction and increased tissue firmness. Greater breast size has been associated with increased retraction after BCT (eFigure 63-16).[70,689-691] This problem can be at least partially overcome by the use of higher photon energies[71] and the prone or lateral decubitus position, or sometimes having breast reduction surgery at the time of tumor excision.[39] Doses to the entire breast much above 50 Gy in 2-Gy fractions seem to worsen results,[692] as do large fraction sizes when doses above 45 Gy are given.[693] Giving a breast boost worsens cosmetic results modestly because of fibrosis and skin changes such as telangiectasias.[388,468] The use of a hockey-stick field or other techniques resulting in imperfectly matched field edges can cause substantial fibrosis and skin changes at areas of overlap (eFigure 63-16).

Figure 63-7 This patient was treated for right breast cancer in 1974 and left breast cancer in 1991; the photograph was taken 2 years after the last treatment. The right side was treated using a 4-MV linear accelerator to a dose of 46.8 Gy to the breast and regional nodes, followed by an electron boost. The left side was treated on a 6-MV accelerator, giving 45 Gy to the breast only followed by an electron boost. On the right, she has substantial fibrosis and retraction of the breast superiorly, a hyperpigmented and fibrotic ridge superiorly as a result of match-line overlap between the tangential and supraclavicular/axillary fields, and substantial telangiectasias in the electron-boost field. In contrast, the cosmetic result on the left is good, with an easily visible surgical scar in the upper outer quadrant but few other changes. In later follow-up (February 1997), telangiectasias began to appear in the left-sided electron boost field also *(not shown)*.

Cosmetic results are similar whether chemotherapy is given before or after RT.[434] Cosmetic results tend to be inferior in patients receiving concurrent chemotherapy and RT compared to sequential regimens, although not all studies agree on this point.[552] Overall cosmetic results appear little affected by endocrine therapy or its sequencing with RT.[167,694-696]

Patients with poor cosmetic results can sometimes benefit from surgical correction.[38] However, such surgery can cause complications.

PATIENT FOLLOW-UP

Follow-up Visits and Testing

The major goal of surveillance following BCT is to detect ipsilateral local or regional recurrences and new ipsilateral or contralateral primary tumors sufficiently early to prevent the development of distant metastases. Imaging studies of other organs and serum tumor markers should not be routinely performed in asymptomatic patients.[697]

Patients commonly have an interval history and physical examination every 3 months to 4 months for the first several years after treatment and then every 6 months to 12 months indefinitely. However, there are no data showing this schedule to be superior to others. Randomized trials in Britain and Canada in patients with low risks of ipsilateral and contralateral breast cancer development found that follow-up by primary care physicians or telephone follow-up by nurses resulted in equal overall outcome as in-person follow-up by specialists.[698-700]

The optimal frequency of mammograms after BCT is not known. It is rare to find recurrence within the first year after treatment.[701] Some physicians recommend unilateral mammograms every 6 months for as long as 5 years after treatment.[702] However, there are no randomized trials on this issue, and most retrospective studies have not found a benefit to this approach.[703,704] A study at the Netherlands Cancer Institute in

eFigure 63-16 Example of a poor cosmetic result in a patient with large breasts as a result of excessive fibrosis and retraction. Note also the hyperpigmented and fibrotic ridges seen at the medial and superior borders of the left breast because of overlap between a hockey-stick field and breast tangential fields.

Amsterdam found no difference in rates of finding impalpable contralateral breast cancers or tumor stage whether mammograms were performed annually or every 2 years.[705]

MRI is more sensitive than other imaging modalities.[706-708] However, the low risk of recurrences or contralateral new primaries and high salvage rates imply that indiscriminate use of follow-up MRI will have little, if any, impact on OS.[709-711] Its use might be more beneficial for women age 40 years or younger at initial diagnosis.[712,713]

Presentation of Local Recurrence

Most local failures in the first 5 years to 10 years after initial therapy are in or near the tumor bed. A larger proportion occurs in other quadrants with longer follow-up.[193,714-719] This pattern suggests that "relapses" can be the result of either regrowth of tumor cells left following initial therapy or to new, unrelated primary tumors developing later. Location alone is not sufficient to distinguish between these two possibilities, as shown by molecular profiles.[720,721]

Roughly one third to one half of local recurrences in older studies were detected solely by mammography, with the rest divided nearly equally between those found on physical examination without radiologic signs and those detected both by both.[722] In more recent studies a higher proportion of recurrences were detected only with mammography.[723,724] The physical and radiologic characteristics of the recurrence differ from those of the original presentation in a substantial proportion of patients.[725] Hence, patients presenting with radiologically occult primaries should be followed with mammography as well as physical examination, and vice-versa.

Physical examination following treatment usually shows only mild thickening without a mass effect. However, either surgery or RT may cause masslike fibrosis that may occasionally be difficult to distinguish from a local recurrence. Changes that occur more than 1 year to 2 years following the completion of RT can be the result of benign causes (e.g., fat necrosis) but must generally be viewed suspiciously. Recurrences may be especially difficult to detect for patients with infiltrating lobular carcinomas, which often produce only minimal thickening or retraction at the biopsy site without a mass. In rare patients, the only sign of recurrence may be diffuse breast retraction. Recurrence in the nipple alone, presenting as Paget's disease, seem rare.

Mammographic changes may take 2 years to 3 years to reach their final state.[726] There is substantial overlap in appearance between benign and malignant lesions.[727] Microcalcifications that develop in a quadrant different from the initial tumor have a high likelihood of being malignant.[728] Recurrences of infiltrating lobular carcinomas are particularly likely to be radiographically occult.

Differential Diagnosis and Further Evaluation

The most common benign cause of suspected recurrence is probably fat necrosis. Biopsy is often required to confirm the clinical impression. Sarcomas are fortunately rare in this patient population but must be kept in mind.

Ultrasound may sometimes be helpful in distinguishing benign and malignant lesions. Significant early contrast enhancement with gadolinium is seen on MRI in nearly all patients with recurrent cancer but can also occur with fat necrosis and fibrosis.[729,730] However, in general negative imaging studies should not prevent early fine-needle aspiration cytology or core biopsy of ambiguous or clinically worrisome lesions.

It is sometimes difficult to distinguish between radiation-induced cellular atypia and malignancy, even on open biopsies.[731] In turn, a negative minimally invasive biopsy should not stop further pursuit of a suspicious lesion.[732]

TREATMENT OF LOCOREGIONAL FAILURE

Five percent to 10% of patients with a recurrence in the treated breast present with concurrent distant metastases.[733,734] Positron emission tomography with FDG may find more sites than CT and bone scan.[735] A similar proportion of patients will have either locally extensive recurrences or concomitant inoperable regional nodal recurrences that preclude surgery. It is rare that axillary exploration finds nodal tissue in patients who have had prior dissection,[736] and hence redissection or SNB does not seem warranted in the absence of suspicious adenopathy. Repeat SNB is feasible for those who have only had SNB before.[737] Aberrant lymphatic drainage is common in patients who had prior AxD or SNB.[737-739]

Five-year relapse-free survival rates after salvage mastectomy for patients with an isolated operable breast relapse are 60% to 80%, with OS and cause-specific survival rates of 80% to 85%.[733] Ten-year rates are about 20% lower. Postoperative complications are rare. Chest-wall recurrence occurs in 10% or fewer patients following salvage mastectomy; most such patients will develop progressive local disease despite further treatment. The ultimate risk of distant relapse following local failure appears similar after either initial treatment with CS alone or CS and RT.[740]

Several factors correlate with outcome after salvage mastectomy. Subsequent failures are rare in patients with noninvasive recurrences but occur in 30% to 50% of patients with invasive cancers.[741-744] Patients with smaller invasive recurrence have better outcome than patients with larger tumors or diffuse recurrences.[745] Lymphovascular invasion, high tumor proliferation rate, and triple-negative receptor phenotype at the time of recurrence are also associated with a worse outcome.[746-748] Patients with multiple adverse factors do worse than those with none or one.[748] Patients who recur in the skin alone or with an inflammatory-type picture have a poor prognosis.[745,749,750] The longer the time to failure after initial therapy, the better the prognosis, although this has not been true for all series.[745] Patients with likely new primaries rather than a true recurrence may also do better.[751]

Numerous studies have used further CS with or without additional RT in patients with a local failure after initial CS and RT.[752,753] Overall outcome has generally been comparable or superior to that for patients treated with mastectomy, but this approach has usually been used predominantly for smaller, more favorable tumors.[754] Second local failure rates have been 20% to 30% in most studies,[755,756] though some have lower rates.[757] Many groups have given localized RT following excision with variable results, although the risk of serious complications appears low.[472,758-766] A European trial found a 5-year second local failure rate of 6% in 217 patients treated with lumpectomy and brachytherapy, with median follow-up of 3.9 years.[766] High histologic grade was the only significant risk factor on their multivariate analysis, though age 55 years or younger and negative hormone receptors were also significant on univariate analysis. A study at the European Institute of Oncology of 161 patients found the 5-year second local failure rate was still 15% for their "favorable" group (patients with a tumor 2 cm or smaller relapsing more than 4 years after initial treatment).[756] A study from Osaka, Japan, found a much lower rate of second breast relapses in patients with ER-positive tumors (12%), compared to patients with ER-negative tumors (45%),[765] but this was not found in the Milan study (27% and 30%, respectively).[756]

Breast-conserving salvage therapy has been performed in 30% to 70% of patients initially treated with CS alone.[223,226,228,767] In a series from Women's College Hospital, Toronto, the 5-year actuarial second local recurrence rate was 69% for patients treated with further BCS alone and 11% for 14 patients treated with BCS and RT.[768]

An international randomized trial found chemotherapy benefitted patients with ER-negative tumors but not those with ER- or PR-positive ones following isolated local or regional recurrence after either BCT or mastectomy.[769,770] However, results were not stratified by the initial surgery and type of recurrence.

About half of patients with isolated axillary recurrences can be cured by surgery or additional RT. However, few if any patients with supraclavicular or internal mammary nodal recurrences are long-term survivors.[166,722,771-774]

CONCLUSIONS

BCT provides highly satisfactory cosmetic results without compromise of local tumor control or survival for the great majority of patients with early-stage breast cancer. This approach has been one of the great success stories of modern oncology. Cooperation between surgeons, radiologists, pathologists, medical oncologists, and radiation oncologists is critical in achieving this goal.

CHAPTER

64 Breast Cancer: Postmastectomy Radiation, Locally Advanced Disease, and Inflammatory Breast Cancer

Benjamin D. Smith

INCIDENCE

Locally advanced breast cancer accounts for approximately 12% to 15% of invasive breast cancers diagnosed in the United States, with an age-adjusted incidence of approximately 16 cases per 100,000 women per year.

BIOLOGIC CHARACTERISTICS

Locally advanced breast cancer represents a heterogeneous collection of disease. Some are neglected primaries that have slowly progressed to an advanced stage whereas others result from rapid disease growth as a result of an aggressive biology. Neglected primaries are more common in unscreened patients and are characteristically low to intermediate nuclear grade cancers that are hormone receptor–positive and HER2/neu-negative. In contrast, locally advanced breast cancers diagnosed between screening intervals or shortly after the first sign or symptom of the disease commonly have high-grade and high-proliferative indices. These cancers are commonly estrogen and progesterone receptor–negative and may have amplification of HER2/neu. Inflammatory breast cancer is the most aggressive subgroup of locally advanced breast cancer presenting with rapid disease growth and involvement of the dermal lymphatics. Inflammatory breast cancer has a high propensity for metastatic spread and carries a relatively poor prognosis.

STAGING EVALUATION

All patients with locally advanced breast cancer should undergo a history and physical examination, diagnostic mammography, and serum studies. To evaluate extent of locoregional disease, imaging modalities such as chest computed tomography (CT), breast magnetic resonance imaging (MRI), or ultrasound are often helpful, with ultrasound identifying clinically relevant extraaxillary adenopathy in 37% of patients. Screening for distant metastasis should be conducted using either a combination of chest and abdomen CT plus bone scan or fluorodeoxyglucose-positron emission tomography (FDG-PET)/CT.

THERAPY

Locally advanced breast cancer requires multimodality treatment that includes multiagent chemotherapy, surgery, radiation therapy, and endocrine therapy when indicated. Neoadjuvant chemotherapy plays an important role in shrinking initially unresectable disease so that it becomes resectable. In addition, neoadjuvant chemotherapy may allow carefully selected patients to undergo breast-conserving surgery. After chemotherapy and surgery, all patients with locally advanced breast cancer should receive radiation to the breast or chest wall and the undissected regional lymph node basins (axillary apex, supraclavicular, and, in general, internal mammary). Patients with ER+ disease should also receive tamoxifen or an aromatase inhibitor for a minimum of 5 years. All patients with HER2/neu-positive disease should receive trastuzumab.

RESULTS

The outcome for patients with locally advanced breast cancer has significantly improved over the past two decades, with overall 5-year survival of 70% in the general population of patients with tumors >5 cm or four or more involved nodes. Long-term locoregional recurrence rates after surgery and radiation therapy for patients with locally advanced disease range from 10% to 25%, depending on the particular features of the disease.

INTRODUCTION

There is no single accepted definition of locally advanced breast cancer. The term is most often used to refer to a patient with clinical stage III breast cancer (see Staging) whose disease is unresectable at the time of diagnosis because of extension of the primary tumor to the skin or chest wall or extensive regional lymph node metastases. However, patients with resectable disease that is either large (>5 cm) or involves four or more axillary nodes are often also included in the definition of "locally advanced." This chapter will draw the distinction between locally advanced breast cancer that is unresectable at diagnosis and that which is resectable. It will also discuss postmastectomy radiation therapy (PMRT), including considerations of PMRT for patients with stage II disease that is not locally advanced.

Locally advanced breast cancer was once considered a fatal disease. Before the routine use of chemotherapy, the vast majority of patients developed distant metastases and died.[1-3] In the past, locoregional treatments such as mastectomy alone, radiation therapy alone, or combined surgery and radiation therapy were used, but outcomes were generally poor.[1-3] Fortunately, with integration of chemotherapy and endocrine therapy with appropriate surgery and radiation therapy, locoregional control, distant disease-free survival, and overall survival have improved substantially.[4,5] This improvement in

distant disease-free survival has also heightened the survival benefit of radiation conferred by achieving locoregional control.[6] Accordingly, care for locally advanced breast cancer requires careful coordination of a multidisciplinary team of specialists to achieve optimal results.

EPIDEMIOLOGY

With introduction of screening programs, a modest reduction in the incidence of locally advanced breast cancer was noted through the 1980s and 1990s.[7] It is not entirely clear whether the incidence has continued to decline in the 2000s. Estimates provided by the American Cancer Society indicate that the incidence of regional stage breast cancer in white women decreased by approximately 1.6% per year between 2006 and 2010, whereas incidence remained stable in black women.[8] However, analysis of Surveillance, Epidemiology, and End Results (SEER) data indicates that the incidence of locally advanced breast cancer (defined as size >5 cm or four of more involved lymph nodes, and no distant disease) was stable between 2004 and 2010, with an age-adjusted incidence of approximately 16 cases per 100,000. SEER data further indicate that locally advanced breast cancer accounts for approximately 12% to 15% of all invasive breast cancers.

There are still subgroups of patients in the United States for whom locally advanced breast cancer remains an epidemiological problem. For example, the incidence of tumors greater than 5 cm is approximately 40% higher in African American women than white women.[8] There are many possible reasons for the higher incidence of locally advanced breast cancer in African Americans, including decreased access to medical care, less use of screening mammography, and biological differences in the cancer. Specifically, breast cancers in African American women tend to be of higher grade and more often lack estrogen receptors (ERs) compared to white women.[9,10] In the developing world, approximately half of patients present with locally advanced disease.[11,12]

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

Locally advanced breast cancer can result either from rapid disease growth with early spread to the lymphatics or from a delay in diagnosis. A thorough patient history and physical examination combined with an assessment of the tumor's biological features can help to distinguish these two categories. Typically, rapid disease growth occurs in the setting of high-grade tumors with high proliferative indices; such tumors are more likely to be ER–negative disease or overexpress HER2/neu. These tumors may develop during the interval between screening mammograms. In contrast, a high percentage of locally advanced breast cancers are of low or intermediate grade and are hormone receptor–positive. Oftentimes, such patients have not undergone screening and may present for medical care months after their first breast symptom.

Inflammatory breast cancer, a subcategory of locally advanced disease, has a unique clinical presentation and biological traits. The diagnosis of inflammatory carcinoma is made on the basis of the clinical history and physical examination findings. The clinical history of a patient with inflammatory breast cancer should include a description of breast erythema, warmth, and heaviness that have a relatively rapid onset and progression (typically progress over a period of 3 months or less). On physical examination, brawny edema of the breast is present, which may or may not be associated with a breast mass. It is important to distinguish inflammatory breast cancers from neglected breast primaries that slowly progress over many months to up to a year. Neglected locally advanced cancers typically present as a large breast mass or advanced adenopathy resulting in secondary inflammatory changes in the breast that may mimic those of inflammatory breast cancer.

Histopathologically, inflammatory breast cancer is most commonly characterized by high histological grade, a high percentage of cells in the S phase, aneuploidy, absent ER expression, and high expression of *p53* and epidermal growth factor.[13] Some authors have found that HER2/neu is not more commonly overexpressed in inflammatory breast cancer than in noninflammatory advanced disease,[13,14] although more recent studies have reported higher rates of HER2/neu overexpression.[15] The potential higher rate of both HER2/neu and epidermal growth factor receptor has permitted new opportunities for clinical trials investigating targeting these tyrosine kinase receptors.

One of the pathological hallmarks of inflammatory breast cancer is invasion into the dermal lymphatics and erythema of the skin, which may in part be representative of tumor angiogenesis. Shirakawa et al found inflammatory breast cancer xenografts to have a particular pattern of neovascular growth, in which blood vessels within cancer tissue did not have a lining of endothelial cells.[16] In addition, human inflammatory breast cancer specimens have been noted to have a higher microvessel density pattern compared to noninflammatory breast cancer.[17,18]

The most important advance in understanding the underlying biology of breast cancer, including locally advanced disease, is the growing appreciation of the importance of molecular subtype as a tool to predict benefit from targeted therapies such as endocrine therapy or trastuzumab and to prognosticate outcomes. As initially described by Perou et al, breast cancers may be broadly classified into four categories: Luminal A (classically ER positive, HER2/neu negative), Luminal B (classically ER+, HER2/neu positive), HER2-enriched (classically ER-, HER2/neu positive), and basal-like (classically ER-, HER2/neu negative).[19,20] In patients with locally advanced breast cancer treated with mastectomy and radiation, these categories predict likelihood of locoregional control, with basal-like and HER2-enriched tumors experiencing the highest risk of locoregional recurrence and luminal A/B tumors experiencing the lowest risks.[21-23]

PATHOLOGY AND PATHWAYS OF SPREAD

The majority of locally advanced breast cancers demonstrate invasive ductal histology. Invasive lobular histology may also be seen, particularly because tumors of this histology may progress to a large size before becoming clinically or radiographically apparent. Favorable breast cancer histologies such as tubular, medullary, or mucinous rarely present with locally advanced disease.

The pathways of spread of locally advanced breast cancer are most commonly through the regional lymphatics. Involvement of the axillary levels I and II lymph nodes is common for patients presenting with a T3 or T4 primary. In addition, such patients are at risk for disease in the level III axillary, infraclavicular, supraclavicular, and internal mammary lymph nodes.[24] Disease can further spread along nodal channels to nodal basins outside the classic boundaries of regional disease, for example, the anterior mediastinum, ipsilateral cervical nodal basin, or even the contralateral axilla. Figure 64-1 shows common clinical and radiographic findings in locally advanced breast cancer and the associated stage of disease. Patients with locally advanced disease are also at risk of hematogenous spread, most commonly to the lung, liver, bone, and brain.

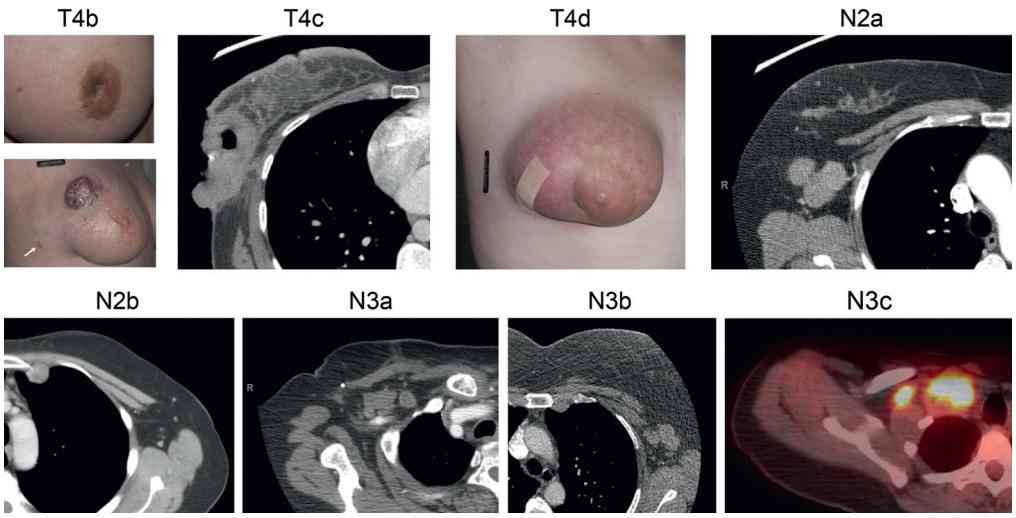

Figure 64-1 T4b, The top photograph depicts a patient with skin edema. Note the peau d'orange changes with increased visibility of the skin pores, edema of the areola, and retraction of the nipple. The bottom photograph depicts a patient with all three findings that can indicate T4b disease: skin edema, ulceration, and a satellite lesion *(see arrow)*. This patient had a neglected breast cancer with an ulcerating mass in the upper outer quadrant that became superinfected, developed into an abscess, and required surgical drainage. T4c, This computed tomography (CT) image shows an ulcerating mass that is extending to involve the serratus anterior muscles of the chest wall. T4d, This patient presented with rapid onset of diffuse breast erythema and was diagnosed with inflammatory breast cancer. N2a, This CT image shows a conglomerate of axillary lymph nodes that are adherent to one another. This is the radiographic correlate of the clinical finding of matted lymph nodes. Classically, this clinical and radiographic finding is the result of the extranodal extension of the tumor resulting in adherence of lymph nodes to one another. N2b, This patient had clinical involvement of the left internal mammary chain in the absence of axillary involvement. N3a, This patient had a necrotic, biopsy-proven lymph node in the infraclavicular space, which is the space medial to the medial margin of the pectoralis minor muscle and tracks along the subclavian artery and vein. N3b, This patient had involvement of both the axillary and internal mammary nodal basins. N3c, This patient had involvement of the supraclavicular nodal basin noted on positron emission tomography/CT.

CLINICAL MANIFESTATIONS, PATIENT EVALUATIONS, AND STAGING

Patients with locally advanced breast cancer commonly present after detecting a breast mass on self-examination. For noninflammatory cancers, there is often a significant interval from the period of first noticing the breast abnormality to the time of presentation for medical care. During this interval, the breast mass usually increases in size. After a long delay before seeking treatment, patients can present with a bleeding or ulcerative mass that occupies the majority of the breast. Over time, some breast cancers can involute or even autoamputate the breast. Superinfection and abscess may occur.

In most cases, regional adenopathy is evident at the time of diagnosis of T3 or T4 primary breast cancers. Pain, limited range of motion, edema, and weakness or numbness of the arm is possible in patients with advanced axillary or supraclavicular adenopathy.

In contrast to the relatively slow progression of noninflammatory locally advanced breast cancer, patients with inflammatory breast cancer most frequently describe a rapid onset of breast erythema and increasing breast size or heaviness. Often, these changes progress over days to weeks and are frequently misdiagnosed as breast cellulitis. Figure 64-1 shows a photograph of the presenting appearance of the breast in a patient with inflammatory breast cancer. The history of presenting signs and symptoms is the critical determinant in classifying a breast cancer as inflammatory.

All patients presenting with locally advanced disease require a comprehensive initial history and physical examination. It is critical to establish the time course of presenting signs and symptoms because these elements are necessary to distinguish inflammatory breast cancer from other T4 tumors. In addition to breast symptoms, the history should include questions concerning changes in general health and questions specifically relating to symptoms possibly due to metastases (e.g., bone pain or change in neurological status).

The initial physical examination is of critical importance in patients with locally advanced breast cancer. Unlike patients with early-stage disease, the majority of patients with T3 or T4 tumors are treated with neoadjuvant chemotherapy. This treatment significantly shrinks the tumor in most patients, and careful documentation of the pretreatment extent of disease is important for determination of subsequent locoregional therapies. The breast examination should document breast asymmetry, mass size, and whether the mass is freely mobile, skin erythema or edema, and skin or nipple retraction. Mobility of the primary mass should be tested with the pectoralis major muscle contracted and relaxed to distinguish chest wall invasion from invasion into the pectoralis muscle. Skin edema is best assessed with the patient in the supine position. Edema of the skin causes thickening, which makes the hair follicles more prominent, resulting in the classic "peau d'orange" appearance. This can best be appreciated by gently pinching the affected skin between the thumb and first finger. Figure 64-1 shows a patient who presented with T4 primary disease and was found to have peau d'orange on initial examination. The axilla and infraclavicular and supraclavicular fossae should be examined with the patient upright, and regional adenopathy should be described to include the size, consistency, and mobility of axillary, infraclavicular, and supraclavicular lymph nodes. The internal mammary lymph nodes are infrequently palpable, even when involved with disease. Despite this, the parasternal area should be examined for asymmetrical prominence with the patient supine.

After completion of an examination, the primary tumor and nodal basin should be assigned a clinical T and N stage, based on the physical examination findings supplemented by

relevant imaging findings and results of any needle biopsies. Based on clinical grounds, stage III breast cancer is established by any of the following: advanced T stage (T4 based on invasion of the chest wall excluding pectoralis muscles [T4a]; skin involvement including edema, ulceration, or satellite lesion [T4b]; both chest wall and skin involvement [T4c]; or inflammatory cancer [T4d]) or advanced N stage (N2 based on matted axillary nodes [N2a] or clinically involved internal mammary nodes in the absence of axillary nodes [N2b] or N3 based on involvement of the infraclavicular [N3a], internal mammary plus axillary [N3b], or supraclavicular nodes [N3c]). It should be noted that clinical stage III breast cancers are often considered unresectable at diagnosis and require neoadjuvant therapy to facilitate complete surgical resection. Patients staged as clinical T3 N1 are also classified as clinical stage III, although such patients' tumors may be resectable without neoadjuvant therapy.

Patients with clinical stage I or II breast cancer may undergo initial surgery and then be upstaged to pathologic stage III, most commonly because of the finding of four or more involved axillary nodes on review of the axillary dissection specimen. Such patients may be considered to have locally advanced breast cancer by some authors, but nevertheless have initially resectable disease even without neoadjuvant therapy because of a lower presenting clinical stage. The seventh edition of the American Joint Commission clinical and pathological staging system is provided in the breast cancer overview chapter.

All patients with locally advanced disease should be staged using bilateral diagnostic mammography, basic serum chemistry tests and blood counts, a CT scan of the chest and abdomen, and bone scan. FDG-PET fused with a CT is increasingly used as an alternative to bone scan and axial CT. As shown in Figure 64-2, FDG-PET may have value in guiding radiation field delineation in patients with inflammatory breast cancer by demonstrating the location and extent of regional adenopathy.[25] Patients with skin involvement should have pretreatment photographs to document extent of involvement. In addition, in our institution we routinely use ultrasonography to assess the extent of disease in the regional lymph nodes and have reported that ultrasound detected additional involved nodes beyond the levels I and II axilla in 37% of patients with locally advanced breast cancer.[24] Although not required, breast MRI can be helpful in patients where there is uncertainty regarding invasion of the chest wall or pectoralis or to identify otherwise occult primary tumors in patients with a clinical suspicion for inflammatory breast cancer.[26] Serum tumor markers such as carcinoembryonic antigen (CEA), CA15.3, and CA27-29 are used by some practitioners but are currently not recommended as standard of care.[27]

TREATMENT OVERVIEW

Patients with clinical stage III disease are optimally treated with a combined-modality approach. The incorporation of systemic treatments into the management of locally advanced disease, along with improvements in surgical and radiation therapies, have significantly improved the outcomes of patients with advanced disease. For example, early studies in which patients with advanced disease were treated with mastectomy or radiation therapy reported 5-year survival rates of only 25% to 45%.[1-3] In contrast, recent SEER data have shown that patients with advanced-stage disease, when treated with a combination of surgery, radiation therapy, and

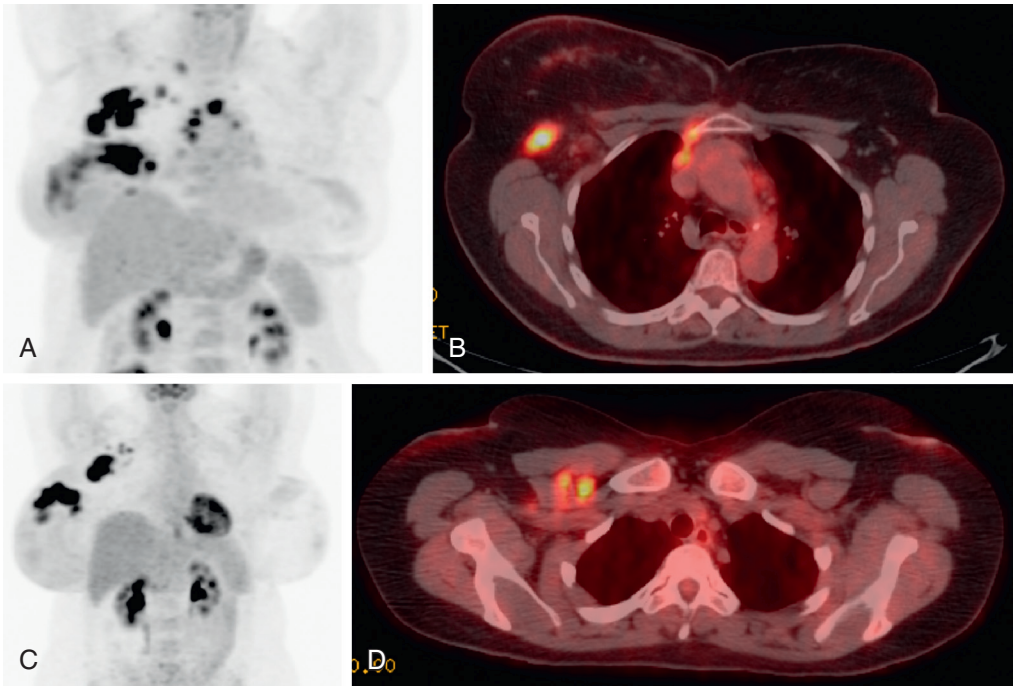

Figure 64-2 This figure depicts the positron emission tomography–computed tomography (PET-CT) findings from patients with inflammatory breast cancer. Panels **A** and **B** depict a triple negative inflammatory breast cancer with involvement of the ipsilateral axillary, infraclavicular, supraclavicular, internal mammary, and mediastinal nodal basins. Panels **C** and **D** depict an ER-, HER2/neu-amplified inflammatory breast cancer with involvement of the ipsilateral axillary and infraclavicular nodal basins. Both patients experienced major responses to chemotherapy, underwent modified radical mastectomy, and received postmastectomy radiation therapy to 51 Gy at 1.5 Gy per fraction delivered twice daily, with an additional boost, most commonly 15 Gy at 1.5 Gy per fraction delivered twice daily to the chest wall and the initially involved nodal basins. The PET-CT findings were helpful in delineating both the initial and boost fields.

chemotherapy, have 5-year survival rates of approximately 70%. In our institutional experience, we have reported a 5-year survival rate of 80% for patients with stage IIIA disease and 45% for patients with stage IIIB disease.[4]

Combined-modality treatments are best administered with input from a coordinated multidisciplinary team of surgeons, medical oncologists, and radiation oncologists. For patients with advanced but resectable breast cancer, mastectomy followed by adjuvant chemotherapy and radiation therapy is an acceptable therapeutic approach. Equally appropriate is to use chemotherapy as the first therapeutic intervention (called *neoadjuvant chemotherapy*). For patients with unresectable disease at the time of diagnosis as a result of T4 primary tumors or advanced lymph node disease, neoadjuvant chemotherapy is considered the standard of care.[28]

Treating patients with chemotherapy prior to surgery has several potential advantages. One advantage is that it gives selected patients with T3 or T4 tumors the option of being treated with breast-conserving surgery. Indeed, numerous studies have indicated that neoadjuvant chemotherapy achieves a substantial reduction in the size of the primary tumor and nodal metastases in more than 80% of cases, which often permits a breast-conserving approach that achieves an acceptable esthetic outcome.[29-32] A second advantage is that neoadjuvant chemotherapy allows for assessment of the primary tumor's response to a particular chemotherapy regimen. For the minority of patients whose disease does not respond or progresses, this assessment facilitates a change to a different regimen, allowing for the most effective chemotherapy to be given as early as possible and also avoiding unnecessary toxicity from an ineffective therapy. A third advantage is that the extent of residual disease informs prognostication[33] and may influence locoregional treatment decisions. A final advantage of neoadjuvant chemotherapy is that it facilitates expeditious testing of promising new agents because the Food and Drug Administration has recently approved the use of pathologic complete response as an endpoint to support accelerated approval of new agents.

One desired advantage of neoadjuvant chemotherapy that has not been realized is the hope that earlier administration of chemotherapy would increase the probability of eradicating preexisting micrometastatic disease. Unfortunately, the two largest trials that compared neoadjuvant and adjuvant chemotherapy found that delivering chemotherapy before surgery provided no overall survival advantage compared to delivering chemotherapy after surgery. Specifically, the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-18 randomized 1523 patients with early-stage, operable breast cancer to receive four cycles of doxorubicin/cyclophosphamide (AC) either before or after surgical treatment. After long follow-up, the overall survival and disease-free survival rates were nearly identical between the two groups.[34] Interestingly, there appeared to be an advantage for neoadjuvant chemotherapy for the younger patients and an advantage for the adjuvant chemotherapy in the older patients. A second large, randomized, prospective trial conducted by the European Organization for Research and Treatment of Cancer (EORTC) also demonstrated equivalent rates of survival and distant metastases between pre- or postoperative chemotherapy treatment with four cycles of fluorouracil, epirubicin, and cyclophosphamide (FEC).[31,35]

The increasing use of neoadjuvant chemotherapy has raised many questions concerning the surgical and radiotherapeutic management of patients with locally advanced breast cancer. Accordingly, it is best to have surgeons, radiation oncologists, and medical oncologists participate in decisions regarding treatment sequencing and provide the necessary multidisciplinary coordination to address the added complexity that neoadjuvant chemotherapy brings to the treatment of patients with locally advanced breast cancer.

LOCOREGIONAL TREATMENT OF PATIENTS WITH ADVANCED PRIMARY DISEASE

Breast Conservation after Neoadjuvant Chemotherapy

Historically, all patients with advanced primary breast cancers underwent mastectomy and postmastectomy radiation therapy as the preferred locoregional treatment. However, the high response rates associated with neoadjuvant chemotherapy have allowed for breast conservation in selected patients with advanced disease. The NSABP and EORTC trials comparing neoadjuvant chemotherapy with adjuvant chemotherapy in patients with stage II or III breast cancer found that breast-conservation rates were higher in the neoadjuvant chemotherapy arms.[29,31] This increase was directly because of a greater percentage of patients with T3 disease being offered breast conservation after first responding to chemotherapy. One concern over using chemotherapy before breast-conserving surgery is that many advanced breast cancers do not shrink concentrically to a solitary nidus in response to neoadjuvant chemotherapy. In such cases, surgery directed at the primary core may leave a high burden of microscopic disease around the tumor bed site, which may lead to higher likelihood of local recurrence.

Some clinical data indeed indicate that patients with advanced tumors who have been treated with breast-conserving surgery after neoadjuvant chemotherapy have higher rates of breast cancer recurrence. For example, in the NSABP B-18 trial, the local recurrence rate in patients with large primary tumors in whom a response to neoadjuvant chemotherapy allowed a breast-conserving surgery was twice that in patients with smaller tumors who were treated with surgery first (15.7% versus 7.6%, respectively).[29] Other series have also shown relatively high local recurrence rates in patients who receive neoadjuvant chemotherapy.[36,37] From these data it is clear that breast-conserving procedures after neoadjuvant chemotherapy are more complex, that multidisciplinary coordination is important, and that proper patient selection for breast conserving procedures is critical. Carefully planning for breast conserving surgery by, for example, placing a clip in the tumor at the time of initial biopsy and diagnosis, may facilitate localization of the tumor after chemotherapy and improve long-term local control.[38]

With appropriate patient selection and multidisciplinary management, the outcome of breast conservation for selected patients with locally advanced breast cancer can be excellent.[39,40] Investigators from M. D. Anderson have developed and validated a prognostic index to predict likelihood of long-term locoregional recurrence in patients treated with neoadjuvant therapy and breast conserving surgery. The prognostic index assigns a point for each of the following variables: clinical N2/3 disease, lymphovascular invasion, residual pathologic tumor size >2 cm, and multifocal residual disease. For patients with 0, 1, or 2 points, 5-year risk of locoregional recurrence is only 7%. In contrast, for patients with 3 or 4 points, 5-year risk of locoregional recurrence is 31%.[40] Accordingly, this prognostic index can be used to select patients who are most appropriate for breast conservation after neoadjuvant chemotherapy. For patients with a high prognostic score who are motivated for breast conservation, consideration should be given to more extensive surgery or more intensive imaging, such as MRI, to guide the surgical resection volume.

TABLE 64-1 10-Year Locoregional Recurrence and Overall Survival Rates in Randomized Trials Investigating Irradiation after Mastectomy and Systemic Treatments

Trial	No. Patients	Treatment Arm	Locoregional Recurrence	Overall Survival
Danish 82b[39] (10-year data)	1708	Irradiation	9%	54%
		No irradiation	32%	45%
Danish 82c[40] (10-year data)	1375	Irradiation	8%	45%
		No irradiation	35%	36%
Danish 82b/c[42] (18-year data)	3083	Irradiation	14%	37%
		No irradiation	49%	27%
Vancouver[44] (20-year data)	318	Irradiation	10%	47%
		No irradiation	26%	37%

Mastectomy and Postmastectomy Radiation Therapy

A modified radical mastectomy (resection of the breast, pectoralis fascia, and levels I and II axillary lymph nodes) remains the most common surgical treatment for patients with locally advanced breast cancer. Nevertheless, risks of locoregional recurrence after this surgery remain high if radiation is not also given. Postmastectomy radiation therapy (PMRT) benefits this cohort of patients by reducing locoregional recurrence and thereby improving overall survival.

Despite the fact that postmastectomy radiation has been evaluated in more than 25 trials conducted over 40 years, there remain a number of significant controversies over its use. Historically, it was questioned whether the benefits of postmastectomy radiation were offset by its associated toxicity. Specifically, in 1987, Cusik et al published the first meta-analysis of data from PMRT trials and reported that radiation use was associated with a poorer overall survival rate.[41] In a subsequent analysis, Cusik et al reported that PMRT decreased the breast cancer death rate but increased the nonbreast cancer death rate,[42] which resulted in equivalent overall survival rates between the two groups.

The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) has performed a more recent and comprehensive meta-analyses of trials investigating postmastectomy radiation therapy.[43] The 2005 publication of this meta-analysis included data from 9933 patients treated on clinical trials with mastectomy, axillary clearance with or without PMRT. The results of this study clearly demonstrated that PMRT reduced isolated locoregional recurrence rate for patients with lymph node-positive disease treated with mastectomy. Specifically, PMRT decreased the 15-year isolated locoregional recurrence rate for patients with lymph node–positive disease from 29% to 8%.[43] The more revolutionary finding was that this significant absolute improvement in locoregional control reduced the 15-year breast cancer mortality rate from 60% (no radiation) to 55% (radiation). This finding was particularly important in that previous meta-analyses suggested that the benefit of adjuvant radiation was limited to locoregional control.

It is important to recognize that the benefits of adjuvant radiation for patients with locally advanced disease may be greater than that reported in meta-analyses. Many of the trials included in meta-analyses included patients at low risk for locoregional recurrence, used unconventional radiation doses, fractionation patterns, and radiation field designs, and enrolled patients in a much earlier era where systemic therapies were either less effective or entirely omitted. To minimize these confounding effects, Van de Steene et al conducted a similar meta-analysis but excluded trials that began before 1970, trials with small sample sizes, trials with relatively poor survival rates, and trials that used radiation fractionation schedules that are no longer standard practice.[44] When these less-than-optimal studies were excluded, PMRT significantly improved overall survival, reducing odds of death by 12.4%. In addition, Whelan et al performed a meta-analysis of the published PMRT trials that included systemic therapy in both treatment arms. In this analysis, the addition of radiation after mastectomy was also shown to reduce the risk of any recurrence (odds ratio, 0.69) and mortality (odds ratio, 0.83).[45]

The most recent Phase III randomized trials investigating PMRT were initiated almost three decades ago but remain relevant in that they used more modern radiation treatment techniques and dose fractionation and included some form of systemic therapy for all patients. Table 64-1 displays the results from these trials. The Danish Breast Cancer Cooperative Group (DBCCG) 82b trial randomized 1708 premenopausal women with stage II or III breast cancer to receive mastectomy followed by nine cycles of cyclophosphamide/methotrexate/5-fluorouracil (CMF) chemotherapy or mastectomy, radiation therapy, and eight cycles of CMF chemotherapy.[46] The simultaneously run DBCCG 82c study randomized more than 1300 women who are postmenopausal to receive mastectomy and tamoxifen or mastectomy, tamoxifen, and radiation therapy.[47] Patients randomized to receive radiation therapy in these studies had a lower 18-year rate of locoregional recurrence and a higher 18-year overall survival rate.[48,49] A smaller trial, conducted in Vancouver, British Columbia, randomized 318 women who are premenopausal with lymph node-positive disease to receive mastectomy and CMF chemotherapy with or without PMRT.[50,51] Again, patients who underwent radiation therapy had lower 20-year rates of locoregional recurrence and similar improvement in the 20-year overall survival rate.

Exploratory analyses of the Danish trials classified the impact of PMRT on both locoregional control and survival stratified by molecular profile of the treated tumor.[21,22] Several interesting conclusions may be drawn from these studies. First, long-term risks of locoregional recurrence were similar regardless of ER or HER2/neu status in patients who did not receive PMRT. It should be noted, however, that endocrine therapy was not used in the DBCG 82b and only 1 year of tamoxifen was administered in 82c. It is likely that patients with ER+ positive disease receiving optimal endocrine therapy may have lower locoregional recurrence risks even without radiation than reported in these studies. The relative benefit of radiation in reducing locoregional recurrence, however, did vary by tumor molecular profile. Specifically, patients with ER+ disease experienced a greater than 90% relative reduction in risk of locoregional recurrence when treated with PMRT, whereas patients with triple-negative disease experienced a 67% relative reduction and patients with ER-, HEr2/neu-positive disease experienced a 50% reduction. With regard to survival, PMRT significantly improved long-term overall survival for patients with ER+ disease, but failed to improve overall survival for those with either triple-negative disease or ER-, HER2/neu-positive disease. These findings underscore the

TABLE 64-2 10-Year Locoregional Recurrence Rates in Clinical Trials That Used Mastectomy and Systemic Treatments without Irradiation

Trial	No. Patients	Systemic Therapy	Locoregional Recurrence	
			Patients with 1-3 Positive Lymph Nodes	Patients with >3 Positive Lymph Nodes
Recht et al[56]	2016	CMF	13%	29%
Katz et al[54]	1031	Doxorubicin-based	10%	21%
Wallgren et al[57]	5352	Varied	14% 19% to 27%*	24% 24% to 34%*
Taghian et al[58]	5758	Varied	13%*	24% to 32%

CMF, *Cyclophosphamide, methotrexate, 5-fluorouracil.*
**Higher rates were associated with high-grade disease and lymphovascular space invasion.*

potential heterogeneity underlying the relationship between locoregional recurrence benefit and survival benefit of PMRT. It is hoped that introduction of more effective systemic therapies for HER2/neu-positive and triple-negative breast cancer will not only improve overall outcomes for these patients, but also, through controlling distant micrometastatic disease, allow such patients to experience a meaningful survival benefit from radiation.

There is significant current controversy over whether PMRT is indicated for patients with stage II breast cancer with 1 to 3 positive lymph nodes. The majority of the patients enrolled in the Danish and British Columbia randomized trials had 1 to 3 positive lymph nodes, and based on the positive findings from these studies, many feel that all patients with lymph node–positive disease should receive radiation treatments. The difficulty in interpreting these data, however, is that many patients in these trials did not undergo formal levels I and II axillary dissection. The median number of axillary lymph nodes resected was only 7, with 76% of the patients having fewer than 10 lymph nodes removed and 15% having 3 or fewer lymph nodes removed.[46] This diverges from standard U.S. practice in which the median number of nodes removed is approximately 15.[52] Accordingly, some of the patients reported to have 3 or fewer positive lymph nodes likely would have had 4 or more positive lymph nodes if a more extensive surgical procedure had been performed. Correspondingly, their risk of a chest wall or supraclavicular recurrence would be higher than that estimated for patients with only 1 to 3 positive nodes based on more thorough, and thus more accurate, axillary lymph node dissection. In addition, failure to remove these additional involved axillary lymph nodes would predispose patients to axillary recurrence, which could be avoided by a more complete axillary dissection. Indeed, in an earlier publication of the Danish 82b trial, it was reported that 45% of all locoregional recurrences occurred in the axilla.[53] The Danish group reanalyzed their data and evaluated only the patients with 1 to 3 positive lymph nodes who had at least 8 lymph nodes removed at the time of mastectomy. This publication still demonstrated a significant reduction in locoregional recurrence with the use of radiation (27% to 4%) and also continued to demonstrate an absolute 9% survival advantage for radiation in this cohort.[54]

The most recent analyses from the EBCTCG comparing mastectomy with levels I and II axillary dissection with or without adjuvant radiation also evaluated the benefit of radiation according to the number of positive lymph nodes.[55] This analysis included data from approximately 8135 patients treated in 22 trials that were started between 1964 and 1986 and demonstrated a significant benefit in locoregional recurrence (20% versus 4% at 10 years) and survival (47% versus 38% at 15 years) for the patients with 1-3 positive lymph nodes, in addition to noting benefits for the patients with 4 or more positive lymph nodes and no measurable benefit for patients with node-negative disease.

Based on these data it would appear that PMRT is warranted for all patients with lymph node-positive disease. However, a number of studies performed in the United States suggest that patients with one to three positive lymph modes have a much lower risk of locoregional recurrence after mastectomy and chemotherapy. These data are summarized in Table 64-2. In general, these data suggest that the 10-year locoregional recurrence risk for patients with one to three positive lymph nodes is approximately 12%, which is almost three times lower than the locoregional recurrence rate in the no radiation arms of the Danish trials. Correspondingly, the expected locoregional control benefit to be gained from the addition of PMRT would be much less.

Two nonrandomized institutional studies suggest this. An analysis from M. D. Anderson found that the use of PMRT reduced the 10-year locoregional recurrence risk for patients with stage II disease and one to three positive lymph nodes from 13% to 3%.[56,57] Similarly, investigators from Massachusetts General Hospital found that PMRT reduced the 10-year risk of locoregional recurrence from 11% to 0% for patients with one to three positive lymph nodes.[58] Whether this degree of benefit is clinically meaningful with respect to patient survival remains a matter of controversy. Another important consideration is that locoregional recurrences after mastectomy can develop after 10 years of follow-up. Therefore, the 10-year data presented in Table 64-2 may underestimate the true percentage of patients with persistent locoregional disease after surgery and chemotherapy. Specifically, in the 20-year update of the Vancouver, British Columbia, randomized trial, approximately 20% of the total number of locoregional recurrences in the group randomized to no PMRT developed after 10 years of follow-up.[51]

Some series have identified subgroups of patients with stage II breast cancer and 1 to 3 positive lymph nodes that have higher risks of locoregional recurrence.[56,57,59-62] Factors that identify these subgroups include young age, the presence of extracapsular extension greater than 2 mm, tumor size larger than 4 cm, positive or close (<2 mm) surgical margins, lymphovascular space invasion, invasion of the skin, nipple, or pectoralis muscle, fewer than 10 lymph nodes resected, and a 20% or greater proportion of involved to dissected lymph nodes. It is important to recognize that these factors were identified in retrospective subset analyses and are not prospectively validated.

The ASTRO and ASCO consensus statements regarding PMRT recommended that an additional trial be performed to further clarify the benefit of PMRT for women with stage II disease and one to three positive lymph nodes.[63,64]

Unfortunately, an Inter-Group trial designed to determine the benefits of PMRT for these patients closed owing to poor accrual. Prospective trials evaluating the benefits of regional lymph node irradiation in primarily N1 patients have been conducted in Canada (MA.20) and Europe (EORTC 22922/10925) but results are not yet published. Findings from these large randomized trials are likely to significantly influence our understanding of the benefits of regional lymph node irradiation and PMRT in patients with one to three positive nodes.

Postmastectomy Radiation Therapy after Neoadjuvant Chemotherapy

As previously highlighted, the use of neoadjuvant chemotherapy has significantly increased in recent years, particularly for patients with advanced primary tumors. One of the most important questions raised by this increased use concerns the indications for PMRT. In patients treated with mastectomy first, the decision to administer radiation therapy is made on the basis of the pathological extent of disease. This is because pathological quantification of disease is much more precise than clinical and radiographic examinations. Accordingly, the ASTRO and ASCO consensus statements regarding PMRT have recommended that treatments be based in large part on the pathological determination of disease extent in lymph nodes.[63,64]

Neoadjuvant chemotherapy changes the extent of pathological disease in 80% to 90% of cases. Thus, data elements available to the clinician in generating a recommendation for or against PMRT in the neoadjuvant setting include the initial clinical stage, the final pathologic stage after delivery of chemotherapy, and the degree of difference between the two, which indicates the response, or lack thereof, to neoadjuvant chemotherapy. Prospective trials to determine whether response to chemotherapy may be used to inform decisions regarding radiation therapy are under way.[65] In the meantime, indications for PMRT following neoadjuvant chemotherapy and mastectomy must be based on the available nonrandomized literature.

For example, the largest study to assess locoregional recurrence rates after neoadjuvant therapy included 3088 patients treated on NSABP B-18 and B-27, two trials which used neoadjuvant chemotherapy and prohibited radiation after mastectomy. The key finding from these studies was that response to neoadjuvant chemotherapy correlated with risk of locoregional recurrence, supporting the hypothesis that chemotherapy response may also predict which patients do and do not require radiation therapy. Specifically, patients with a pathologic complete response to neoadjuvant chemotherapy in both the primary tumor and the axillary nodes experienced the lowest risk of locoregional recurrence, whereas patients with residual invasive disease in the breast who were pathologically node-negative had an intermediate risk of locoregional recurrence and patients with residual positive lymph nodes had the highest risk of locoregional recurrence. For example, in patients treated with mastectomy without radiation who were found to have residual nodal positivity, the risk of locoregional recurrence ranged from 11.2% to 22.4%. This risk was thought to be sufficiently high to justify consideration of PMRT. In contrast, for patients who converted from node-positive to node-negative after chemotherapy, locoregional recurrence risk was 0%, suggesting that PMRT may be safely omitted if a nodal pathologic complete response is achieved.[66]

To date, only one published study has evaluated the efficacy of PMRT in comparison to no PMRT in patients treated with neoadjuvant chemotherapy. This study compared the outcomes of 579 patients who received neoadjuvant chemotherapy, mastectomy, and radiation therapy with those of 136 patients who were treated with neoadjuvant chemotherapy and mastectomy alone.[67] All patients included in this study were treated on prospective trials at M. D. Anderson Cancer Center, but it is important to recognize that radiation therapy was not a randomized variable in any of these trials. Therefore, there were significant imbalances in the prognostic factors between the two groups, with those being referred for radiation therapy having more extensive disease. Despite the imbalances in both T and N clinical stage, the locoregional recurrence rate was significantly lower in the patients treated with PMRT than in those treated with neoadjuvant chemotherapy and mastectomy alone (10-year locoregional recurrence rates were 8% and 22%, respectively, $p = 0.001$). More importantly, as indicated in Table 64-3, treatment with radiation therapy was associated with better overall and cause-specific survival rates in selected groups of patients with high-risk disease. In addition, multivariate analysis showed that PMRT was independently associated with improved cause-specific survival, (HR = 0.49; 95% CI, 0.34 to 0.71; $p < 0.001$) and locoregional recurrence-free survival (HR = 0.21; 95% CI, 0.12 to 0.37; $p < 0.001$).

TABLE 64-3 10-Year Locoregional Recurrence and Overall Survival for Selected Subgroups of Patients in the M. D. Anderson Cancer Center Series Investigating the Efficacy of Postmastectomy Irradiation after Neoadjuvant Chemotherapy[60]

Characteristic	Treatment	Locoregional Recurrence	Cause-Specific Survival
T4 disease	Irradiation	15%	45%
	No irradiation	46%	24%
N2/N3 disease	Irradiation	12%	49%
	No irradiation	40%	27%
IIIB/IIIC disease	Irradiation	15%	44%
	No irradiation	51%	22%

That paper also addressed the question of whether PMRT is still needed in patients with clinical stage III breast cancer who achieve a pathologic complete response to neoadjuvant chemotherapy. For such patients, the locoregional recurrence rate was 3% if PMRT was given compared to 33% if PMRT was omitted ($p = 0.006$). In addition, using a broader definition of favorable response as having less than 5 cm of disease and fewer than four positive lymph nodes, similar benefits were noted. For those with stage III disease who achieved a favorable response using these criteria, the locoregional recurrence rates were 9% for those receiving radiation therapy versus 20% for those not receiving radiation therapy.[67]

On the basis of these data, it is reasonable to recommend PMRT for all patients with clinical T3 or T4 tumors or clinical stage III disease regardless of their response to neoadjuvant chemotherapy. In terms of clinical stage I or II breast cancer, PMRT should be recommended for patients with four or more positive lymph nodes after chemotherapy and for the unusual patient in whom the disease progresses and the primary tumor exceeds 5 cm in diameter. On the basis of the NSABP B-18 and B-27 data, it is also reasonable to consider PMRT for patients with only one to three involved nodes, although this remains an area of controversy and merits further study. These recommendations were articulated in a National Cancer Institute Statement of Science publication on this topic.[28]

A framework for radiation therapy decision making in patients treated with neoadjuvant chemotherapy and mastectomy was also recently created by the Athena Breast Health

Network based on the results of a systematic literature review.[68] This framework defined a select group of patients expected to have a risk of locoregional recurrence less than 10% without PMRT, defined as older than 40 years, clinical stage I/II (T1-2 N0-1), ER+, no lymphovascular space invasion, no extracapsular extension, and after neoadjuvant chemotherapy either a pathologic complete response or only one to three residual involved lymph nodes. The authors correspondingly recommended withholding postmastectomy radiation for such patients, although as mentioned previously, PMRT may be considered in light of the B-18/B-27 data. For all other patients, locoregional recurrence risk is expected to be higher and PMRT is generally warranted.

TECHNIQUES OF IRRADIATION

Radiation treatment plays a critical role in the management of locally advanced breast cancer, and as such the design of treatment fields is of critical importance. For patients with stage III disease, the initial target volume should include the breast and chest wall and draining lymphatics. At a minimum, the undissected axillary apex and the supraclavicular fossa lymph nodes should be included. In our institution, we also include the internal mammary lymph nodes as a therapeutic target. One rationale for including these structures is that the internal mammary lymph nodes frequently contain disease in patients with locally advanced disease, particularly those with medial and central tumors.[69]

A variety of techniques can be adopted to include these targets in the radiation field. Initially, patients should be immobilized with their ipsilateral arm abducted (90 degrees to 120 degrees) and externally rotated. In assessing arm position, it is important to have the soft tissues of the arm cranial to the junction of the tangent and supraclavicular fossa field to avoid unnecessary irradiation of the proximal arm. In addition, skin folds within the supraclavicular fossa should be flattened as much as possible. After positioning and immobilization, patients are placed on a 5-degree to 15-degree angle board to flatten the slope of the chest wall in the region of the sternum. This enables an electron field treating the internal mammary nodes to be as appositional as possible, which improves dosimetric coverage and decreases skin dose.

In our institution, a CT simulator, specially equipped with a large bore to accommodate the patient arm position, is used. Radioopaque wires are placed on the surgical scar(s), drain sites, and clinical treatment borders. The interface border between the chest wall and breast field and the supraclavicular field is typically placed at the bottom of the clavicular head, which ensures adequate coverage of the typically undissected axillary apex lymph node region.[70] A scout view of the patient is obtained to assess positioning. If the projection of the supraclavicular field is estimated to include a large volume of apical lung, then the patient may be repositioned at a lower slant angle or the junction between the supraclavicular field and breast and chest wall fields may be raised to decrease anticipated radiation of the lung from the supraclavicular field. CT images are then acquired and the appropriate isocenters are determined and marked along with appropriate set-up points. Areas of interest are then contoured on the CT slices. Typically, we contour the tumor bed (for cases of breast conservation), the internal mammary artery and vein in the upper three interspaces (i.e., from the caudal edge of the first rib to the cranial edge of the fourth rib), and the undissected level III axillary apex lymph nodes. Regions of any residual involved lymph nodes are also contoured.

For patients treated with breast-conserving surgery, the breast is typically treated with medial and lateral tangent photon fields. These fields are created with matched, nondivergent deep and cranial borders. A nondivergent cranial border is created through rotation of the couch. The nondivergent deep border is typically achieved by overrotating the gantry or a half-beam block. The collimators are rotated to match the chest wall slope, and any volume that extends cranially above the match line into the supraclavicular field is blocked. For patients with advanced disease or tumor located in the central or medial breast, we attempt to include the contoured internal mammary structures by widening the deep border in the upper half of the field (often called *deep tangents* or *half-wide tangents*). CT-simulation allows physicians to assess a variety of gantry angles for these tangents and pick the optimal angle that minimizes lung volume while avoiding irradiation of the contralateral breast.

Figure 64-3 shows an example of a deep tangent field that includes the upper internal mammary lymph nodes in the field. A supraclavicular and axillary apex field is matched to the tangents with a nondivergent half-beam block. The gantry of this field is rotated 10 degrees to –20 degrees to be off the spinal cord and esophagus yet still afford adequate coverage of the medial supraclavicular nodes.[71] For patients with advanced disease, we typically place the lateral border of the

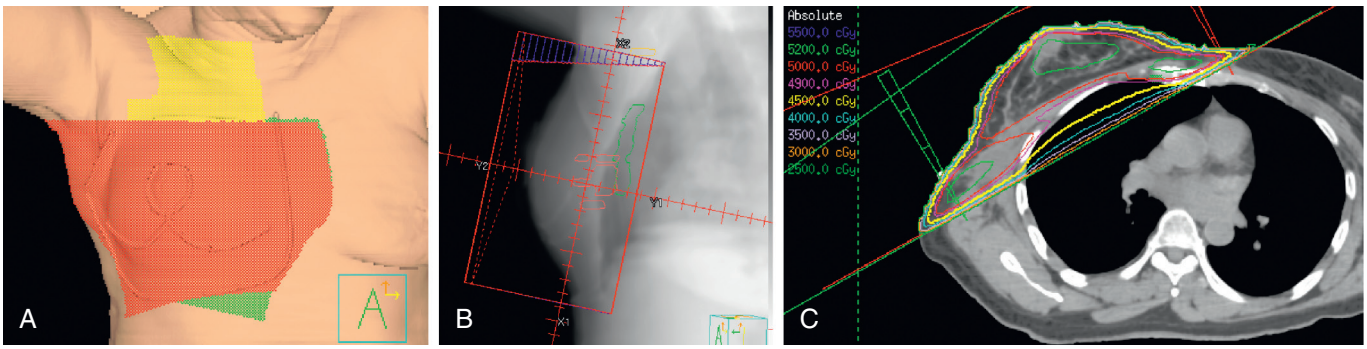

Figure 64-3 This patient had a triple negative cancer of the lower outer quadrant of the right breast with six radiographically suspicious axillary nodes on ultrasound, clinical stage T1c N1a. She received neoadjuvant chemotherapy followed by breast conserving surgery with reduction mammoplasty and axillary lymph node dissection, revealing a pathologic stage of ypT0 N1mic. She received radiation to the right breast using partially wide tangents to encompass the ipsilateral internal mammary nodes and a supraclavicular field to encompass the ipsilateral supraclavicular and infraclavicular nodal basins. Panel **A** shows the skin rendering for her treatment fields. Panel **B** shows the digitally reconstructed radiograph for the medial tangent, illustrating the "partially wide" technique which encompasses the internal mammary nodal chain as shown in green. Panel **C** shows the axial dose distribution, with the breast tissue covered by the 49-Gy isodose line *(shown in purple)* and the internal mammary nodal chain *(shown in green)* covered by the 45-Gy isodose line *(shown in yellow)*.

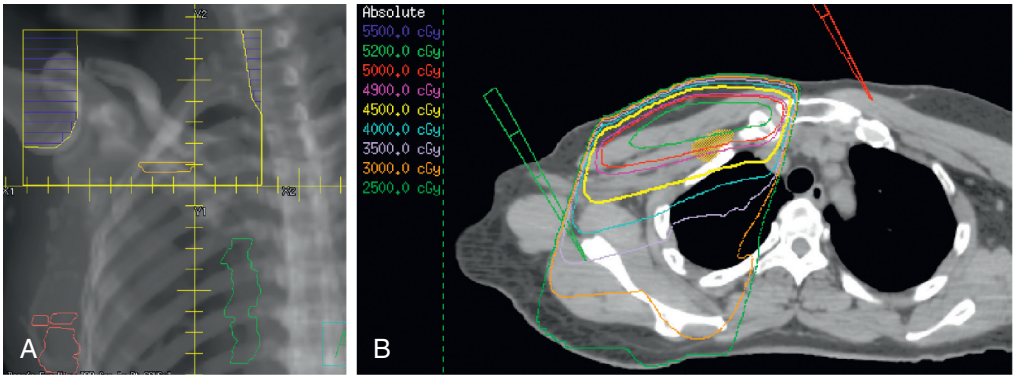

Figure 64-4 This figure shows the supraclavicular field used to treat the patient described in Figure 64-3. The superior border is set approximately at the level of the cricothyroid membrane, the medial border abuts the trachea, the lateral border is set at the lateral margin of the pectoralis major, and the inferior border is set at the inferior margin of the clavicle. The level III axillary and infraclavicular nodal basin is contoured *(shown in orange)*. A mix of lower and higher energy photons, each prescribed to their respective depth of maximum dose, is selected to ensure adequate coverage of the contoured level III axillary nodal basin with a dose of 45 Gy *(shown in yellow)*.

supraclavicular field at the lateral margin of the pectoralis major muscle to facilitate coverage of Rotter's space and the anterior soft tissues of the breast and chest wall and axilla. Figure 64-4 shows an example of such a field. A supplemental photon beam directed toward the region of underdosed axillary target is used to ensure the targeted axilla receives a minimum dose of 45 Gy in the following situations: axillary dissection was not performed, gross disease remaining in the axilla, or high burden of disease in the levels I and II axilla.

For patients treated after mastectomy, we typically target the chest wall and draining lymphatics with a four-field technique. The supraclavicular and axillary apex field is identical to that described previously. The lateral chest wall is treated with an opposed tangent technique similar to that used for a breast. The medial chest wall and internal mammary lymph nodes are treated with a medial electron field that includes the contoured internal mammary vessels and is angled 15 to 30 or more degrees. The angle is selected to minimize the cold triangle at the junction between the electron and tangent fields, with coverage ≥35 Gy at the cold triangle considered acceptable in our practice. This field is matched to the tangents on the skin for patients without T4 disease and overlapped by 3 mm in patients with T4 disease. Figure 64-5 shows examples of such fields. One advantage of this technique is that it provides relatively broad circumferential coverage of the chest wall, something that is important, particularly for patients with T4 tumors. In addition, the technique allows for exclusion of the cardiac silhouette from the high-dose region.

We treat our initial targets to a total dose of 50 Gy in 25 fractions over 5 weeks, but accept coverage of our contoured nodal targets with the 90% isodose line. For patients treated with mastectomy, we use a 3-mm to 5-mm bolus over the chest wall every other day for 2 weeks and then as needed to assure that a brisk radiation dermatitis develops (Figure 64-6). However, this dermatitis should not lead to a treatment interruption and moist reactions are to be avoided if at all possible. After completing a course of treatment to 50 Gy, we treat the chest wall with a generous boost of electron fields for an additional 10 Gy in five fractions (typically a combination of a medial and lateral electron field with a hinge angle ≤35 degrees and encompassing 5 cm to 10 cm beyond the mastectomy scar and the tumor bed location of the original primary) (Figure 64-7). In addition, we treat all sites of unresected but initially involved adenopathy in the internal mammary, infraclavicular, and supraclavicular regions with a radiation boost. If ultrasonography or other imaging has shown a resolution of disease in these areas, we deliver an additional boost of 10 Gy in five fractions. If gross residual disease persists on imaging, we increase the boost treatment to 16 Gy in eight fractions (Figures 64-8 to 64-10).

In our institution, we treat most patients with inflammatory cancer with an accelerated radiation schedule, based on a retrospective study that suggested that this schedule improved the outcome compared to a historical data set.[72] The initial target volumes are treated to 51 Gy in 1.5-Gy fractions given twice a day for 17 treatment days. Subsequently, the boost fields are treated with an additional 15 Gy in 1.5-Gy twice-daily fractions over 5 treatment days. We have found that this fractionation schedule is associated with an improved rate of locoregional control and has an acceptable toxicity profile.

Treatment plans showing radiation dose in multiple off-axis slices should be used to determine optimal beam parameters. Tangential photon fields are delivered using a forward-planned, field-in-field technique to achieve optimal three-dimensional dose homogeneity. CT treatment planning with heterogeneity correction factors is also used to improve dose modeling. Electron energies for the medial chest wall and internal mammary lymph node fields should ensure that the 90% isodose line covers the contoured volume and avoids irradiation of the heart. In addition, photon energies for the supraclavicular field should be chosen to ensure that the 90% isodose line fully covers the contoured, undissected level III axilla. It is frequently necessary to split the electron internal mammary field into two different fields, a higher energy field to cover the contoured lymph nodes, and a lower energy field caudal to the contoured nodes, to prevent excessive exit of dose into the heart or lung.

Dose-volume histogram (DVH) criteria for evaluating treatment plans remain an area of investigation, with little available data to discriminate a safe from nonsafe plan. Population-based data support a linear, no-threshold relationship between mean cardiac dose and cardiac event risk, suggesting that cardiac dose should be kept as low as reasonably achievable.[73] In our practice, respiratory gating with deep inspiration breath-hold is commonly used to reduce incidental cardiac irradiation, and most patients with left-sided breast cancers treated with radiation to encompass the ipsilateral internal mammary lymph nodes have a mean heart dose less than 4 Gy. For right-sided patients, mean heart dose is typically <2.5 Gy. Regarding lung irradiation, a reasonable target is to keep the ipsilateral lung V20 ≤ 35%, although in select

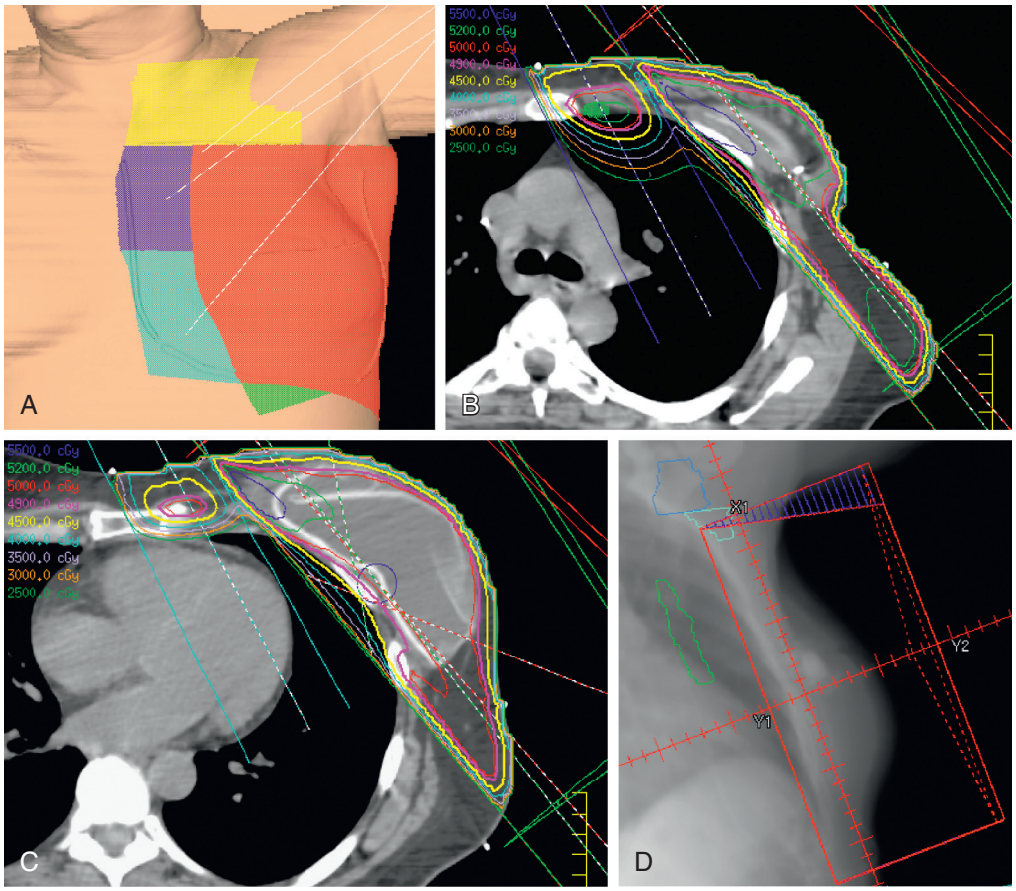

Figure 64-5 This patient had a T3 N1 left breast cancer treated with upfront skin-sparing mastectomy and axillary lymph node dissection with placement of a submuscular tissue expander. The expander was inflated during adjuvant chemotherapy and then deflated one day before simulation to a fill volume of 300 ml. Panel **A** shows the skin rendering of the various treatment fields, Panel **B** the axial dose distribution at the level of the contoured internal mammary lymph nodes, Panel **C** the axial dose distribution at the level of the heart, and Panel **D** the digitally reconstructed radiograph for the medial tangent field. The internal mammary nodal target is covered by the 45-Gy isodose line, as shown in yellow. In this case, the internal mammary electron field was split into two fields, a 12-MeV field to cover the contoured first three interspaces *(purple color in Panel **A**)*, and a 9-MeV field to cover just the lower medial chest wall and avoid the heart *(shown in light blue)*. This patient was treated in breath hold to optimize cardiac sparing. Her mean heart dose was 305 cGy and her ipsilateral *(left)* lung V20 was 24%.

cases the ipsilateral lung V20 may be higher. It is important to underscore that there is not a strong correlation between lung DVH parameters and risk of pneumonitis, and that plans should be optimized as carefully as possible given a patient's underlying anatomy and disease. A higher lung or heart DVH may be permissible in a patient with aggressive locoregional disease for whom radiation is essential to long-term disease control and survival.

INCORPORATION OF POSTMASTECTOMY RADIATION AND BREAST RECONSTRUCTION

Advances in breast reconstruction have significantly improved the quality of life for many patients who undergo mastectomy. However, when considering breast reconstruction, it is critical that surgical oncologists, plastic surgeons, and radiation oncologists work together to coordinate PMRT and reconstruction. This is because radiation often affects the cosmetic outcome of reconstruction and reconstruction can adversely affect the optimal design of radiation fields.

One important consideration is the timing of breast reconstruction. Immediate breast reconstruction has the advantage of permitting a skin-sparing mastectomy, which can preserve the native scaffolding of the breast contour and enhance the final cosmetic outcome. However, skin-sparing mastectomy may be contraindicated for some cases of locally advanced disease, such as inflammatory breast cancer or locally advanced disease involving the skin, where skin that might be spared during a skin-sparing mastectomy is at risk of harboring disease. Moreover, radiation treatments of a reconstructed breast have been shown by numerous authors to adversely affect the cosmetic outcome. A series from M. D. Anderson Cancer Center reported a 42% rate of implant failures when treated with PMRT compared to a 10% failure rate in patients who did not require PMRT.[74] Another series noted a 5-year complication rate of 27% in patients who had their tissue expanders or implants irradiated.[75] These complication rates are higher with longer follow-up times. Radiation also has adverse effects on autologous tissue reconstruction. In a series of 41 patients who underwent an immediate TRAM flap reconstruction and then received radiation, 78% experienced a volume loss, 56% had firmness within their flap, and 24% required an additional flap.[76]

Immediate reconstruction can also affect radiation field design. An interesting study evaluated PMRT fields in a cohort of 106 patients who had undergone immediate reconstruction and compared the field design to a matched control set of patients without a reconstruction at the time of treatment.[77]

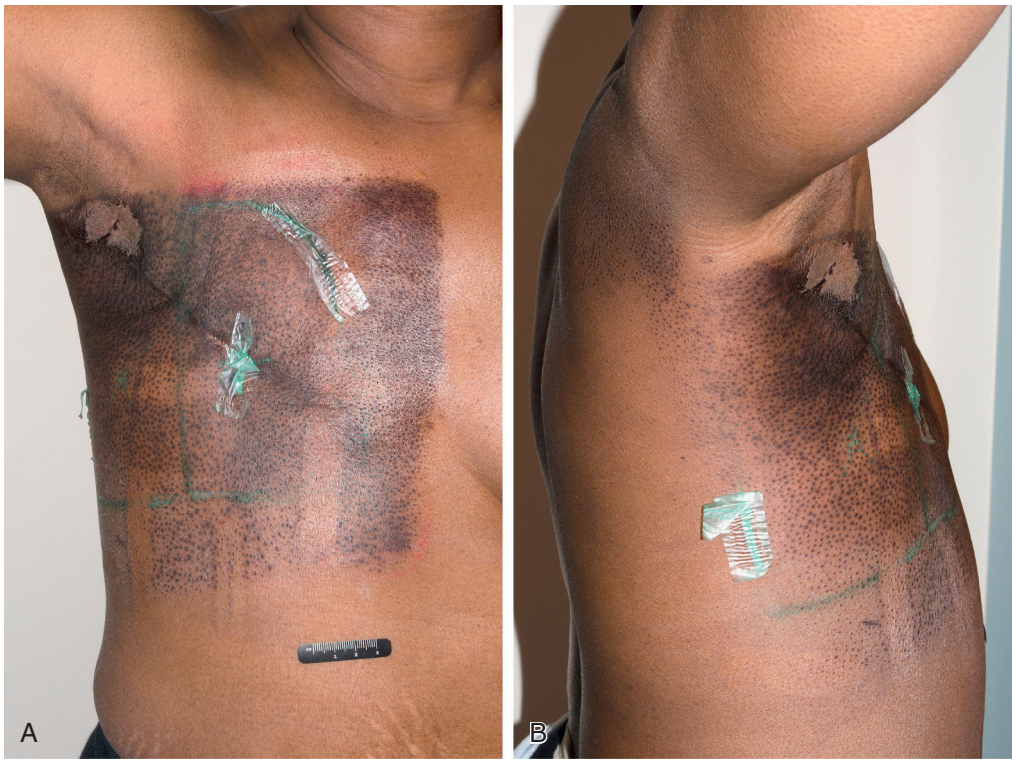

Figure 64-6 Anteroposterior **(A)** and lateral **(B)** views of a patient at the completion of 60 Gy in 30 fractions for a locally advanced breast cancer (50 Gy in 25 fractions using photon-electron technique to the chest wall and undissected nodal basins followed by 10 Gy in 5 fractions of an appositional electron boost using medial and lateral electron fields). The borders for her electron boost fields are outlined in green. This patient developed a grade 2 dermatitis with brisk erythema and hyperpigmentation that were essentially confluent across the chest wall and centered in follicles. There was no moist reaction. For patients with locally advanced breast cancer, this degree of skin reaction is appropriate. Care should be taken not to exceed this amount of skin reaction, thereby avoiding need for a treatment break before reaching the prescription dose.

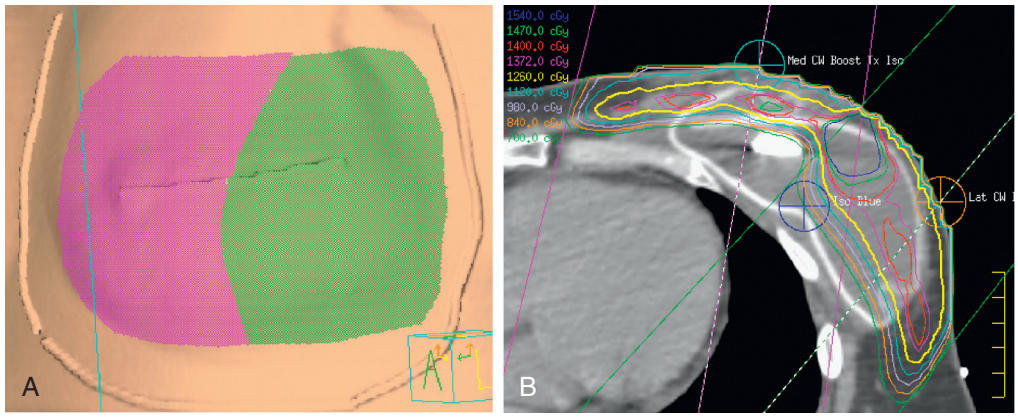

Figure 64-7 The chest wall boost fields used for the patient in Figure 64-5. The medial electron field was 6 MeV and the lateral was 12 MeV. She has a close (<2 mm) deep margin in the upper outer quadrant, so a higher energy for the lateral electron field was selected to ensure deeper coverage. The dose was 14 Gy in 7 fractions. Boost treatment was delivered in free breathing as breath-hold did not confer any additional benefit. Panel A shows the skin rendering, illustrating that the boost fields were designed to cover the skin flaps overlying the tissue expander. Panel B shows the axial dose distribution, with the 90% isodose line shown in yellow.

The authors reported that in 52% of the reconstruction cohort, a compromise had to be made in the treatment planning process compared to only a 7% rate for the control group. These compromises included inferior coverage of the chest wall, increased volume of lung or heart included in the radiation field, or inability to cover the internal mammary lymph nodes.

Accordingly, some patients with locally advanced disease may be best served by having a delayed reconstruction. Following radiation of the chest wall, it is often difficult if not impossible to undergo tissue expansion and placement of an implant such that most patients who undergo a delayed reconstruction require an autologous tissue flap. For selected cases that are candidates for a skin-sparing mastectomy, one can also considered a delayed-immediate reconstruction. In this procedure, a skin-sparing mastectomy is performed with placement of a tissue expander. The expander is inflated in the postoperative period but then partially deflated just before simulation to allow for optimal geometric design of the fields. After the acute skin reaction subsides, the expander

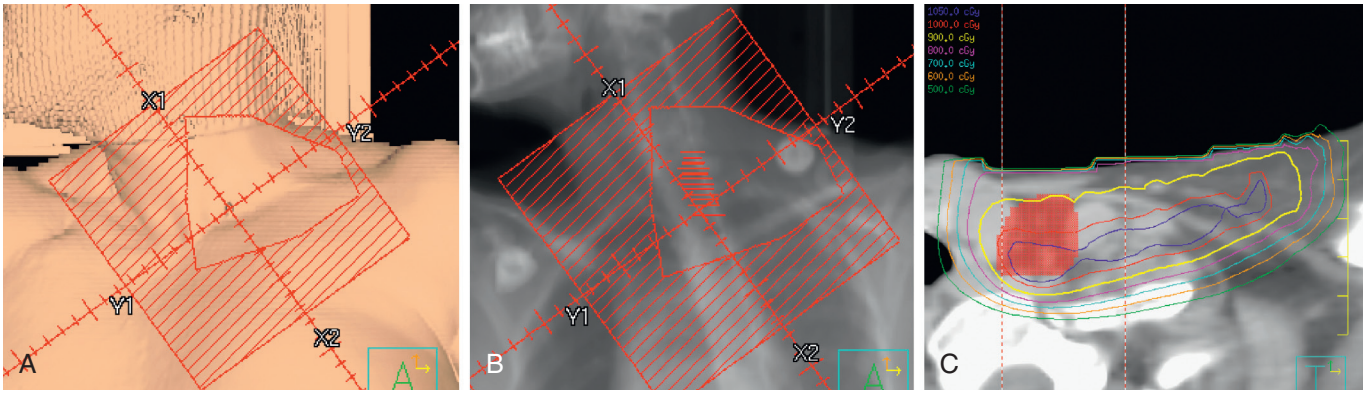

Figure 64-8 This patient had an ER+, HER2/neu-amplified left breast cancer, clinical stage T2 N3c, with biopsy-proven ipsilateral axillary and supraclavicular adenopathy. Her supraclavicular adenopathy was not palpable but was visualized on ultrasound. She responded to neoadjuvant chemotherapy and never had any cross-sectional imaging to document the precise location of initial involvement of the supraclavicular basin. She received a supraclavicular boost of 10 Gy in five fractions which resulted in long-term disease control and no major toxicity to the neck, although she did develop upper extremity lymphedema. Panel **A** shows the skin rendering for the supraclavicular boost field, Panel **B** the digitally reconstructed radiograph, and Panel **C** the axial dose distribution. The red contour is the medial supraclavicular nodal basin which was contoured to assist in treatment planning. The patient was treated in the open neck position with an aquaplast mask to unfold skin folds and improve coverage of the lateral low neck.

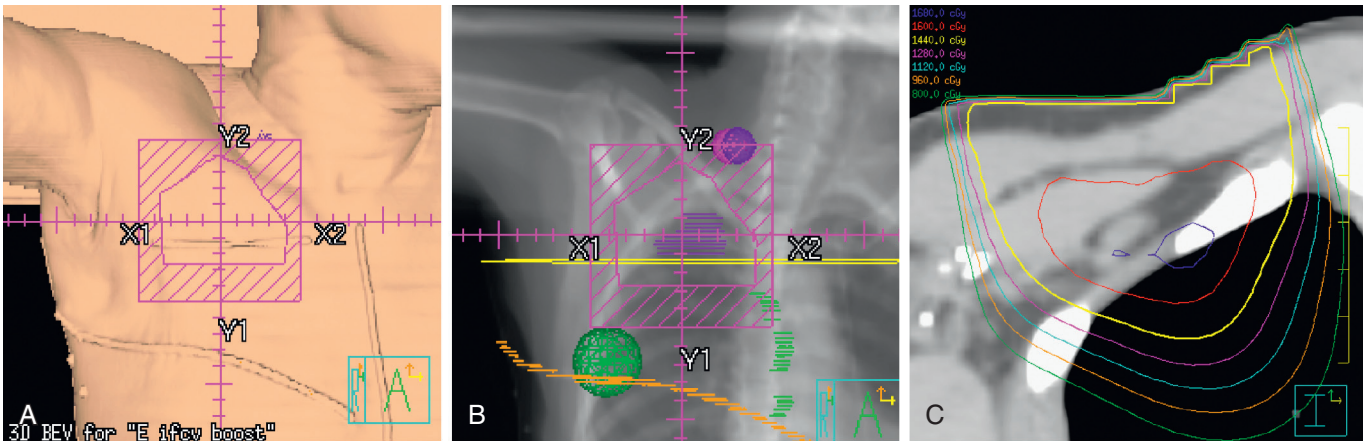

Figure 64-9 This is a patient with biopsy-proven infraclavicular and level II axillary disease that was treated with neoadjuvant chemotherapy and modified radical mastectomy. However, her level II lymph node was not resected at the time of modified radical mastectomy and remained grossly involved based on postoperative ultrasound. A dose of 16 Gy in eight fractions was delivered as an "infraclavicular" boost to encompass the levels II and III axillary nodal basins. (It should be noted that the terms *level III axilla* and *infraclavicular* are used synonymously in this chapter.) Panel **A** shows the skin rendering for the infraclavicular boost field, Panel **B** the digitally reconstructed radiograph, and Panel **C** the axial dose distribution. The yellow isodose line is the 90% isodose line; 16-MeV electrons were used to ensure that the 90% isodose line covered the involved level II axillary node. Note that the involved level II axillary node can be seen deep to the pectoralis minor on Panel **B**. It is important to carefully evaluate the postoperative anatomy at the time of simulation for any residual lymph nodes that may be involved. Postoperative ultrasound can be helpful to establish pathologic involvement and facilitate biopsy if indicated. When in doubt, integrating a boost confers relatively little morbidity and can help to eradicate residual macroscopic disease. For example, this patient's lymph node completely responded to her radiation and assumed a benign appearance within 3 months of completing radiation.

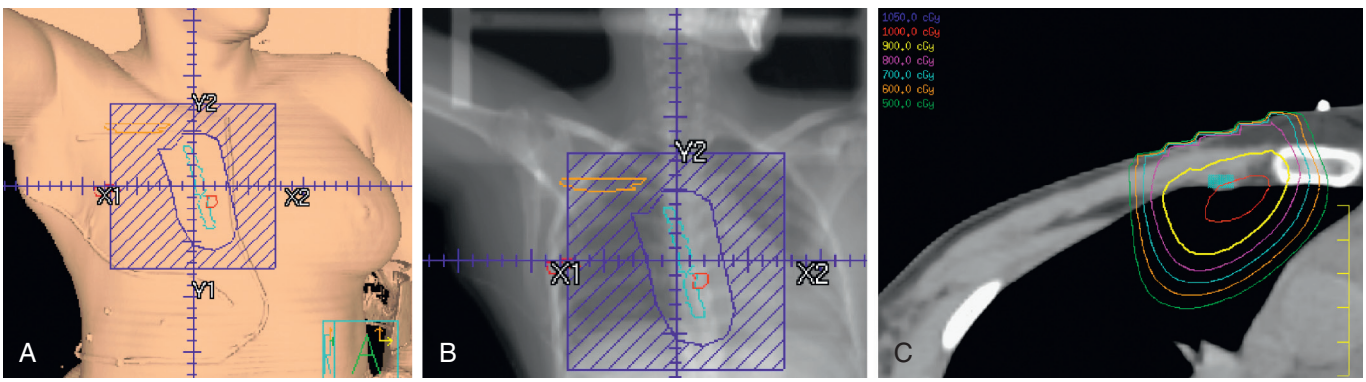

Figure 64-10 This is the internal mammary boost field used for the patient with T4c disease shown in Figure 64-2. She initially had involvement of a lymph node in the third internal mammary interspace, but this completely resolved during neoadjuvant chemotherapy based on serial ultrasound. Panel **A** shows the skin rendering for the internal mammary boost field, Panel B the digitally reconstructed radiograph, and Panel **C** the axial dose distribution. The red wireframe structure in Panel **B** is the area where the node was initially located, and the green indicates the internal mammary nodal chain in the first three interspaces. The prescription dose is 10 Gy in five fractions, but we attempt to cover the contoured target with the 90% isodose line, shown in yellow in Panel C. Seven-MeV electrons were used. Of note, this patient also required an infraclavicular boost, so the superolateral margin of the internal mammary boost field is modified to prevent overlap with the infraclavicular nodal field.

may be reinflated and, ultimately, replaced with an autologous tissue flap. Early results using this approach have been promising.[78]

OUTCOME

The routine use of chemotherapy and hormonal therapy has significantly improved the outcomes for patients with stage III breast cancer. Before the use of systemic treatments, few patients survived 10 years after surgery or radiation therapy.[1-3] In comparison, 67% of patients with stage IIB or IIIA disease and 33% of patients with stage IIIB/C disease survive 10 years if treated with anthracycline chemotherapy, surgery, radiation therapy, and hormonal treatments.[4] For patients with locally advanced breast cancer diagnosed in the early 2000s, SEER data indicate that 5-year survival is approximately 70%.

Multimodality treatment has also been able to improve long-term locoregional recurrence rates. For patients treated with chemotherapy, appropriate surgery, and endocrine therapy when indicated, combined with high quality radiation therapy planned in the three-dimensional era, 5-year locoregional recurrence risk is less than 5%.[67,79]

The subgroup of patients with locally advanced breast cancer who respond poorly to initial neoadjuvant chemotherapy remains a therapeutic challenge. It is clear that patients with a significant volume of residual primary disease or four or more lymph nodes after neoadjuvant chemotherapy have a poor prognosis, with disease-free survival rates of only 25% and locoregional recurrence rates as high as 25%.[67] New therapeutic approaches are needed for this cohort.

INFLAMMATORY BREAST CANCER

Inflammatory breast cancer is a unique and aggressive subgroup of locally advanced breast cancer manifested by rapid disease onset and the clinical findings of skin erythema, edema (peau d'orange), breast induration, warmth, and asymmetric enlargement. Typically, there is extensive lymphovascular invasion by tumor emboli that involve the superficial dermal plexus of vessels in the papillary and high-reticular dermis.

Inflammatory breast cancer comprises 1% to 6% of primary breast cancers.[80] There are no randomized prospective clinical trials that have specifically evaluated treatments in patients with inflammatory breast cancer. M. D. Anderson has one of the largest single-institution experiences in the treatment of inflammatory breast cancer, with a multidisciplinary clinic dedicated to the management of this disease. For patients managed in this multidisciplinary clinic who typically received both anthracycline- and taxane-based chemotherapy and HER2/neu-directed agents when indicated, 3-year overall survival was 82%, compared with 63% for patients treated in a previous era.[81] This finding underscores the importance of aggressive polychemotherapy, targeted therapy, and coordinated, multidisciplinary care to optimize outcomes for patients with inflammatory breast cancer.

The current standard of care for patients with inflammatory breast cancer is initial neoadjuvant chemotherapy followed by mastectomy, if feasible, and PMRT. In our institution, we have used an accelerated radiation schedule, giving patients twice-daily treatments (1.5 Gy twice daily to a total dose of 51 Gy to the chest wall and draining lymphatics, followed by a boost to the chest wall of an additional 15 Gy). In an initial retrospective analysis, this twice-daily schedule to 66 Gy total dose was associated with a locoregional recurrence rate of 16%, which was much lower than the 42% rate during the era when treatment was given to 60 Gy or when once-a-day radiation schedules were used.[72] An update of this experience reported that the majority of patients continued to have a benefit from the higher 66 Gy dose but that this dose was also associated with a 17% rate of grade 3 or greater toxicity. Patients who were older than age 45 and had favorable pathological responses to neoadjvuant chemotherapy and negative surgical margins were found to do equally well with the 60-Gy dose, and as such in this selected cohort the higher toxicity with 66-Gy does not appear to be warranted.[82]

Patients who do not respond favorably to neoadjuvant chemotherapy have a poor prognosis and may require locoregional therapy with preoperative radiation therapy or definitive radiation therapy alone. For patients with inflammatory breast cancer who present with distant metastases, recent data indicate that patients with a major response to chemotherapy who go on to receive mastectomy and PMRT can do relatively well, with 50% 5-year overall survival and 32% 5-year disease-free survival.[83] This finding suggests that aggressive local therapy may specifically benefit patients with metastatic inflammatory breast cancer provided they experience a major response to chemotherapy; further research is indicated to corroborate these findings.

TREATMENT ALGORITHMS

Figures 64-11 and 64-12 show treatment algorithms for patients with locally advanced breast cancer and patients with inflammatory breast cancer, respectively.

NEW THERAPEUTIC APPROACHES

The current era is arguably the most exciting in the history of breast cancer therapeutics. Development of novel therapies that target the estrogen receptor pathway and the HER2/neu pathway has already revolutionized treatment, and additional active agents seem to appear on an almost yearly basis. Given the demonstrated synergy between radiation and systemic therapy with regard to improving survival outcomes, it is likely that the introduction of newer agents may actually increase the survival benefit conferred by radiation.

Triple-negative, chemotherapy-refractory locally advanced breast cancer remains an area of considerable therapeutic challenge. Platinum agents have shown activity in triple-negative breast cancer and may begin to play an increasingly important role for this subtype.[84] In addition, for patients with either unresectable disease or those at high risk for locoregional recurrence after resection, it is possible that concurrent chemoradiation may become an important component of therapy. At present, data are limited but experiences exist to support consideration of concurrent taxane- or platinum-based chemoradiation.[85-87] Our own experience with concurrent capecitabine and radiation has shown mixed results, with some long-term control in patients who are estrogen receptor–positive, but uniformly poor outcomes for triple-negative disease.

Finally, technological advances in radiation therapy continue to influence how breast cancer radiation is delivered and planned. Many centers are increasingly using intensity-modulated radiation therapy or arc-based therapy, yet the long-term implications of low dose radiation exposure to the entire thorax remain an area of active debate.[88] The increasing dissemination of proton therapy may also influence treatment approaches to locally advanced breast cancer, particularly in patients with unfavorable anatomy for standard approaches or with extensive disease extending into the mediastinum (Figure 64-13). Given the prevalence of breast cancer and the societal imperative to control growth in healthcare spending, there will likely be growing pressures to develop and embrace effective yet economical radiation treatment strategies for locally advanced breast cancer.

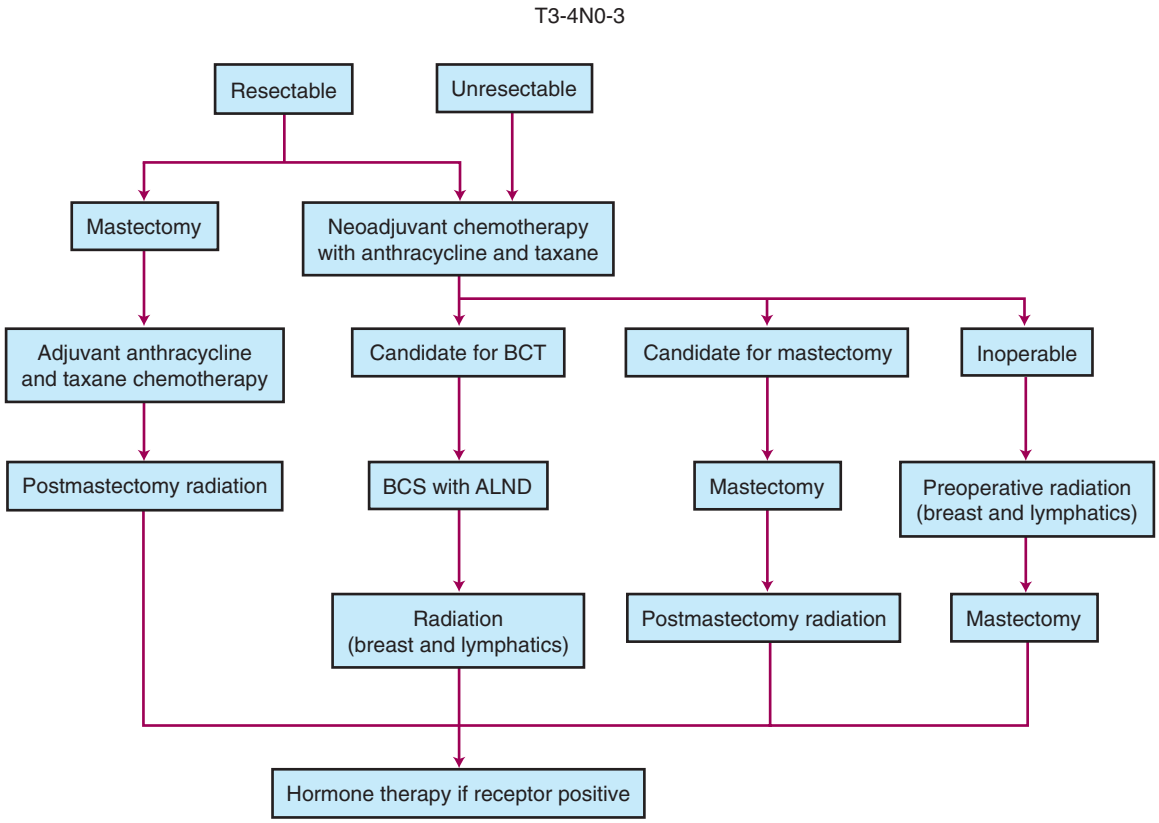

Figure 64-11 **A treatment algorithm for patients with locally advanced breast cancer.** *ALND,* Axillary lymph node dissection; *BCT,* breast-conserving therapy.

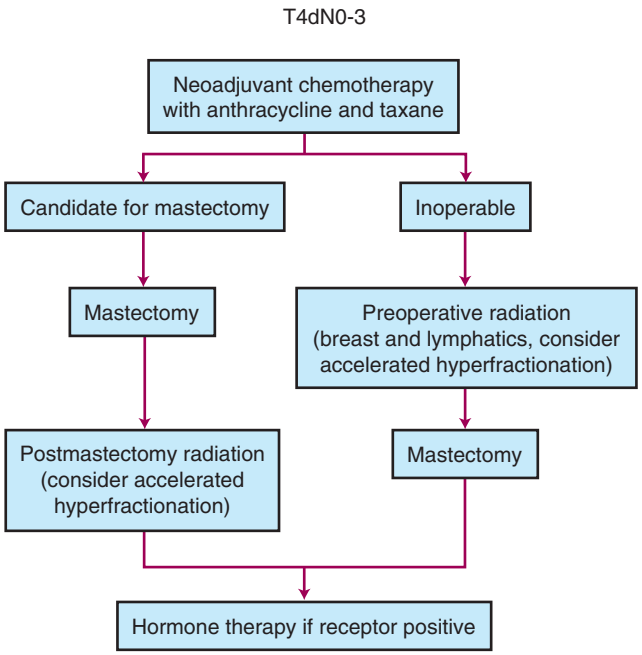

Figure 64-12 **A treatment algorithm for patients with inflammatory breast cancer.**

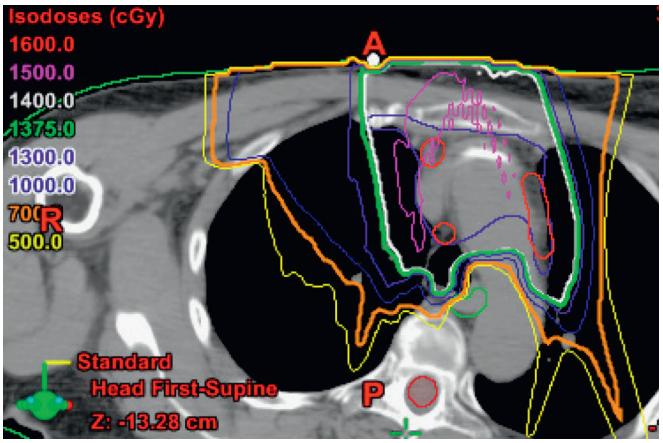

Figure 64-13 This patient had triple negative inflammatory breast cancer; her initial positron emission tomography–computed tomography (PET-CT) is shown in Figure 64-2, **A-B**. She experienced a major clinical response to neoadjuvant chemotherapy and underwent modified radical mastectomy showing minimal residual disease. She received postmastectomy radiation therapy with a photon field directed to her involved mediastinal nodes for the first 51 Gy delivered at 1.5 Gy twice a day. She then received a proton boost as shown in this figure to the supraclavicular, infraclavicular, internal mammary, and anterior mediastinal nodal basins. A dose of 14.4 Gy in eight fractions delivered once daily was used. She did well with no major pulmonary or cardiac toxicity and remains alive without evidence of recurrence several years after completing radiation.

CONCLUSIONS

Radiation therapy plays a vital role in the management of locally advanced breast cancer, synergizing with optimal surgery, and systemic therapies to optimize long-term locoregional control and survival. Thoughtful multidisciplinary integration of radiation with the other members of the breast cancer multidisciplinary team is vitally important to optimize cure rates and patient quality of life after treatment. Future improvements in biologic understand of breast cancer and systemic treatments should synergize with radiation to further improve outcomes for patients with locally advanced breast cancer.

CHAPTER 65

Soft-Tissue Sarcoma

Kaled M. Alektiar

EPIDEMIOLOGY AND PATHOLOGY

Soft-tissue sarcomas (STS) account for approximately 1% of adult cancers in the United States. The estimated number of newly diagnosed cases in the year 2014 was projected to be 12,020, with a slightly higher male-to-female ratio and 4,740 deaths. The peak incidence of STS is the fifth decade of life, but histology such as rhabdomyosarcoma has a peak incidence in the first decade of life. The most common site is the extremity (40%) followed by visceral (22%), retroperitoneal and intraabdominal (16%), trunk (10%), and other (12%). There are about 50 histologic types of STS, the most common being liposarcoma, undifferentiated pleomorphic sarcoma and myxofibrosarcoma, synovial sarcoma, and leiomyosarcoma. About 65% of STS are high grade and 35% are low grade.

BIOLOGIC CHARACTERISTICS

About 30% of STS have signature translocations, such as *SS18-SSX1* or *SS18-SSX2* in synovial sarcoma or t(12;16) in myxoid liposarcoma. Other sarcomas have oncogenic mutation such as *KIT* in gastrointestinal stromal tumor (GIST). The large majority of STS exhibit more complex genomic patterns. These molecular studies are having a significant impact on our understanding of the pathogenesis of STS and are providing more refined tools for classifying these tumors.

STAGING EVALUATION

Lesion size, mobility, relationship to the investing fascia, and adjacent neurovascular structures or bone are important parts of the tumor assessment. All soft-tissue masses deep to the fascia should be considered sarcoma until proven otherwise. Histologic confirmation, typically with core biopsy, is necessary. For extremity STS, imaging includes magnetic resonance imaging (MRI) of the extremity and chest computed tomography (CT). In patients with low-grade and small lesions, a plain chest radiograph may be sufficient. Imaging of the spine is important in patients with myxoid liposarcoma. For intraabdominal STS, CT chest, abdomen, and pelvis is preferred for assessment of the primary tumor as well as potential spread to lung, peritoneum, or liver. Major prognostic factors are pathologic grade, tumor size, and depth of involvement. These factors, combined with the presence of nodal involvement (rare except in certain histologic subtypes), and distant metastases, comprise the TNM stage classification.

PRIMARY THERAPY

Surgery is the main treatment for all STS. The role of adjuvant radiation therapy (RT) is well-established in extremity STS. One randomized trial showed that when RT was added to limb-sparing surgery, the results were equivalent to amputation in terms of survival. Two other trials showed that adjuvant RT significantly improved local control in the setting of limb-sparing surgery. RT is mainly external beam radiation therapy (EBRT) either preoperatively or postoperatively. A randomized trial comparing the two sequences showed significantly higher rate of wound complication with preoperative EBRT, but fewer long-term complications. Typical dose for preoperative EBRT is 50 Gy at 2 Gy per fraction, and for postoperative EBRT, 63 Gy at 1.8 Gy. Clinical target volume (CTV) is generated by expanding gross tumor volume and tumor bed by 4 cm longitudinally and 1 cm axially (except near bone, where no margin is added). The role of adjuvant chemotherapy remains controversial. For nonextremity sites, the role of adjuvant RT is less clear, and treatment recommendations need to be individualized.

PALLIATION

The main treatment for most metastatic STS is chemotherapy. Combination doxorubicin and ifosfamide provide higher rate of response than doxorubicin alone but without significant impact on survival and with higher toxicity rate. Treatment should be individualized; synovial sarcomas tend to respond better to combination chemotherapy, angiosarcomas to paclitaxel, and leiomyosarcomas to gemcitabine and docetaxel. Resection of lung metastasis is appropriate in patients with good performance status and limited extent of metastatic disease. There is an emerging role for stereotactic body radiation therapy (SBRT) in the treatment of lung or spinal metastasis.

STS account for approximately 1% of adult cancers in the United States. The number of newly diagnosed cases in year 2014 was projected to be 12,020, with a slightly higher male-to-female ratio; 6550 in males and 5470 in females. The estimated number of deaths was 4740.[1] These tumors can arise from any part of the body and can affect all age groups. Based on 10,000 cases of STS from Memorial Sloan Kettering Cancer Center (MSKCC), the most common site is the extremity (40%) followed by visceral (22%), retroperitoneal and intraabdominal (16%), trunk (10%), and other (12%). In general, the peak incidence of STS is the fifth decade of life, but histology such as rhabdomyosarcoma, tends to occur in young patients where

the peak incidence is in the first decade of life. About 65% of STS are high grade and 35% are low grade. Tumor size distribution is as follows: large (≥10 cm) in 38% of patients, medium in 31%, and small (≤5 cm) in 31%. Depth (with respect to the superficial fascia) is considered deep in 87% of cases and superficial in 13%. The three most-common histologic types are liposarcomas, undifferentiated pleomorphic sarcomas (previously known as malignant fibrous histiocytoma), and leiomyosarcomas.

The predominant form of relapse for STS is distant, mainly to lungs for extremity STS, and lung and liver for retroperitoneal and intraabdominal as well as visceral STS. In retroperitoneal and intraabdominal STS, local recurrence (LR) is more common than distant recurrence, whereas the opposite is true for extremity and visceral STS. Extremity and trunk STS have the highest rate of survival, about 60% disease-specific survival at 10 years, whereas retroperitoneal and visceral have the lowest, 40% at 10 years.

ETIOLOGY AND EPIDEMIOLOGY

Environmental Factors

The majority of STS develop without having clear predisposing factors. In some patients environmental, immunologic, and familial factors have been reported. Among environmental factors, exposure to radiation is one of the most commonly cited risk factors. The exact mechanism of radiation-associated sarcomas is not clear. It is possible that the genetic defect that may have led to the development of the first cancer for which RT was administered, may in turn, have led to the induction of the RT-associated sarcoma.[2] An example is the risk of secondary cancers in hereditary as opposed to nonhereditary retinoblastoma. In a study of 1604 patients with retinoblastoma who survived at least 1 year after diagnosis, the cumulative incidence of a second cancer at 50 years after diagnosis was 51% for hereditary retinoblastoma and 5% for nonhereditary retinoblastoma. The conclusion from this study was that genetic predisposition has a substantial impact on risk of subsequent cancers in patients with retinoblastoma.[3] The incidence of radiation-associated STS is not well established because in part of a long latency period. In a study from Finland of 295,712 patients with cancer treated with radiation and/or chemotherapy, 147 sarcomas were found compared with 88.5 expected. STS comprised 86% of the sarcomas. At 10 years of follow-up, the cumulative incidence of sarcoma was 0.03% (95% confidence interval [CI], 0.017% to 0.037%) among patients who received radiotherapy and 0.02% (95% CI 0.017% to 0.032%) among patients who did not receive radiotherapy.[4] The prognosis of RT-associated STS is significantly worse than sporadic STS independent of histologic type.[5]

The exposure to chemical carcinogens, including Thorotrast, vinyl chloride, and arsenic, have been linked to hepatic angiosarcomas. Workers exposed to phenoxyherbicides, chlorophenols, and dioxins had higher mortality rates from cancer compared with controls, and the increase was highest for STS.[6-8] There have been conflicting reports about occupational exposure to phenoxyacetic acids detectable in chlorophenols (frequent in wood preservatives) and certain herbicides.[9-12] Trauma is not considered a risk factor for STS; often a minor trauma draws the attention to the lesions. The question of whether the trauma from orthopedic surgery may increase the risk of sarcoma was addressed in a study from the Finnish Arthroplasty Register. A cohort of 24,636 patients with primary osteoarthritis and metal-on-polyethylene total hip arthroplasty who had been entered in the Finnish Arthroplasty Register were assessed for cancer risk. The mean follow-up time was 13 years. The numbers of cancer cases observed were comparable to the incidence in the general population.[13]

Immunologic Factors

Systemic or regional immunologic factors have been linked to STS. For systemic factors, HIV-related Kaposi's sarcoma, which is linked to human herpes virus 8, is well documented. Patients who are immunosuppressed such as patients who have undergone transplants are also at increased risk of smooth muscle tumors that are linked to Epstein-Barr virus. Chronic lymphedema, which could be considered a regional immunodeficiency phenomenon (Stewart-Treves syndrome), has been implicated in the development of lymphangiosarcoma in patients with breast cancer treated with radical mastectomies and axillary lymph node dissection.[14] It is important to note that this sarcoma is not directly linked to radiation exposure because some of these patients did not have radiation and even those who did, many developed their lymphangiosarcoma outside the radiation field.

Hereditary Factors

STS are occasionally associated with inherited genetic conditions. Neurofibromatosis type I is an autosomal dominant disorder with deletion or loss of function of *NF1* on chromosome 17. The product of *NF1* is neurofibromin, which generally suppresses RAS activity. The risk of developing a malignant peripheral nerve sheath tumors in these patients is about 10% over a lifetime.[15] Li-Fraumeni syndrome is another autosomal dominant hereditary cancer syndrome with a spectrum of tumors including breast cancer (most common), sarcomas (second-most common), leukemia, brain tumors, and adrenocortical carcinomas.[16,17] The underlying abnormality is germline deletion of the *p53* suppressor gene. The function of *p53* is to guard the integrity of the genome against DNA-damaging agents or hypoxia. When normal *p53* is activated, it leads to cell cycle arrest at G1 and induction of DNA repair. Gardner's syndrome, a subset of familial adenomatous polyposis, is associated with the development of intraabdominal desmoids.[18] In these patients there is loss of expression of the adenomatous polyposis coli (APC) gene.

PREVENTION AND EARLY DETECTION

General screening for sarcoma in the population at large is problematic given its rarity. Patients at increased risk for sarcoma require a more detailed clinical evaluation at a lower threshold of intervention than one might use in general practice. Deep lesions always require investigation, especially if there is a history of growth, and any superficial or deep abnormality of skin or soft tissues in patients with a history of prior RT requires careful evaluation. Predisposing genetic tendencies should be considered.

Unfortunately, in the clinical management context, the cause of an individual sarcoma is of limited significance because it generally does not affect therapeutic decision making beyond the fact that patients who have sarcomas arising in a previously irradiated field cannot easily receive further RT, and there may be limitations in surgery as well.

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

Considerable progress has been made in the field of molecular genetics of STS. To some extent STS can be divided into two

genomically distinct groups: sarcomas with specific genetic alterations and sarcomas with complex genetic alteration.

Sarcomas with Specific Genetic Alterations

This group includes STS with either a reciprocal chromosomal translocations, which account for 30% of sarcomas (e.g., *SS18-SSX1* or *SS18-SSX2* in synovial sarcoma), or specific-activating mutation (e.g., *KIT* in gastrointestinal stromal tumors). Most translocation-associated sarcomas arise de novo and seem to maintain their simple genetic abnormality throughout their clonal evolution.[19] The karyotypes of these tumors are simple and near diploid. The fusion genes resulting from the translocations can encode abnormal transcriptional proteins, growth factors, or tyrosine kinases. An example of aberrant transcriptional protein is FUS-CHOP protein resulting from t(12;16) in myxoid liposarcoma. The FUS-CHOP oncoprotein regulates transcriptions of adipocytic maturation factors as well as angiogenic and proinflammatory factors. An example of growth factor abnormality, involves upregulation of platelet-derived growth factor-B (PDGFB) when fused with collagen 1 alpha 1 (COL1A1), resulting from t(17;22) as seen in dermatofibrosarcoma protuberans. Oncogenic mutation in *KIT*, and to a lesser extent in platelet-derived growth factor receptor-α (PDGFR-α), is an example of mutation in a driver gene.

Sarcomas with Complex Genetic Alterations

The majority of STS belong to this group. The karyotypes of these sarcomas are complex with a great deal of genomic instability including changes in chromosome number, unbalanced translocations, genetic deletions, and amplifications.[20] Several genes responsible for maintaining the integrity of the genome such as *TP53, NF1, PTEN, CDKN2A, CDKN2b,* and *RB1* are often deleted in these sarcomas. These tumors contain several genomic aberrations in the genome of a single tumor and heterogeneity of aberrations across tumors of a given type.[19] Most of these tumors arise de novo, but a subset show histological progression (e.g., progression of well-differentiated to dedifferentiated liposarcoma) that is accompanied by increasing genetic complexity.

The better understanding of sarcomas at the molecular level is having an impact on our understanding of its pathogenesis, is improving our diagnostic accuracy in a group of tumors known for histological complexity, and is beginning to give us new insights on how to treat some of these tumors. The therapeutic implications and the improved classifications of sarcomas will be discussed later in the chapter.

Molecular pathogenesis of sarcomas can be viewed in three broad categories. Transcriptional target dysregulation results from abnormal fusion proteins in translocation-associated STS. Mutations in key genes and signaling pathways constitute another mechanism in sarcomagenesis. As mentioned previously, oncogenic mutation in *KIT* or in PDGFR-α is an example of mutation in a driver gene. Most sarcomas, however, including those that are translocation-associated, do not have a well-defined driver mutation. Some of the common mutations in signaling pathways include *TP53, NF1,* and *PI3K*. *TP53* mutations are seen in about 17% of pleomorphic liposarcomas, *PI3K* mutations in 18% to 20% of myxoid and round cell liposarcomas, and *NFI* in 8% to 11% of myxofibrosarcomas and pleomorphic liposarcomas. A DNA copy number alteration is the third mechanism in sarcoma pathogenesis. This is the hallmark for sarcomas with complex genetic alterations. However, even within this group, the complexity varies, with some sarcomas being moderately complex as seen in some dedifferentiated liposarcoma (Figure 65-1).

PATHOLOGY AND PATHWAYS OF SPREAD

Pathology Classification

Pathologic classification of STS is challenging. There are about 50 histologic types of STS. Traditional approaches relied heavily on trying to match the morphology of STS with what is thought to be the soft tissue of origin of the sarcoma. Such an approach has its limitations, for example, synovial sarcomas do not arise from the synovium per se. Malignant fibrous histiocytoma (MFH), considered one of the most common histologies, was thought to derive from histiocytes. Not only was that derivation unfounded, the term *MFH* itself is questionable because on reexamination many of these tumors could be classified along other lineages.[21]

The current emphasis in pathologic classification of STS is more on the line of differentiation of the tumor, such as adipocytic (e.g., liposarcomas), fibroblastic and myofibroblastic (myxofibrosarcoma), smooth muscles (leiomyosarcoma), skeletal muscles (rhabdomyosarcomas), nerve sheath (malignant nerve sheath tumors), undifferentiated (undifferentiated pleomorphic sarcoma), and uncertain differentiation (synovial sarcoma). Light microscopic examination plays a significant role in assigning histologic type and grade.

Grading of STS is critical; in fact, the staging system is primarily driven by it. There are several grading systems in use: at MSKCC a two-tier system is used (high versus low), the American Joint Committee on Cancer (AJCC) staging system uses a three-tier system (grades 1, 2, and 3). Irrespective of the system, grade is highly predictive of outcome, in terms of LR, distant spread, and survival. These different grading systems rely, to a varying degree, on tumor differentiation, mitosis, degree of necrosis, and histologic subtypes. No grading system is perfect; at MSKCC the two-tier system is preferred because of its simplicity. Low grade is equivalent to grade 1 in the three-tier system, and high grade is equivalent to grade 2 or 3.

In addition to morphology, there has been a great emphasis on using immunohistochemistry to better assign a line of differentiation. Some of the common markers used to determine line of differentiation include desmin, vimentin, cytokeratin, and S-100 to name a few. Newer markers are being used to detect specific molecular aberrations such as MDM2/CDK4 amplification in well-differentiated and dedifferentiated liposarcomas to separate them from benign lipomatous tumors. Perhaps the biggest improvement in STS classification has been through molecular testing. For example, signature translocations such as t(X; 18) is diagnostic for synovial sarcomas. STS rank second to hematological malignancies in the number of signature translocations (Table 65-1). The molecular tests used to detect a translocation generally include reverse transcriptase-polymerase chain reaction (RT-PCR), and fluorescence in situ hybridization (FISH). The 2013 World Health Organization (WHO) classification of soft-tissue tumors relies on morphology, immunohistochemistry, and genetic features[22] (Box 65-1).

Selected Pathologic Subtypes

Liposarcoma

Liposarcoma is the most common histology when all sites are considered. In the 2013 WHO classification, there are four subtypes of liposarcoma: myxoid, dedifferentiated, pleomorphic, and not otherwise specified. Atypical lipomatous tumor and well-differentiated liposarcoma are considered intermediate (locally aggressive) in the WHO classification. Most well-differentiated liposarcomas (WDL) occur in the fifth to seventh decades of life. Extremity is the most common location (about 75%) followed by retroperitoneum. These low-grade tumors

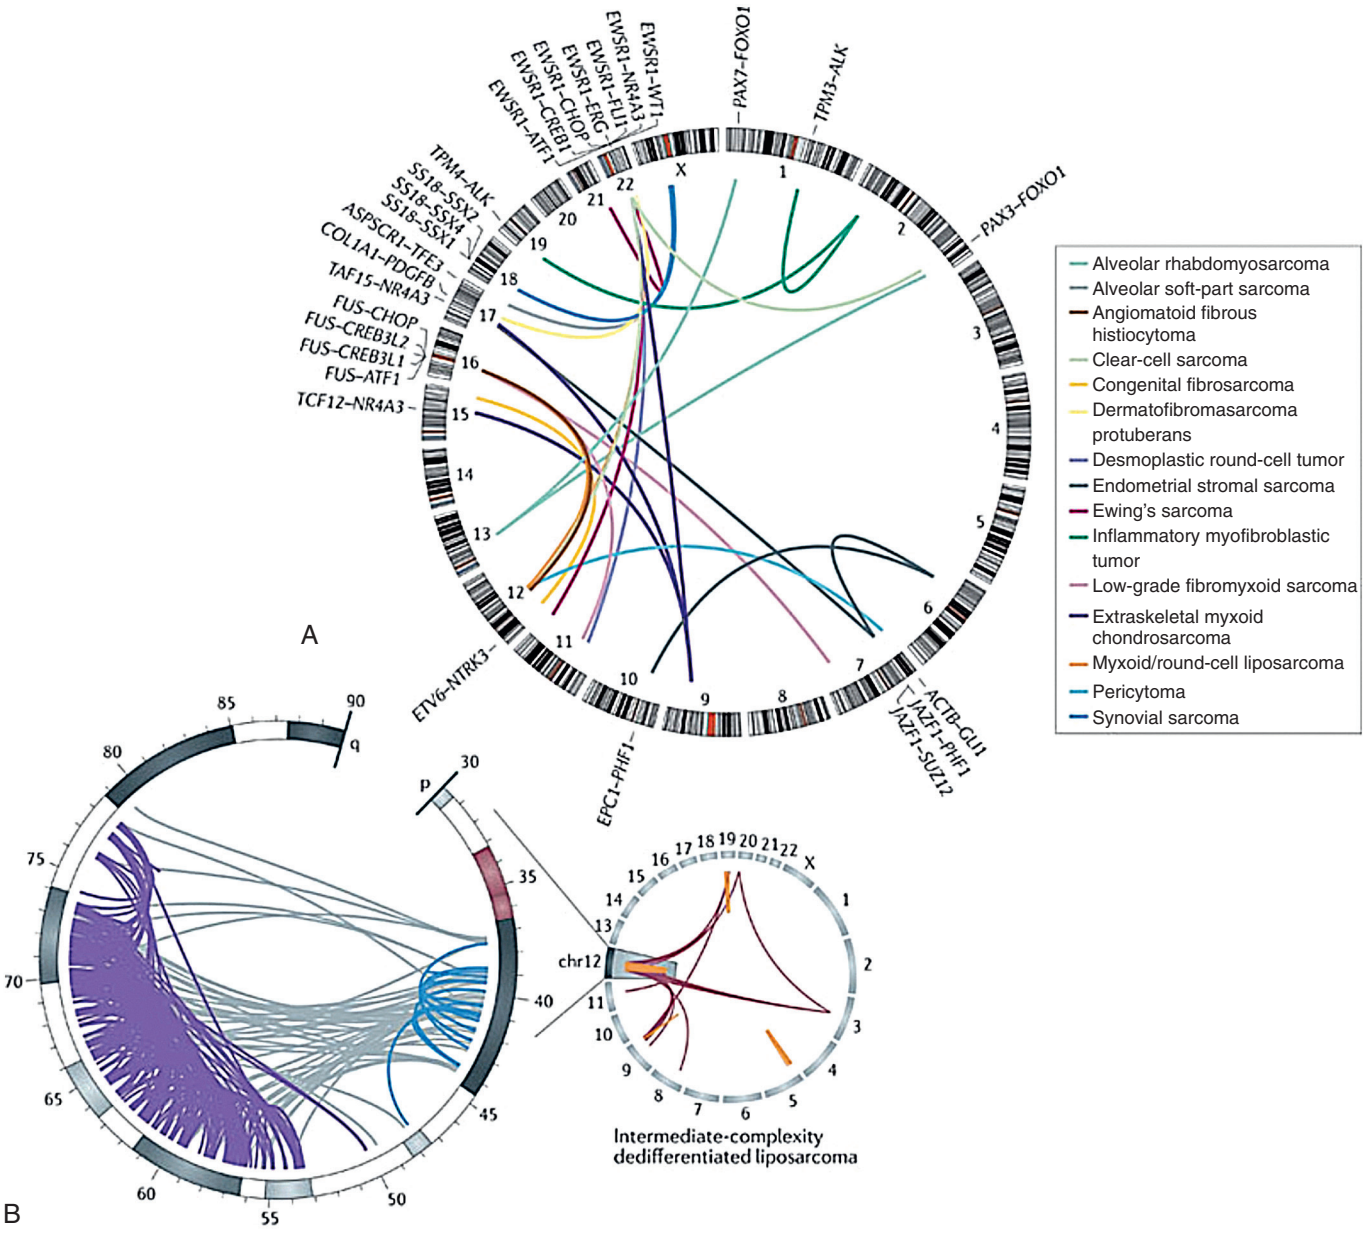

Figure 65-1 The structure of sarcoma genomes. **A,** Common translocations in soft-tissue sarcomas. The ring represents the whole genome from chromosome 1 to 22 as well as *X* chromosome. Example, translocation between chromosome 18 and chromosome X in synovial sarcomas. **B,** The right panel shows somatic structure of an intermediate-genomically complex sarcoma, a dedifferentiated liposarcoma. There are interchromosomal rearrangements shown in dark red and intrachromosomal rearrangements are shown in orange. The left panel shows the pathognomonic chromosome 12q amplifications in greater detail.

tend to have an indolent course with low risk for distant recurrence irrespective of site. Extremity WDL can recur locally, but the risk is relatively low to justify routine use of adjuvant RT, especially in the primary setting. In contrast, WDL in the retroperitoneum tends to recur often.

Myxoid liposarcoma has a signature translocation[19,20] at t(12:16) in 90% of cases and t(12;22) in less than 5%. They are predominantly seen in extremity sites (most common liposarcoma in extremity) and affect younger patients usually in the third to fourth decades of life. The term *round cell* is no longer used in association with myxoid liposarcoma based on the 2013 WHO classification; these tumors are graded to reflect the spectrum of their behavior. Recognizing myxoid liposarcoma has significant clinical implications for radiation oncologists because these tumors are exquisitely radiosensitive[23,24] (Figure 65-2). In addition they tend to metastasize to unusual sites for STS, such as the spine.[25]

Dedifferentiated liposarcomas are often seen in the retroperitoneum (75%), but other sites include spermatic cord, trunk, and head and neck. It commonly affects older patients and on imaging, the tumors can have a mixture of solid masses (similar to other STS), mixed with areas of "fatty-looking"

tissues. Microscopically this is represented by a mixture of WDL and dedifferentiated liposarcomas.

Pleomorphic liposarcomas are the least common liposarcomas. They can arise in an extremity or the retroperitoneum. They are high-grade lesions with aggressive behavior. At MSKCC, a nomogram has been developed to predict the outcome of liposarcoma across different sites.[26]

TABLE 65-1 Translocation-Associated in Selected Soft-Tissue Sarcoma

Histologic Subtype	Translocations	Genes Involved
Alveolar sarcoma of soft parts	t(X;17)(p11;q25)	*TFE3-ASPL*
Clear cell sarcoma	t(12;22)(q13;q12)	*EWSR1-ATF1*
Desmoplastic small round cell tumor	t(11;22)(p13;q12)	*EWSR1-WT1*
Ewing's	t(11;22)(q24;q12) t(21;22)(q22;q12)	*EWSR1-FLI1* *EWSR1-ERG*
Myxoid liposarcoma	t(12;16)(q13;p11) t(12;22)(q13;q12)	*FUS-DDIT3* *EWSR1-DDIT3*
Rhabdomyosarcoma (alveolar)	t(2;13)(q35;q14) t(1;13)(p36,q14)	*PAX3-FOXO1* *PAX7-FOXO1*
Synovial sarcoma	t(X;18)(p11;q11) t(X;18)(p11;q11)	*SS18-SSX1* *SS18-SSX2*

Undifferentiated Pleomorphic Sarcoma

MFH used to be the most common type of STS. Several studies, however, have shown that many of such pleomorphic tumors, using immunohistochemistry and other ancillary studies, could be assigned a line of differentiation, such as liposarcomas, leiomyosarcomas, and rhabdomyosarcomas.[21] The 2013 WHO classification does not recognize MFH as an entity; instead many such tumors now belong to a category called *undifferentiated/unclassified sarcomas*. Within this new category there are several subtypes: pleomorphic, spindle, round cell, epithelioid, and not otherwise specified.

Undifferentiated pleomorphic sarcomas (UPS) generally affect older patients typically in the sixth and seventh decades of life. Most patients present with deep lesions in the extremity, especially thigh. Retroperitoneal location is not common; pleomorphic sarcoma morphology in this location is more likely to be dedifferentiated liposarcoma. These tumors are high grade and exhibit complex genetic alterations. The natural history is extraordinarily variable, reflecting the heterogeneity of these lesions. The most common site for metastases from pleomorphic sarcomas is the lung (90%), bone (8%), and liver (1%), with rare regional lymph node metastases.[27]

Myxofibrosarcoma

These tumors used to be considered a subtype of MFH, myxoid MFH. In the WHO classification, myxofibrosarcoma is recognized as its own entity, belonging to the fibroblastic and myofibroblastic tumors category. Myxofibrosarcoma often arise in

BOX 65-1 Histologic Classification of Soft-Tissue Sarcoma (Selected Histologies)

FIBROBLASTIC AND MYOFIBROBLASTIC TUMORS

Intermediate (Locally Aggressive)

Desmoids-type fibromatoses.
Intermediate (rarely metastasing)
Dermatofibrosarcoma protruberans
Solitary fibrous tumor

Malignant

Adult fibrosarcoma
Myxofibrosarcoma
Low grade fibromyxoid sarcoma
Sclerosing epithelioid fibrosarcoma

ADIPOCYTIC TUMORS

Intermediate (Locally Aggressive)

Atypical lipomatous tumor
Well-differentiated liposarcoma

Malignant

Myxoid liposarcoma
Dedifferentiated liposarcoma
Pleomorphic liposarcoma
Liposarcoma–not otherwise specified

SMOOTH MUSCLE TUMORS

Leiomyosarcoma

SKELETAL MUSCLE TUMORS

Malignant
Rhabdomyosarcoma
Embryonal rhabdomyosarcoma
Alveolar rhabdomyosarcoma
Pleomorphic rhabdomyosarcoma
Spindle cell and sclerosing rhabdomyosarcoma

VASCULAR TUMORS

Epithelioid hemangioendothelioma
Angiosarcoma of soft tissue
Kaposi's sarcoma

PERIVASCULAR TUMORS

Malignant glomus tumors

NERVE SHEATH TUMORS

Malignant peripheral nerve sheath tumor (MPNST)
Malignant triton tumor
Glandular MPNST
Epithelioid MPNST
Malignant granular cell tumor

TUMORS OF UNCERTAIN DIFFERENTIATION

Alveolar soft part sarcoma
Clear cell sarcoma
Epithelioid sarcoma
Desmoplastic small cell tumor
Extra-skeletal Ewing's sarcoma
Extra-skeletal myxoid chondrosarcoma
Neoplasms with perivascular epithelioid cell differentiation (PEComa)
Synovial sarcoma

UNDIFFERENTIATED/UNCLASSIFIED SARCOMAS

Undifferentiated pleomorphic sarcoma (UPS)
Undifferentiated spindle cell sarcoma
Undifferentiated round cell sarcoma
Undifferentiated epithelioid sarcoma
Undifferentiated sarcoma–not otherwise specified

GASTROINTESTINAL STROMAL TUMORS

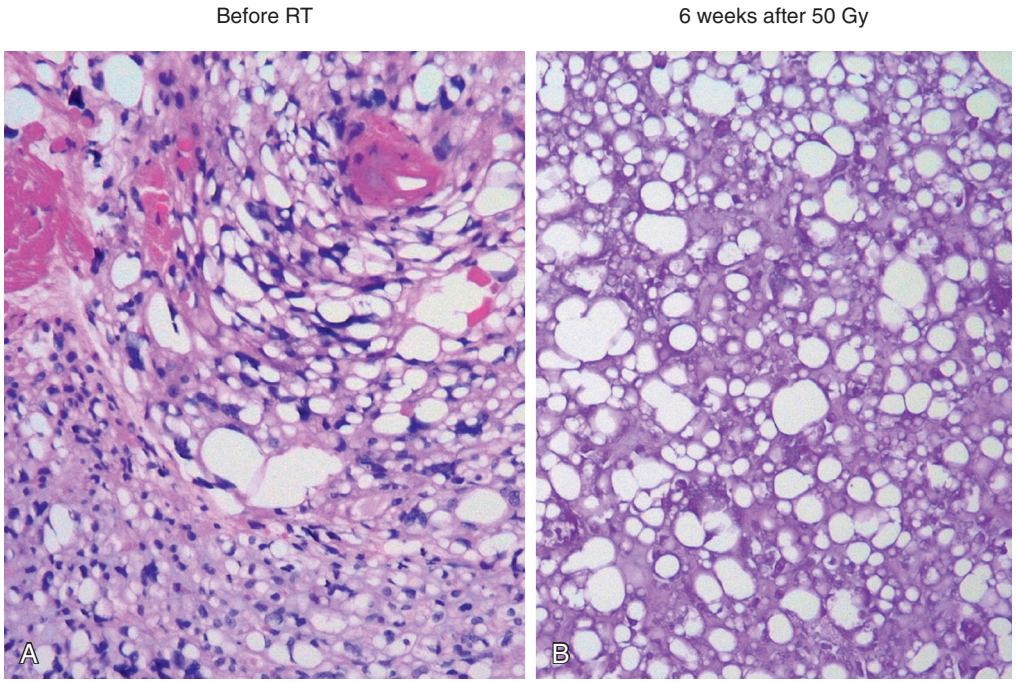

Figure 65-2 Demonstration of the exquisite radiosensitivity of myxoid liposarcoma to radiation. **A,** Before radiation therapy (RT); **B,** Approximately 95% necrosis after 50 Gy of RT.

extremity sites especially in older patients and is considered one of the most common histology in this patient population. These sarcomas have no distinct genetic abnormalities. The majority are high grade. It is an important histological subtype for radiation oncologists to recognize because of its propensity for LR. Some of the myxofibrosarcoma present as diffuse superficial lesions, making it difficult to appreciate the true extent of the disease on imaging and at time of surgical resection. This could explain the high rate of LR even when adjuvant radiation is given. However this should not be considered as a sign of radioresistance. Mutter et al compared high-grade leiomyosarcoma (n = 88) to high-grade myxofibrosarcoma (n = 144) in the setting of primary nonmetastatic extremity lesions.[28] Myxofibrosarcoma presented more frequently with tumors larger than 5 cm ($p < 0.001$), deep location ($p = 0.03$), upper extremity site ($p = 0.015$), and higher rate of positive and close margins ($p < 0.001$). The 5-year LR rate was not significantly different, 14.6% for myxofibrosarcoma compared with 13.2% for leiomyosarcoma ($p = 0.5$). What was different was the pattern of LR; of 17 myxofibrosarcoma LRs, 47% occurred out of field compared to 8% for leiomyosarcoma ($p = 0.04$). In addition once LR developed in patients with myxofibrosarcoma, many (35%) went on to develop subsequent and sometimes multiple LRs compared with no subsequent LRs in the leiomyosarcoma group ($p = 0.05$). Thus, it is important to separate the rate of initial LR in myxofibrosarcoma, which seems to be similar to other histologies such as leiomyosarcoma, from the repeated subsequent recurrences in the same index case, giving the impression that most myxofibrosarcomas recur after radiation.

Leiomyosarcoma

Leiomyosarcomas (LMS) affect women more often than men even after accounting for gynecologic LMS. By far the most common site is the retroperitoneum; other sites include gastrointestinal viscera, extremity, vessels (e.g., leiomyosarcoma of inferior vena cava), and skin. Site plays an important role in prognosis, with cutaneous LMS having the best prognosis. LMS often presents as a small nodule with low-grade features, and generally wide excision is sufficient treatment. In contrast, retroperitoneal and vascular LMS have much worse prognosis. LMS are genomically complex; there is an amplification of myocardin (MYOCD) in about 70% of retroperitoneal LMS.[29] When high-grade LMS were compared to high-grade myxofibrosarcomas in primary extremity lesions,[28] the 5-year rate of distant metastasis was significantly higher in LMS (54.1% versus 24.3%; $p = 0.014$).

Synovial Sarcoma

Synovial sarcomas are high-grade tumors that tend to affect young adults and adolescents. Like other sarcomas, extremity is the most common site, but head and neck is a relatively common site. Calcifications on plain films or CT scan can be seen in some synovial sarcomas. The two main histological types are the monophonic and the biphasic, with the monophonic type being the most common. In biphasic synovial sarcomas there is a mixture of epithelial and spindle cell components. Synovial sarcomas[19,20] have a distinct translocation t(X; 18). The fusion involves of SS18 from chromosome 18 and either SSX1 (two thirds of cases) or SSX2 (one third of cases) on the *X* chromosome.[30,31] At MSKCC, there is a synovial sarcoma–specific nomogram to help predict outcome in this group of tumors.[32]

Gastrointestinal Stromal Tumors

Gastrointestinal stromal tumors (GISTs) are thought to originate from intestinal cells of Cajal. In the past, many of these tumors were classified as LMS. GISTs affect mainly adults and can arise anywhere in the gastrointestinal tract with stomach and small intestine being the most common sites. In a small number of cases they arise from the mesentery, omentum, or retroperitoneum. A common presentation for GISTs is a GI bleed or an abdominal mass. Metastases occur predominantly within the peritoneal cavity and the liver. The molecular understanding of GISTs has revolutionized how GISTs are diagnosed and treated, which will be discussed later in the chapter.

These tumors have oncogenic mutations in the *KIT* or PDGFR-α genes in 85% and 5% of cases, respectively.[33,34] *KIT*

and *PDGFR*-α mutations are mutually exclusive. These mutations are driver mutations, which explain the great success in treating them with the tyrosine kinase inhibitor imatinib.[35,36] The most common location of KIT mutations are exon 11 in about two thirds of cases and exon 9 in 10%. Having an exon 9 mutation seems to infer worse tumor response to imatinib than an exon 11 mutation.[37] About 10% of GISTs do not exhibit *KIT* or *PDGFR*-α mutation and are called wild type. Some of these wild-type GISTs have BRAF mutations, NF1 mutations, succinate dehydrogenase subunit mutations, and RAS-family mutations.[20]

Clear Cell Sarcoma

These sarcomas used to be called malignant melanoma of soft parts because of some histological similarity with melanomas (intracellular melanin and immunoreactivity for S-100 and HMB45). However, these tumors have a signature[19,20] translocation t(12;22) seen in 70% of cases, which is not observed in cutaneous melanomas. They affect young adults mainly in the second to fourth decades of life and have predilection for distal lower extremity sites (ankle and foot). These tumors are considered high grade and have high propensity for spread including to lymph nodes. Sentinel lymph node biopsy or positron emission tomography/computed tomography (PET/CT) should be considered at time of initial evaluation.

Epithelioid Sarcoma

There are two types of epithelioid sarcomas: classic type, and proximal type. Classic type affects patients mainly in the third decade of life, with preference for distal upper extremity sites (hand and forearm). They present as a slow growing nodule and in some cases they can be multinodular, making it difficult to assess their true extent. They are high grade and have a high propensity for LR as well as regional lymphatic spread. The use of sentinel lymph node biopsy or PET/CT should be considered at time of initial evaluation. The patterns of local recurrence are challenging because some may occur quite a distance away from the primary site. The proximal type, tend to affect older patients than the classic type. Most common location is pelvis, including perineum and genital tract. These tumors are highly aggressive.

Pathways of Spread

Local Disease

Most extremity STS tend to spread in a longitudinal direction within the muscle groups where they originated. As they extend, lesions invade muscle and contiguous structures and occasionally envelop major neurovascular structures. The extending border comprises an outer perimeter of edematous tissue intermixed with a reactive zone of neovascularity with interspersed tumor satellites and pseudopodia. This surrounding area is generally termed the *pseudocapsule* and may encourage erroneous interpretation of anatomic disease containment and encourage enucleation. Such operations, frequently called *shell outs*, almost invariably mean that residual disease remains.

STS generally respect barriers to tumor spread in the axial plane of the extremity such as bone, interosseous membrane, and major fascial planes, and this feature should be exploited in planning tissue-preserving approaches to management. Thus, the margins of RT should be wide in the cephalocaudal direction but in the cross section there may be much greater security in defining nontarget structures. The importance of the osteo-fascial compartments of the extremities is that, from an anatomic standpoint, they operate as functional units and are protected from each others' risks of tumor contamination in the absence of inappropriate violation of the subdividing fascial septa. The latter may occur with misplaced surgical intrusion, including inappropriate placement of drain or biopsy tracts.[38]

The fascial structures are also important because they guard tumors arising superficial to the fascia investing the muscles of the region from the deeper structures. Tumors arising in subcutaneous tissues are staged differently to those arising deep to the fascia. In the event that the fascia has been disrupted, as is often the case after an "unplanned" sarcoma resection with positive margins, it may provide a route for deep contamination by tumor.

Extremity lesions arising in extracompartmental spaces such as the axilla, femoral triangle, sartorial canal, and popliteal space have the ability to extend proximally and distally at considerable distances with less anatomic restraint and early involvement of the neurovascular bundle.[39] For nonextremity lesions, the direction of sarcoma growth is also along the involved musculature, but care must be taken to ensure that the fascial planes are appropriately recognized and encompassed in surgical or RT target volumes.[40]

Regional Lymph Node Involvement

In STS there is generally no need for any specific regional lymph node treatment. Important exceptions to this generalization include epithelioid sarcoma, clear cell sarcoma, angiosarcoma, and rhabdomyosarcoma[41,42] (Table 65-2). Traditionally, lymph node involvement has been associated with an adverse prognosis rivaling that of distant metastasis. However, data suggest that isolated lymph node metastasis may not be as deleterious a factor.[43-45] This is reflected in the most recent version of the TNM staging system (see later section on staging).[46]

Distant Metastasis

Most sarcomas present with localized disease, and overt metastasis is present in only 10% of cases at diagnosis. Typically, the patient is asymptomatic and staging investigations are required to demonstrate metastases. The predominant risk is to the lungs. Spread to bone can be seen with myxoid liposarcoma, where it may be the first site of relapse. Myxoid liposarcoma also has the unusual characteristic of developing isolated soft-tissue metastases. In patients with retroperitoneal sarcoma and intraabdominal visceral sarcomas, the liver is a more common site of first metastasis.

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING FOR EXTREMITY STS

Clinical Manifestations

About 40% of all STS originate in the extremities; of these about 60% are thigh STS. The most common presentation of extremity STS is a painless mass. If pain or other symptoms are evident, it usually indicates origin from or invasion of neurovascular structures. Erythema and warmth may be evident depending on the vascular and tissue response. Some patients will present with large, slow-growing lesions that may restrict joint motion; and larger tumors may ulcerate skin or invade adjacent compartments. In general, superficial lesions are smaller than those deep to fascia, and upper extremity lesions tend to be smaller than those in lower extremity.

Patient Evaluation

The overall initial evaluation of a patient with STS is summarized in the diagnostic algorithm (Figure 65-3). Clinical assessment should include history and clinical examination, with particular attention to the relationship to the investing

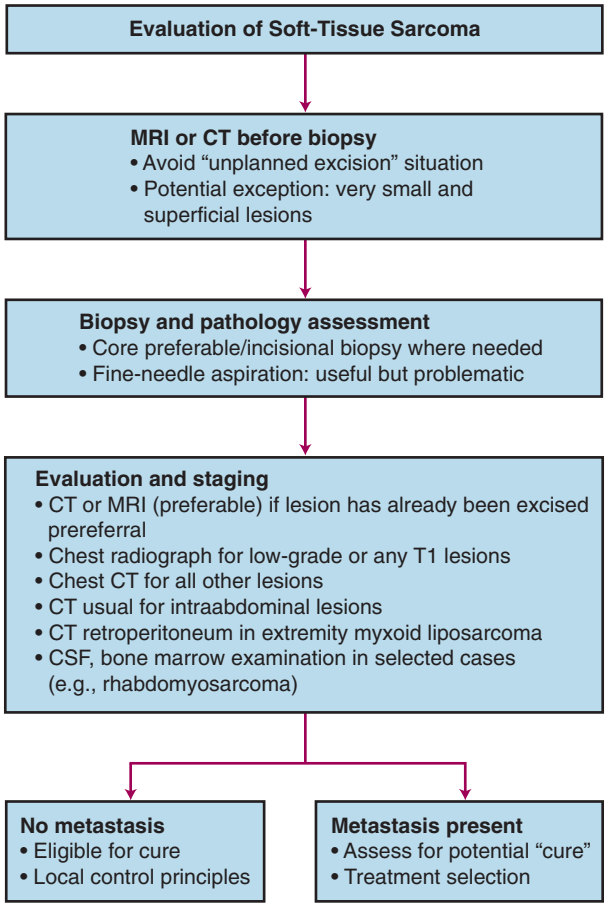

Figure 65-3 Diagnostic algorithm for the initial evaluation of a patient with soft-tissue sarcoma. All soft-tissue masses deep to the investing fascia should be considered sarcomatous until proven otherwise. Emphasis is needed on the type of biopsy and pathologic assessment. Most patients require computed tomography (CT) or magnetic resonance imaging (MRI) for the local disease assessment, and most patients require CT to exclude metastatic disease. Cerebrospinal fluid (CSF) analysis for tumor cytology is indicated in parameningeal rhabdomyosarcoma.

fascia deep to the subcutaneous fat (i.e., whether superficial versus deep) and adjacent neurovascular structures or bone as well as lesion size and mobility.

All soft-tissue masses deep to the investing fascia should be considered to be sarcoma until proven otherwise. A prior inappropriate excision may jeopardize the form and outcome of local treatment by contaminating tissues that were uninvolved initially. Thus, to minimize the risk of undesirable outcome, prebiopsy imaging is necessary.

Imaging of Primary

MRI is considered the optimal imaging modality to assess the primary lesion in extremity STS. Most STS will appear as low-signal intensity on T1-weighted images and high-signal intensity on T2-weighted images. MRI is highly accurate in delineating the extent of a soft-tissue abnormality and peritumoral edema. It is important to note, that although MRI is a highly sophisticated imaging modality, it is not diagnostic of STS and pathological confirmation is required before initiation of therapy.

Critical aspects to ascertain from an MRI include size of the lesion, its relationship to the investing fascia (superficial or deep), and proximity to neurovascular structures and bone (Figures 65-4 and 65-5). The multiplanar imaging and soft-tissue detail rendered by MRI makes this modality ideal for treatment planning of STS of the extremity.

A CT of the extremity is a reasonable substitute for MRI. A "blinded" study by the Radiation Diagnostic Oncology Group[47] that compared MRI and CT in patients with malignant bone and soft-tissue tumors showed no specific advantage of MRI over CT. Although CT has lower soft-tissue resolution than MRI, it has an advantage over MRI in assessing bone involvement. Plain x-rays are of little value in the evaluation of STS other than detecting calcifications or bony involvement.

PET/CT is being used increasing in STS, but its role in assessing the primary tumor is not well defined. There are some suggestions that it could be used to predict early response to chemotherapy.[48]

Establishing the Diagnosis

The biopsy should be carefully designed to facilitate subsequent surgical removal and adjuvant therapy. Core needle biopsy is the most commonly used approach nowadays and

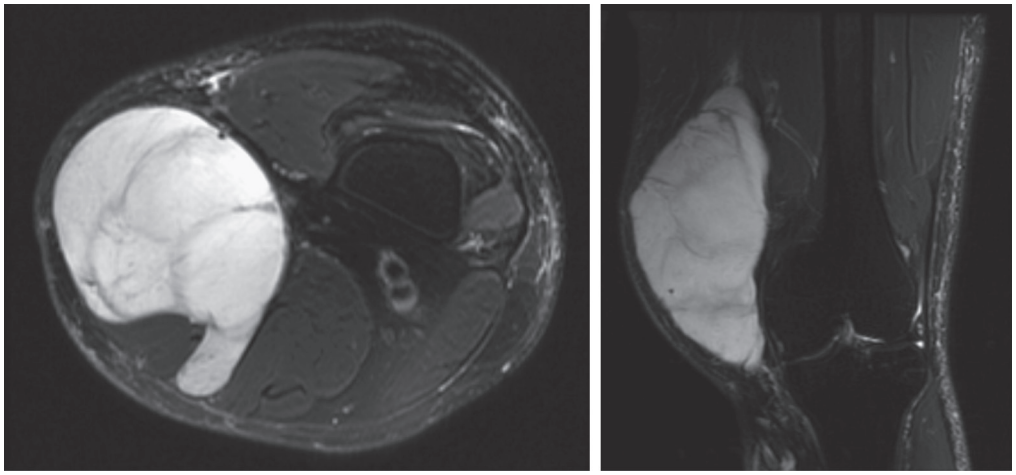

Figure 65-4 Magnetic resonance imaging of the knee.

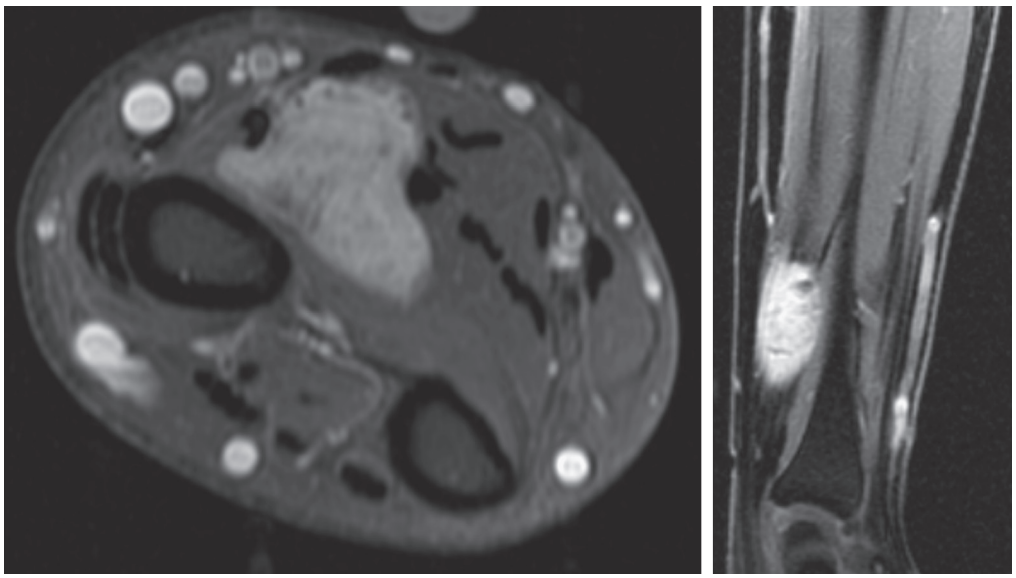

Figure 65-5 Magnetic resonance imaging of the forearm

its accuracy is well established. In a report on 530 patients, core needle biopsy could differentiate STS from benign soft-tissue tumors with an accuracy of 97.6%. High-grade sarcomas were differentiated from low-grade sarcomas with an accuracy of 86.3%. Tumor subtype was accurately assigned in 88.0% of sarcomas.[49]

An incisional biopsy provides the highest yield because sufficient tissue for additional immunohistochemistry, electron microscopy, molecular assessment, and cytogenetics is made available. Disadvantages of this approach may include complications and potential delay in initiation of neoadjuvant therapies if there are wound problems. Excisional biopsy should be avoided to the extent possible because of its potential impact on subsequent therapies including definitive surgery and radiation. If the orientation of an excision is perpendicular to, rather than along, the long axis of the extremity, the reexcision will be challenging. The role of fine-needle aspiration biopsy (FNAB) is controversial in making initial diagnosis of STS.[50] FNA however, has an important role in establishing the presence of recurrence, both local and distantly.

Exclusion of Metastasis

The most common site for metastasis in extremity STS is the lungs. Either chest x-rays or CT could be used. Although chest CT is considered the gold standard, it is not clear if it is needed for all STS of the extremity. In a report on 1170 patients with newly diagnosed STS, the efficacy of chest x-rays in identifying pulmonary metastatic disease was compared with CT of the chest. The incidence of lung metastasis on CT was 8.3%. The accuracy of chest x-ray was 96.9% compared to 99.6% for CT. The stage of STS (tumor size, grade, and depth), influenced the yield. If the chest x-ray was used as the only imaging tool this would results in lung metastasis being missed in 4.9% of stage III disease (>5 cm, deep, and high grade). In contrast, less than 0.5% of metastasis would be missed if patients with stage IA (≤5 cm, low grade, and superficial) had chest x-rays alone.[51] Spinal metastasis with or without lung metastasis can be seen in patients with myxoid liposarcoma (Figure 65-6). Therefore, spinal MRI is sometimes recommended for these patients.[52] In a study of 109 adult patients with STS who

**Superficial tumor is located exclusively above the superficial fascia without invasion of the fascia; deep tumor is located exclusively beneath the superficial fascia, superficial to the fascia with invasion of or through the fascia, or both superficial yet beneath the fascia.*
†Presence of positive nodes (N1) in M0 tumors is considered stage III.

underwent PET/CT as part of their initial staging, only 5 (4.5%) were upstaged. Of the 5 patients, 3 had extrathoracic metastasis, 1 had both thoracic and extrathoracic, and 1 had lung metastasis not identified on chest CT.[53] It is unclear if routine use of PET/CT is indicated in the initial staging of STS. Perhaps the exception would be for histologies with a high rate of nodal metastasis or nonthoracic spread patterns.

Staging

The Union for International Cancer Control (UICC)/AJCC TNM (seventh edition) staging system[46] is the most widely employed staging system for STS and is unusual within the overall TNM classification system in that it incorporates histologic grade with anatomic disease characteristics. The system is based on grade (three-tiered system), size partitioned at the 5-cm break point, and lesion depth as "a" (superficial tumor arising outside the investing fascia) or "b" (a deep tumor that arises beneath the fascia or invades the fascia) (Table 65-3). All STS subtypes are included except hollow visceral sarcomas, Kaposi's sarcoma, fibromatosis (desmoid tumor), and sarcoma arising from the dura mater, brain, and parenchymatous organs. Some aspects of the AJCC seventh edition differ from the previous edition. Tumor grade uses three-tiered system and tumor depth is reported but it does not change stage grouping. Nodal involvement without distant metastasis is considered stage III.

PRIMARY THERAPY FOR EXTREMITY STS

Surgery

General treatment principles for nonmetastatic extremity are shown in Figure 65-7. Surgical resection in the form of limb-sparing surgery is the main treatment for extremity STS. The aim is to try to get about a 2-cm margin of normal tissue around the gross tumor. The important aspects of such surgery, especially as it pertains to the radiation oncologist, include the following: was complete gross resection achieved, were adjacent major nerve or bone manipulated, and what type of wound closure was performed? Complete gross resection with an adequate margin is important to ensure that the resection went beyond the pseudocapsule of the tumor. Having said this, the size of the margin need not be 2 cm all around. Often fascia, bone, and neurovascular structures represent a natural barrier to STS local spread. If the tumor was close to bone or major nerve, striping the periosteum or neurolysis is considered an adequate margin. Such manipulation of bone or nerve, however, increases the risk of fracture or neuropathy when adjuvant RT is used. Occasionally cortical bone resection or resection of major nerve is required if the STS invades them. For wound closure, it is important to know if it was a primary skin closure or required tissue transfer in the form of skin graft or myocutaneous flap because of its potential impact on wound complications especially when RT is being considered.

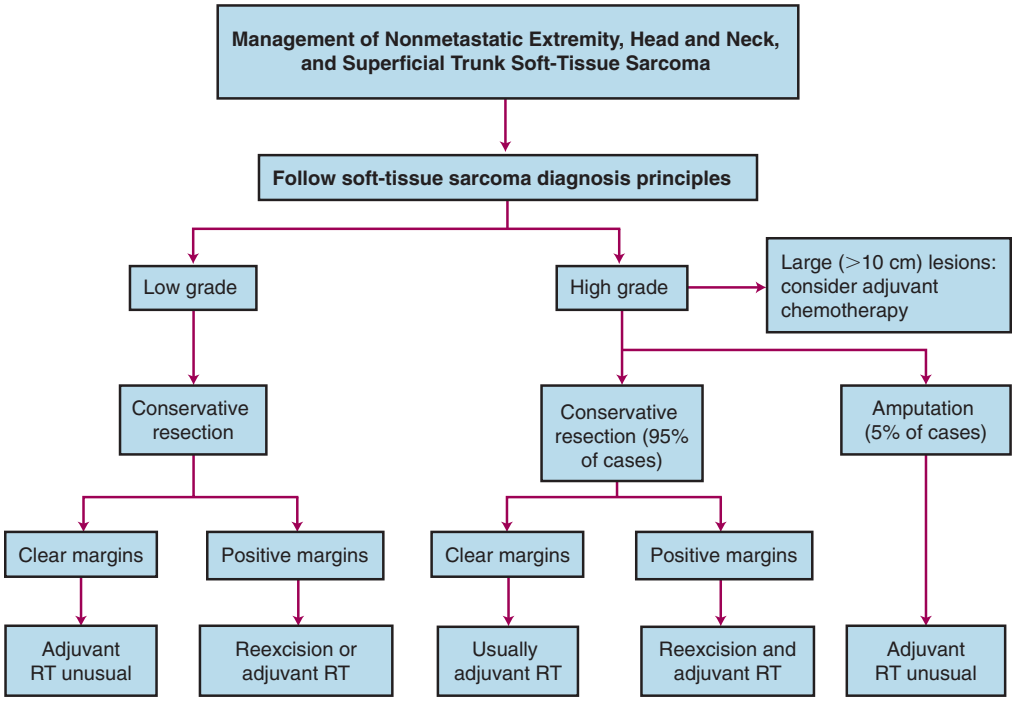

Figure 65-7 The focus of this schema predominantly addresses the local treatment of these lesions and recognizes that systemic chemotherapy is controversial. In unfavorable presentations in a fit patient, chemotherapy may be considered, although in general this is an institution-specific preference. Of note, the predominant approach involves tissue preservation with conservative surgery and adjuvant radiation therapy (RT). Selected patients may be treated with surgery alone, and rarely, patients (5% of cases) require amputation.

The use of amputation as the initial surgical treatment in STS should be rare. The notion that unless amputation is performed, the sarcoma will spread have been address by a randomized trial from the National Cancer Institute (NCI). The trial compared amputation ($n = 16$) to wide local excision and postoperative external beam radiation ($n = 27$) in patients with high-grade STS of the extremity. There were four local recurrences in the limb-sparing group and none in the amputation group ($p = 0.06$). However, there were no differences in the 5-year disease-free survival (DFS) rates (71% and 78%; $p = 0.75$) or overall survival (OS) rates (83% and 88%; $p = 0.99$) between the limb-sparing group and the amputation treatment groups.[54] At MSKCC[55] the rate of amputation is only 5% to 10% since the 1980s. Amputation should be considered only[56,57] where the tumor involves several compartments or invades major nerves (thigh STS involving both sciatic and femoral nerves). Another scenario would be a distal lower extremity lesion when a below-knee amputation prosthesis may provide better functional outcome than a limb damaged by tumor, extensive surgery and RT.[58]

Role of Adjuvant Radiation

Before discussing the role of RT in the management of STS, it is important to differentiate between radiosensitivity and radioresponsiveness. Radiosensitivity refers to the inherent response of cancer cells to radiation, and radioresponsiveness refers to how quickly a tumor regresses after radiation. These two parameters do not always correlate. The slow rate of regression of STS after RT, an example of poor radioresponsiveness, is often mistaken for radioresistance. The benefit of adjuvant RT in terms of local control has been demonstrated in two randomized trials. The first trial from MSKCC randomized 164 patients after limb-sparing surgery to radiation in the form of brachytherapy (BRT) or no further radiation. There were 78 patients in the adjuvant BRT arm and 86 patients in the no further RT arm. With a median follow-up time of 76 months, the 5-year actuarial local control rates were 82% and 69% in favor of brachytherapy ($p = 0.04$). This improvement in local control was most evident for patients with high-grade histology; local control for the BRT arm was 89% compared with 66% for surgery alone ($p = 0.0025$). There was no improvement in local control for patients with low-grade tumors. The 5-year freedom-from-distant-recurrence rates were 83% and 76% in the BRT and no BRT groups ($p = 0.6$), respectively. The 5-year disease-specific survival rates were also not different; 84% compared with 81% ($p = 0.65$), respectively.[59]

The second trial, from the NCI, was similar to the MSKCC trial except that EBRT was used instead of BRT. Ninety-one patients with high-grade lesions were randomized; 47 to receive EBRT and 44 to not receive EBRT. With a median follow-up of 9.6 years, a highly significant decrease ($p = 0.0028$) in the probability of LR was seen with radiation, but no difference in OS was shown. Of 50 patients with low-grade lesions (24 randomized to resection alone and 26 to resection and postoperative radiotherapy), there was also lower probability of LRs ($p = 0.016$) in patients receiving EBRT, again, without a difference in OS.[60]

As mentioned previously, some histologic subtypes such as myxoid liposarcoma are exquisitely sensitive to adjuvant RT, with 5-year local control rates in the range of 97%.[61,62] Other histologies may not be as radioresponsive as myxoid liposarcomas and local control may vary, but there is no evidence that certain histologic subtype are resistant to radiation. Italiano et al[63] reported on 237 primary resected synovial sarcomas. The use of adjuvant RT was associated with significant reduction in the rate of LR (hazard ratio [HR]: 0.43; $p = 0.026$). In another study of 83 extremity synovial sarcomas, the 10-year

local control was 86% for upper-extremity lesions and 80% for lower-extremity lesions.[64] Clearly adjuvant RT plays a significant role in the treatment of STS of the extremity. Nonetheless, there is still considerable debate about indications, timing, type, volume, dose, and morbidity profile.

Indications for Adjuvant RT

Who should receive adjuvant RT? Based on the results of aforementioned two trials, it is clear that addition of RT to limb-sparing surgery significantly improves local control in extremity STS. Yet there has been several attempts to try to identify a subset of patients in whom adjuvant RT could be omitted.[65] In a report from MSKCC, patients with small (<5 cm) high-grade STS who had negative margins after oncologic resection had equivalent local control whether adjuvant RT was used or not. However, even within this favorable group of patients, age more than 50 years (relative risk [RR] = 6; 95%; p = 0.001), and central (groin, axilla) tumor location (RR = 3; p = 0.005) were highly predictive of LR.[66] This indicates that one or two prognostic factors such as size or grade may not be adequate to determine who should receive adjuvant RT. At MSKCC, a nomogram was developed to try to estimate the risk of LR in patients with primary nonmetastatic STS treated with limb-sparing surgery alone.[67] There were 684 patients with a median follow-up of 58 months; the 3-year and 5-year actuarial local recurrence rates were 11% and 13%, respectively. Factors included in the nomogram were age (≤50 versus >50), size (≤5 versus >5 cm), margin status (negative versus close/positive), grade (low versus high), and histology (atypical lipomatous tumor and WDL versus other). The STS nomogram predicted the LR rate with a C-index of 0.73. Such a nomogram can serve as a valuable clinical tool for assessing an individual patient's risk of LR and guiding adjuvant treatment decisions (Figure 65-8).

Timing of Adjuvant RT

The National Cancer Institute of Canada (NCIC) conducted a randomized trial in extremity STS comparing preoperative (n = 94) to postoperative EBRT (n = 96). With 3.3 years median follow-up, there was an identical local control between the two arms with an early improvement in OS (p = 0.0481) in the preoperative RT arm[68] that was not substantiated with 5-year results.[69] The 5-year results for preoperative versus postoperative RT, respectively, were: local control, 93% versus 92%; metastatic relapse free, 67% versus 69%; recurrence-free survival, 58% versus 59%; OS, 73% versus 67% (p = 0.48); and cause-specific survival, 78% versus 73% (p = 0.64). Only resection margin was significant for local control. Tumor size and

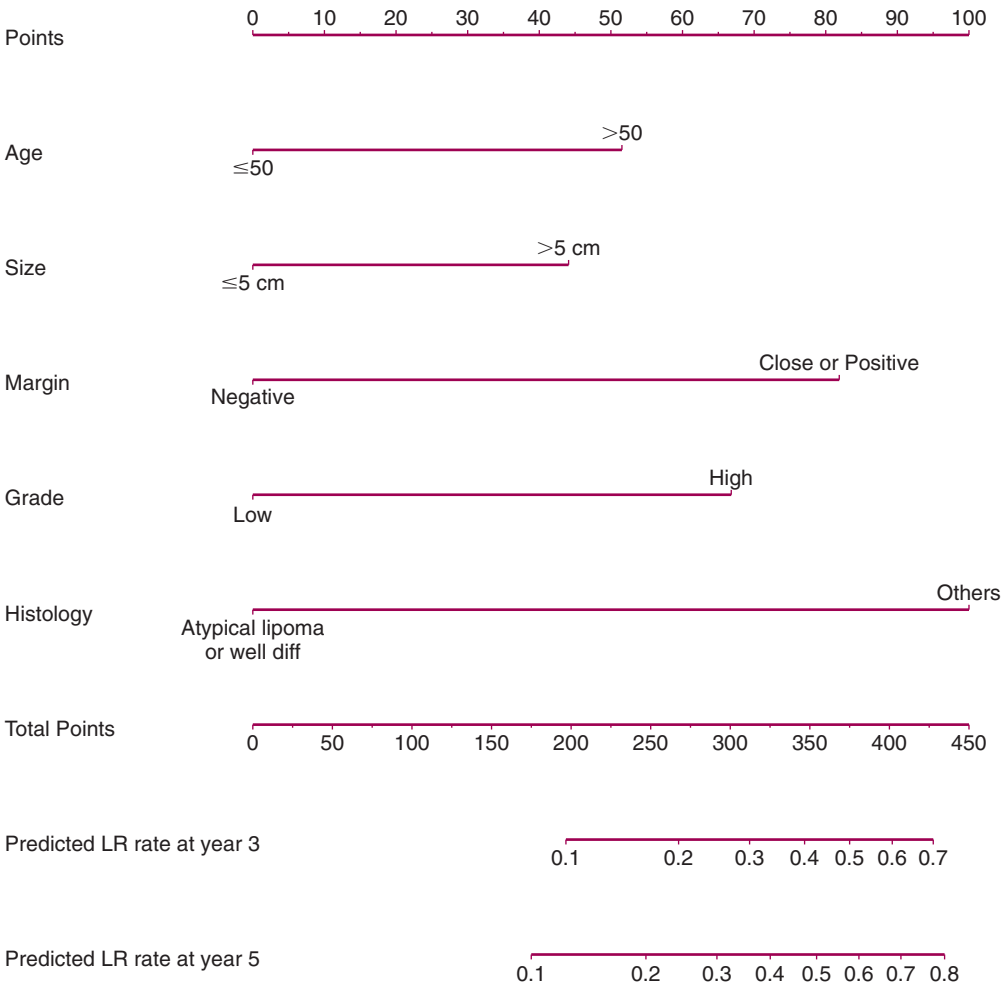

Figure 65-8 Nomogram for predicting risk of local recurrence (LR) at 3 years and 5 years in primary soft-tissue sarcomas of the extremity after surgery alone.

grade were the only significant factors for metastatic relapse, OS, and cause-specific survival. Grade was the only consistent predictor of recurrence-free survival.[69]

A literature-based meta-analysis of oncologic outcomes of preoperative versus postoperative EBRT analyzed a total of 1098 patients from five eligible studies. The risk of LR was somewhat lower after preoperative RT, but even more importantly the risk of metastatic spread did not increase with the delay in surgical resection with preoperative EBRT.[70] The latter finding is an important one to highlight to patients, who are often concerned about the delay in initiating surgery. Furthermore, Sampath et al[71] assessed the impact of RT sequencing on OS and cause-specific survival using the National Oncology database and found 1087 patients who received RT with surgery. OS was significantly improved with preoperative RT versus postoperative RT, with a median survival of 124 months and 90 months, respectively ($p = 0.02$).

Type of Adjuvant RT

There are several radiation modalities that could be used in the treatment of STS of the extremity (Figure 65-9). The most common one is conventional EBRT as employed in the NCIC trial.[68] Other modalities include BRT as used in the MSKCC trial,[59] but there has never been a head-to-head comparison of BRT to conventional EBRT. More recent techniques include intensity-modulated radiation therapy (IMRT) and image-guided radiation therapy (IGRT).

Brachytherapy

BRT has several advantages; patients usually leave the hospital having completed all their treatment in about 2 weeks compared to a 5- to 7-week course of EBRT. The evaluation of the tumor bed at the time of the operation by both the surgeon and the radiation oncologist can far exceed any imaging modality in its accuracy, and the rapid dose fall off with BRT spares more normal tissue than EBRT. There are also some limitations to BRT. Based on the MSKCC trial[59] the benefit of BRT in terms of local control was limited to high-grade STS. For patients with low-grade STS[72] LR occurred in 5 of 23 patients (22%) in the no-BRT group and 6 of 22 patients (27%) in the BRT group ($p = 0.60$). In a subsequent report from MSKCC limited to patients with primary nonmetastatic high-grade STS treated with adjuvant BRT ($n = 202$), the 5-year local control was 84 % with a median follow-up of 61 months. The local control was not uniform across disease sites; it was 91% for lower-extremity lesions, 76% for nonshoulder upper extremity, and 44% for shoulder location ($p < 0.001$). One possible explanation for poor results with BRT in the shoulder location is tumor bed geometry.[73]

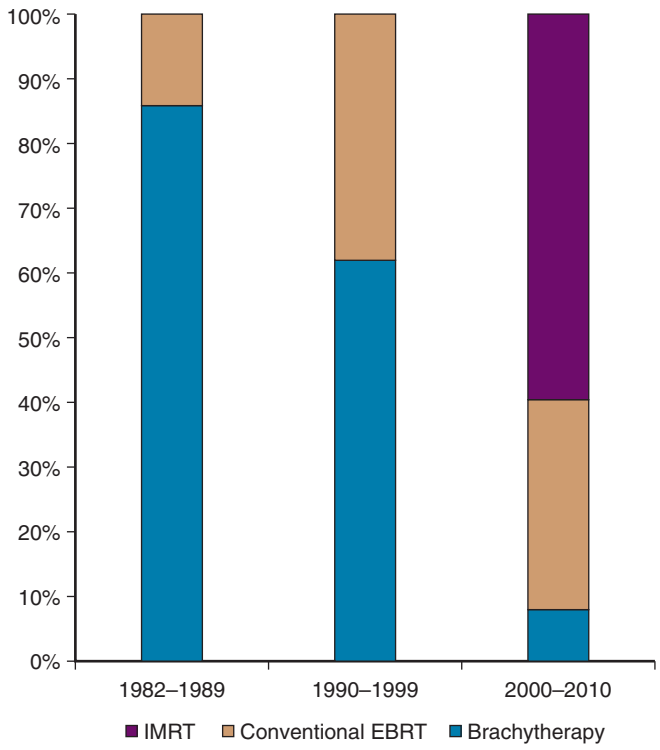

Figure 65-9 Trends of the type of adjuvant radiation therapy in primary soft-tissue sarcomas at Memorial Sloan Kettering Cancer Center. *EBRT*, external beam radiation therapy; *IMRT*, intensity-modulated radiation therapy.

Intensity-Modulated RT

IMRT can provide improved dose distribution in STS of the extremity because of steep dose gradients between target and normal tissues trial.[74] Preliminary results of IMRT in 31 adult patients with primary nonmetastatic extremity STS, who were treated at MSKCC were encouraging in terms of morbidity, despite the locally advanced nature of patients included in that study.[75] The question was whether the high conformal nature of IMRT may adversely impact local control. In a subsequent report from MSKCC on 41 patients (median follow-up: 35 months), the 5-year local control was 94%. This was achieved despite having a positive or close (<1 mm) margin in 51% of patients.[76] In a comparison between BRT ($n = 71$) and IMRT ($n = 63$) in primary nonmetastatic high-grade extremity STS, IMRT provided significantly better local control. With a median follow-up of 46 months, the 5-year rate of local recurrence was 8% for IMRT compared to 19% for BRT ($p = 0.04$). That difference retained its significance on multivariate analysis ($p = 0.04$). Of note, there were significantly more patients with positive and close margins ($p = 0.006$), and tumor >10 cm ($p = 0.005$) in the IMRT group than the BRT group.[77] In a separate report IMRT ($n = 164$) was compared to conventional EBRT ($n = 155$), in primary nonmetastatic extremity STS. With a median follow-up 49 months, the 5-year rate of local recurrence was 7.6% with IMRT as opposed to 15.1% with conventional EBRT ($p = 0.05$). That difference retained its significance on multivariate analysis ($p = 0.02$). There were significantly more patient with positive and close margins ($p = 0.04$) in the IMRT group.[78]

Image-Guided RT

In a Phase II trial using image-guided IMRT, O'Sullivan et al[79] reported on 59 patients with lower-extremity STS. The main purpose of the study was to evaluate whether this technique would influence the rate of wound complications with preoperative radiation (these results will be discussed later). With a median follow-up of 49 months, the 5-year local control rate was 88.2%. The RTOG-0630 Phase II trial using preoperative IGRT in extremity STS was recently completed. It defined the preoperative RT volume for intermediate- to high-grade tumors larger than 8 cm, as the clinical target volume (CTV) including the gross tumor and clinical microscopic margins with suspicious edema as defined by MRI T2-weighted imaging, plus 3-cm margins in the longitudinal dimension. The volume could be shortened to include only the end of a compartment. The radial margin was defined as 1.5 cm, including any portion of the tumor not confined by an intact barrier to spread. For lower-grade tumors the CTV still included the gross target volume (GTV) and suspicious edema, plus 2-cm margins in the longitudinal directions. The radial margin from the lesion was 1 cm, including any portion of the

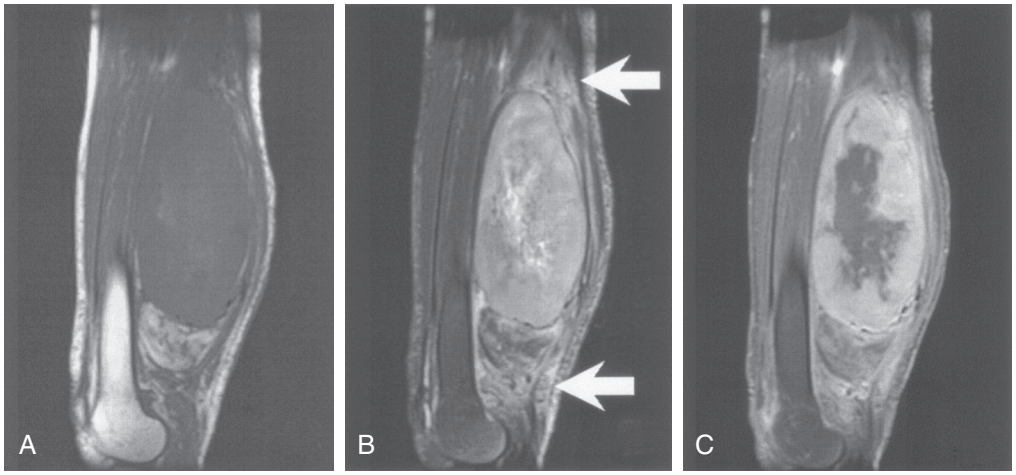

Figure 65-10 Sagittal T1-weighted **(A)**, fat-suppressed fast spin-echo T2-weighted **(B)**, and contrast-enhanced fat-suppressed T1-weighted **(C)** magnetic resonance images of a liposarcoma of the posterior thigh. Peritumoral increased T2-weighted signal intensity *(arrows)* seen both proximally and distally to tumor periphery on T2-weighted image **(B)**, with mild corresponding enhancement on contrast-enhanced T1-weighted image **(C)**.

tumor not confined by an intact barrier to tumor spread. Of the 79 evaluable patients who underwent preoperative IGRT, 5 did not have subsequent surgery. Local control was achieved in 69 of 74 patients who underwent resection.[80]

RT Target Volume

In the era of CT and MRI, the RT target volume has undergone significant modifications. The need to cover muscles, within a compartment, from insertion to insertion is no longer needed. Therefore, accurate delineation of tumor volume is critical especially in the setting of preoperative EBRT. The Radiation Therapy Oncology Group (RTOG) performed a study to determine potential variation in delineating GTV in STS of the extremity. There was almost perfect agreement between experts in GTV delineation for upper- and lower-extremity STS.[81] In a subsequent report, the RTOG consensus was to delineate GTV as the gross tumor defined by T1 contrast-enhanced MRI.[82]

Although GTV delineation with the aid of MRI seems straightforward, how much margin to include beyond the GTV, to create the clinical target volume (CTV), is more challenging. The local growth characteristics of STS have suggested that tumor cells may be located in the surrounding soft tissues at some distance from the main tumor mass.[83] The original observation led to the development of the concept of a "reactive zone" surrounding the lesion, situated between the tumor edge and adjacent normal tissues. In a report from Princes Margret Hospital (PMH) on 15 patients, sarcoma cells were identified histologically in the tissues beyond the tumor in 10 of 15 patients who had not received previous RT. In six cases, tumor cells were located within 1 cm of the tumor margin, and in four cases malignant cells were found at a distance greater than 1 cm and up to a maximum of 4 cm. The location of tumor cells beyond the margin did not correlate with tumor size, nor did it correlate with the location or extent of peritumoral changes[84] (Figure 65-10).

The RTOG consensus regarding CTV was that it should include the GTV plus 3-cm margin in the longitudinal directions and 1.5 cm radially.[82] But the concern was whether a mere 3-cm expansion is sufficient to cover peritumoral edema. Therefore, in a subsequent study, the GTV and CTV were outlined, and then areas of suspicious edema on T2-weighted images were outlined separately. The median volume of suspicious edema not included in the CTV was only 0.3 cm^3. Thus, the conclusion was that CTV, formed from GTV expansion of 3 cm longitudinally and 1.5 cm radially, is likely to include peritumoral edema in the majority of cases. However, the CTV should be manually altered to include any area of suspicious edema that is not already included in the CTV.[85]

At MSKCC, a 4-cm expansion in the longitudinal directions is often used to keep in line with volumes from randomized trial data,[68] especially NCIC where the margin was 5 cm from GTV to field edge (equivalent to 4-cm expansion from GTV to CTV). This expansion margin however could be shortened if it extended beyond the compartment. The radial expansion margin is often 1 cm to 1.5 cm excluding skin surface, intact fascial barriers, and bone. The planning target volume (PTV) at MSKCC is created by adding a 1-cm uniform expansion margin to the CTV.

Immobilization is critical to minimize setup errors in general but especially when using IMRT. How to position the treated extremity is critical. Ideally the extremity should be placed as close to neutral anatomical position as possible while trying to limit "spill over of radiation" to normal tissues and structures outside the treated target. With conventional EBRT sometimes it is a compromise, but with IMRT it is often possible to place the treated extremity in a neutral anatomic position because several beams are generally used. Another important aspect of immobilization is to minimize rotational setup variations. For example, when treating a thigh STS, immobilization of the foot is more critical than the thigh itself. When IMRT is combined with daily IGRT and a clinically proven immobilization method,[86,87] the CTV to PTV expansion can be decreased from 1 cm to 0.5 cm.

For patients treated with postoperative EBRT, the starting point is the tumor bed rather than GTV. However, it is recommended that the original tumor extension (the resected GTV) should be recreated within the planing CT. Placing surgical clips at the boundaries of the tumor bed, at time of resection, is extremely helpful. On CT simulation axial cuts, the tumor bed often is manifest as a hypodense region compared to adjacent normal muscle. Inclusion of the scar as well as drain

site in the tumor bed is important as long as they are in close proximity. To create the CTV, a similar expansion margin to that with preoperative radiation is used (i.e., 4 cm in longitudinal directions and 1 cm to 1.5 cm axially from tumor bed). In the event that the surgical scar and drain sites extend far beyond the tumor bed, simply including them within CTV (minimal margin) should be sufficient. Adding 4-cm expansion margins to scar or drains that extend far beyond tumor bed might be prohibitive from a normal tissue tolerance point. In the postoperative setting, a cone down is often employed after 45 Gy to 50 Gy. The CTV is created from tumor bed plus 1 cm to 1.5 cm in long axis and 1 cm radially. PTV is created by adding a 1-cm margin uniformly. A review by Haas et al[88] outlines the steps of volume creations and CTV and PTV expansion in preoperative as well as postoperative settings (Figures 65-11 and 65-12).

There is an ongoing trial by the National Cancer Research Network (NCRN) in the United Kingdom that is comparing a 5-cm longitudinal margin from GTV or 1 cm from the surgical scar, whichever is longer, versus a 2-cm longitudinal margin (axial margin is 2 cm in both arms), to assess if a reduced volume of postoperative RT will increase limb function without compromising local control.

When using BRT in extremity STS at MSKCC, single-plane implant is often used. Catheters are placed parallel along the long axis of the extremity and are sutured to the tumor bed to provide stability. The distance between catheters should be about 1 cm. The starting point is the tumor bed defined by surgical clips. In the longitudinal margin, 2 cm is added, and axially, 1 cm is added. No attempts are made to cover scar or drain sites.

Radiation Doses

For patients treated with preoperative EBRT, the typical dose is 50 Gy in 25 fractions. One of the debatable areas is whether

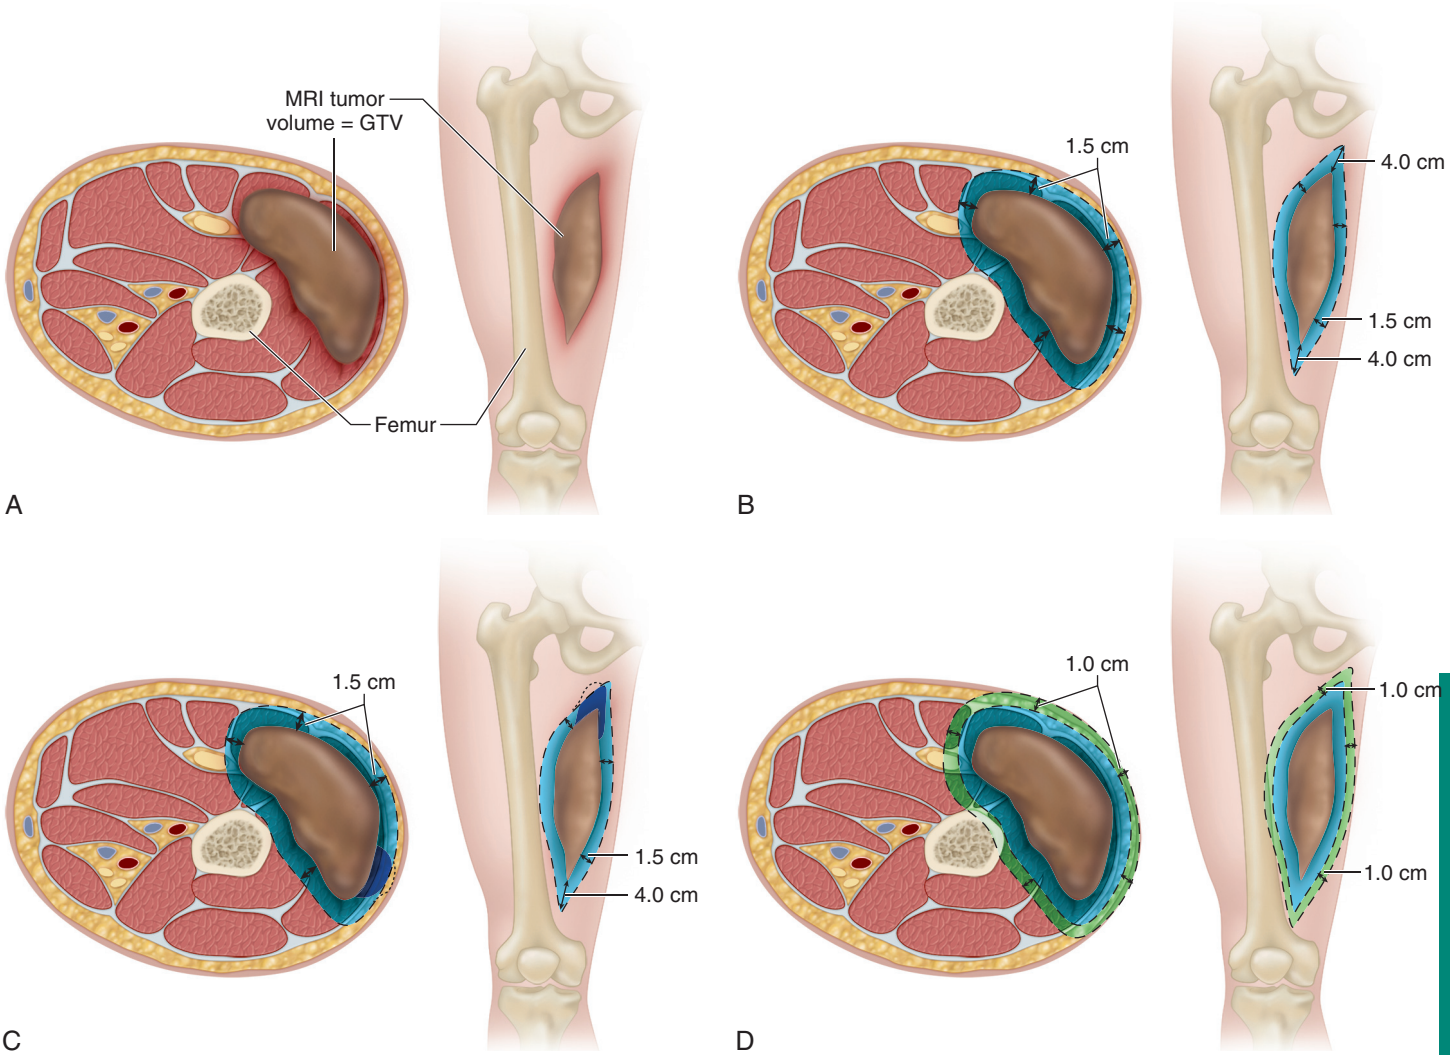

Figure 65-11 Target definitions in the preoperative setting. **A,** Patient to be treated with preoperative radiation therapy. Sarcoma delineated using T1-weighted, postgadolinium magnetic resonance imaging (MRI) scan fused to planning computed tomography (CT) scan. This gross tumor volume (GTV) does not include peritumoral edema, generally best seen on T2-weighted MRI scan. **B,** GTV transversely expanded with 1.5 cm but constrained at surfaces of fascia and bones, unless invaded. Longitudinally, expansion was 4 cm. Note: this was a sarcoma case without peritumoral edema. **C,** Sarcoma case with peritumoral edema with GTV also transversely expanded with 1.5 cm and constrained at surfaces of fascia and bones, unless invaded. Longitudinally, expansion was 4 cm. Note: CTV has been manually edited (bold dashed line) to encompass edema zone in both transverse and coronal planes. Peritumoral edema indicated by striped zone. **D,** Delineation of final preoperative planning target volume (PTV) by expansion of CTV with 1 cm in all directions, although PTV can vary by local institutional protocols. Obtained with permission.

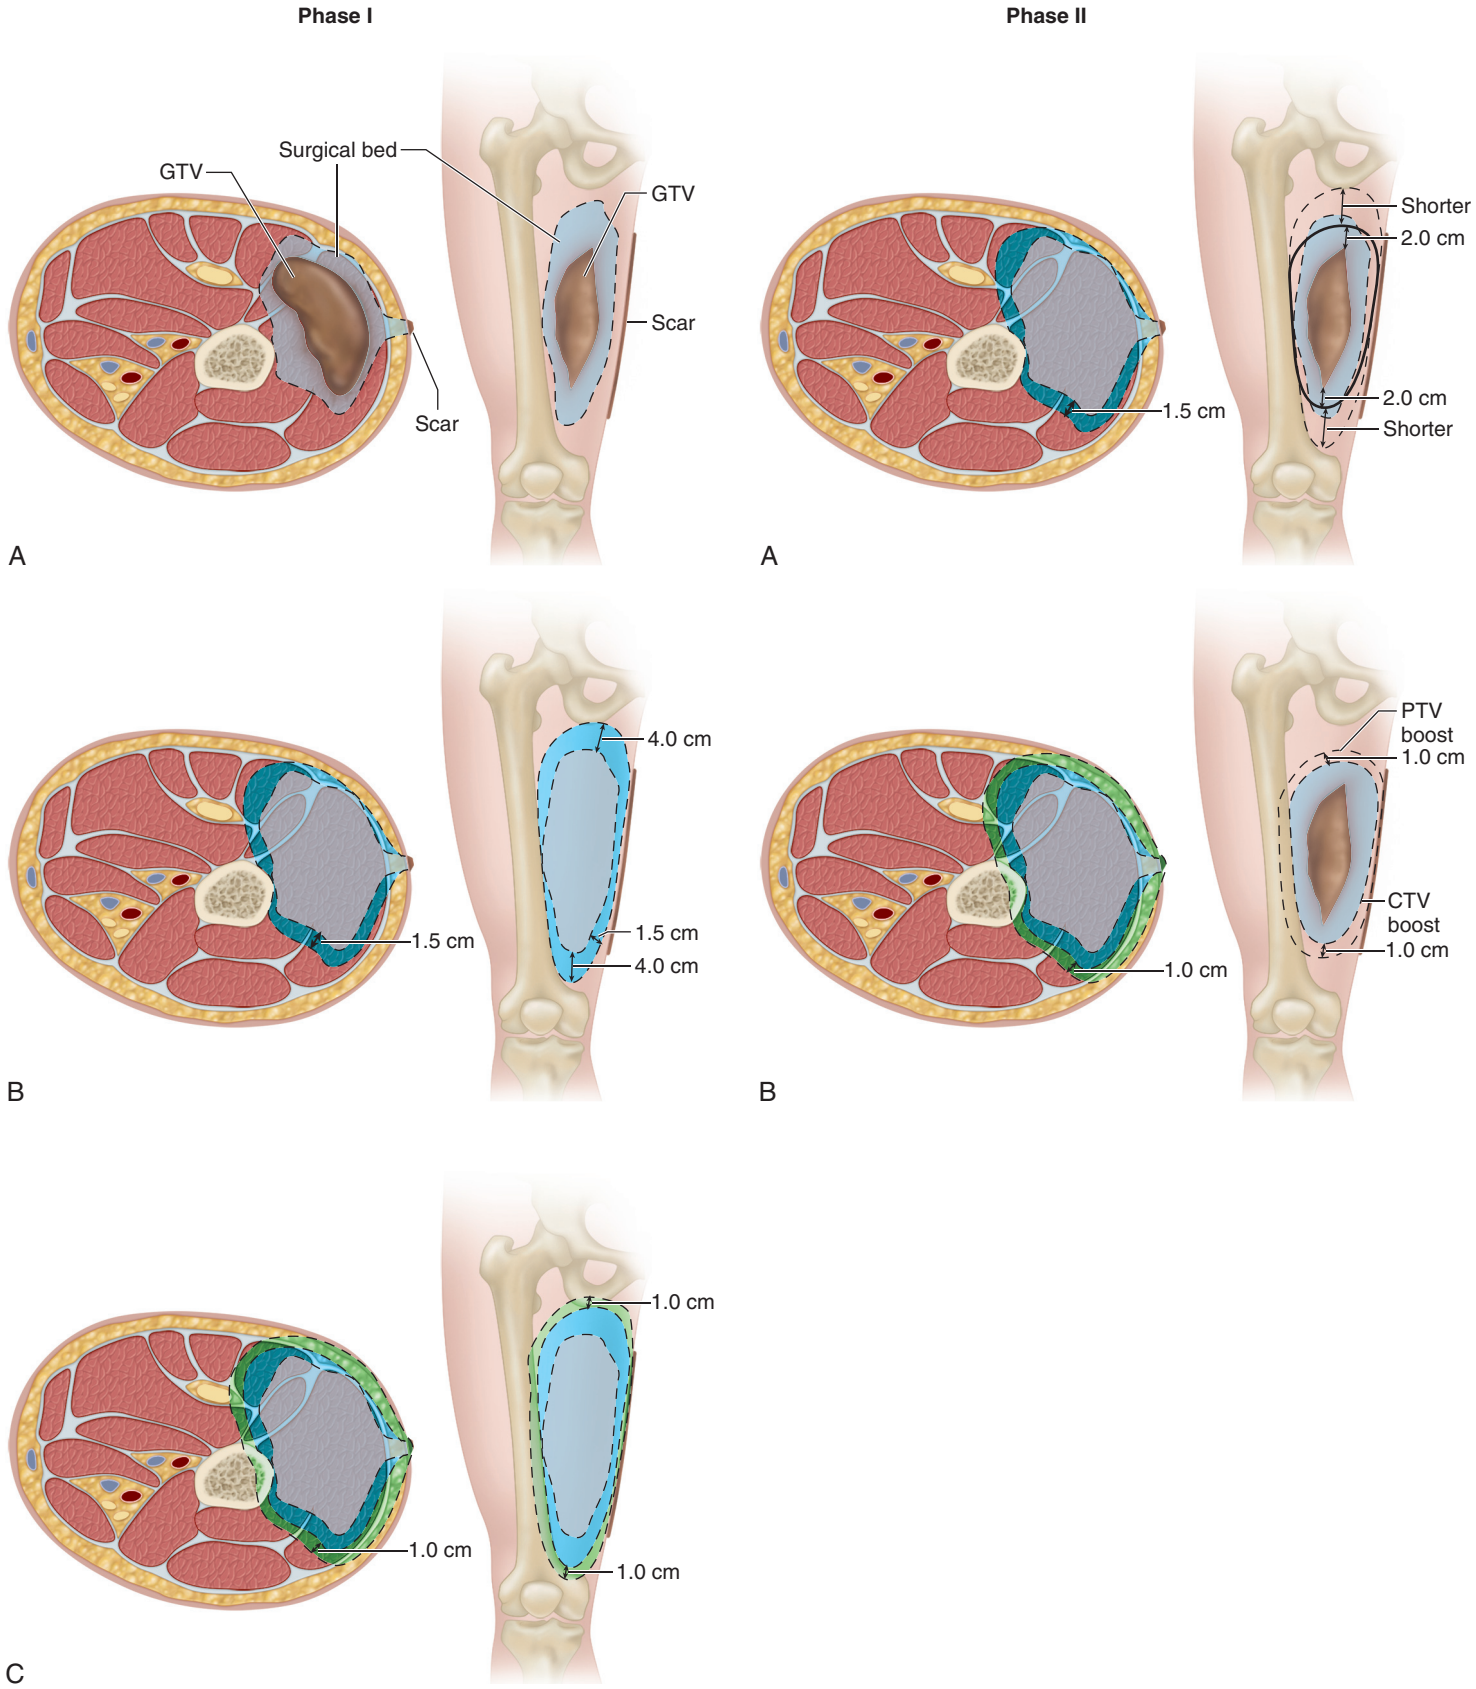

Figure 65-12 Phase I: Target definitions for postoperative radiation therapy (RT). **A,** Patient to receive postoperative RT. Both original sarcoma extensions (gross tumor volume [GTV]) visualized, as well as surrounding surgical bed. **B,** Margins for postoperative RT elective clinical target volume (CTV) are shown; these margins were 1.5 cm in transverse plane onto, but constrained at, surfaces of bones and fascia, unless involved with tumor at surgery. Note: elective CTV remains inside the skin. Furthermore, the elective CTV is longer than the marker of the skin scar. If 4-cm expansion of reconstructed surgical volume in longitudinal direction is shorter than surgical scar, elective CTV will need to be expanded to include the surgical scar. **C,** Expansion of 1 cm in all directions to produce postoperative elective planning target volume (PTV), although PTV can vary by local institutional protocols. Phase II: Target definitions for postoperative RT boost. Postoperative boost CTV was the same volume as the postoperative elective CTV, except craniocaudally **(A)**. In longitudinal direction, elective CTV is 2 cm longer on both sides than the reconstructed sarcoma GTV before surgery. **B,** Expansion of 1 cm in all directions of boost CTV to produce boost PTV, although PTV can vary by local institutional protocols. Obtained with permission.

additional RT is required for patients who undergo oncologic resection after preoperative radiation and were found to have positive surgical margins. In a study from PMH, 52 patients were treated with preoperative RT alone (50 Gy), whereas 41 received preoperative RT plus a postoperative cone down to a total of 66 Gy. The 5-year local control was 90.4% for those treated to 50 Gy alone compared with 73.8% for those who received additional postoperative cone down ($p = 0.13$). Although this data cannot be considered conclusive, it is important to balance the potential added advantages of more radiation beyond 50 Gy, to potential disadvantages in terms of morbidity.[89]

With postoperative EBRT, typically initial volume is treated to 45 Gy to 50 Gy followed by a cone down to bring the total dose to 63 Gy to 66 Gy depending on tumor grade, margin status, and location (normal tissue tolerance). For patients with positive microscopic margins after an oncologic resection, the use of adjuvant radiation has been shown to reduce the risk of LR at 5-year from 46% with surgery alone to 26% with the addition of radiation.[90] But it is clear that the risk of LR is still high in these patients, even when RT is added. The question then is, should the dose of radiation be escalated? Delaney et al[91] advocated for a dose higher than 64 Gy and reported a 5-year local control rate of 82%. Yet it is important to note that not all positive margins are created equal. In a report from PMH,[92] the 5-year local control rate was 85.4% in patients where a positive margin was anticipated at the time of oncologic resection. It seems that a small, isolated positive resection margin, planned from the outset with the intention of sparing a critical structure (major nerve or bone), has a favorable outcome, provided adjuvant RT is appropriately applied. In contrast, those with unanticipated positive margins at the time of oncologic resection had a local control rate of 63.4%. A third positive margin category in that report was for patients who had prior unplanned excision and were found to have positive margins at time of reexcision. Their 5-year local control was 78.9%. Patients who underwent prior unplanned excision represent a challenge, regarding whether to perform a reexcision and with regard to the role of radiation because many of these patients may have residual disease after the unplanned excision.[93,94] At MSKCC, all such patients undergo an oncologic reexcision. Occasionally, the reexcision reveals no residual sarcoma on pathologic examination. In a report from MSKCC, 200 such patients with primary nonmetastatic STS were assessed.[95] None of these patients received adjuvant RT. At 5-year, the risk of LR was 9%. However, for patients who were older than 50 years, the rate was 15% compared to 5% for those who were younger than 50 ($p = 0.001$). Similarly the rate for stage III was 26% compared to 7% for stages I to II ($p < 0.001$).

From the preceding discussion it is clear that margin status should not be looked at in isolation. Having a pathologically negative reexcision is no guarantee for excellent local control in patients older than 50 years or those with stage III disease. Conversely, having a positive margin is not always an indication for radiation dose escalation especially for patients with low-grade WDL, where an argument could be made that they do not need any radiation. For patients with gross residual disease after an oncologic resection, the dose should be 66 Gy to 70 Gy as long as it does not exceed normal tissue tolerance.

When using BRT at MSKCC, the dose is prescribed to the median peripheral dose rate (MPDR). The distance from the catheters to the MPDR is ideally 0.5 cm. With low-dose rate (LDR) BRT, the dose rate is typically 9 Gy to 10 Gy per day over 4 days to 5 days to a total of 45 Gy. Care should be taken to avoid hot spots in skin. With high-dose rate (HDR) BRT, the dose is typically 36 Gy given twice daily in 10 fractions over 5 days. The American Brachytherapy Society recently published a consensus regarding the role of BRT in sarcoma. Recommended dose is 45 Gy to 50 Gy with LDR when given alone and 15 Gy to 25 Gy when given with EBRT (45 Gy to 50 Gy). For patients treated with pulse dose rate, the doses are similar to those with LDR. For HDR, when used alone the dose is 30 Gy to 54 Gy, and 12 Gy to 20 Gy when combined with 45 Gy to 50 Gy of EBRT.[96]

Morbidity of Radiation

The aim of adjuvant RT in STS is limb preservation oncologically and functionally. The most common acute side effect of adjuvant RT in extremity STS is dermatitis. With conventional EBRT, it is not uncommon to develop moist skin desquamation, especially around skin folds (axilla and groin) or when the radiation beams angle is tangentional with skin surface. Moist desquamations can often lead to treatment interruption. The rate of grade-2 or higher radiation dermatitis in the postoperative arm of NCIC[68] was 68% compared to 36% with preoperative RT ($p < 0.0001$). This is not surprising because the dose of radiation as well as the volume irradiated is significantly less with preoperative EBRT.

When IMRT was compared to conventional EBRT, grade-2 or higher radiation dermatitis with IMRT[78] was significantly less (31.5 versus 48.7%, $p = 0.002$). The mean duration of treatment interruption in the IMRT group was 0.8 days, compared with 2.2 days in the conventional EBRT group ($p < 0.001$).

Another common acute side effect is wound complications. In the NCIC trial,[68] the primary endpoint was significant wound complications defined as needing reoperation, deep wound packing for more than 120 days, or wound infection requiring intravenous antibiotics. The rate was 35% in those treated with preoperative EBRT compared to 17% for those treated with postoperative EBRT ($p = 0.01$). It is important to note that although wound complications are a common side effect with radiation, they are not unique to radiation. In the MSKCC trial[97] comparing surgery alone to surgery and BRT, the rate of significant wound complication was 14% in the surgery alone arm compared with 24% with BRT ($p = 0.13$). In addition the rate of wound complications are not the same across extremity sites. In a separate report from MSKCC,[98] comparing upper- to lower-extremity STS, the rate of wound complications requiring reoperation was 1% for upper extremity compared with 11% for lower extremity ($p = 0.002$). In the NCIC trial the largest number of wound complications was seen in thigh STS.[68] Even within the thigh, rate of wound complications differ; in a report from MSKCC on 255 primary STS of thigh treated with adjuvant RT,[99] the rate of wound complications requiring reoperation was 4.9% in anterior compartment lesions as opposed to 14.6% for medial and posterior compartments ($p = 0.014$). Data regarding wound avoidance using IGRT, revealed a rate of 30.5% significant wound complications, which were not statistically different than the rate in the NCIC trial.[79] In some STS of the extremity, tissue transfer in the form of skin graft or myocutaneous flap are required. In a report on 43 patients who did have tissue transfer, the rate of reoperation was only 6% when postoperative RT was administered, indicating that once the tissue transfer is healed, it tolerates postoperative RT well.[100]

With regard to late toxicity, subcutaneous fibrosis is rather common. In the NCIC trial, the rate of grade 2 or higher was 31.5% in the preoperative RT arm compared to 48.2% for the postoperative arm. The corresponding rates for joint stiffness were 17.8% in the preoperative RT arm and 23.2% in the postoperative arm, respectively.[101] Edema is another potential long-term side effect of adjuvant RT. In the NCIC trial, grade-2 or higher edema was seen in 15.1% of patients treated with preoperative RT compared to 23.3% for those treated

TABLE 65-4 Results of IMRT in Extremity Soft-Tissue Sarcomas

†Limited to lower extremity.

postoperatively.[101] Some of the predictors of lymphedema include tumor size more than 5 cm and deep locations.[102] The site of STS also plays an influence on the rate of edema. In patients with thigh STS, the rate of lymphedema is 25.7% for medial thigh compartment tumors compared to 9% for primaries of the anterior and posterior compartment ($p = 0.005$), reflecting the rich lymphatic in the medial compartment.[99] The use of IMRT[78] seems to have a beneficial impact on lymphedema in extremity STS. The rate of grade-2 or higher edema is 7.9% for IMRT compared to 14.9% for conventional RT ($p = 0.05$).

Peripheral neuropathy can occur in the setting of adjuvant RT in extremity STS. In thigh STS[99] the rate of neuropathy is higher for posterior compartment lesion than anterior and medial (21.1% versus 3.5%, $p < 0.001$). Another predictor in that study was neurolysis where the rate was 27% as opposed to 5.2% for those who did not have neurolysis ($p = 0.0003$). For patients treated with BRT it is important to make sure that the radioactive sources are not in close proximity to a major nerve.

The rate of bone fracture is not that high (about 4% to 5%) when all extremity sites are combined. However, in patients who develop fractures, most of them occur in the lower extremity.[103,104] Dickie et al reported on 21 patients with lower-extremity STS who developed fracture and matched them with a random sample of 53 patients who did not develop fractures.[105] The risk of fracture was lower when V40 <64%, mean dose <37 Gy, or D-max anywhere along the length of bone was <59 Gy. Because most fractures in the lower extremity are femoral, the group at PMH developed a nomogram to assist in predicting the risk of femoral fracture. Important predictors include female gender, older age, anterior compartment location, extent of periosteal stripping, large tumor size, and high dose of RT.[106] The use of IMRT may provide a dosimetric advantage in reducing the dose to the femur when treating thigh STS. Folkert et al reported[107] on 82 primary thigh STS treated with adjuvant IMRT. With a median followup of 55 months, the risk of femoral fracture was 7.4%. This rate was much smaller than the expected rate (26.4%) from the PMH nomogram. Late toxicity (grade 2 or higher) data from the Phase II trial assessing IGRT in lower-extremity STS[79] showed subcutaneous fibrosis (9.3%, joint stiffness, 5.6%, and edema, 11.1%). Preliminary data from the RTOG 0630 Phase II trial are also encouraging in terms of late toxicity. Of 57 evaluable patients, the 2-year rates of grade-2 or higher late toxicity were subcutaneous fibrosis 5.4%, joint stiffness 5.4%, and edema 5.2%, respectively.[108]

In summary, when weighing risks and benefits of adjuvant RT in extremity STS, it is important to take into consideration the uniqueness of each anatomic region. Patients with upper-extremity STS are ideal candidates for preoperative RT because the rate of wound complications is relatively low. Thus, the patient gains all the benefits of a low rate of late toxicity without incurring a high risk of wound complications. But even within lower-extremity STS, a medial thigh STS may benefit from the lower dose of RT with the preoperative approach, rather than compounding an already high risk of edema with the high dose of RT required in the postoperative setting. Modern techniques of RT such as IMRT (Table 65-4) and more recently IGRT seem to have a favorable morbidity profile.

RT Alone

RT is most effective when used with surgery. Occasionally patients may not be a good candidate for surgery because of advanced age or comorbidities. Tepper et al[109] treated 51 patients with definitive photon beam irradiation to a total dose of 64 Gy to 66 Gy. The 5-year local control and survival rates were 33% and 25%, respectively. Local control was better for tumors <5 cm (87.5%) than in tumors 5 cm to 10 cm (53%) or larger than 10 cm (30%). In an update by Kepka et al on 112 patients who underwent RT for gross disease, local control at 5 years was 51%, 45%, and 9% for tumors <5 cm, 5 cm to 10 cm, and >10 cm, respectively. Patients who received doses less than 63 Gy had inferior 5-year local control (22% versus 60%); DFS (10% versus 36%), and OS (14% versus 52%). Although higher dose of RT was associated with better outcome, those who received more than 68 Gy were more likely to develop complications.[110] Another strategy to employ when giving definitive RT is radiosensitization. Rhomberg et al reported the results of a randomized trial comparing RT alone to RT and radiation sensitizer razoxane. In the subset of patients with gross disease ($n = 82$), the razoxane/RT arm demonstrated improved local control (64% versus 30%, $p < 0.05$). Acute skin reactions were enhanced in the "sensitizer" arm, but late toxicity was not increased.[111]

Chemotherapy for Nonmetastatic Extremity STS

The need for effective chemotherapy in primary high-grade STS of the extremity is clear, based on high risk of developing distant metastasis (up to 50% for high-grade large lesions). Unfortunately, data from several randomized trials have been inconclusive at best.

Adjuvant Chemotherapy

Doxorubicin has been extensively used in the treatment of STS, including several randomized trials comparing resection to resection followed by chemotherapy. In a meta-analysis[112] of 1568 patients (886 extremity sites), adjuvant chemotherapy had a significant impact on DFS but not OS. The 10-year DFS rate was 55% with chemotherapy compared to 45% with surgery alone ($p = 0.0001$). OS rate, however, was 54% with chemotherapy compared to 50% with surgery alone ($p = 0.12$).

This meta-analysis was criticized for including some patients with low risk of distant metastasis, and the chemotherapy regimen in many of the trials was considered suboptimal. A study from Italy limited to high-grade tumors randomized patients after surgery to observation ($n = 51$) or chemotherapy ($n = 53$) consisting of five cycles of epirubicin and ifosfamide.[113] Initial results showed significant improvement in DFS as well as OS; however, on longer follow-up the difference in OS was no longer statistically significant.[114] One

explanation for the loss of significance was small sample size. A recently completed European Organisation for Research and Treatment of Cancer (EORTC) 62931 trial randomized 351 patients with high-grade STS (about 80% were located in extremity or limb girdle) after resection to observation (176) compared with five cycles of doxorubicin and ifosfamide. The 5-year OS rates were almost identical; 66.5% in the chemotherapy arm and 67.8% in the observation arm. The corresponding 5-year relapse-free survival rates were 54.9%, and 52.9%, respectively. The cumulative incidence of metastasis was 35% in both groups.[115]

Neoadjuvant (Preoperative) Chemotherapy

There are several theoretical advantages of neoadjuvant over adjuvant chemotherapy. First, early initiation of systemic therapy; second, an unfavorable response to chemotherapy early on may obviate the need of more therapy; and lastly, it may have local response advantages, rendering subsequent surgery less radical. There are no randomized trials comparing the two approaches. A randomized trial by the Italian and Spanish Sarcoma Groups, compared three cycles of preoperative epirubicin and ifosfamide (n = 164) to the same chemotherapy followed by two more cycles postoperatively (n = 164). Of the 328 patients on this trial, about 90% had tumors in the extremity or limb girdle. With a median follow-up of 63 months, the 5-year OS was 68% for patients who were treated preoperatively and 71% for those treated preoperatively as well as postoperatively. Patients with extremity site did not fare better than the whole cohort. Five-year OS for the cohort was 69.7% and for extremity subset it was 68.6%. The 5-year cumulative incidences of distant metastasis were 32.6% and 33%, respectively.[116] Of note, the 5-year cumulative incidence of distant metastasis in the surgery alone arm of the EORTC 62931 trial[115] was also 34%.

Because of the inability to mount a large randomized trial addressing the role of chemotherapy in the adjuvant or neoadjuvant setting, several attempts have been made to pool data from large established cancer centers in the United States. One such study included all patients treated or not treated with adjuvant or neoadjuvant chemotherapy at M. D. Anderson Cancer Center (MDACC) and MSKCC; it showed no statistical difference in OS for patients treated with chemotherapy versus no adjuvant chemotherapy. There was a suggestion that chemotherapy delayed the manifestation of distant metastasis but did not prevent it.[117] Another comparison of data from the University of California–Los Angeles (UCLA) and MSKCC showed that adjuvant chemotherapy may be useful for synovial sarcomas.[118] A third comparison, this one between MSKCC and the Dana-Farber Cancer Center institutional databases[119] suggested a significant improvement in disease-specific survival in patients with high-grade extremity STS greater than 10 cm. In interpreting such data it is important to recognize biases that may exist, and it seems clear that randomized trials are sorely needed in the United States.

Combined Radiation and Chemotherapy

There are several approaches to combining radiation and chemotherapy depending on the setting. Regarding the postoperative setting, in the chemotherapy arm of the EORTC 62931, chemotherapy was delivered first followed by postoperative RT. In the control arm, postoperative RT had to start within 6 weeks of surgery. The 5-year cumulative incidence of locoregional relapse was 18.9% in the chemotherapy arm compared to 23.7% in the control arm. This showed that a delay in starting RT in the setting of adjuvant chemotherapy did not adversely impact local control. However, it is important to note that both the surgeon and radiation oncologist had to agree to delay RT for a patient to be eligible.[115]

In the preoperative setting, the group at Massachusetts General Hospital (MGH) developed a strategy of using three cycles of doxorubicin, ifosfamide, mesna, and dacarbazine (MAID) interdigitated with two 22-Gy courses of preoperative RT (11 fractions each) for a total dose of 44 Gy in localized, high-grade, large (>8 cm) extremity and truncal STS. This was followed by surgical resection. Postoperatively, three more cycles of MAID were given and an additional 16 Gy (8 fractions) boost dose was given for patients with positive margins. In the most recent update of their experience, 63 patients were evaluated. With a median follow-up of 46 months, the locoregional and distant 5-year recurrence-free survival rates were 91% and 64%, respectively. The 5-year OS and disease-specific survival rates were 86% and 89%, respectively. Thirty-four (52%) patients had grade-3 or grade-4 acute hematologic chemotherapy-related toxicity. There were no treatment-related deaths or secondary myelodysplasia.[120]

The RTOG performed a Phase II trial based on this regimen. In the most recent update of this trial,[121] 64 patients were analyzed. With a median follow-up of 7.7 years in surviving patients, the 5-year rates of locoregional failure (including amputation) and distant metastasis were 22.2% and 28.1%, respectively. Estimated 5-year rates of DFS, distant disease-free survival, and OS were 56.1%, 64.1%, and 71.2%, respectively. Ninety-seven percent experienced grade-3 or higher toxicity, including three deaths (two as a result of acute myelogenous leukemia). Other investigators, when using preoperative chemotherapy opted to deliver the radiation postoperatively[122] or in a concurrent fashion. Fakhrai et al[123] reported on a randomized trial comparing preoperative chemotherapy (six cycles of doxorubicin and ifosfamide) and RT to preoperative RT alone. In the chemotherapy arm, preoperative RT was given in accelerated fashion (3 weeks) to a total dose of 51 Gy in twice a day fractions of 1.7 Gy. This course of RT was administered with cycles three and four during which, only ifosfamide was given. The rate of LR was 13% in the chemoradiation arm and 22% in the preoperative RT alone arm (p = 0.38).

In summary, large randomized trials have failed to show a significant improvement in OS for patients with nonmetastatic STS receiving chemotherapy including doxorubicin and ifosfamide. However, when combined with other smaller trials, there may be a marginal benefit in term of OS. Therefore, it is not unreasonable to offer chemotherapy to younger patients with relatively sensitive subtypes such as high-grade myxoid liposarcoma and synovial sarcoma chemotherapy.

INTRAABDOMINAL STS

Retroperitoneal Sarcomas

STS of the retroperitoneum represent about 15% of all STS. Liposarcomas (mainly well-differentiated and dedifferentiated subtypes) are the most common histologic type (42%) followed by LMS (29%).[124] Most of these tumors are large in size at time of presentation,[125] with 60% of them being larger than 10 cm and only 6% being less than 5 cm. Some of these tumors may grow to an enormous size, especially WDL, without symptoms. Typical symptoms when present include nonspecific abdominal pain, anorexia, and weight loss.

Metastasis to lungs but also to liver may occur in retroperitoneal STS, thus initial assessment should include CT of chest, abdomen, and pelvis. Core biopsy with image guidance is preferred over blind core biopsy because of significant heterogeneity within many of these tumors, where solid areas representing dedifferentiated liposarcoma are intermixed with WDL. Retroperitoneal sarcomas are currently classified by the TNM system. However, another classification system has been developed based on grade, completeness of resection, and

distant metastases.[126] For class 1 (low grade, grossly complete resection, and no metastases) the stage-specific 5-year survival rate was 89%. For class 2 (high grade, grossly complete resection, and no metastases) the 5-year survival was 40%. For class 3 (any grade, incomplete resection, and no metastases) it was 26%; and for class 4 (distant metastases) it was 17%.

The management of a suspected retroperitoneal sarcoma is summarized in Figure 65-13, and the mainstay of treatment is complete surgical resection. Adjuvant RT could be recommended, but the benefits unlike in extremity STS are uncertain. In addition, when evaluating patients for these treatments an important component should include the determination of vital organ function that may be compromised by RT and surgery. Of particular importance are the functional capacity of the liver and the differential function of the kidneys because one may need to be resected or irradiated. Chemotherapy has not shown benefit.

Surgery for Retroperitoneal Sarcoma

The optimal primary treatment of retroperitoneal sarcoma is en bloc excision of the tumor with adjacent involved viscera and a margin of uninvolved tissue.[127-132] Achieving a complete gross resection is critical. In a report from MSKCC[125] ($n = 278$), the most important predictor of poor disease-specific survival was incomplete gross resection (RR: 4; $p = 0.001$). It is not necessary to remove adjacent organs, unless these organs are involved. The rate of complete gross resection is improving. In a recent report from Italy, Gronchi et al[133] reported a 90.8% rate of complete gross resection in 523 patients with primary retroperitoneal STS. However, the 5-year rate of LR was 31.1%, DFS was 39.4%, and OS was 56.8%. Of the 523 patients (36.9% received adjuvant RT), 128 developed LR as a first event, and 93 developed distant metastasis. Such patterns of relapse highlight the challenge of retroperitoneal STS, where the LR rate is higher than the distant metastasis rate even when 90% complete gross resection is achieved.

Adjuvant RT

The high risk of local failure after surgery has made additional RT an attractive option for retroperitoneal sarcoma, but its role is controversial. Unlike in extremity STS, there are no randomized trials comparing surgery to surgery and radiation. Doses of radiation given in extremity STS may exceed tolerance especially when given postoperatively. There have been several strategies to address the dosimetric challenges when treating retroperitoneal STS. Although the debate about preoperative versus postoperative RT in extremity STS may not be answered to everyone's satisfactions, there is no question that preoperative RT is the preferred approach in retroperitoneal STS. The typical large tumor mass in retroperitoneal STS often serve as an in situ tissue expander that displaces small bowel and other radiosensitive viscera from the radiation field. There are several reports in the literature about preoperative RT in retroperitoneal STS. Pawlik et al[134] reported long-term results of two prospective trials using preoperative RT to 45 Gy to 50 Gy followed by resection in 72 patients. When the analysis was limited to the 54 patients who had preoperative RT and underwent complete gross resection (22 patients receive intraoperative radiation), the 5-year rate of local control was 60%, DFS 46%, and OS 61%. Gronchi et al reported on a Phase I-II trial using preoperative RT to 50.4 Gy given concurrently with three cycles of high-dose long infusion ifosfamide.[135] Of the 83 patients enrolled, 79 underwent surgery. With a median follow-up 4.8 years, the 5-year DFS was 45% and OS 59%. The cumulative incidence of LR was 37% and distant recurrence 26%.

Other strategies included adding intraoperative radiation (IORT) to EBRT with encouraging results.[136-138] The main advantage of IORT is to be able to dose escalate, while physically or with the help of shielding, to reduce the dose to adjacent normal structures. Typical dose of external beam is usually 45 Gy to 50 Gy and that of IORT 10 Gy to 15 Gy (Table 65-5). At MSKCC, HDR IORT is used, whereas at MGH and Mayo Clinic it is mainly electron IORT. The target to be treated with IORT is mainly the posterior structures (paraspinal tissues and vessels) where surgeons have difficulty obtaining wide negative margins. The reported 5-year local control with such an approach ranges from 59% to 83%. At the Mayo Clinic, 3 of 43 patients (7%) with primary disease developed LR as opposed to 17 of 44 patients (49%) who were treated for locally recurrent disease.[137] The reported 5-year OS ranges from 48% to 74%, again with better results in patients with primary disease. Moderate to significant complications are not infrequent.[136-138] Special consideration should be given to peripheral neuropathy because it is a dose-limiting toxicity of IORT. The rate ranges from 6% up to 37%, and it is influenced by the type of IORT. Patients treated with HDR IORT have a low rate of peripheral neuropathy (6%) compared with 15% to 37% with electron IORT.[136-138]

The use of proton therapy and IMRT has been investigated at MGH.[139] They reported on 28 patients; 75% received preoperative IMRT or protons and 11 received additional IORT. With a median follow-up of 33 months, the 3-year local control was 90% for primary lesions ($n = 20$) and 30% for recurrent. Dose-painting IMRT has been suggested as an alternative to preoperative RT plus IORT. The rationale being, that what needs dose escalation is not the whole target volume, but instead the posterior structures (vessels and paraspinal tissues) as is used with IORT. Tzeng et al[140] reported on 16 patients treated with such an approach to a total dose of 57.5 Gy. Complete gross resection was achieved in 14 of 16 patients. With a median follow-up of 28 months, the 2-year local control was 80%, and the rate of late gastrointestinal toxicity was 6%. At MSKCC, the current approach for adjuvant RT when needed is the dose-painting approach. The expansion margin around the GTV to create a CTV is typically 1.5 cm. The expansion margin from CTV to PTV is 1 cm. This volume is treated to 50.4 Gy in 28 fractions. Posterior structures are dose painted to 60.2 Gy at 2.15 Gy per fraction (Figure 65-14). Some have taken this concept one step further and limited the radiation to the posterior structures only. Bossi et al reported on 18 patients with retroperitoneal liposarcomas treated to 50 Gy preoperatively with such an approach. With median follow-up of 27 months, there were two LRs and one distant relapse.[141]

In summary, the management of retroperitoneal STS is challenging. Even in modern surgical series where in 90% of

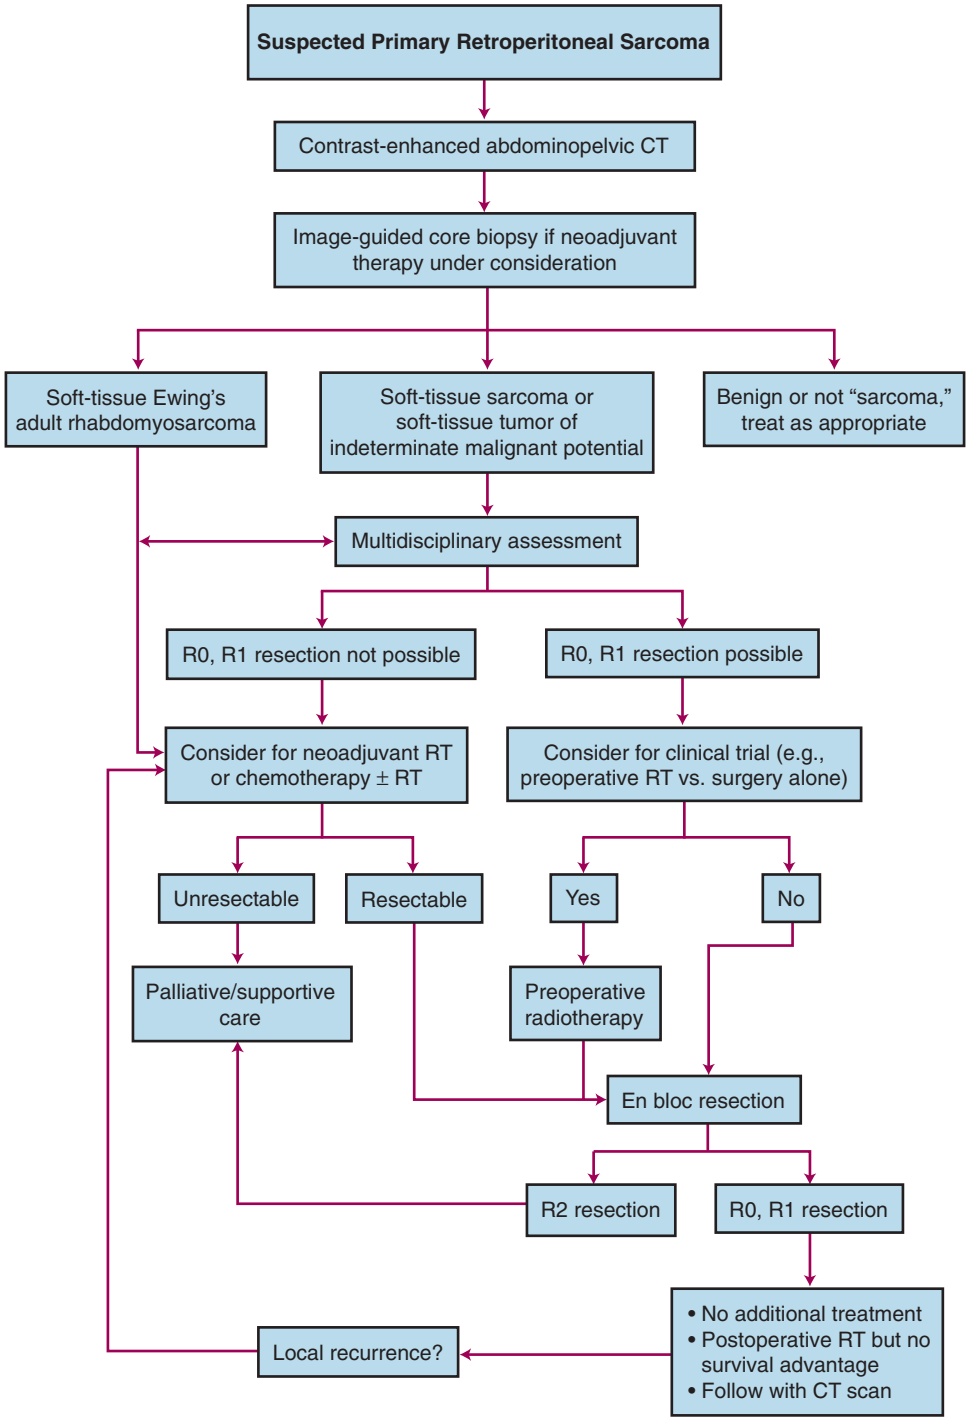

Figure 65-13 Treatment and diagnostic algorithm for a suspected retroperitoneal soft-tissue sarcoma. These lesions are often low-grade liposarcomas and resemble mature fat, presenting difficulties for the pathologist in ascertaining a pathologic diagnosis of sarcoma even when multiple image-guided biopsies are attempted. The clinician may need to determine the appropriate choice of treatment even when the diagnosis is clinically highly suspicious, but biopsy sampling artifact may make confirmation of pathologic diagnosis improbable without definitive resection. The place of induction approaches, especially preoperative RT, needs to be considered on an individual basis in such cases. Not included in the algorithm is the critical necessity to evaluate the functional capacity of the patient, which should especially include differential evaluation of both kidneys before resection or irradiation (see text). *CT,* Computed tomography; *R0,* microscopically clear resection; *R1,* microscopically positive but grossly clear resection; *R2,* resection with macroscopic gross residual disease; *RT,* radiation therapy.

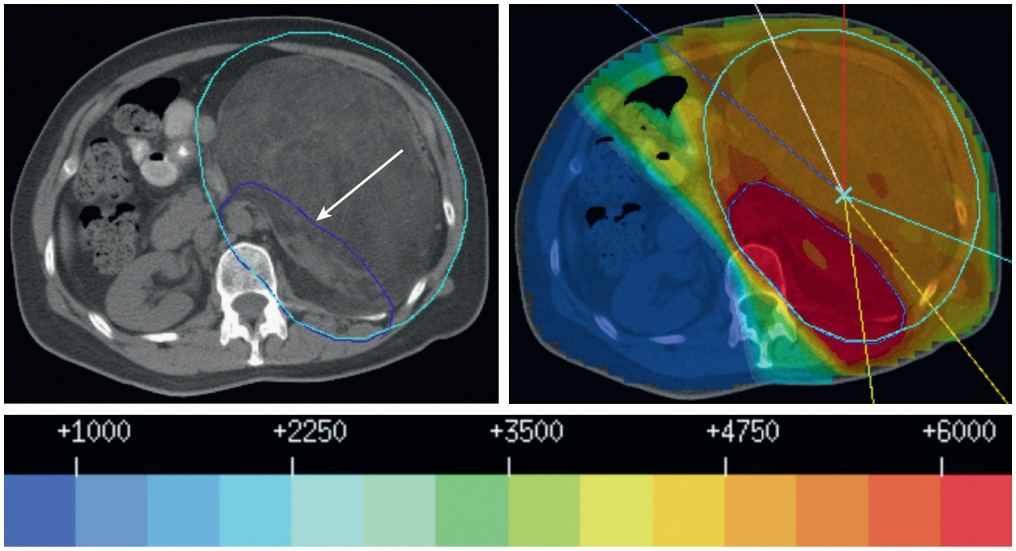

Figure 65-14 Dose-painting preoperative intensity-modulated radiation therapy in retroperitoneal soft-tissue sarcomas. Arrow indicates posterior structures. Orange zone is 50.4 Gy and red zone is 60.2 Gy (bowel excluded).

cases complete gross resection was obtained, the 5-year risk of LR was about 30%. The typical pattern of relapse was more local than distant suggesting a potential role for adjuvant RT. But unlike extremity STS, there are no prospective randomized trials to support its role and the toxicity is not minimal. If adjuvant RT is to be used, preoperative RT to 45 Gy to 50 Gy is preferred over postoperative RT. There are several approaches to dose escalation. IORT for 10 Gy to 15 Gy in addition to 45 Gy to 50 Gy EBRT have been used with good outcome. It seems that those with primary disease are the one who benefit the most. Data on dose-painting IMRT are preliminary but encouraging.

Primary Gastrointestinal Stromal Tumors

GISTs are the most common mesenchymal tumors of the gastrointestinal tract. The incidence is on the rise in part because of better recognition of these tumors using immunohistochemistry and molecular diagnostics.[142] With an incidence of 4000 cases per year in the United States, GISTs are now considered the most common type of sarcoma.[143] As mentioned previously, these tumors have oncogenic mutations in *KIT* or PDGFR-α. They typically affect patients in their fifth and sixth decades of life. The primary treatment is surgical resection. Tumor size, mitotic index, tumor location, and tumor rupture during surgery are independent predictors of recurrence after complete resection.[144] The modified National Institutes of Health (NIH) criteria use tumor size (three breakpoints: 2 cm, 5 cm, and 10 cm), mitotic count, and location (gastric versus nongastric) for risk stratification after surgery.[145] For patients with high-risk disease, the 10-year recurrence-free survival is 36.2%, for intermediate risk, 86.9%, low risk, 89.7%, and for very low risk, 94.9%.

Management of GISTs has dramatically changed with the use of imatinib, a selective tyrosine kinase inhibitor of *KIT* and PDGFR-α. The median survival of patients with metastatic GIST treated with this agent improved on average, from 9 months to more than 4 years.[143,145-147] Imatinib was also found effective in the adjuvant setting for patients with high-risk disease.[148]

Most of the current research focuses on the duration of treatment and correlation of kinase genotypes and outcome. Imatinib 400 mg daily is considered adequate for most patients with metastatic disease. Treatment should be continued on a lifelong basis. A randomized trial from the French Sarcoma Group[149] reported 2-year progression-free survival of 80% in patients randomized to continue on imatinib after 3 years of therapy as opposed to 16% in the group randomized to discontinue therapy after 3 years ($p < 0.0001$). The location of *KIT* mutation on exon 11 compared with exon 9 seems to influence the response to imatinib.[150] Patients with exon 9 mutations do worse; therefore, in the metastatic setting, a daily dose of 800 mg instead of 400 mg is recommended. In the adjuvant setting, a randomized trial[151] showed that compared to 1 year of adjuvant imatinib, 3 years of imatinib improved DFS and OS.

STS OF UNCOMMON SITES

Head and Neck STS

Head and neck STS comprise only about 5% of STS. They may originate within the upper aerodigestive tract or in the subcutaneous tissues of the scalp, facial tissues, or neck. Presentations vary in tumor size and locations, ranging from a superficial mass to upper aerodigestive tract obstructive symptoms, cranial nerve dysfunction, or proptosis.

They differ from extremity STS in several aspects. They tend to be smaller at presentation, have relatively high rate of aggressive histologies, such as angiosarcomas, and the risk of local recurrence exceeds that of distant spread.[152] Mattavelli et al[153] reported on 127 patients with STS of the head and neck who underwent surgical resection. Of the 127 patients, 122 (73%) were smaller than 5 cm. The rate of positive margins was 32%. Adjuvant RT was given to 36% of patients and chemotherapy to 26%. With a median follow-up of 66 months, the 5-year LR rate was 17% and distant recurrence 11%. The 5-year OS was 73%. Adjuvant RT should be considered because of the tight surgical margins. O'Sullivan et al[154] reported on 40 consecutive patients treated with preoperative RT to 50 Gy. The

actuarial 2-year local relapse-free rate was 80%, and the metastatic relapse-free rate was 85%. Major wound complications occurred in 8 of 40 patients (20%) within 120 days of surgery.

Cutaneous angiosarcoma of the head and neck region, which is most common site for this histology, deserves special consideration. These tumors occur in the dermal tissues of the head and neck, typically on the scalp (about 50% of cases) or facial skin. It is a disease of elderly patients who are Caucasian and is rarely seen in patients of African origin.[155] These lesions commonly present as purple, bruiselike lesions, with time progressing to ulceration and chronic bleeding. The multifocal nature of these angiosarcomas represents a significant challenge for local therapies. Lateral extension through the dermis makes assessment of the surgical margins difficult. Pawlik et al reported on 29 patients with scalp angiosarcomas in whom clear margins of resection were achieved in only 21.4% of patients.[156] Guadagnolo et al[157] reported on 70 patients: 20 (29%) were treated with surgery alone, 27 (39%) with RT alone, and 23 (33%) with surgery and radiation. Chemotherapy was given to 44 patients. Median follow-up was 2.1 years. The OS rate was 43% at 5 years, and local control was 43%. Of the 50 patients who received RT (median dose 60 Gy), 22 (44%) developed LR (68% in-field, 23% marginal, and rest outside field). Those treated with surgery and radiation had significantly better local control than those treated with surgery or RT alone (84% versus 24%, $p < 0.0001$).

Postoperative RT with wide margins to minimize marginal recurrences is recommended, but RT techniques remain challenging because of the large convex surface of the scalp and the desire to avoid irradiating underlying brain beyond tolerance. Newer approaches that combine IMRT with other techniques are now available.[158] Metastasis is common and occurs mostly in regional lymph nodes and the lung. Patients with advanced disease have a poor prognosis, but there can be dramatic responses to chemotherapy in a minority of patients, with paclitaxel being the most promising.[159,160] A Phase II trial with sorafenib, a tyrosine kinase inhibitor of vascular endothelial growth factor receptor that also blocks *RAF* signaling, has shown significant activity against angiosarcoma.[161]

Breast Sarcomas

Primary breast sarcoma is rare, but histologic subtypes are diverse, ranging from phyllodes tumors (the most common) with relatively good prognosis to radiation-associated angiosarcomas on the other end of the spectrum. Most patients present with a breast mass, although RT-associated angiosarcomas may also present as purple skin discoloration. Treatment recommendations are a hybrid between extremity STS and adenocarcinoma of the breast. Unlike breast adenocarcinomas, breast STS tend to be larger; thus, mastectomy is used more often. Axillary lymph node dissection is not routinely needed because of a low risk of nodal involvement. Breast-conserving surgery can be attempted as long as adequate negative margins are obtained.

Treatment of phyllodes tumor is based on the degree of malignancy. Those with benign tumors generally do not require adjuvant radiation. For patients with borderline or malignant phyllodes, the need for RT depends on whether the patient underwent mastectomy or lumpectomy. Belkacemi et al reported 5-year local control of 91% with mastectomy alone and 92% with mastectomy and RT, indicating that RT is not needed after mastectomy unless there are positive margins.[162] Pezner et al[163] reported on 169 patients with malignant phyllodes tumors who underwent lumpectomy alone. With a median follow-up of 64 months, the 5-year local control was only 79.4% and other studies confirm a LR rate of about 20% with lumpectomy alone.[164] In contrast, Barth et al reported on a prospective study of 46 patients who had negative margins after lumpectomy and received postoperative radiation to 50.4 Gy. With a median follow-up of 56 months, the 5-year local control was 100%. These results favor the use of postoperative RT after lumpectomy. The role of chemotherapy in the management of this disease is limited.[165]

Radiation-associated angiosarcomas deserve a special consideration. It is a potential long-term sequela after breast irradiation, with an estimated cumulative incidence of 0.3% at 15 years after treatment.[166-168] But this histology is not uniquely radiation related. Radiation naïve patients can develop angiosarcoma in the breast.[169] RT-associated angiosarcomas tend to occur in older patients and involve the dermis, as opposed to sporadic cases, which present as a parenchymal mass in younger patients. The prognosis of RT-associated angiosarcomas is poor; Torres et al[170] reported on 95 patients (95.7% with localized disease), the 5-year local control was 50.7% and OS 53.5%.

Thoracic STS

Thoracic STS are a heterogenous group with lesions arising from the chest wall, mediastinum, or pleura. Durani et al[171] reported on 337 patients with localized disease. The mean age was 50 years and median size was 8 cm. Location was soft tissue and chest wall in 85.5%, mediastinum 9.5%, and pleura 5%. Adjuvant RT was given to 51.4% of patients and chemotherapy to 40.7%. With a median follow-up of 4.7 years, the 5-year rate of LR was 14%, and, 90.8% (306 of 337) in the subset of patients with primary disease. The use of RT was associated with significant improvement in local control. The 5-year distant relapse rate was 17% and OS was 65%. Chest wall STS are often treated in a similar fashion to extremity STS. The preoperative approach should be encouraged to limit the volume of lung receiving a high dose of radiation.

ATYPICAL-BEHAVING STS SUBTYPES

Pediatric-Type STS in Adults

Certain histologic types of STS such as rhabdomyosarcoma and Ewing's sarcoma are seen predominantly in children, but they can still occur across the age spectrum.[172] When such histologies are encountered in adult patients it raises the issue of how they should be treated. In pediatric STS, there is heavy reliance on chemotherapy but less so in adults, and the dose of RT in pediatric STS is less than what is used in adult STS.

Rhabdomyosarcoma

Rhabdomyosarcoma (RMS) in the 2013 WHO classification includes the following main subtypes: embryonal, alveolar, and pleomorphic.[22] Alveolar RMSs have distinct translocations that help distinguish it from other RMSs. There is signature translocations in t(2;13) in 60% of cases and in t(1;13) in 20% of cases. Embryonal RMS is characterized by loss of heterozygosity (LOH) at chromosome 11p15.5. Embryonal and alveolar RMSs are predominantly seen in children but they can occur in adults up to the age of 45. Pleomorphic RMS display complex genetic alterations and tends to occur in adults older than 45 years.

RMS is one of the sarcomas associated with a risk of lymph node metastasis. RMS is divided into four groups, and three risk categories that take into account not only typical TNM findings but also tumor site and histology.

The prognosis of adult RMS is worse than in children. Whether this is a reflection of different biology or

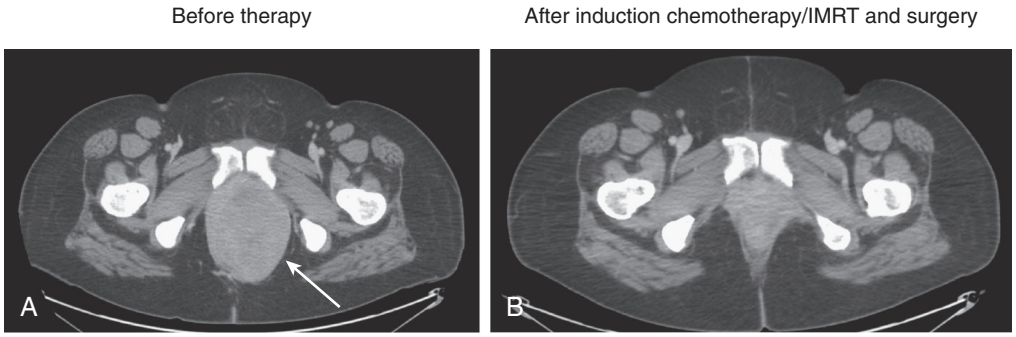

Figure 65-15 Ewing's sarcoma of the perirectal region: **A,** Tumor mass at presentation *(arrow)*, **B,** after induction chemotherapy, preoperative intensity-modulated radiation therapy (IMRT) to 50.4 Gy and surgery. Pathology at surgery did not reveal any residual disease.

aggressiveness of treatment is not entirely clear. In a report from MSKCC[173] of 148 patients (16 years old or older) with RMS, the patients treated on or according to RMS protocols had better OS (54% versus 36%; $p = 0.03$). RT to the primary site was given to 65% of patients. In the subset of patients with nonmetastatic disease ($n = 94$), the 5-year LR rate was 34% and the 5-year OS was 45%. It could be argued that the aggressive multimodality approach, as used in pediatric RMS, is warranted in adults as well. The doses of postoperative RT in pediatric RMS are modest, usually 36 Gy to 41 Gy. It is unclear if such doses are adequate for adults with RMS. Certainly, for patients with pleomorphic RMS the postoperative RT dose should be 63 Gy to 66 Gy, similar to other adult STS.

Extraskeletal Ewing's Sarcoma

Most Ewing's sarcomas in children are primary bone sarcomas, whereas most adult Ewing's sarcomas arise in soft tissue (about 75%). The most common site is the lower extremity (25%) followed by upper extremity (18%). These tumors have signature translocations t(11;22) in 90% of cases and the second-most common translocation is t(21;22). Martin et al[174] reported on 46 adult patients with primary disease, and with a median follow-up of 29 months, the 5-year survival was 60%. The general treatment guidelines follow those with bone Ewing's sarcoma including the use of systemic chemotherapy and radiation (Figure 65-15). Again the typical postoperative dose of RT for pediatric Ewing's sarcomas is 45 Gy to 50 Gy, and whether that is adequate for adults is unclear.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans is a superficial tumor that often manifests as a deceptive dermal, raised, purple or red lesion(s) in the lower neck, upper chest, and shoulder girdle regions, although any site may be involved. This tumor arises from the dermis and exhibits a characteristic slow but persistent growth over many years. It affects mainly patients of middle age. More than 90% of these tumors are characterized by the t(17;22)(q22;q13) reciprocal chromosomal translocation that is now becoming the hallmark feature of the diagnosis. The main treatment is surgical resection with wide margins. Another approach is Mohs's micrographic surgery. Paradisi et al[175] pooled results from the literature and reported six recurrences in 463 cases for Mohs's surgery (1.3%), as opposed to 288 recurrences in 1394 cases for wide local excision (20.7%).

Castle et al[176] reported on 53 patients treated with surgery and radiation (median dose 60 Gy for postoperative RT and 50 Gy for preoperative RT). With a median follow-up of 6.5 years, the 5-year local control was 98%. The authors recommended that adjuvant RT should be considered for patients with large or recurrent tumors or when attempts at wide surgical margins would result in significant morbidity. Imatinib has demonstrated antitumor effects in advanced disease harboring t(17;22). Data from two Phase II trials of imatinib showed objective response rate approaching 50% in locally advanced or metastatic dermatofibrosarcoma protuberans.[177]

Aggressive Fibromatosis

Also referred to as extraabdominal desmoid tumors, aggressive fibromatosis is a benign neoplasm capable of local infiltration and destruction. It affects young adults and can arise anywhere in the body but predominantly in extremity girdles, abdominal wall, and extremity. Wide surgical excision is the treatment of choice. But recurrence is frequent; the treatment should be individualized because this tumor is benign, patients are relatively young, and it is advisable to withhold or delay RT and systemic treatments if at all possible.

Gronchi et al[178] reported on 203 patients treated with surgery the 5-year DFS was significantly better for primary compared to recurrent lesions (81% versus 59%, $p < 0.01$). In the subset of patients with primary disease ($n = 128$; 15.6% received adjuvant RT); the 5-year DFS for those with positive margins was not significantly different than those with negative margin (79% versus 82%, $p = 0.5$). The corresponding figures in the subset of patients with recurrent disease ($n = 75$; 26.7% received adjuvant RT) were 47% versus 65%, but that difference did not reach statistical significance ($p = 0.17$). This data indicate that adjuvant RT may not be required in primary disease even with positive margins. In contrast, data from MDACC showed that if resection margins were positive after surgery alone, the 10-year recurrence rate exceeded 50% but was reduced to 31% in patients who received RT ($p = .007$). In addition, in patients treated with RT for gross disease, the 10-year actuarial relapse rate was 24%, making this a viable option for such patients.[179] In a subsequent report they recommended that for patients who have undergone surgery with positive resection margins, postoperative RT to a total dose of 50 Gy in 25 fractions with a 5-cm to 7-cm margin on gross tumor was advised. For unresectable gross disease, RT alone to a total dose of 56 Gy in 28 fractions delivered via a shrinking field technique after 50 Gy was recommended.[180]

Imatinib has demonstrated clinical activity in recurrent or advanced nonresectable aggressive fibromatosis. The French Sarcoma Group reported the results of a Phase II trial using imatinib for progressive and recurrent aggressive fibromatosis.[181] Forty patients were treated with imatinib (400 mg/day for 1 year) with 1 complete response, 3 partial confirmed

responses, 28 cases of stable disease, and 3 cases with progressive disease observed. The 2-year progression-free rate was 55%. Recent data seem to indicate even better activity of sorafenib against these tumors.[182]

SALVAGE TREATMENT AND PALLIATION

Local Recurrence

General management approaches for locally recurrent STS are summarized in Figure 65-16. For patients who develop LR (nonmetastatic) and are radiation naïve, they should be treated in a similar fashion to primary disease. For previously irradiated lesions, greater individualization is needed. BRT in addition to surgery is often an option. Torres et al[183] reported on 62 patients with locally recurrent STS after prior RT; 25 were treated with surgery alone and 37 with surgery and reirradiation. The types of reirradiation were as follows: LDR BRT to 45 Gy to 50 Gy in 33 patients, 3 preoperative RT to 45 Gy to 50 Gy, and 1 postoperative RT to 64 Gy. The overall 5-year local control was 51%; 39% in the surgery alone group compared with 58% for surgery and reirradiation ($p = 0.4$). Complications requiring outpatient or surgical management were more common in patients who had undergone reirradiation (80% versus 17%, $p < 0.001$). Thus, the additional morbidity with reirradiation has to be weighted against potential benefit.

Metastatic Disease

Surgery

With the propensity for isolated lung metastasis in STS, consideration of pulmonary metastasectomy is always warranted. The International Registry of Lung Metastases reported 5206 patients with pulmonary metastases resection, 2173 of whom had bone sarcomas or STS. Patients with single metastases and long disease-free intervals were recognized as having the best outcome.[184] The importance of achieving complete resection was highlighted by Billingsley et al. In the 719 patients with lung metastasis from STS, the OS rate was 25%. In the group that underwent complete resection, the 3-year survival rate was 46%. In contrast, those who underwent incomplete resection did not fair much better than those who did not have resection.[185]

Radiation

Until recently, radiation played only a minor role in the management of metastatic STS. But with the advances in SBRT, a

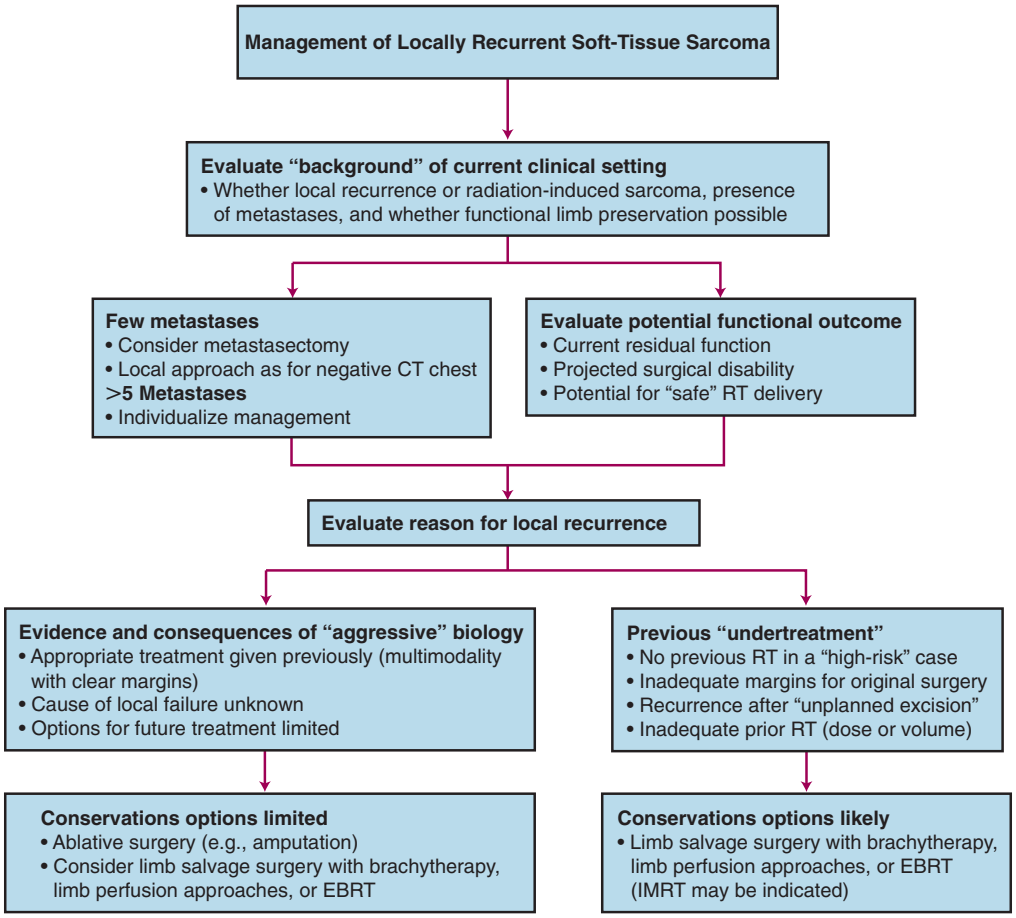

Figure 65-16 Management algorithm for the treatment of locally recurrent soft-tissue sarcoma. These lesions are complex to manage, and the clinician must consider various elements that include the potential that the lesion may be an irradiation-induced sarcoma, appreciating the reasons underlying the recurrence, the impact of concurrent metastases on decision making, and the options for protecting functioning tissue at the site of the recurrence. *CT,* computed tomography; *EBRT,* external beam radiation therapy; *IMRT,* intensity-modulated radiation therapy; *RT,* radiation therapy.

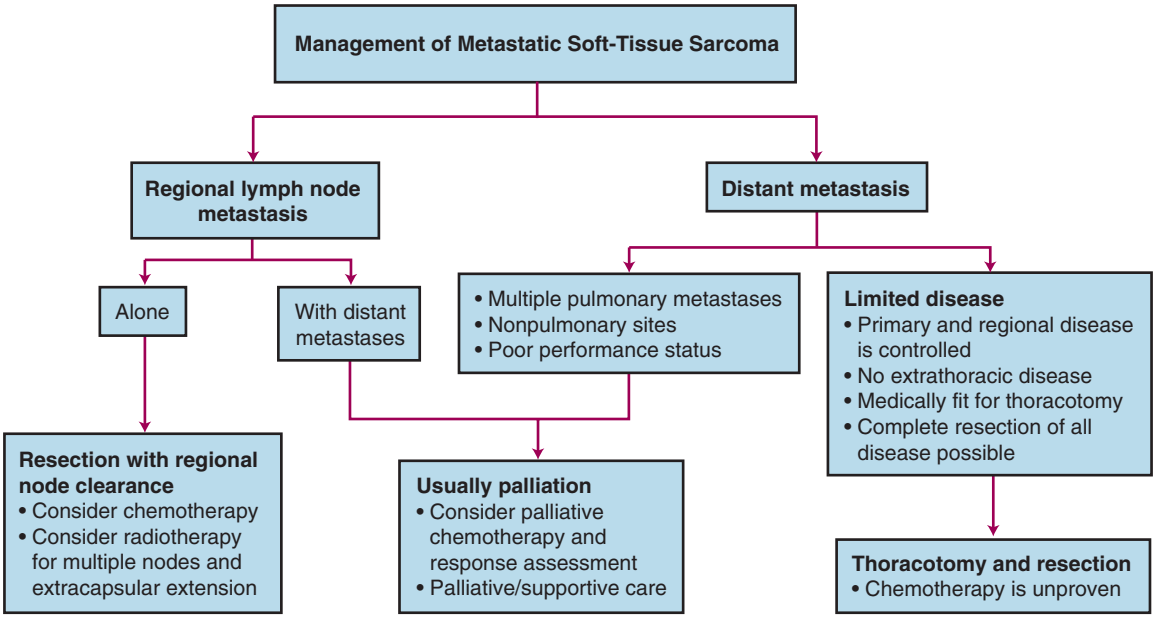

Figure 65-17 Management algorithm for the treatment of metastatic soft-tissue sarcoma. Patients with these lesions have potentially salvageable disease that requires careful selection before initiating intensive treatment approaches.

subset of patients with limited metastatic burden and good performance status seems to benefit from it. Dhkal et al[186] reported on 15 patients with lung metastasis who underwent SBRT, generally 50 Gy in 5 Gy fractions. The 3-year local control was 82%. In a report from UCLA,[187] 16 patients were treated with SBRT to a median dose of 54 Gy in three to four fractions. With a median follow-up of 20 months, the control rate was 94%. In a systematic literature review regarding hypofractionated SBRT in variety of metastatic tumors to lung including STS, the 2-year local control and OS for the single-fraction therapy were 78.6% and 50.3%, respectively, and with the fractionated therapy they were 77.9% and 54%. Reported toxicities were low.[188]

For patients with spinal metastasis SBRT is an attractive option. In a report from MSKCC,[189] 88 patients were treated with hypofractionated or single-fraction SBRT. Local control at 12 months was 87.9%. Those treated with single fraction (median dose 24 Gy) did better ($p = 0.007$). Grade-3 late toxicity was 4.5%.

Chemotherapy for Metastases

General management principles for metastatic STS are highlighted in Figure 65-17. A complete and durable response to systemic chemotherapy in metastatic STS is uncommon. Single-agent doxorubicin is the most commonly used drug in the first-line treatment of metastatic STS[20] and produce response rates ranging from 12% to 24%. The response rate with single-agent ifosfamide[20] is higher typically ranging from 20% to 25%. Bramwell et al performed a meta-analysis on data on 2281 participants from eight randomized controlled trials comparing single-agent doxorubicin to doxorubicin-based combination chemotherapy and concluded that single-agent doxorubicin was the optimal therapy.[190] Median survival ranged from 7.7 months to 12.0 months with single-agent doxorubicin and was 7.3 months to 12.7 months with combination chemotherapy.

In a recent randomized trial,[191] 228 patients were randomized to doxorubicin alone and 227 to doxorubicin and ifosfamide. All patients had metastatic or unresectable disease. There was no significant difference in OS between the groups; median OS was 12.8 months in the doxorubicin group compared with 14.3 months in the doxorubicin and ifosfamide group (HR: 0.83; $p = 00.076$). More patients in the doxorubicin and ifosfamide group than in the doxorubicin group had an overall response (26% versus 14%; $p < 0.0006$). The most common grade-3 and grade-4 toxic effects were all more common with doxorubicin and ifosfamide than with doxorubicin alone, and they included febrile neutropenia (46% versus 13%), anemia (35% versus 5%), and thrombocytopenia (33% versus <1%), respectively.

Individualization of treatment is important because certain histologies respond differently. In a retrospective review of EORTC chemotherapy trials, ifosfamide-containing regimens provided better response rate than doxorubicin in patients with synovial sarcomas. Conversely, patients with LMS were less responsive to ifosfamide-containing regimens.[192] Thus, ifosfamide is not typically recommended for LMS, instead gemcitabine and docetaxel are often used. Maki et al reported on a Phase II randomized trial comparing gemcitabine and docetaxel to gemcitabine alone in patients with metastatic STS; the combination yielded superior progression-free survival and OS especially for patients with LMS.[193] As mentioned previously, patients with metastatic angiosarcomas seem to respond well to paclitaxel.[194]

Pazopanib, a multitargeted tyrosine kinase inhibitor, has been used in nonlipomatous STS. In a recent trial,[195] 369 patients with metastatic STS, progressing despite previous standard chemotherapy, were randomly assigned in a 2:1 ratio to receive pazopanib ($n = 246$) or placebo ($n = 123$). Median progression-free survival was 4.6 months for pazopanib compared with 1.6 months for placebo ($p < 0.0001$). OS was 12.5 months with pazopanib versus 10.7 months with placebo ($p = 0.25$). As we begin to unlock the pathways involved in sarcomatogenesis (Figure 65-18), newer targeted therapies based on the specific genomic alterations will be used.[196,197]

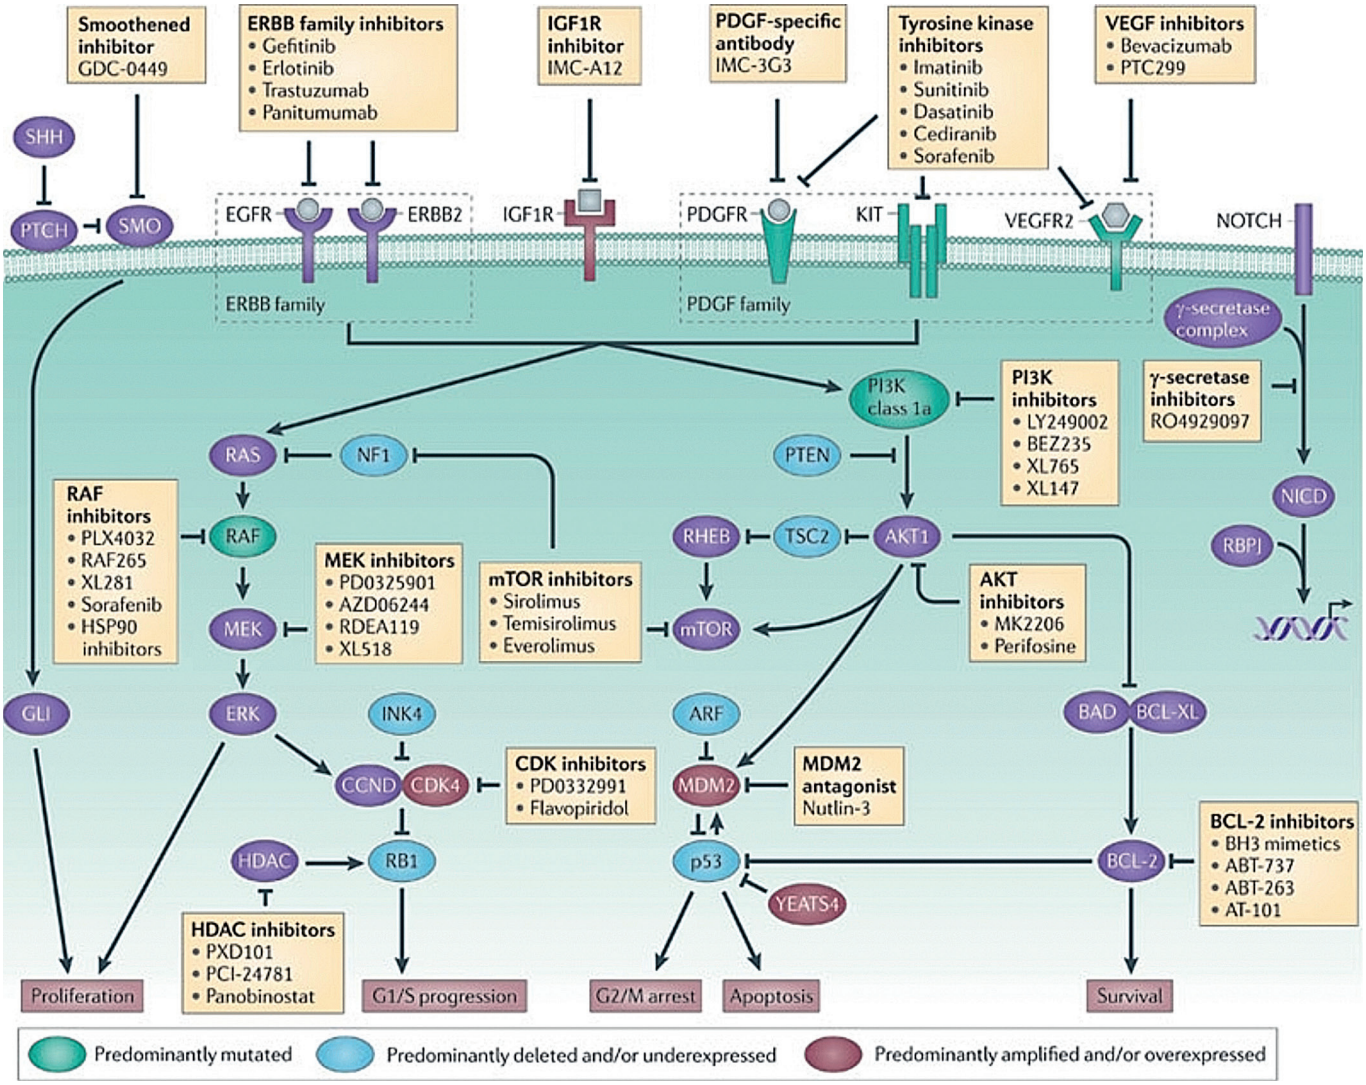

Figure 65-18 Pathways for targeted therapy in sarcoma. Subsets of nodes are colored by their dominant alteration type (mutated, deleted, or amplified). Yellow boxes indicate targeted agents in clinical use or early development.

CHAPTER

66 Benign Diseases

William G. Rule, Michael Heinrich Seegenschmiedt, and Michele Halyard

DEFINITION AND CLASSIFICATION OF BENIGN DISEASES

Many diseases that are pathologically benign (nonmalignant) do not act clinically benign, causing significant symptoms or dysfunction to the patient. A number of these entities can be successfully treated with ionizing radiation. The use of irradiation for benign diseases dates back centuries, with initial uses coming from results obtained using x-rays for experimental purposes. Sokoloff reported positive results in radiotherapy of painful "rheumatoid diseases" as early as 1898.[1] The traditional classification of benign diseases amenable to radiotherapy as inflammatory, degenerative, hyperproliferative, functional, and other types of disorders is currently outdated. Worldwide, irradiation of benign diseases has become more important, although indications and treatment concepts have changed considerably with increasing information regarding acute and late effects of radiation therapy. Today, clear differences between countries do exist regarding radiation therapy use in nonmalignant conditions because of historical clinical traditions and differences in training.[2-6]

Indications for the Implementation of Radiotherapy

Benign diseases have several features that may justify the use of radiotherapy. They can grow invasively and aggressively. For example, desmoids (aggressive fibromatoses) and keloids can be cosmetically disfiguring and functionally disturbing. Endocrine orbitopathies may be life threatening. Refractory hepatic hemangiomas (Kasabach-Merritt syndrome) or juvenile angiofibromas in facial regions of children or adolescents may require radiotherapy. There may be an indication for irradiation when benign diseases have a lasting effect on quality of life by causing pain or other serious symptoms, or if other therapeutic options are not available, have failed, or may induce more side effects. Overall, however, radiotherapy is *rarely* the first option for treatment of most nonmalignant diseases. Therefore, the process leading up to informed consent must be especially thorough. Particular attention should focus on the risk for long-term consequences, such as the induction of secondary malignancies, including solid tumors or leukemia.

Long-Term Risk for Tumor Induction

Considering international data about the emergence of tumors and leukemias after whole-body exposure to ionizing radiation (United Nations Scientific Committee on the Effects of Atomic Radiation [UNSCEAR], Biological Effects of Ionizing Radiation [BEIR]), the risk for tumor induction can be calculated on gender- and age-related bases.[7] The average lifetime risk for exposure to radiation is lower in men (9.5%) than in women (11.5%). Table 66-1 summarizes the age- and gender-specific risks for tumor induction.

Principles of Irradiation of Benign Diseases

The principles of irradiation of benign diseases can be summarized in 10 statements (Box 66-1). These should be carefully considered for each patient in whom irradiation is being evaluated.

RADIOBIOLOGIC ASPECTS

The radiobiologic mechanisms, known from the treatment of malignant disease, and the identified proliferating target cells are only partially applicable to benign diseases. Other radiation-sensitive target cells and cellular and functional mechanisms should be considered as target points for ionizing radiation. However, radiotherapy is probably not working via one particular mechanism but rather through a complex interaction of different effects.

Reactions in Connective Tissue

Several mechanisms are triggered by ionizing radiation in connective tissues. Following any trauma or acute or chronic inflammation, several cell systems regulate the repair process where fibroblasts play a central role, particularly during the reparative phase, which is characterized by high cell production and stimulation of specific growth factors. Furthermore, ionizing radiation also has a pivotal influence on cellular differentiation.[8,9]

For some hyperproliferative events, fibroblast overreaction is responsible for the disease process (e.g., during the early stage of Dupuytren's contracture, during the early phase of Peyronie's disease, in keloids, and in the progression of aggressive fibromatosis [desmoid]). The increase in fibroblast production can be modified by ionizing radiation, which influences differentiation and suppresses cell proliferation.

Reactions in the Vascular System

The endothelial cells of the capillaries and the larger arterial and venous blood vessels possess a high proliferative potential and are the origins of various cytokine-mediated cellular reactions. Intercellular adhesion molecule 1 (ICAM-1), a mediator of the leukocyte-endothelial interaction, is induced by low radiation doses.[10] Similarly, selectins mediate the penetration of mononuclear blood cells into the interstitial tissue. Endothelial prostaglandin release is also modulated by ionizing radiation.[11] Cellular and membrane functions can be modified when they are exposed to radiation.

Large single or total doses may cause endothelial damage, leading to sclerosis and obliteration of small blood vessels. Higher fractionated doses or single doses are used for cerebral arteriovenous malformations (AVMs) or symptomatic vertebral hemangiomas, and lower single and total doses are applied to reduce inflammatory processes such as endocrine orbitopathy and pseudotumor orbitae.

TABLE 66-1 Tumor Induction Depending on Age and Gender: Relative Lifetime Risk

Age-group (Years)	Men (%/Sv)	Women (%/Sv)
≤10	25.0-26.0	32.0-33.0
11-20	15.0	19.0
21-30	13.0-14.0	17.0
31-40	7.0	8.0
41-50	5.0	6.0
51-60	4.5	5.0
61-70	3.5	4.5
71-80	2.5	3.0
>80	1.0	1.5

From Jansen JTM, Broerse J, Zotelief J, et al: Assessment of carcinogenic risk in the treatment of benign disease of knee and shoulder joint. In Seegenschmiedt MH, Makoski H-B, editors: Kolloquium Radioonkologie/ Strahlentherapie, Radiotherapie bei gutartigen Erkrankungen, Vol 15, Altenberge, Germany, 2001, Diplodocus Verlag, pp 13–15.

BOX 66-1 Principles of Irradiation of Benign Diseases

1. Estimate the natural course of disease without therapy.
2. Consider the potential consequences of nontreatment of the patient.
3. Review data about alternative therapies and their therapeutic results.
4. Conduct a risk-to-benefit analysis compared with other possible measures.
5. Prove that the indication is justified if conventional therapies have failed, if risks and consequences of other therapies are greater, and if nontreatment would have more dramatic consequences than irradiation for the patient.
6. Consider the potential long-term radiogenic risks to the individual patient.
7. Inform each patient about all relevant details of radiotherapy: target volume, dose concept (single and total dose), duration of single session and whole irradiation series, relevant radiogenic risks, and side effects.
8. Obtain written consent from the patient following thorough patient education.
9. Ensure long-term aftercare to document results.
10. Request a competent second opinion in case of doubt and if the provided patient's data or treatment decisions are uncertain.

Data from Seegenschmiedt MH, Katalinic A, Makoski H, et al: Radiation therapy for benign diseases. Patterns of care study in Germany. Int J Radiat Oncol Biol Phys 47:195–202, 2000; Micke O, Seegenschmiedt MH: The German Working Group guidelines for radiation therapy of benign diseases. A multicenter approach in Germany. Int J Radiat Oncol Biol Phys 52:496–513, 2002.

Reactions in Painful Processes

Degenerative processes in hypotrophic tissues such as tendons, ligaments, and joints can cause pain by chronic inflammation and trigger various forms of functional impairment of the musculoskeletal system. Radiation does not influence the degenerative process but may reduce inflammation and as a consequence, improve function of affected joints and limbs and achieve pain relief.[12,13]

Mechanism of Action

To know individual target cells and potential pathogenic mechanisms of the various benign diseases also means to coordinate the radiation therapy concepts accordingly and consistently. The dose concepts applied in benign diseases differ greatly from each other because of other potential mechanisms of action (Table 66-2).

TABLE 66-2 Mechanisms of Action and Dose Concepts

Mechanisms of Action	Single Dose (Gy)	Total Dose (Gy)
Cellular gene and protein expression (e.g., eczemas)	<2	<2
Inhibition of inflammation in lymphocytes (e.g., in pseudotumor orbitae)	0.3-1	2-6
Inhibition of fibroblast proliferation (e.g., in keloids)	1.5-3	8-12
Inhibition of proliferation in benign tumors (e.g., in desmoids)	1.8-3	45-60

BENIGN DISORDERS OF THE HEAD AND NECK AND CENTRAL NERVOUS SYSTEM

Benign tumors of the central nervous system (CNS) can lead to severe, life-threatening symptoms resulting from local expansion and pressure on neighboring normal structures. Depending on the growth rate, the surrounding normal tissues can potentially adapt and delay symptoms and the subsequent clinical diagnosis.

Pituitary adenomas, meningiomas, vestibular schwannomas, craniopharyngiomas, and chordomas are important benign CNS tumors treated with irradiation. These are covered fully in Chapters 23, 28, 29, and 30 and will not be discussed here.

Arteriovenous Malformation

Definition and Clinical Features

Intracranial AVMs are rare vascular abnormalities consisting of widened arteries with connections to the normal capillary bed that enables oxygenated blood to enter directly into the venous system. Approximately 80% of AVMs are located supratentorially. The incidence of AVMs is unknown. Its prevalence is below 0.01% (≈18:100,000) in the Western hemisphere. Most AVMs are discovered at the age of 20 years to 40 years. AVMs can extend to aneurysms and rupture (2% to 5% per year).[14] Neurologic symptoms associated with AVMs include headaches, hemorrhage, and cramp attacks, which may culminate in sudden death through bleeding. Increased risk of hemorrhage includes prior hemorrhage, exclusive deep venous drainage, associated aneurysms, and deep location, which can influence surgical and or radiosurgery decision making.[14,15] Lethality after the first bleeding episode occurs in up to 30%; 10% to 20% of survivors have long-term neurologic defects. Spontaneous regression is rare.[15] Diagnosis of AVMs is made with imaging techniques such as angiography and magnetic resonance imaging (MRI).

The aim of therapy is the prevention of bleeding by complete obliteration of the nidus, the improvement of neurologic malfunctions, if feasible, and preferably, minimal therapy-induced side effects. For this purpose, the options of minimally invasive endoscopic surgery, endovascular embolization, and stereotactic radiosurgery (SRS) are available. For therapy

planning, precise knowledge regarding the size, location, arterial feeders, and venous drainage of the nidus is required.

Surgical Treatment

The therapy of choice is the elective complete excision of the AVM vascular abnormality. Particularly with small AVMs in superficial, noneloquent regions of the brain, microsurgery results in high cure rates. Larger AVMs are treated initially with embolization before surgery or SRS. Only in special cases is surgery performed under emergency conditions to remove life-threatening brain hemorrhages.

Irradiation Options

Arteriovenous malformations are irradiated with SRT/SRS with a linear accelerator or Gamma Knife (see Chapters 7 and 23).

Stereotactic radiosurgery for AVMs dates back to the 1970s. The mechanism of action of SRT/SRS is linked to injury to the vascular endothelium, which causes proliferation of smooth muscle cells and the elaboration of extracellular collagen causing progressive stenosis and obliteration of the AVM.

Fractionated radiation with total doses of up to 60 Gy produced inadequate results.[16-18] Depending on the size and location of the AVM, a single dose of 15 Gy to 30 Gy is required to the periphery of the nidus. If therapy is successful, complete obliteration of the nidus will occur usually no sooner than 2 years from treatment, with many taking 3 years or longer. This delay in obliteration does leave the risk of bleeding until complete obliteration occurs. The obliteration rate after SRT or SRS is 65% to 95% (Table 66-3).

The side effects of SRT/SRS are mostly chronic and follow the time course of AVM obliteration: focal radionecroses or leukoencephalopathies occur 9 months to 3 years after SRT, but they may also appear after several weeks.[17,21,22,24,25,28-36] The risk correlates strongly with the irradiated brain volume, location of the AVM, and the total dose.[37-39] The brain volume irradiated with more than 10 Gy is an important predictive factor.[40,41]

Whether unruptured AVMs should be treated or observed has been a matter of debate. The ARUBA trial, a randomized trial of unruptured brain AVMs compared the risk of death and symptomatic stroke. Patients were randomized to either medical management for symptoms treated with pharmacologic agents alone or medical management with interventional therapy including neurosurgery, stereotactic radiotherapy, or embolization, alone or in combination. The trial was halted early because of the superiority of the medical management group because the risk of death or stroke was significantly lower compared to the intervention group.[42]

Glomus Tumor or Chemodectoma

Definition and Clinical Features

Glomus tumors (synonyms are chemodectomas or nonchromaffin paragangliomas) are rare benign tumors that can occur in multiple anatomic locations:

1. Paragangliomas occur at the carotid glomus, along the carotid, mostly near the bifurcation.
2. Jugular paragangliomas are found near the skull base in the region of the jugular bulb.
3. Paraganglioma of the tympanic glomus occurs in the region of the tympanum.
4. Other paragangliomas occur at the larynx, near the aorta, in pulmonary locations, and in the orbital cavity.

Approximately 50% of tumors are located near the skull base in the jugular fossa. The age peak is 45 years. The tumors are usually unilateral; only 10% to 20% are bilateral or multiple.[43] They grow slowly, rarely have endocrinologic activity, and degenerate into malignant forms in 5% to 10% of patients. They can also infiltrate bone, vessels, the middle ear, and cranial nerves (CN). The main symptoms are headaches, CN failure (CN V to XII), dysphagia, pulsatile tinnitus, vertigo, and hypacusis. Without therapy, there is the risk for CN injury; the swelling can be so extreme as to be life threatening. The diagnosis is made clinically and with high-resolution computed tomography (CT) and MRI.

Surgical Treatment

Although glomus tumors grow slowly, they can cause severe problems and, therefore, must be treated. In the carotid region, primary tumor resection after previous embolization is the therapy of choice. At the skull base or at the tympanum, neurosurgical interventions carry more risk, and therefore, fractionated radiation is often favored. In the case of incomplete surgery, the patient should initially be observed, and further treatment should only be started if the tumor grows.

Irradiation Options

Depending on the size and location of the lesions, the indication for RT may be either *primary* irradiation in the case of functional or other inoperability (mostly, jugular paragangliomas) or *adjuvant* irradiation for R1 to R2 resections or irradiation of *recurrence* if there is progression after surgery. Conventional fractionated three-dimensional (3D) conformal radiation therapy with 45 Gy to 55 Gy is the norm. The clinical target volume (CTV) is restricted to the tumor region with a safety margin to cover microscopic extensions.

Irradiation of paragangliomas produces control rates as good as or even better than surgery.[44] Even in large, diffusely growing or multiple tumors, radiation produces a local control rate of 88% to 100%.[26,27,44-46] Kim et al noted a recurrence rate of 22% with doses of less than 40 Gy, whereas recurrences occurred in only 1.4% with doses of more than 40 Gy.[45] Frequently, tumor rests are detectable on imaging for several years. Therapeutic success is usually assessed in terms of the regression of CN failures and the lack of tumor progression. A dose of 45 Gy to 50 Gy does not complicate surgery that might become necessary later.

Stereotactic single-dose radiation and Gamma knife therapy have efficacy in the treatment of paragangliomas.[26,27,44-51] The results are favorable compared to fractionated radiation, with excellent local control rates and acceptable side effects. Sheehan et al reported data regarding 134 patient procedures from eight Gamma knife centers including prior resection in 51 patients. The median tumor margin dose was 15 Gy. With a median duration of follow-up of 50.5 months (range, 5 months to 220 months), overall tumor control was 93% at last follow-up with an 88% actuarial tumor control 5 years after surgery. Worsening CN function was seen in 11% of patients despite radiological evidence of control.[52] No secondary malignancies were noted.

Irradiation of paragangliomas of the carotid glomus can acutely cause pharyngeal mucositis and chronically may lead to skin fibrosis and dryness of the pharyngeal mucosa on the irradiated side. Irradiation of jugular or tympanic paragangliomas can lead to acute skin reactions in the external acoustic canal, tube ventilation dysfunction, reduced sound conduction, and salivary retention may occur on the ipsilateral side.

Juvenile Nasopharyngeal Fibroma

Definition and Clinical Features

Juvenile nasopharyngeal fibromas (JNFs), which is a synonym is angiofibromas, are rare, benign, strongly vascularized tumors in the head and neck region, affecting mainly male juveniles. JNFs develop in the sphenoethmoidal suture and can spread from the epipharynx and the main nasal cavity via the sphenopalatine foramen and into the pterygopalatine fossa. After bony destruction, there is spread into the paranasal sinuses, the infratemporal fossa, the orbital space, and the middle cranial fossa.

Intracranial spread occurs in about 25% of cases. Typical symptoms are epistaxis and impaired nose breathing. Depending on the pattern of spread, facial swelling as well as orbital (e.g., blindness) and intracranial symptoms (e.g., CN failure) may occur. A biopsy can cause massive bleeding so that histologic confirmation of diagnosis is often not performed. The presence of hormone receptors shows the influence of androgynous hormones. Spontaneous remission after puberty is possible, but therapy can hardly be delayed when the symptoms increase and when complications are threatening.[53,54]

Surgical Treatment

In JNF, the main emphasis is placed on surgery combined with embolization to decrease the size of the tumor.[55,56] Small tumors that are restricted to the posterior nasal cavity and the nasopharynx can be completely removed after embolization. A JNF with lateral spread is also an indication for surgery. Endoscopic surgical approaches have been used in treating these tumors as a means of decreasing morbidity.[57,58] Through surgery, the local control rates for most JNFs without intracranial spread range up to 100% with minimal toxicity.[53,54,57,58]

Irradiation Options

Radiotherapy is an effective treatment for JNF. In locally advanced disease, complete resection is often not possible, and tumors with intracranial spread should receive primary irradiation. Other indications for radiation are tumor rests, inoperability, or local recurrence after initial surgical resection. With modern CT-based treatment planning, high control rates are achieved in locally advanced JNF as well. Intensity-modulated radiation therapy (IMRT) is often recommended.[59]

Total doses of 30 Gy to 55 Gy (1.8 Gy to 2 Gy per fraction) are said to be effective, but for large tumors, doses of 40 Gy to 46 Gy are currently recommended.[60-64] With conventional fractionated radiation, control rates of 80% to 100% can be reached. Remission of JNFs after radiation often requires several months[61]; sometimes, complete remission, as detected by imaging techniques, does not occur even after years, although there is no further growth.

Radiation side effects include mucositis, xerostomia and caries, dysfunction of the pituitary gland, CN failure, temporal lobe necrosis, osteoradionecrosis, growth impairment of the facial skull, cataract, glaucoma, and atrophic rhinitis, but these can be limited through careful radiation planning and highly conformal radiation. Radiation-induced tumors occur in up to 4% of cases, particularly in young patients; this has to be weighed against the risk for sudden death or severe morbidity after surgery.

BENIGN DISORDERS OF THE EYE AND ORBIT

Macular degeneration and endocrine orbitopathy (Graves' disease) are important benign diseases of the eye or orbit that are treated with irradiation. They are discussed in detail in Chapter 31 and will not be covered here.

Pterygium

Definition and Clinical Features

Pterygium is a wing-shaped fibrovascular proliferating tissue originating at the lens epithelium at the border between the conjunctiva and the cornea. It normally extends from the medial (nasal) corner of the eye to the cornea and beyond. The highest incidence occurs in hot, dusty, dry, and sun-exposed regions (desert belts). In such areas, even people in their 20s and 30s can be affected.[65,66] Typical symptoms are the sensation of having a foreign body in the eye and tearing. Motility problems are sometimes present. If the cornea is affected, vision may be impaired.

Surgical Treatment

Surgery is the mainstay of treatment, with treatment indicated if vision is threatened by the pterygium growing toward the pupil or if cosmesis is affected. Historically, the initial approach was bare sclera excision, which removes the pterygium from the cornea and conjunctiva, leaving the bare sclera exposed. Absent adjuvant therapy, recurrence rates have been reported to be as high as 88%.[67] Currently accepted therapeutic strategies include conjunctival or limbal autografts with or without mitomycin C intraoperatively or postoperatively. Amniotic membrane grafting has been used, but appears to be inferior to conjunctival or limbal autografting. With the use of the aforementioned adjuvants, recurrence rate reduction (compared to bare sclera excision alone) in both primary and recurrent cases is in the range of 40% to 95%. Vision-threatening and non-vision-threatening complications are relatively rare but can include scleral thinning or ulceration, delayed

conjunctival epithelialization, iritis, corneal edema, corneal perforation, symblepharon, corneal dellen, astigmatism, pyogenic granuloma formation, ocular pain, photophobia, and foreign body sensation.[67-70]

Irradiation Options

Radiotherapy is indicated after local resection of a recurrent pterygium, but some centers also report success with primary or preoperative radiation of the pterygium.[71] Besides rare orthovoltage therapy,[72] brachytherapy with beta radiators and eye applicators is usually employed. Normally, radionuclide strontium-90, a fission product of uranium-235 (half-life period, 28 years), which decays to yttrium-90 (half-life period, 64 days) is used. Strontium-90 radiation has a maximum energy of 0.546 MeV; for yttrium-90 it reaches 2.27 MeV.[73] The eye applicators have an effective diameter of 8 mm to 12 mm. The affected lesion is generously covered by the applicator for a certain time. If lesions are large, they are treated with a circular motion toward the corneal limbus.[74]

Most clinical studies have used postoperative radiation for recurrence prophylaxis with subsequent relapse rates of 1.5% to 11%. Van den Brenk[75] observed only 1.4% recurrences in 1300 treated pterygia (1064 patients). Irradiation was carried out once a week (days 0, 7, and 14 postoperatively). Paryani et al[74] achieved a recurrence rate of only 1.7% in 825 eyes with 60 Gy in six fractions of 10 Gy (once a week). Wilder et al[65] report a recurrence rate of more than 11% in 244 eyes after 24 Gy in three fractions of 8 Gy (once a week). In comparison to placebo irradiation, a Dutch double-blind randomized study with one fraction of 25 Gy showed significantly lower recurrence rates (local relapse in the irradiation arm in only 3 of 44 tumors and in the placebo arm in 28 of 42 tumors).[76]

Radiogenic consequences such as severe scleromalacia and corneal ulcerations occur in up to 4% to 5% of cases after application of higher total doses and after single-dose radiation of 20 Gy to 22 Gy.[77,78]

Choroidal Hemangioma

Definition and Clinical Features

Choroidal hemangiomas are slowly growing benign vascular tumors originating from the vessels of the choroid. The *diffuse type* (ages 5 years to 10 years, almost always associated with Sturge-Weber syndrome) and the *local type* (ages 30 years to 50 years) can be distinguished.[79] Symptoms are determined by the size and location of the tumor. If the hemangioma is located close to the papilla or macula, vision changes, metamorphopsia, and secondary retinal detachment are observed. In case of direct macular involvement, chronic glaucoma frequently develops. A threat to vision can occur and is the main indication for therapeutic intervention. On ophthalmoscopic examination, hemangiomas appear as a red-orange swelling with concomitant clinical phenomena (e.g., glaucoma, retinal detachment). Further diagnostic procedures are ultrasound, fluorescence angiography, CT, MRI, and scintigraphy (phosphorus-32).[80]

Nonradiotherapeutic Treatment

Indications for therapy depend on the progression of the lesion and the severity of symptoms (visual impairment, retinal detachment, or secondary glaucoma). Small lesions outside the field of central vision are treated with photodynamic therapy, photocoagulation, or transpapillary thermotherapy (e.g., to prevent retinal detachment).[81,82] Lesions near the macula or papilla are not coagulated because there is a risk for central scotoma. The same holds for incomplete retinal detachment and for the diffuse type (Sturge-Weber syndrome). In general, the currently favored therapeutic intervention is photodynamic therapy. Intravitreal bevacizumab alone, or in combination with local therapy, has also been used.[83-86] Patients with small, well-circumscribed lesions and patients with a history of longstanding visual loss can potentially be observed.[87,88]

Irradiation Options

Irradiation can be delivered by photons, protons, or brachytherapy. It is typically indicated in cases of no or minimal response to other local therapies and particularly in cases of critical proximity to the macula or papilla because invasive measures can threaten vision.[80] After successful irradiation, the primary lesion flattens, the retina reattaches partially, or perhaps, completely, and the eye and vision are maintained. Visual acuity is often improved. A loss of visual acuity affects almost exclusively eyes with existing location-dependent maculopathy. Early initiation of radiation can potentially lead to better long-term results.[89,90]

Schilling et al[90] irradiated 36 localized and 15 diffuse hemangiomas with 20 Gy in 10 fractions of 2 Gy. After 5 years, 23 eyes (64%) of the localized type achieved complete retinal reattachment. Visual acuity was stable in 50% and improved in 50%. Favorable results were also achieved for the diffuse type. In locally advanced cases, irradiation of the hemangioma cannot conserve visual acuity but can often maintain the eye as a whole.

Radiation with photons or protons is typically conventionally fractionated (1.8 Gy to 2 Gy per fraction) to total doses of 18 Gy to 20 Gy (local type) or 30 Gy (diffuse type). In cases of unilateral location, a lateral stationary field that tilts slightly posterior is used to protect the other eye and the chiasm. In bilateral disease, opposing lateral fields with lens protection are used.

Brachytherapy is carried out in localized hemangiomas with eye plaques, with iodine-125 seeds being the preferred source. Doses from the apex to the base of the lesion vary between 30 Gy and 240 Gy. Results are excellent in the sense of a permanent resorption of the subretinal edema, complete retinal attachment, and maintenance of vision.[89,91-94]

Potential radiogenic side effects are retinopathy and papillopathy with doses of more than 30 Gy. Despite lens-protecting radiation techniques, cataracts occasionally develop as well. With external beam techniques, protons may have the additional benefit of minimizing the risk of secondary malignancy induction compared to photons, which is an issue of particular relevance in pediatric cases.[95-99]

Idiopathic Orbital Inflammation or Pseudotumor Orbitae

Definition and Clinical Features

Lymphoid diseases of the orbit are rare and have a broad range, including pseudotumor orbitae (PO) and malignant lymphomas.[97,100] There are three possible nonmalignant causes: (1) an infectious process, for example, in transmitted sinusitis; (2) an autoimmune process; or (3) a fibroproliferative process.

PO typically occurs in patients of middle age, with clinical signs and symptoms that can result in a broad differential diagnosis. Thus, other causes of orbital space involvement such as granulomatous diseases (e.g., sarcoidosis, Wegener's granulomatosis), local infections, malignancies, or autoimmune diseases have to be excluded. Frequently, the acute onset of symptoms, unilateral disease, and impaired eye motility point to pseudotumor. On imaging, the infiltrates appear in retrobulbar adipose tissue (≤80%), enlarged eye muscles (≤60%), thickening of the optic nerve (≤40%), and proptosis (≤70%). On the basis of clinical diagnosis and diagnostic imaging, it can be difficult to differentiate between

benign and malignant changes; therefore, biopsy is essential.[101]

Nonradiotherapeutic Treatment

Surgical excision can be used in accessible lesions, but recurrences are frequent.[102] Corticosteroids are the most important component of medical therapy, but up to 50% do not respond adequately.[96,103] Some patients are forced to discontinue corticosteroid use secondary because of untoward side effects.[94,104] Beyond corticosteroids, there is increased interest in nonspecific as well as targeted immunomodulatory therapies in the management of PO. However, there are a limited number of studies demonstrating overt clinical benefit with these agents in patients not responding to initial corticosteroid therapy.[96] Without therapy, visual acuity can deteriorate seriously and permanently. The potential for malignant transformation of orbital pseudotumors is unclear.

Irradiation Options

Irradiation is typically reserved for patients who have not responded to initial corticosteroid therapy. As noted by Lambo et al, radiotherapy has response rates of 70% to 100%.[100,101,104-107] Recommended doses vary between 0.5 Gy and 3 Gy per fraction and total doses of 20 Gy to 35 Gy.

In Europe, a treatment attempt with a low dose of two fractions of 0.5 Gy per week up to a total dose of 5 Gy (first series) has been used.[107] In the case of nonresponse after 4 weeks, irradiation is changed to daily 1.5 Gy to 2 Gy fractions up to 30 Gy to 40 Gy as a total dose (second series). In the United States, most patients are treated with initial doses of approximately 20 Gy to 30 Gy at standard fractionation.[108]

Irradiation Technique

After CT planning, patients are treated via anterior and lateral fields with 1:3 weighting and wedged filters for dose homogenization while the patient's eyes are open. In bilateral disease, parallel opposing lateral fields with a half-block technique[102] or two anterior electron fields are used.

Irradiation Side Effects

With careful treatment planning, serious radiation-related side effects are rare (keratitis, retinopathy, cataracts, etc.).

BENIGN DISEASES OF JOINTS AND TENDONS

Dose Concepts

It has been known since the beginning of the 20th century that low doses of ionizing radiation may have analgesic and anti-inflammatory effects.

Nonradiotherapeutic Treatment

Numerous conservative measures, such as oral, local, or systemic application of medications, lifestyle modifications, physical therapy, and so on are the mainstay of management. Radiation therapy is rarely used in the United States for primary management of these diseases, but its use is certainly more common in other countries.

Irradiation Options

In Germany, guidelines and dose concepts for radiotherapy of benign diseases were developed during the past 10 years to 15 years, where a dose per fraction of 0.5 Gy to a total dose of 6 Gy can, and has been, used.[2,3,109] Conditions that have been treated include bursitis, tendonitis, subacromial syndrome (rotator cuff syndrome), tennis elbow (epicondylopathia humeri), calcaneodynia (heel spur), and degenerative joints with cartilaginous destruction (osteoarthritis).[108,110-115]

BENIGN DISEASES OF CONNECTIVE TISSUE AND SKIN

Desmoid (Aggressive Fibromatosis)

Definition and Clinical Features

A desmoid is a benign growth of connective tissue originating in the deep muscular-aponeurotic structures in the region of muscle fascias, aponeuroses, tendons, and scar tissue. The incidence of new cases is two to four per 1 million inhabitants per year. Women are affected twice as frequently as men (1:1.5 to 2.5). Desmoids occur most frequently during the third and fourth decades of life, but children can be affected as well. Mesenteric desmoids are commonly associated with the *APC* gene mutation as in Gardner's syndrome.[116]

Desmoids are differentiated into extraabdominal (≈70%) and intraabdominal (≈10%) desmoids and those located in the abdominal wall (≈20%). Extraabdominal forms tend to recur locally. Intraabdominal forms are associated with the autosomal dominantly inherited Gardner syndrome. Histologically, desmoids are similar to low-grade (G1), highly differentiated fibrosarcomas. Mitotic activity is low, and cellular atypia is rare. Locally infiltrating growth and nonencapsulation has earned the name of "aggressive fibromatosis" for this disease. Local recurrences after resection alone are quite common particularly after marginal or intralesional excision.[117,118] Pretreatment imaging with MRI is used to estimate the size and infiltration into other organs and incision biopsies are performed to distinguish benign from malignant lesions. Although prognosis for survival is good, these lesions may impair function, impact quality of life, and cause life-threatening events.

Nonradiotherapeutic Treatment

Desmoids can regress spontaneously or they can grow to a huge size, but they rarely cause death.[119] Surgery with a safety margin of 2 cm to 5 cm is considered the gold standard. After R0 resection, no adjuvant therapy is usually required. After R1 resection, treatment options include observation if the lesion is in a site where re-resection is feasible; if not, postoperative radiation is reasonable. Good long-term control can be achieved by resection alone, but up to 50% of patients develop local recurrence, which requires surgical and other measures subsequently.[120] Hormonal intervention with tamoxifen, progesterone, and toremifene can exert growth inhibitory effects.[121-123] Overall antiestrogens produce an effect in approximately 50% of patients as determined by systematic review.[124] Nonsteroidals, vitamin C, and chemotherapeutic agents have been tested.[125,126]

Irradiation Options

Radiotherapy is indicated in cases of local inoperability and after R2 resection and in R1 resection if repeated surgery would not be feasible or has already been performed for local recurrence. Radiotherapy is often used adjuvantly or as primary treatment. Adjuvant radiotherapy significantly reduces local recurrence rates compared with surgery alone. With total radiation doses of more than 50 Gy, the local recurrence rate decreases from 60% to 80% with surgery alone to 10% to 30% after adjuvant RT. With normal fractionation and single doses of 1.8 Gy to 2 Gy, a total dose of 50 Gy to 55 Gy is recommended postoperatively. For inoperable or recurring desmoids, some recommend a total dose of 60 Gy to 65 Gy.

After primary radiotherapy, the local control rate does not differ substantially from that after adjuvant irradiation.[3,117,120,127-133] A recent Phase II pilot study evaluated the response of patients with inoperable progressive disease of primary, recurrent, or incompletely resected desmoids receiving 56 Gy in 28 fractions and demonstrated a 3-year local control rate of 81.5%.[134]

Irradiation Results

In most studies, tumor size has no prognostic influence on local control rates. According to a meta-analysis (698 cases in 13 studies), the local control rate after R0 resection and radiotherapy was improved by 17% compared with that of surgery alone. For macroscopic (R2) and microscopic (R1) tumor residual, patients treated with adjuvant radiotherapy had even better results.[135,136] In 2001 to 2002, patterns of care study on the use of radiotherapy for treatment of desmoids were carried out in Germany; 345 patients were subjected to evaluation. The desmoids were distributed in the extremities (81.2%; 280 tumors), the trunk (13.9%; 48 tumors), and the head and neck region (4.9%; 17 tumors). A total of 204 patients (59%) were irradiated for locally recurrent or unresectable desmoids: 141 (40.8%) for high-risk situations postoperatively, 44 for unclear resection status, 49 after R1 resection, and 28 after R2 resection. Most patients were intensively pretreated, on average with two (range, one to five) operations. The median time of observation after therapy was 43 (range, 4 to 306) months. A total of 67 recurrences (19%) were seen after radiation. The long-term local control rate was 81.4% after primary radiotherapy of nonresectable desmoids and 79.6% after postoperative irradiation of resected desmoids. A precise topographic analysis of recurrences was possible in 124 patients or 22 recurrences (18%); 12 (54%) of the recurrences were located within and 10 (46%) were located outside the target volume or at the edge of the field.

Peyronie's Disease

Definition and Clinical Features

Peyronie's disease is a chronic and mostly progressive inflammation and connective tissue excrescence of the tunica albuginea in the cavernous bodies of the penis.[137] It usually affects men between the ages of 40 years to 60 years. Its cause is unknown. Strands of scar lead to the typical bending of the penis, which may cause severe pain during erections. Spontaneous remission is described only rarely.

Nonradiotherapeutic Treatment

There is no simple and successful standard treatment. Vitamin E, para-aminobenzoate, and steroids are said to have a favorable influence during the early phase. There are also local therapeutic attempts with ultrasound or shock waves as well as with corticoid, procaine, and hyaluronic acid injections. Surgery is the standard of care for stable Peyronie's, disabling deformity, or erectile dysfunction unresponsive to drug therapy. Several different surgical procedures are used including tunical shortening or lengthening and the use of penile prostheses. Each surgical procedure comes with potential complications and differing levels of postoperative satisfaction; thus, no one surgical treatment is considered standard.[138]

Irradiation Options

Although radiation therapy has been used in the treatment of Peyronie's, results have been mixed. Low-dose radiation appears to be effective in early stages in patients with painful erections not improving over time or by using oral or intralesional methods. Ionizing radiation can delay further induration and lead to softening of lumps and strands that cause pain, bending, and functional problems of the penis. Radiotherapy can be used during the early stages of Peyronie's disease, but in the later stages, there are hardly any radiosensitive fibroblasts and inflammatory cells left. Irradiation is carried out with gonadal protection (lead apron or capsule), and the glans penis is spared. The nonerect penis is pulled forward manually by the patient and is irradiated via a dorsal stationary field with orthovoltage or electrons up to 6 MeV with a 5-mm to 10-mm bolus.

Conventional fractionation is 20 Gy in 2-Gy fractions, but it is possible to use hypofractionation with a single dose of 2 Gy to 4 Gy two to three times per week up to a total dose of 12 Gy to 15 Gy.[139-142]

However, the actual effectiveness of radiation is unknown because of the absence of criteria for success. As well, randomized, controlled trials comparing interventions do not exist. This leads some to recommend that radiation not be used in this setting.[138]

Irradiation Results

Within 12 months to 24 months, radiotherapy leads to an improvement of symptoms in two thirds of all patients with early-stage disease. Local pain and associated clinical symptoms decrease in up to 75%. Angulation (25% to 30%) and dysfunction of the penis (30% to 50%) show less response because these symptoms often indicate that the disease is already in a more locally advanced stage.[140-142]

Dupuytren's Contracture (Morbus Dupuytren) and Morbus Ledderhose

Morbus Dupuytren (MD) (Dupuytren's contracture) and morbus Ledderhose (ML) are two spontaneous connective tissue diseases in which the palmar or plantar aponeurosis is affected. Two thirds of patients show bilateral involvement. The disease is more common in the hands (MD) than in the feet (ML). It mostly appears from the age of 40 years onward. Depending on geographic region and racial factors, its prevalence is 1% to 3%. Initially, subcutaneous lumps with skin fixation appear; later, there are strands that may reach as far as the periosteum. With increasing connective tissue hardening, flexion contractures develop in the metacarpophalangeal or proximal interphalangeal joints, and grabbing (MD) or walking (ML) is impaired. Mostly, the fourth and fifth phalanges of the hand (MD) or the first and second toes of the foot (ML) are affected. The extent of the extension deficit determines clinical staging in MD.

Nonradiotherapeutic Treatment

Spontaneous regression is initially possible. Without therapy, more than 50% of people affected show disease progression after 5 years. Surgery is indicated if there is functional impairment.

Irradiation Options

Radiotherapy can be considered during the early stages of disease. The target cells are the strongly proliferating radiosensitive fibroblasts and inflammatory cells. The aim of therapy is to avoid further progression. Normal fractionation is 2 Gy per fraction to a total dose of 20 Gy or 3 to 4 Gy per fraction to a total dose of 12 Gy to 15 Gy.

Irradiation Results

Many studies demonstrate a good response to radiotherapy in the form of stabilized disease (70% to 80%). Only a small number of patients with early-stage disease, however, experience degeneration of lumps and strands (20% to 30%). Only a

few studies have controlled long-term observation for more than 2 years.[143] Betz et al reported the results of long-term results of 208 hands irradiated in 135 patients treated with orthovoltage therapy.[143] Patients received 30 Gy in 10 fractions treated split course with a 6- to 8-week break between courses. Patients were staged according to a modified version of staging described by Tubiana et al.[144] In this staging system, patients with stage N/I had clinical symptoms in addition to minor defects in extension (1 degree to 5 degrees). Eighty-seven percent of patients with stage N and 70% of patients with stage N/I stabilized or regressed. With more advanced stages, disease progression was seen in 62% of stage I patients (clinical symptoms with extension deficits of 6 degrees to 45 degrees), and 86% of stage II patients (clinical symptoms with extension deficits of 46 degrees to 90 degrees). No benefit was seen in patients with more advanced extension deficits. Also, the time period from first recognition of symptoms to radiation therapy onset influenced success, with better long-term results seen when irradiation was used within the first year of diagnosis versus those treated after 48 months ($p < 0.001$). Long-term relief of such symptoms as pruritus and scratching, tension, pressure, and burning occurred in 66% of patients. There was no increase in postsurgical complications, and only 32% of patients experienced minor late toxicity such as dry desquamation or skin atrophy. No evidence of secondary malignancy was seen. The authors concluded that radiation therapy is effective in the prevention of progress and relief of patient symptoms in early-stage contracture.

Keloids and Hypertrophic Scars

Definition and Clinical Features

Keloids are excessive tissue excrescences in the region of scars, and they may occur in case of skin injury from surgery, burns, chemical burns, or inflammation (e.g., acne) or even spontaneously. They differ from hypertrophic scars by their infiltrating character, causing local pain and inflammation reactions or even triggering long-term progression. Hypertrophic scars show thickening without surrounding reaction and can flatten spontaneously.

Keloids appear mostly in the upper body and in regions with high skin tension (e.g., above the sternum, at the earlobes, and in the joint regions). The cause of the disorder is still undetermined, but there is a genetic and race-specific predisposition.

Nonradiotherapeutic Treatment

Besides surgical excision of hyperplastic tissue with cosmetic disfigurement and functional disruptions, it is possible to use a conservative procedure with pressure and silicon bandages, steroids, plant extracts, or steroid injections for smaller lesions. In more than 50% of cases, there is local recurrence after excision of keloids alone.

Irradiation Options

Indications for irradiation are either demonstrated recurrences postoperatively or a high-recurrence risk (e.g., marginal resection borders, wider spread, unfavorable location). Fibroblasts, mesenchymal cells, and inflammatory cells are the target cells. Prophylactic irradiation immediately after excision of the recurrence is most effective. The local recurrence rate after postoperative irradiation is 20% to 25%.

Irradiation is initiated 24 hours after surgery at the latest. Orthovoltage (70 kV to 150 kV), electrons (<6 MeV), and brachytherapy with iridium-192 implants or with strontium-90 dermaplate are used.[145-148] The target volume is limited to the scar plus a 1-cm safety margin. The recommended dose is 12 Gy to 25 Gy, typically with 3-Gy to 4-Gy fractions.[109,147,149-152] Single-dose irradiation with 7.5 Gy to 10 Gy is effective.[153] Keloids in certain areas such as the chest wall tend to have a higher risk of recurrence, possibly because of tension placed on the tissue after surgical excision. Data from Ogawa et al suggest that doses of 20 Gy in 4 fractions should be considered for these areas. Recurrences on the chest wall decreased from 39% with 15 Gy in 3 fractions to 14.3% with 20 Gy.[149]

Other Diseases of Connective Tissue and Skin or Cutaneous Appendages

Acute and chronic inflammatory changes of the skin (furuncle, carbuncle), of the nailbed (paronychia), and those that affect the sweat glands of the armpit and groin (hidradenitis suppurativa) can lead to chronic and therapy-refractive inflammation that is painful and can seriously impair the function of those affected by the disease. If all local treatment measures are exhausted, if there is a confirmed resistance to antibiotics, and if further surgical measures are rejected, irradiation can be implemented with single doses of 0.5 Gy to 1 Gy daily up to a total dose of 10 Gy.

Gynecomastia

Radiotherapy for gynecomastia, a benign proliferation of breast tissue, is most commonly used in the setting of hormonal therapy for prostate cancer as either a prophylactic measure or as a treatment for painful gynecomastia in patients. The prevalence of gynecomastia in patients undergoing complete hormonal blockade is 15%, increasing to 75% with antiandrogen monotherapy.[154] Radiotherapy, when used prophylactically, appears to significantly decrease the incidence of gynecomastia but does not appear to relieve mastodynia.[155,156] Bilateral radiotherapy of the mammary region is performed with 8-MeV to 12-MeV electrons. Historically, four to five fractions of 3 Gy, up to a total dose of 12 Gy to 15 Gy, have been used to prevent pain or further growth of the mammary gland.[157] More recently, studies have evaluated the use of single-fraction radiation therapy.[154,158] Tyrrell et al published the results of a randomized, sham-controlled, double-blind, parallel-group multicenter trial involving 106 men with prostate cancer and no gynecomastia/or breast pain.[158] Patients received either a single dose of 10-Gy electron beam radiotherapy or sham radiotherapy. Bicalutamide was administered for 12 months from the day of radiotherapy. Physician-assessed gynecomastia was significantly lower with radiation therapy compared with sham radiotherapy (52% versus 85%; $p < 0.001$) with the incidence of ≥5 cm gynecomastia (measured by calipers being 11.5% with radiation therapy versus 50.0% for sham radiotherapy). More patients in the sham group experienced moderate to severe gynecomastia compared to the radiation therapy group (48% versus 21%). Radiation therapy also slowed the development of gynecomastia. There was no statistical difference in the incidence of breast pain with radiotherapy (83%) and sham radiotherapy (91%). There was a nonsignificant reduction in patients experiencing breast pain with prophylactic radiation therapy.

However, radiotherapy cannot reverse gynecomastia.

Plantar Warts

Plantar warts can be painful and functionally as well as cosmetically disturbing. In older studies, control rates of more than 80% were achieved with orthovoltage irradiation (10 Gy in one fraction, or 15 Gy in five fractions of 3 Gy). The warts fell off without consequences after several weeks.[159] Over the past several decades, the use of radiation for plantar warts has declined, so it is rarely used.

BENIGN DISORDERS OF BONY TISSUES

Aneurysmal Bone Cysts

Definition and Clinical Features

Aneurysmal bone cysts are benign vascular cystic lesions in the metaphasis of bones, which can cause functional impairment, pathologic fractures, and damage to neighboring structures. They can infiltrate the surrounding soft tissue. Despite their nonmalignant character, cysts can lead to bone destruction and thus lead to serious problems, which is why treatment is recommended once a cyst has been diagnosed, particularly if the vertebral column is affected.[160-162]

Surgical Treatment

Therapy is primarily surgical (resection or curettage with or without bone grafting) as long as this does not lead to a considerable functional impairment. Following curettage alone, cysts recur in up to 60% of patients, with lower rates reported in patients with allografting.[163,164] After complete resection, the risk of recurrence is minimal.[160-162]

Irradiation Options

Radiotherapy can be used in patients with cysts that cannot be treated by surgery or if curettage is difficult because of the size or location of cysts. Cyst progression or repeated recurrences are also indications for radiotherapy. Because more than 50% of patients are 10 years to 19 years old, radiation doses should be kept as low as possible, with strong consideration for the utilization of protons if at all possible.[95] Nobler et al[165] reported one recurrence in a total of 11 patients who were irradiated with total doses of 12 Gy to 31.6 Gy. A dose of 10 Gy to 30 Gy in 1.8-Gy to 2-Gy fractions over 1 week to 3 weeks seems to be adequate to control aneurysmal bone cysts reliably.[166-168]

Pigmented Villonodular Synovitis

Definition and Clinical Features

Pigmented villonodular synovitis (PVNS) is a rare proliferative disease affecting the synovia of joints and the tendon sheaths.[169] There are two types of disease: the strictly localized and the diffuse involvement of synovial membranes.[170] In most cases, the lesion is restricted to one joint, though can spread to muscles, tendons, and skin.

Surgical Measures

Surgical excision normally consists of synovectomy, which is rarely complete, particularly in large joints such as the knee.[171] Joint replacement has also been used.[172] Recurrence is seen in up to 45% of patients[173]; therefore, the addition of perioperative or postoperative irradiation is appropriate in patients with high-risk disease.[174,175]

Irradiation Options

O'Sullivan et al[170] reported on 14 patients who were irradiated with 30 Gy to 50 Gy in 15 to 35 fractions at Princess Margaret Hospital. The patients had different risk factors: microscopic residual tumor (7), macroscopic tumor (7), tumor more than 10 cm (5), tumor 5 cm to 10 cm (7), recurrences (8), and skin infiltration with ulceration (2). During an average observation period of 69 months (13 months to 250 months), 1 patient had persistent tumor 8 months after radiotherapy with 30 Gy in 15 fractions. All but 2 patients had tumor control. On the basis of the Princess Margaret Hospital results, radiation with a dose of 40 Gy in 20 fractions has been recommended.

Other institutions have evaluated their results with adjuvant irradiation after surgical resection and have achieved similar results. The German Cooperative Group on Radiotherapy in Benign Diseases (GCG-BD) conducted a pattern-of-care analysis of the results of postoperative RT for PVNS in 41 patients from 14 institutions.[174] The radiation dose ranged from 30 Gy to 50 Gy (median, 36 Gy; median single dose, 2 Gy). Local control was achieved in 95% of patients.

Vertebral Hemangiomas

Definition and Clinical Features

Vertebral hemangiomas are benign vascular lesions that can lead to a resorption of the affected bone.[176-178] Normally, only one vertebral body is affected. Hemangiomas are usually diagnosed by their radiologic picture of rarefaction with vertical, dense trabeculae in a honeycomb pattern. Most lesions require no therapy. In most cases, symptoms occur during the fourth or fifth decade of life.[179-182] Women are affected more frequently than men.[183] Spread of the tumor into the extradural space, hemorrhage, or rare compression fractures can lead to bone marrow compression.

Surgical Treatment

Surgical relief can become necessary, but it can be difficult owing to the danger of hemorrhage.[184-187] In most cases, only partial resection is possible, and postoperative irradiation can be considered.[176,177] Recently, less radical options such as vertebroplasty have been effectively used.[188-190]

Irradiation Options

The GCG-BD evaluated the results of radiation for vertebral hemangiomas in 84 patients from seven German institutions.[191] The RT dose ranged from 4.5 Gy to 45 Gy (median, 34 Gy; median single dose, 2 Gy). The overall response (complete plus partial response) was 90.5%, with long-term local control of 80.9%.

Rades et al[192] analyzed data from 339 patients with symptomatic vertebral hemangiomas from publications of the past 50 years. There were 222 patients who had to be excluded, either because surgery was part of the treatment (98 patients) or because the data were incomplete (124 patients). Of the remaining 117 patients, 54 patients received 36 Gy to 44 Gy (group A) and 62 patients 20 Gy to 34 Gy (group B). After a median observation period of 36 months (range, 6 months to 312 months), 39% of group A and 82% of group B patients had complete pain relief. The researchers recommend a total dose of 40 Gy.

Heterotopic Ossification

Definition and Clinical Features

Heterotopic ossification (HO) can appear following trauma or surgery of the hip (total hip replacement) in 10% to 80% of cases, and with varying degrees of severity. HO consists of real bone and is located in the periarticular soft tissues.[193] Ten percent develop extensive HO, causing pain and functional impairment. Patients with HO frequently complain of pain only a few days after surgery. Radiologic studies detect calcified structures with blurred contours 3 weeks to 6 weeks postoperatively.

The etiology of HO is only partially known. It is assumed that the pluripotent mesenchymal cells, which are present ubiquitously in periarticular soft tissue, develop into osteoblastic stem cells under certain conditions.[194]

For all patients with an indication for a hip replacement, there should be an individual estimation of the risk of HO before carrying out surgery. Patients who already have ipsilateral or contralateral HO carry the greatest risk. After a second surgery, 90% to 100% of those patients redevelop HO.[195-197]

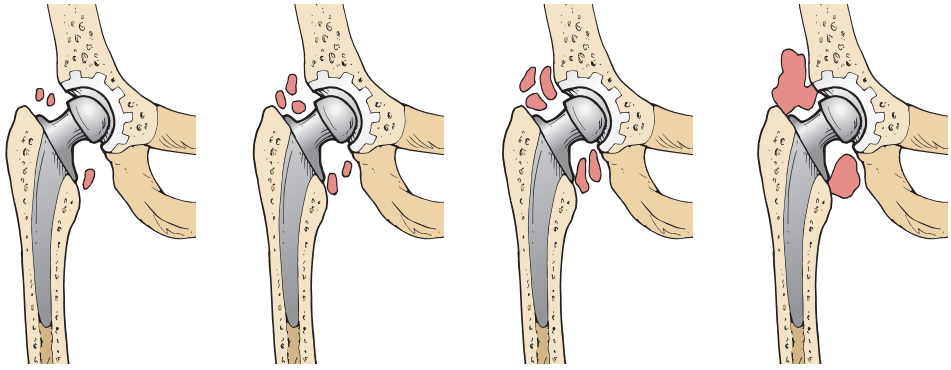

Figure 66-1 Staging of heterotrophic ossifications. **Grade I,** Bone islands within soft tissue around hip. **Grade II,** Exophytes of pelvis or proximal femur end with a minimum distance of 1 cm. **Grade III,** Exophytes of pelvis or proximal femur end with a distance of less than 1 cm. **Grade IV,** Bony ankylosis between proximal femur and pelvis.
From Brooker AF, Bowerman JW, Robinson RA, et al: Ectopic ossification following total hip replacement. J Bone Joint Surg 55A:1629–1632, 1973.

Patients with moderate or severe osteophytes at the femoral head and socket also have a high risk for HO, with an incidence of more than 50%.[198,199] After acetabular fractures, HO appears in 90% of hips. Fifty percent of those patients develop HO with clinical pathology.[200,201] Ankylosing spondylitis and the (rare) idiopathic hyperostosis of the skeleton are other influencing factors.

Diagnosis and Classification

Extensive ossifications lead to mobility impairment of the hip joint and cause pain. If HO is suspected, radiographs of the hip should be taken. Discrete changes in the radiograph can be seen at 2 weeks after surgery at the earliest. The literature provides a multitude of staging approaches. The most frequent one is the classification of HO according to Brooker et al[193] (Figure 66-1). To keep it simple, HO grades III and IV, according to Brooker et al, are designated as severe or clinically relevant, although there may not be any pain or mobility impairment.

Nonradiotherapeutic Treatment

Surgery

Clinically relevant (i.e., usually ankylosing) HO that has appeared after surgery should be removed to mobilize the joint and to remove pain. Complete removal of HOs is not essential if this is difficult and burdened with a higher risk. Most authors consider it necessary to wait for maturation of the forming ectopic bone and to reoperate only after 6 months to 1.5 years.

Medical Therapy

A number of medical options have been evaluated as prophylaxis against the development of HO. Although ethane hydroxy-diphosphates (EHDPs) have been used as prophylaxis, the treatment results are not convincing.[202-205] In contrast, some studies show that nonsteroidal anti-inflammatory drug (NSAID) use (indomethacin being the most commonly used), is effective in patients with a high risk of HO, with one meta-analysis noting that perioperative NSAID use resulted in a one half to two thirds reduction in the risk of HO development.[206-212] Selective cyclooxygenase-2 inhibitors have been tried, with promising results; though the concern for potential cardiovascular toxicity has tempered their use, particularly in patients with preexisting cardiovascular disease.[205]

Irradiation Options

Radiotherapy for prophylaxis of HO has been employed since the late 1970s and has proved to be effective. The initial dose was 20 Gy in 10 fractions.[213-218] Multiple dose schedules have been used. Various authors have pointed out that radiotherapy should be started no later than day 4 after surgery.

In three randomized studies, a dose of 10 Gy was compared with 20 Gy,[216] or with 17.5 Gy in five fractions,[219] and a single fraction of 8 Gy versus 10 Gy.[220] There was no significant difference between the effectiveness of high and low doses. Severe ossification occurred in 7% of patients with low and 5% of patients with high irradiation doses. No difference could be observed between fractionated and single-dose irradiation.

Preoperative radiation treatment with 7 Gy to 8 Gy in one fraction has been used successfully in patients with high-risk disease.[221] There appears to be no significant difference in clinically relevant HO compared with patients who are irradiated postoperatively.[222]

The relative roles of RT, indomethacin, and other NSAIDs for HO prophylaxis have been discussed by Pakos et al.[223-226] In a 2004 meta-analysis of seven randomized trials by Pakos et al,[223] irradiation was demonstrated to be more effective than NSAIDs for HO prophylaxis in preventing grade-3 to grade-4 ossification, but the absolute risk difference was only 1.2%. Pakos et al[225] subsequently reported a randomized trial in 96 patients comparing postoperative radiation (7 Gy in a single fraction) plus indomethacin (first 15 days postoperatively) to indomethacin alone (same 15 days) for HO prophylaxis. Patients receiving the combined treatment of radiation plus indomethacin had a lower rate of subsequent HO (4 versus 13 patients; $p < 0.05$). A systematic review of studies comparing indomethacin to radiation prophylaxis by Blokhuis and Frolke demonstrated an overall HO rate of 8.3% (5 of 60 patients) with radiation versus 8.9% (20 of 224 patients) with indomethacin. Although small, this difference was statistically significant.[227]

Irradiation is tolerated well. Neither fractionated irradiation nor high-single doses lead to an increased frequency of wound-healing disturbances, and there have been no documented cases of radiation-induced malignancies after prophylactic radiation.[228] Because radiation-induced tumors appear rarely and only after latencies of 10 years to 30 years, this risk is virtually irrelevant for most patients because the median age of patients is 65 years.

Irradiation Technique and Procedures

The irradiation field contains the typical localizations of periarticular ossifications, where the cranial field border is located approximately 3 cm above the acetabulum, and the irradiation field includes about two thirds of the implant shaft. Normally, the field size is 14 cm × 14 cm.

The effect of radiotherapy on the ingrowth of bone and fixation of noncemented implants was investigated in dogs[221] and rabbits.[229] After irradiation with 10 Gy (in five or four fractions), the fixation was significantly decreased within 2 weeks to 6 weeks.[229,230] Sumner et al[231] were also able to show that irradiation initially decreases the grade of fixation during the early postoperative phase, but after 4 weeks, the implants in irradiated and nonirradiated bone had the same strength.

In clinical application, the protection of the hip prosthesis with blocks as recommended by Jasty et al,[232] and the use of smaller blocks restricted to acetabular and femoral parts of the prosthesis can lead to ossifications underneath the block. Inadequate irradiation fields led to HO in 13 of 18 hips (76%) after irradiation with 7 Gy.[233] An open irradiation field covers the entire periarticular risk region more completely. Nonfixation of cementless implants was not observed after 6 Gy in one fraction,[234] after 7 Gy in one fraction,[235] or after 17.5 Gy in five fractions.[219,236,237] Because of the animal experimental and clinical studies, there appears to be no objection to irradiating hips with noncemented prostheses without a block. Strong consideration should be given to the utilization of testicular shielding in men interested in fertility as shielding can reduce testicular dose.[238]

Radiation for HO prophylaxis has also been used in patients with elbow trauma requiring surgical fixation. Although it does appear to be safe, a small prospective randomized study did note a significant difference in the nonunion rate between patients who received radiation and those who did not (38% versus 4%, $p = 0.007$).[239-241]

Overview

Larry E. Kun

CANCER IN CHILDREN

An estimated 15,780 newly diagnosed children (10,450 in birth to 14 year olds) and adolescents (5330 in 15- to 19-year olds) were diagnosed with cancer in the United States in 2014.[1] Cancer remains the most-common disease causing death in children; it is second to accidents in all causes of death between birth and 14 years of age. Approximately 1900 cancer deaths occur annually in children and adolescents.[1,2] After a plateau in pediatric cancer survival, the rate of decline in cancer mortality in this age group over the past decade has resumed the progress noted previously in the evolution of combined-modality therapy.[2]

For children ages 1 to 14 years old, the most-common cancers are leukemias and central nervous system (CNS) tumors, together accounting for more 50% of cancers in children. Acute lymphoblastic leukemia (ALL) alone accounts for 26% of cases in children; acute myeloid leukemia (AML), 5%. The other most frequent types are neuroblastoma, non-Hodgkin's lymphomas, and Wilms' tumor. For adolescents 15- to 19-years old, the most-common cancers include Hodgkin's lymphoma, thyroid cancer, CNS tumors, germ cell tumors (especially testicular); other relatively common types include non-Hodgkin's lymphomas, bone tumors, and melanoma (Table I-1).[1] Between 2001 and 2009 epidemiology studies showed a stable overall incidence of cancer in children and adolescents with a noteworthy increase in thyroid and renal carcinomas; a significant increase in overall cancer rates in African American children and adolescents; and a decrease in the incidence of melanoma and extracranial-, extragonadal-germ cell tumors.[3]

With contemporary therapies, long-term disease control—*in most tumor systems tantamount to cure*—is achieved in approximately 80% of children and adolescents; 5-year relative survival increased from 58% for children 1- to 14-years old diagnosed between 1975 and 1977 to 83% for those diagnosed from 2003 to 2009.[1] Survivors of childhood cancer often have physical and functional limitations that prevent them from achieving their full potential and compromise quality of life. Late mortality (30% among those surviving at least 5 years post-diagnosis) is increasingly related to secondary neoplasms and cardiac or pulmonary deaths as a result of treatment, rather than to recurrent cancer.[4,5] The cumulative incidence of second cancers at 30 years following initial diagnosis in childhood was 20.5% in the Childhood Cancer Survivors Study analysis.[6,7] Current strategies and clinical investigations seek to maintain or improve disease control, while reducing therapeutic interventions associated with long-term morbidity and mortality; identifying local-regional and overall disease control achievable with radiation therapy is often weighed against specific radiation-related late morbidities and secondary malignant neoplasms (SMN), in particular.[6-8]

Genetically defined cancer susceptibility or predisposition syndromes are known to account for approximately 10% of pediatric cancers; a recent study suggests that more than 25% of patient with pediatric cancer may have an inherited genetic cause based on a strong family history of cancer, cancer types strongly associated with hereditary cancer, history suggestive of a genetic diagnosis, or family history of another medical condition associated with genetic cancer.[9,10] Many cancer predisposition syndromes have implications not only for primary tumorigenesis but also for enhanced radiation sensitivity related to secondary carcinogenesis and, less frequently, somatic effects.[8,11] Retinoblastoma is the "classic" autosomal dominant hereditary cancer associated with the *RB1* tumor suppressor gene and a high rate of SMNs: a cumulative risk of 36% SMN by 50 years post-diagnosis, data showing a three-fold higher risk following orbital radiation therapy compared to those treated without irradiation.[12-14] Li-Fraumeni syndrome is caused by heterozygous germline mutations in the *TP53* tumor suppressor gene.[15] The syndrome is associated with an increased risk of cancer in children and young adults, especially bone and soft-tissue sarcomas, adrenocortical carcinomas, choroid plexus carcinomas, and frequent multiple primary tumors in a given patient.[16] Aside from the classic neurofibromas and optic nerve/optic tract gliomas associated with neurofibromatosis type 1 (NF1), malignant peripheral nerve sheath tumors, low-grade gliomas outside the visual pathways, and pheochromocytomas occur rather commonly in children and adolescents with NF1.[17] The number of inherited cancer predisposition syndromes related to pediatric oncology is impressive, as is the increasing recognition of late radiation effects in such cohorts.[8,11,17,18]

Approximately two thirds of children with cancer in North America are treated on clinical protocols, primarily studies coordinated by the Children's Oncology Group (COG), one of the pediatric disease-specific consortia (New Approaches to Neuroblastoma Therapy, NANTS; Pediatric Brain Tumor Consortium, PBTC; Therapeutic Advances in Childhood Leukemia and Lymphoma, TACL), and independent trials at the few major institutions able to mount clinical trials. Challenges remain in ensuring appropriate multimodality therapy for adolescents and young adults with pediatric types of cancer, as well as the enormous lack of resources for treating children with cancer in the developing world.[2,3,19,20]

Radiation therapy is a major component of coordinated, multimodality therapy for children. In the most common childhood cancer, ALL, the prior use of preventive cranial irradiation was initially associated with then remarkable cure of ALL, but more recently recognized primarily in

TABLE I-1 Common Neoplasms Occurring in Children and Adolescents

Disease Type	Childhood Cancers (%)	Role for Radiation Therapy
Acute Leukemias	**24**	
• Acute lymphoblastic (ALL)	*18*	1. Limited number may benefit from preventive cranial irradiation (high-risk T-cell, <5% ALL cases) 2. Therapeutic CNS-RT for CNS relapse 3. Total-body irradiation (TBI) or total lymphoid irradiation (TLI) in bone marrow transplantation (BMT) for recurrent/high-risk ALL
• Acute myeloblastic (AML)	*5*	1. TBI in BMT
Central Nervous System	**18**	
• Glial tumors	*12*	1. Local RT for many low-grade presentations, often at progression 2. Local RT for all high-grade presentations
• Ependymomas	*1*	1. Local RT for virtually all presentations
• Craniopharyngiomas	*1*	1. Local RT for incompletely resected or progressive/recurrent tumors
• Medulloblastomas and other embryonal CNS tumors	*3*	1. Systematic craniospinal irradiation + local boost for children ≥ 3 years 2. Local RT in children < 3 years (investigational)
• CNS germ cell tumors	*1*	1. Ventricular RT with local boost and chemotherapy vs. ventricular or craniospinal RT for germinomas 2. Ventricular or craniospinal RT plus chemotherapy for "malignant" germ cell tumor
Malignant Lymphomas	**15**	
• Hodgkin's lymphoma	*9*	1. Local (involved field) in combined modality therapy 2. TLI or TBI in transplantation settings for recurrent disease
• Malignant lymphoid tumors	*6*	1. Local RT for symptom control or recurrent disease
Neuroblastoma	**5**	1. Local regional RT for regionally advanced disease 2. Palliative RT (bone; soft tissue) 3. TBI in high-dose therapy/stem-cell rescue regimens (investigational)
Wilms' Tumor	**4**	1. Local/regional RT in advanced disease or unfavorable histology 2. Visceral RT in metastatic disease
Retinoblastoma	**3**	1. Ocular RT in consolidative or progressive/recurrent settings
Soft-Tissue Sarcomas	**6**	
• Rhabdomyosarcomas	*3*	1. Local/regional RT for most (intermediate/advanced or alveolar histology) presentation
• Other soft tissue	*3*	1. Local/regional RT based on histology, site, size, and age
Bone Sarcomas	**6**	
• Osteosarcoma	*3*	1. Limited postoperative use in central sites
• Ewing's sarcoma	*2*	1. local RT for "nondispensable" primary site 2. Local postoperative RT following marginal resection 3. Visceral and bone RT in metastatic disease
Hepatic Tumors	**1**	1. Limited postoperative or palliative RT
Germ Cell Tumors	**5**	1. Limited local/regional RT

unique association with late morbidities. Current therapeutic approaches largely obviate irradiation except for instances of CNS relapse or in the context of bone marrow transplantation for relapsed, refractory, or genetically virulent forms of ALL, where total body or total lymphoid irradiation is a part of the conditioning regimen.[21-25]

Data from St. Jude Children's Research Hospital show the proportion of newly diagnosed children who receive irradiation for all forms of cancer has increased over the past 18 years from approximately 40% to nearly 60%, even with the elimination of preventive cranial irradiation in institutional ALL protocols.[22] A retrospective study of NCI's SEER database reports significant reduction in radiation therapy, though, between 1973 and 2008 for children with ALL, non-Hodgkin's lymphoma, and retinoblastoma, with modest declines in brain cancer, bone cancer, Wilms' tumor, and neuroblastoma; whether SEER reporting is accurate reradiation utilization is questioned.[26] In major referral centers for pediatric cancer, pediatric cases have increased, particularly in CNS tumors (reported at 25% to 65% of cases undergoing radiation therapy) and for tumors requiring abdominal and pelvic and head and neck irradiation.[27]

Increased utilization of radiation therapy in regional and national referral centers reflects improvements in diagnostic imaging for tumor mapping and in dose conformality with intensity-modulated radiation therapy (IMRT) photon irradiation and the availability of proton beam radiation therapy (PBRT; evolving from standard double scatter technology toward intensity modulated proton therapy with spot beam technology)—all enabling significant reduction in radiation exposure to critical normal structures. Interest in PBRT has been particularly noted in CNS tumors and sarcomas where

dose reduction in neuroanatomic regions related to neurocognitive development and in anatomic sites related to somatic and visceral growth and function has driven centralized referral patterns based on technology.[28-33] Such technologies have favored judicious radiation intervention even in the more vulnerable younger children where rebalancing efficacy and tolerance are critically important, as in CNS atypical teratoid/rhabdoid tumors (AT/RT) and genitourinary rhabdomyosarcomas in girls.[30,34,35] The defensive posture of the radiation oncologist has been replaced by the knowledge base required in clinical and biologic understanding of pediatric cancers, common and evolving drug therapies, and the application of sophisticated radiation technology.

Key radiation parameters are critically important in pediatric therapy, where the relative radiation sensitivities of pediatric cancers compete with the added vulnerabilities of the growing, developing child or adolescent. There are increasing studies in most pediatric CNS tumors, sarcomas, and other common solid tumors showing disease control with diminishing target volumes, essentially shrinking the clinical target volume (CTV) expansion of the tumor volume to take further advantage of three-dimensional treatment planning and more conformal radiation delivery.[35-39] As target volumes are progressively tighter, quality control becomes more critical both at institutional and cooperative group levels. Target volumes in unique tumor settings may actually need to be larger, as with alveolar rhabdomyosarcoma and the potential value of nodal irradiation.[40,41] As well, there have been progressively lower radiation doses shown to be effective in rhabdomyosarcoma, Ewing sarcoma, medulloblastoma, CNS germ cell tumors, and other settings where either (1) combinations of pre- or postirradiation chemotherapy provide an additive effect or (2) postchemotherapy surgery provides microscopic disease only.[35,38,42,43]

Molecularly targeted agents have increasingly been investigated in combination with radiation therapy. Several classes of drugs have shown radiosensitizing potential in preclinical studies and have completed Phase I and Phase II studies in pediatrics (e.g., platelet derived growth factor [PDGF] inhibitors, farnesyl transferase inhibitors [FTI], histone deacetylase inhibitors [HDAC], and Poly[ADP-ribose] polymerase [PARP] inhibitors). The ultimate utility of molecularly targeted agents and the interactions with irradiation will be apparent in tumor systems where specific molecular targets and available pharmacotherapeutics allow prospective clinical trials.

Radiation-related late effects are often more pronounced in children than in adults, especially in somatic changes (growth and development of musculoskeletal tissues) and functional effects (neurocognitive, auditory, endocrine).[6,21,28,32,39,44] Infants and young children are particularly vulnerable to the effects of both irradiation and chemotherapy agents (e.g., alkylating agents, cis-platinum, Adriamycin).[44-46] Alterations in bone growth, muscle development, and intermediate-size arterial caliber tend to be more prevalent in younger patients than in adolescents or adults.[47,48] Threshold radiation levels are recognized for epiphyseal growth, but even low dose exposures can be correlated with changes in height and bone development (both contour and integrity).[48] It is not clear whether visceral tolerances are significantly lower in the younger age group, although the frequent use of combined chemoradiation therapy introduces added concerns regarding radiation tolerance for the heart and lungs, the liver and the kidneys.[49,50] Intermediate-size vessels, particularly at the circle of Willis, show reduced caliber and flow after irradiation in a high proportion of children younger than 1 to 3 years of age, whereas major extracranial vascular effects are otherwise most noteworthy in coronary vessels.[47,51] A high proportion of children evidence hypothyroidism after even low-dose irradiation to the neck; manifestations of reduced testosterone and estrogen levels following low-dose pelvic irradiation are noted after irradiation in childhood or adolescence.[52-54]

Neurocognitive effects of brain irradiation have been well described and correlated with radiation dose, volume, and patient age. Concerns regarding limited life potential attendant to diminished learning and IQ have driven protocol-based attempts to limit radiation use as well as introducing volume and dose constraints in treating children with CNS tumors over the past three decades.[5,21,28,32,39,46,55] Experience with narrow targets to rather high subtotal posterior fossa doses have shown preservation of intellectual function in children as young as 12 months of age in ependymomas.[39,55] Prospective measurements of learning disabilities are key to further assessing the impact of contemporary radiation therapy in localized brain tumors. Clinical trials suggest specific interventions (i.e., pharmacologic and cognitive rehabilitation) may ameliorate some of the learning problems associated with cerebral irradiation.[56]

In pediatric radiation therapy, one must always consider the risk of secondary carcinogenesis, an overall risk that is at least 5% to 10% over three decades of follow-up. The long survival intervals of successfully treated children and the added risks of SMN in the growing or developing tissues (e.g., the pubescent and adolescent breast) and in several of the cancer predisposition syndromes require exquisite balance in indications for radiation therapy and in selecting techniques that might limit carcinogenesis.[4-7,12-14]

The following chapters outline the biology, clinical features, and outcome of the more common pediatric cancers, summarizing the current and evolving roles of radiation therapy in the current approach to childhood cancer and consider the available data and ongoing trials related to radiation modalities and parameters of volume, dose, and fractionation.

CHAPTER

67 Central Nervous System Tumors in Children

Shannon M. MacDonald

INCIDENCE AND OVERALL SURVIVAL

The overall incidence of childhood brain tumors is 5.05 per 100,000 person-years for children birth to 19 years and 4.92 per 100,000 person-years for children less than 15 years of age. Brain tumors are the second-most common childhood malignancy and the most-common primary solid tumor. Pediatric brain tumors are a diverse group of tumors and outcomes are dependent on histologic subtype and treatment. Approximately 75% of children diagnosed with pediatric brain will experience long-term disease-free survival (DFS).

ETIOLOGY

At present, the etiology of most pediatric brain tumors is unknown. Genetic syndromes that may predispose children to certain subtypes of brain tumors include neurofibromatosis, Li-Fraumeni, Gorlin's syndrome, Turcot's syndrome, and ataxia-telangiectasia.

HISTOLOGIC SUBTYPES

- Embryonal tumors
  - Medulloblastoma
  - Supratentorial primitive neuroectodermal tumor (includes pineoblastoma)
  - Atypical teratoid rhabdoid tumor
  - Embryonal tumor with abundant neuropil and true rosettes
- Astrocytic tumors
  - Pilocytic astrocytomas (World Health Organization [WHO] grade 1)
  - Astrocytoma (WHO grade 2)
  - Anaplastic astrocytoma (WHO grade 3)
  - Glioblastoma multiforme (WHO grade 4)
- Ependymoma
  - Myxopapillary (WHO grade 1, usually of spine)
  - Classic/differentiated (WHO grade 2)
  - Anaplastic (WHO grade 3)
- Craniopharyngioma
- Germ cell tumors
  - Pure germinoma
  - Nongerminomatous germ cell tumors
    - Embryonal
    - Yolk-sac
    - Choriocarcinoma
    - Immature teratoma
    - Mixed germ cell tumors (NGGCT components ± germinoma)
  - Mature teratoma
- Choroid plexus tumors

EVALUATION

- History and physical examination
- Magnetic resonance imaging (MRI) of the brain and spine
- Lumbar cerebrospinal fluid (CSF) for patients with embryonal tumors, germ cell tumors and ependymomas α-fetoprotein and β-human chorionic gonadotropin tumor markers in both serum and CSF for germ cell tumors

INTRODUCTION

Childhood central nervous system (CNS) tumors are second in frequency only to leukemia and represent the most-common solid tumor in children.[1] At the time of this writing, the incidence of pediatric brain tumors is 5.05 per 100,000 person-years and only 7% of all brain tumors occur in children. Despite the relative infrequency of this disease, patients with pediatric brain tumor often require radiation therapy and they comprise a large proportion of the overall population of children seen by a radiation oncologist.

The diagnosis of a brain tumor in a child is devastating for both the child and their family. Although many brain tumors are curable, it is always at a cost, and caregivers are often forced to make difficult decisions to determine a treatment course with the best chance of survival, balanced with a side effect profile that will provide an acceptable quality of life for the patient. Technological advances in radiation therapy and surgery, along with biological advances in medicine, have led to marked improvements in the therapeutic ratio for pediatric brain tumors. Progress is also largely attributable to the cooperative nature of pediatric oncology and, critically, the willingness of parents to have their children receive their cancer treatment as part of a clinical trial. Despite major improvements over the past few decades, there is room for further development and advancement in care. Cure is not within reach for all childhood brain tumors, and, for these tumors, improved cure rate remains the focus of research. For highly curable brain tumors, maintaining cure rates and decreasing side effects is the goal of many clinical trials. Current research seeks to better characterize the biology of this group of diseases and to provide and improve curative treatment while preserving function.

MODERN PEDIATRIC RADIATION DELIVERY

Radiation plays a central role in the cure of many brain tumors; however, there is a cost to this curative treatment for most patients. Because of fear of sometimes-substantial late complications, attempts have been made to avoid radiation for some young patients with brain tumors, often with inferior outcomes. Technical advances in both diagnostic and therapeutic

radiology have allowed for major changes in the way we deliver radiation. Targets are now well defined, smaller and allow for a great deal of sparing of the normal healthy brain. Modern treatment allows for even young children to receive localized treatment with reasonable expectations of enjoying healthy and fulfilling lives. Although delay or omission of radiation is reasonable to consider for selected patients, physicians should also consider the consequence of tumor progression, additional chemotherapeutic agents and surgeries, and crucially, the possibility that radiation targets may be larger at the time of eventual treatment if radiation is delayed.

Three-Dimensional Treatment Planning

Most of the major advances in radiation oncology over the past few decades were made possible by developments in diagnostic radiology. Before the advent of computed tomography (CT) and magnetic resonance imaging (MRI), radiation planning was performed using x-rays, referred to as two-dimensional planning. Visualization of the target and adjacent uninvolved structures in three dimensions was not possible. Therefore, treatment generally consisted of generous, simple fields that delivered high dose to areas uninvolved by tumor, and in some cases tumor volumes may not have been adequately covered. Modern planning uses CT and MRI and most departments obtain a CT scan in the treatment position and fuse diagnostic MRI sequences for treatment planning. The most useful MRI sequences for an individual child's brain tumor are tumor type and patient dependent and best determined after careful review with a pediatric neuroradiologist. Because tumor extent is better visualized, margins for error around this volume can be made smaller, thereby allowing for full coverage of the tumor with improved avoidance of the surrounding healthy tissues.

IMRT

With the development of more sophisticated treatment planning software, the ability to simulate plan modification and complex photon beam arrangements became possible. Intensity-modulated radiation therapy (IMRT) refers to highly complex photon radiation planning that delivers small beamlets of photon radiation of various intensity from multiple angles to best shape high dose to the target volume while avoiding high and moderate dose radiation to normal healthy structures. For IMRT planning, the physician defines all structures and inputs the desired target dose and dose and volume limitations for normal structures and prioritizes these goals. The software program then runs multiple iterations of the treatment plan until it finds the best possible plan. Figure 67-1 demonstrates IMRT delivery for a child with an ependymoma. IMRT allows for the most conformal photon plan with high-dose isodose lines closely surrounding the target volume. Although IMRT plans decrease high and moderate dose to nearby structures, these plans typically result in the delivery of low dose radiation to a larger volume of tissue outside of the target. While this may be a little consequence in terms of function, second malignancy is a risk for even low dose radiation.

SRS/SRT

The term *stereotactic radiation*, in part borrowed from neurosurgical localization systems, refers to high-precision radiation therapy using a three-dimensional coordinate system. Stereotactic radiosurgery (SRS) refers to the delivery of a single treatment, whereas stereotactic radiation therapy (SRT) refers to fractionated stereotactic treatment. SRS is accomplished by delivering multiple small beams of radiation to deliver the prescription dose to the target, but a much lower dose to the surrounding tissues. Precision is of paramount importance for SRS and typically rigid frames and fiducial markers are used. Many delivery systems exist for photon based stereotactic treatments and protons can also be used. The rigid frame and immobilization required may be too difficult for many children to tolerate without sedation.

Proton Radiation

Proton radiation has become a more widely used radiation modality for pediatrics over the last decade. Proton radiation is a form of particle radiation that allows for complete sparing of tissue beyond the target volume for a given beam as well as often less dose proximal to the target compared to photon radiation.[2] Proton radiation can be delivered using three-dimensional conformal proton radiation (3DCPT), also referred to as *double-scattered proton technique*. For this treatment, individual proton beams of the required energies are stacked to create a modulated beam or Spread Out Bragg Peak (SOBP). This beam is passed through a brass aperture to shape the beam to the outline of the tumor and a Lucite compensator to allow the beam to conform to the distal edge of the tumor. Protons can also be delivered using a scanning technique.[3] For this treatment individual proton beams are scanned across the tumor in the required location and depth. Scanning can improve conformity and this treatment creates minimal scatter radiation (Figure 67-2). Up until 2006, only 3 proton centers existed in the United States. At the time of this writing, 14 centers exist and many others are in either construction or planning phases despite the high-capital costs involved with

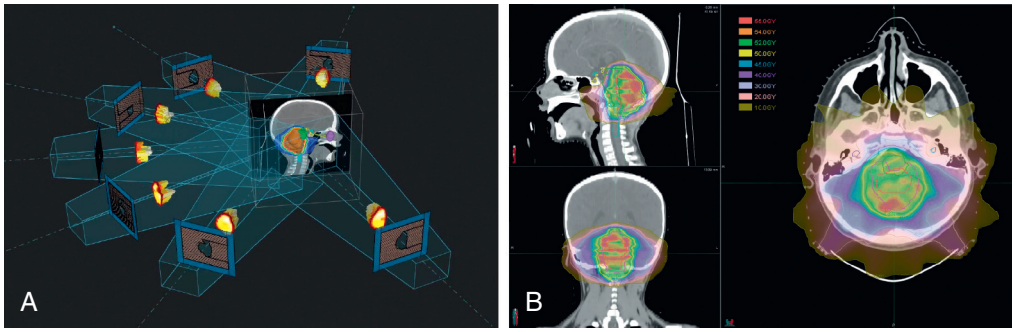

Figure 67-1 Intensity-modulated radiation therapy (IMRT) delivery and plan for a child with an infratentorial ependymoma. IMRT involves the use of highly sophisticated treatment planning software to run multiple iterations of plans involving multiple fields with varied intensity in segments of each field resulting **(A)** in a radiation treatment plan that is highly conformal to the target volume and spares critical nearby structures from high-dose radiation **(B)**.

building a center.[4] Pediatric brain tumors are considered one of the best indications for this type of treatment given the importance of sparing developing tissue from radiation. Although clinical experience is still limited, many publications have supported disease outcomes that are comparable to photons and early indications that morbidity may be less.[5-7] It is important to continue to collect data to confirm both efficacy and improved outcomes to justify increased costs. Although the upfront costs of protons are indeed greater than those of photons, modeling studies have predicted that protons will be cost-effective for selected pediatric brain tumors.[8,9]

Young patients with pediatric brain tumors should receive treatment in facilities with capabilities for anesthesia and preferably with child life specialists on staff. Immobilization and reproducibility are critical to any radiation delivery and can be a challenge for young children. Sedation is necessary for young children who are unable to cooperate, particularly for long treatments. We recommend consideration of anesthesia for children under the age of 7, but even older children may require sedation, especially for treatments longer than 20 or 30 minutes. If it is unclear if sedation is necessary, we recommend a trial run in the treatment room to better assess the child's ability to remain still. Image-guided radiation therapy with daily KV quality images or cone-beam CT is generally used to allow for a small set up margin and to improve accuracy.

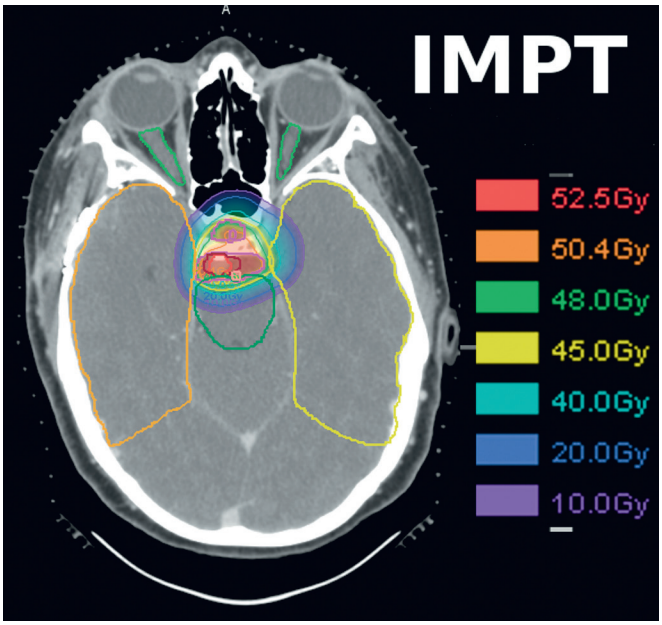

Figure 67-2 Proton beam scanning (PBS) for craniopharyngioma compared to other modalities. PBS is a way of delivering proton therapy with individual Bragg peaks rather than double scattered spread out Bragg peak (SOBP). This leads to improved normal tissue sparing for some tumors and decreases scatter radiation.

EMBRYONAL TUMORS

Embryonal tumors are the most common brain tumors in children under the age of 5, and second in frequency overall, to only low-grade gliomas.[1] Subtypes of embryonal tumors include medulloblastoma, supratentorial primitive neuroectodermal tumors (SPNET), atypical teratoid rhabdoid tumors (ATRT), and the relatively recently described embryonal tumor with abundant neuropil and true rosettes (ETANTR). These tumors are densely cellular, highly malignant small round blue cell tumors that have a propensity to spread through the CSF. Although grouped under embryonal tumors, these subgroups show distinct gene expression profiles, carry different prognoses, and have different patterns of relapse.[10] Although treatment regimens differ, intensive treatment with surgery, radiation, and chemotherapy is indicated for all embryonal tumor subtypes.

MEDULLOBLASTOMA

Medulloblastoma is the most common embryonal tumor that is, by definition, located in the cerebellum. Children are generally young at diagnosis, with a median age at onset of 5 years to 6 years.[11] Approximately 540 cases are diagnosed per year. Children generally present with headache, ataxia, nausea, vomiting, or cranial nerve deficit. Work-up includes a MRI of the brain that characteristically shows a mass in the cerebellum filling the fourth ventricle and obstructing the flow of CSF (Figure 67-3). The differential diagnosis for a tumor in this location in a child includes medulloblastoma, ependymoma,

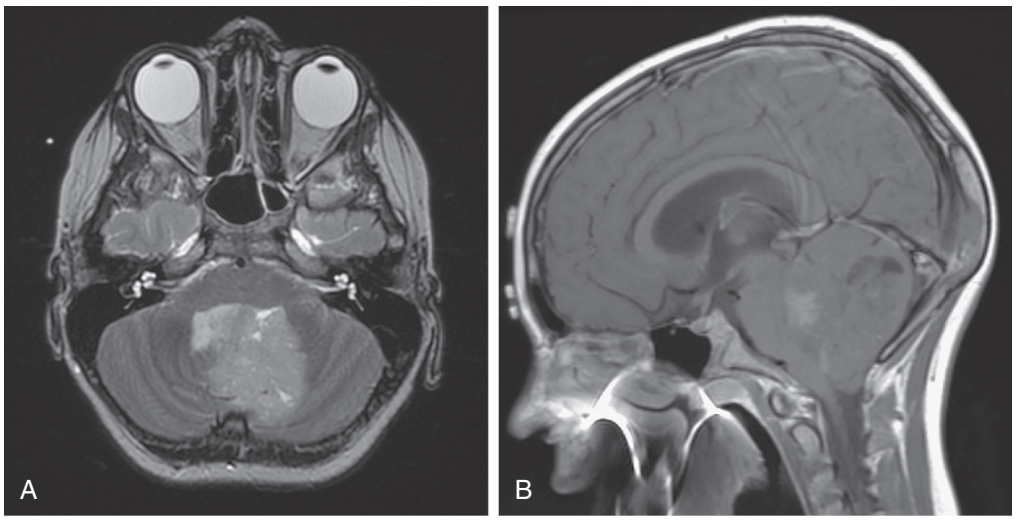

Figure 67-3 Medulloblastoma. Axial T2 **(A)** and sagittal T1 postcontrast **(B)** images showing a partially enhancing T2 bright medulloblastoma centered in the IVth ventricle in the posterior fossa and causing hydrocephalus.

low-grade glioma, and ATRT. Maximal safe resection is recommended for relief of symptoms and as a component of definitive treatment. Additional work-up includes MRI of the spine and a lumbar puncture to obtain CSF. MRI of the spine may be performed before surgery or 10 days to 14 days after surgery, but lumbar puncture should be performed 10 days to 14 days after surgery. Attempting to perform a lumbar puncture before surgery may result in herniation. Medulloblastoma has three main histopathologic subtypes: desmoplastic, classic, and anaplastic/large cell anaplastic. Desmoplastic tumors carry a more favorable prognosis, while frankly anaplastic tumors carry a poorer prognosis.[12,13] Regardless of pathological distinction; all medulloblastomas are considered WHO Grade IV.

At present, a risk-stratification system based on clinical factors divides patients into two risk groups, "high-risk" and "standard-risk," with standard-risk defined as children older than the age of 3 with ≤1.5 cm^2 of residual disease following surgery and no metastatic disease (grossly or in CSF) and all others considered high risk. Approximately 30% of patients will have metastatic disease at diagnosis.[8,9] The Chang staging system is often referred to for description of the extent of metastatic disease; M0, no evidence of metastasis; M1, cells in CSF; M2, seeding in intracranial subarachnoid or ventricles; M3, gross seeding of spine; and M4, extraneural metastasis.[14] The prognosis is worse for patients with gross metastatic disease, but the impact of microscopic disease in the CSF alone less clear.[8,15] In recent years, diffuse anaplastic/large cell histologies have been found to portend a poor prognosis.[13,16] The Children's Oncology Group determined that patients with otherwise standard risk disease but anaplastic histology should be treated on the high-risk COG study ACNS 0332 rather than the low-risk study ACNS0331.

Off-study, we generally make treatment decisions in the setting of a multidisciplinary conference, weighing the risks and benefits for this group of patients considering age and other clinical factors. The DFS for a patient with standard-risk disease treated with chemotherapy and radiation exceeds 80%.[13] Cure rates for high-risk disease are less favorable, but fall between 50% and 70%.[15,17] Children with standard-risk disease with anaplastic histology have a DFS in between these two groups of approximately 73%.[13]

The risk stratification system currently used evolved based on data from the pre-MRI era; it is now quite dated and may not adequately determine risk for all patients. It is likely that a new classification system for medulloblastoma will evolve in the relatively near future. A tremendous amount of convincing data for the use of gene expression profiles to determine prognosis for patients with medulloblastoma has been published over the past decade.[18-21] These data reveal that histologically similar tumors can be grouped into four distinct molecular subgroups with vastly different prognoses.[18] These four core groups, of decreasing disease outcomes, include WNT (wingless), SHH (sonic hedgehog), Group 3, and Group 4.[18] It is almost certain that in the future molecular stratification will play a role in the determination of treatment for all children with this disease. However, at present, it is recommended that this information be used for risk stratification only in the setting of a clinical trial. Institutional trials have already begun to use this information and the next Children's Oncology Group Trial will use molecular profiles in some way. In addition to risk stratification, newly discovered molecular pathways hold promise for more efficacious and less toxic targeted therapies.

Current standard treatment for medulloblastoma consists of treatment to the entire craniospinal axis to a dose of 23.4 Gy, usually with concurrent vincristine, followed by additional radiation to the posterior fossa or tumor bed, plus a margin (involved field) to bring the total dose to this region to 54 Gy.[22] Radiation should commence approximately 31 days after surgery and additional chemotherapy is delivered following radiation. Although involved-field radiation boost as opposed to a boost to the whole posterior fossa is conventional at many institutions, it is not yet considered to be standard of care as results from the COG study, ACNS0331, are not yet available. Several nonrandomized series suggest excellent outcomes without increased rates of failure in the posterior fossa.[23,24] It is important to note that the whole posterior fossa received 36 Gy for most patients studied.

In addition to randomizing patients to involved-field radiation versus whole posterior fossa, ACNS0331 also asked the question of reduced-dose craniospinal irradiation (CSI) (18 Gy) for children 8 years of age or younger with standard-risk medulloblastoma. The use of 18 Gy was based on favorable results from a small series combined with the desire to decrease radiation side effects for these young children.[25] At present, 23.4 Gy is standard for children of all ages, but results from ACNS0331, when available, may show that it is safe to deliver a lower dose for young children. For children with high-risk medulloblastoma, treatment consists of radiation with a CSI dose of 36 Gy followed a boost to 54 Gy to the posterior fossa with chemotherapy. Gross metastatic lesions should receive 45 Gy. The current COG protocol, ACNS0332, is evaluating the addition of daily carboplatin concurrent with radiation and posttreatment isotretinoin.

Management for children under the age of three is a bit more heterogeneous and generally consists of maximal safe resection followed by chemotherapy followed by delayed and usually localized radiation therapy. The radiation volume is often limited to the involved-field for children with localized disease or sometimes even omitted.[26,27] Outcomes are inferior, perhaps to a large extent because of the omission, deferral, or alteration of radiation therapy. The Head Start Trials have reported good outcomes for regimens including intensive chemotherapy and high-dose chemotherapy followed by stem cell rescue (HDCSCR).[26] The current COG study, ACNS0334, delivers intensive chemotherapy including high-dose chemotherapy and stem-cell rescue with or without methotrexate. Radiation is optional on this trial, and when used it calls for delivery of radiation to the involved field to a dose of 50.4 Gy to 54 Gy. With highly conformal treatments such as IMRT or proton radiation, localized treatment provides benefit to the area at highest risk of recurrence without the substantial late effects that delivery of radiation to the entire brain and spine would have for these young children. Children with desmoplastic nodular histology or extensive nodularity have a favorable prognosis and the current COG study ACNS1121 studies the use of intensive chemotherapy without radiation.[28]

The craniospinal volume includes the entire brain and spine. Care should be taken to ensure coverage of the cribriform plate and to give a margin of approximately one vertebral body below the thecal sac, which is typically located near S2 (Figure 67-4). Because it is critical to adequately cover these areas, it is best to confirm the location of these regions with a neuroradiologist. Most CSI treatments are delivered with the patient in the prone position, and most techniques involve field matching with fields matched anterior to the spinal cord, which creates a small area of underdosing in the cord but avoids any areas of overlap. Most centers place the match-line anterior to the cord to prevent hot spots in the cord (demonstrated in Figure 67-5). Care should be taken to minimize hot and cold spots and to "feather" fields to decrease uncertainty. The use of IMRT and scanning proton techniques allow for treatment without matching of fields; because of the lack of exit dose protons avoid exit dose to the thyroid, heart, lungs, abdominal organs and ovaries (Figure 67-6).

Figure 67-4 Care should be taken to carefully identify and ensure adequate coverage of the cribriform plate **(A)** and the thecal sac **(B)**.

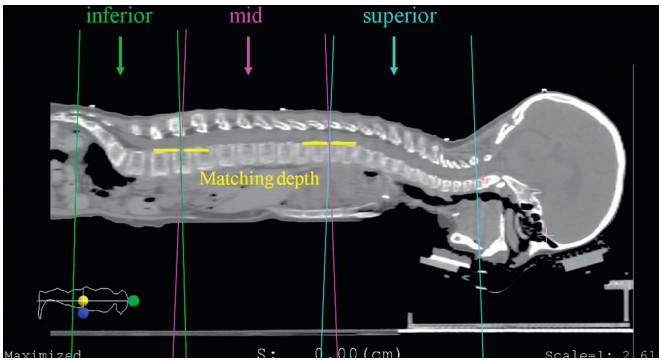

Figure 67-5 Prone CSI field set up demonstrating matching of spinal fields anterior to cord.

The posterior fossa volume is considered as CTV. This volume extends from the tentorium superiorly to C1 inferiorly. Laterally the posterior fossa volume includes the entire cerebellum and extends to the bony occiput and anteriorly this volume includes the brainstem and lower midbrain. The involved field volume GTV should include the tumor bed (anything in contact with the initial tumor before surgery) and any residual gross disease. Care should be taken to account for anatomical shifts following surgery. An expansion of 1 cm to 1.5 cm is typically used to form the CTV for the involved field boost (Figure 67-7).

SUPRATENTORIAL PRIMITIVE NEUROECTODERMAL TUMORS

Supratentorial PNETs are less common than medulloblastomas and account for 2% to 3% of primary brain tumors.[29] The metastatic potential of SPNET is similar to medulloblastoma, but the prognosis as a whole for patients with this disease is worse.[30,31] All patients with SPNETs are therefore considered to have "high-risk" disease and they are eligible for the same COG protocol that enrolls high-risk medulloblastoma patients (ACNS0332). Patients with pineoblastoma older than the age of 3 and patients without metastatic disease, however, seem to have a better prognosis.[30,32-34] Studies of patterns of relapse indicate a higher proportion of local failures for SPNET (other than pineoblastoma) when compared to medulloblastoma. Young children with SPNET/pineoblastoma treated without radiation therapy have dismal outcomes and focal radiation should be strongly considered for children under the age of three.[33,35,36]

The standard CSI dose for this disease is 36 Gy. Although local recurrence is most common for localized disease, no studies have explored lower CSI doses because of the less favorable outcome for this disease. A dose of 54 Gy is delivered to the tumor bed plus a margin of approximately 1 cm within anatomical boundaries. For children under the age of 3, involved-field radiation to 50.4 Gy to 54 Gy is generally recommended.

ATYPICAL TERATOID RHABDOID TUMOR

AT/RT rare malignancies that typically affect young children.[37] Although AT/RT accounts for 1% to 2% of childhood tumors in the brain, it may comprise more than 20% of CNS tumors in infants. These tumors have a mutation that results in a deficiency of INI-1 protein.[37] It is now routine to test all pediatric embryonal CNS tumors for loss of INI-1 to establish the diagnosis of AT/RT.[38,39] Before the discovery of this mutation, many patients with AT/RT were misdiagnosed as having medulloblastoma or SPNET. The prognosis for AT/RT is inferior to that for medulloblastoma and SPNET; however, recent studies with more aggressive chemotherapy have shown improved 2-year progression-free survival (PFS) and OS rates of 53% and 70%, respectively.[40] For patients with localized disease, cure is attainable with aggressive multimodality therapy. Disseminated disease still carries a dismal prognosis with a small chance of cure.

The treatment of AT/RT includes maximal resection of primary disease, intense induction chemotherapy including intrathecal chemotherapy, high-dose chemotherapy followed by stem-cell rescue (HDCSCR) and radiation therapy. For children under the age of 3, localized radiation is recommended. For older children, CSI followed by additional involved field radiation is favored because of risk of dissemination and poor prognosis, but some protocols use involved field RT even for older patients. Early timing of radiation also seems important. The tumor bed and any gross residual disease with a margin of approximately 1 cm should receive a dose of 50.4 Gy to

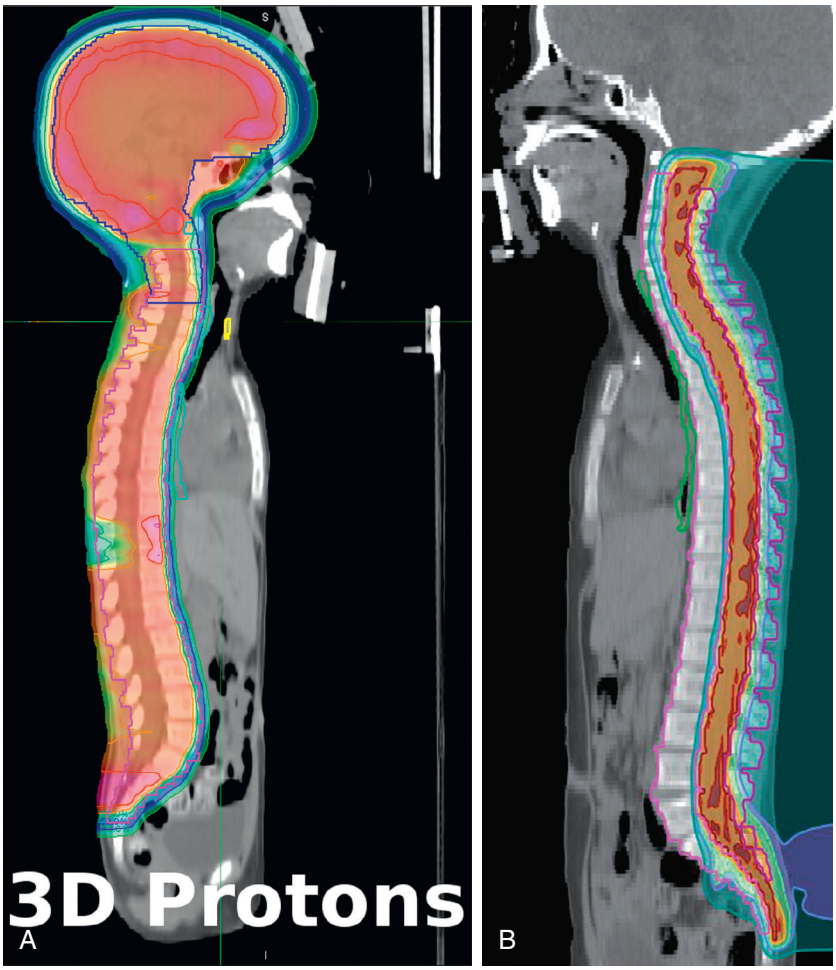

Figure 67-6 Proton radiation for CSI delivering demonstrating the ability to avoid organs anterior to the vertebral bodies. For growing children, the entire vertebral body is included in the target volume to avoid asymmetric growth from partial vertebral body treatment. **A** shows a three-dimensional conformal plan and **B** demonstrates a proton beam scanning technique that avoids hot/cold spots that may be introduced by field-matching.

54 Gy. Although there are limited data on effective CSI dose, given the more aggressive nature of this disease, 36 Gy is most standard for CSI.

ETANTR

Embryonal tumor with abundant neuropil and true rosettes (ETANTR) is a rare and relatively recently described subtype of embryonal tumor with approximately 50 reported cases.[41,42] This tumor usually occurs in young children younger than the age of 4 and is more common in females. Most are supratentorial, but they can occur in the infratentorial region. MRI appearance is similar to that of other embryonal tumors and dissemination is also through the CSF. Management is similar to the management of high-risk medulloblastoma and SPNET. Prognosis is poor and median survival short. Gessi et al reported 75% of patients dead of disease at 9 months; however, long-term survival is possible with one report describing one patient with long-term DFS of 7 years.[43,44]

EPENDYMOMA

Intracranial ependymomas are brain tumors that originate from ependymal cells lining the ventricles or from ependymal cell rests located in the brain parenchyma. They represent 5% to 8% of pediatric brain tumors and approximately 200 to 250 cases are diagnosed per year. Two thirds of these tumors occur in the fourth ventricle; the remainder of ependymomas occurs in the supratentorial compartments of the brain. These children are usually young because ependymoma is most commonly diagnosed in children under the age of four.

Presentation is dependent on location. Children with infratentorial tumors most often present with signs of hydrocephalus and/or cranial nerve deficits (similar to medulloblastoma). Children with supratentorial tumors can present with a variety of symptoms dependent on tumor location. Diagnostic workup includes MRI of the brain and spine and CSF sampling. Localized disease is most common, but metastatic disease can be seen elsewhere in the brain or spine. The diagnosis of metastatic disease based on CSF alone for ependymoma is extremely rare.[45]

Histopathology of ependymomas will reveal classic/differentiated (WHO grade II) or anaplastic (WHO grade III) tumors. Most studies, but not all, indicate that anaplastic tumors have inferior outcomes. The lack of consistency for this prognostic factor may be because of difficulty in assigning tumor grade or the small size of most studies.

The initial treatment is complete surgical removal. Removal of the entire tumor is critical for a favorable outcome and this has been demonstrated clearly in multiple series.[5,46] The 3-year to 5-year PFS rates are on the order of 51% to 88% for gross total resection and from 0% to 54% for subtotal resection.[5,47,48]

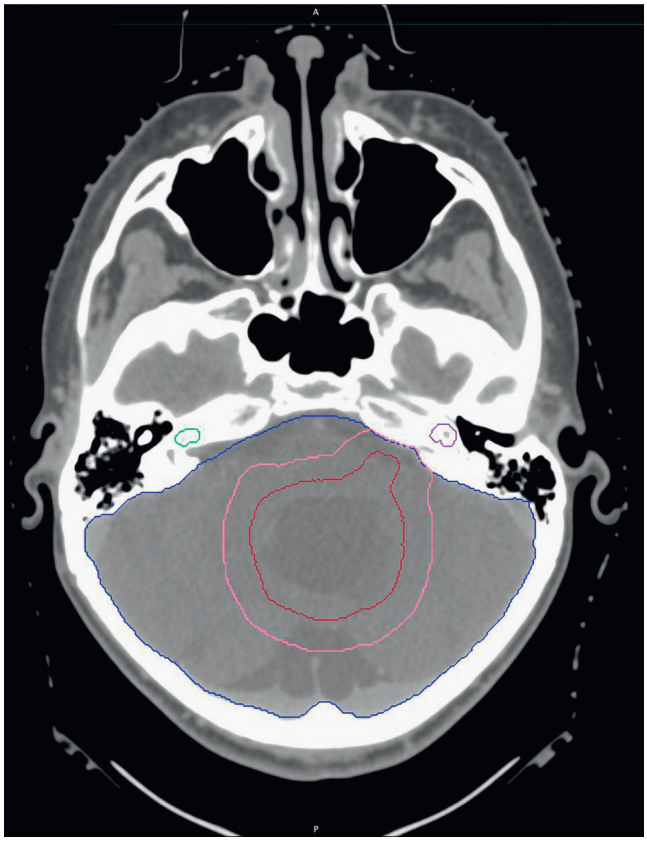

Figure 67-7 Involved field boost *(magenta)* compared to whole posterior fossa boost *(dark blue)*. The involved-field boost decreases the amount of cerebellum and usually brainstem in the treatment field. For many tumors, the distance from the cochlea, temporal lobes, and neuroendocrine structures is greater for the involved-field boost allowing for decreased high dose to these critical structures.

If complete removal is achieved, radiation to the tumor bed plus a margin is recommended. If resection is incomplete, a short course of chemotherapy followed by a second look surgery in attempt to achieve a gross total resection before radiation is favored. Chemotherapy alone is not an option for infratentorial disease as outcomes are dismal with a 5-year event-free survival of only 27%, and all patients alive at this time had received radiation at diagnosis or at time of failure.[49,50]

Although there are concerns about irradiating young children, Merchant et al proved this treatment to be safe and effective and the current and prior COG protocols deliver RT to children as young as 12 months of age. Survival was once thought to be inferior in children under the age of 3, but the St. Jude's experience showed that this was not the case if radiation was delivered, indicating that omission of radiation was the likely reason for reports of inferior outcomes. Because of the relatively young age of these children, highly conformal techniques such as IMRT or proton therapy should be strongly considered.

Infratentorial ependymomas are notorious for extension through the foramina of Luschka and Magendie (Figure 67-8). It is critical to review imaging with neuroradiology to determine the original tumor extension into these regions. Fast imaging employing steady state acquisition (FIESTA)/constructive interference in steady state (CISS) MRI images show CSF and parenchymal interfaces well and may be useful for defining extent of the original tumor or detecting small amounts of residual disease. These images can clearly show cranial nerves and the small amounts of disease spread so often seen with ependymomas.

For radiation therapy, the GTV should include any surface contacted by the original tumor as well as any gross residual disease. Although there will be shifts in tissue position following surgery, it is still useful to fuse the preoperative scan and to contour this volume to become familiar with both the anatomical location of the tumor as well as ependymal and CNS structures in contact with the tumor. This volume serves as a useful guide in contouring the GTV. The CTV expansion should be 5 mm to 10 mm with constraints for anatomical boundaries. The recommended dose to this volume is 54 Gy to 59.4 Gy in 30 fractions to 33 fractions. The recently closed and current COG protocols (ACN0121 and ACNS0831, respectively) prescribe a total dose to 59.4 Gy, but ACNS0831 requires

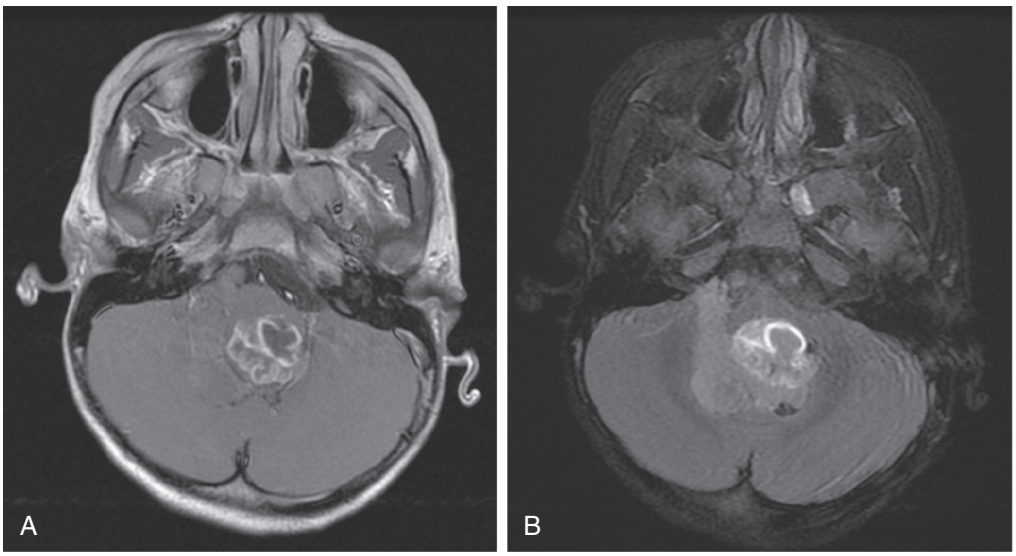

Figure 67-8 Infratentorial ependymoma. Axial images depict an infratentorial ependymoma with extension through the left foramen of Luschka and involving the vertebral and basilar arteries. T-1 post-gadolinium image **(A)** and T2 FLAIR image **(B)** show that this tumor is partially enhancing.

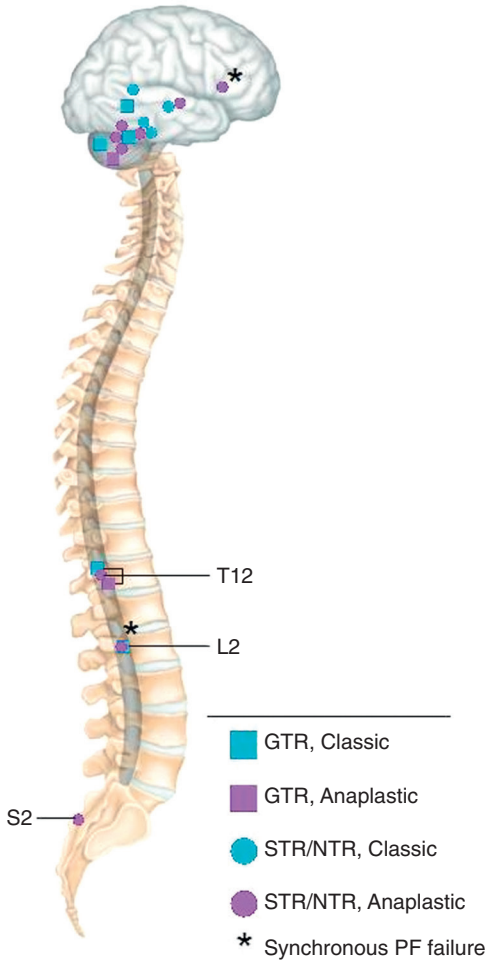

Figure 67-9 Patterns of relapse following involved field radiation for localized ependymoma.

that critical structures (the spinal cord and optics) outside of the area of highest risk be blocked after 54 Gy.[51] Children younger the age of 18 months or with known brainstem injury should receive a total dose of 54 Gy. Off protocol, a dose of 54 Gy to 59.4 Gy is typically used. Some clinicians recommend only delivering dose beyond 54 Gy to residual disease because of brainstem tolerance, whereas others feel the risk of local recurrence for this disease warrants a dose >54 Gy.

Recent studies have shown a proportional increase in distant relapses, owing to improved local control likely attributable to advances in surgical and radiation techniques (Figure 67-9).[5,52] ACNS0831 randomizes children to maintenance chemotherapy with vincristine, cisplatin, etoposide, and cyclophosphamide (VCEC) after radiation to explore in a randomized fashion whether or not additional chemotherapy will improve outcomes and determine how it will be tolerated. Supratentorial WHO Grade II tumors that are completely resected may be observed without radiation on ACNS0831. The last COG study also enrolled a small number of these patients on an observation arm. Off-trial, radiation is standard.

Similar to embryonal tumors, molecular profiling of ependymomas show distinct patterns for supratentorial and infratentorial tumors and indicate that these tumors may be genetically distinct entities. For rare cases of ependymoma that present with metastatic disease, CSI to 36 Gy followed by a localized boost to 54 Gy to 59.4 Gy is recommended unless the child is younger than 3 years of age. Outcomes are generally poor for patients with metastatic disease.[53] Ependymoma recurrences following radiation therapy are challenging to manage, but accumulating data suggests that reirradiation is of benefit for some patients, particularly those with isolated local recurrences.[54,55] Retreatment carries substantial and life-threatening risks, but alternative treatment options are quite limited. These cases should always be thoroughly discussed in a multidisciplinary setting and the risks and benefits of reirradiation thoroughly discussed with the family.

LOW-GRADE ASTROCYTOMA

Low-grade gliomas are the most common pediatric CNS malignancy. Though they may occur anywhere in the brain, the most-common locations are the cerebellum and cerebral hemispheres. Tumors in these locations can usually be treated by surgery alone with excellent long-term DFS; 90% for complete resection in modern series.[56] Additional locations less amenable to surgery include the hypothalamus, thalamus, tectum, optics, and brainstem. For these tumors, chemotherapy or radiation is typically required.

Histological subtypes of pediatric low-grade gliomas include pilocytic (WHO grade I) and diffuse (WHO grade II), with pilocytic astrocytomas accounting for the majority of tumors in young children. Presentation is dependent on location and may be slow to progress because these tumors are slow growing. Diagnostic work-up includes MRI of the brain. Although dissemination is rare in this disease, MRI of the spine is usually obtained at the time of diagnosis. Radiographically, low-grade gliomas may or may not enhance and can have cystic components. When complete surgical resection is not an option, management can be complex and treatment is best determined in a multidisciplinary setting. Biopsy is recommended for most sites to confirm pathology but is not considered necessary for optic and hypothalamic gliomas or tectal gliomas that have a classical appearance on MRI. Surgical intervention may also be needed to relieve pressure on critical structures. Tumors in these locations are almost always pilocytic astrocytomas and biopsy may carry a higher risk of morbidity.

Historically, radiation including a 2-cm to 3-cm margin around visible tumor was the standard of care for low-grade gliomas. Although favorable disease control was reported, late neurotoxicity, particularly for young patients, led investigators to explore chemotherapeutic options. Packer et al reported a 68% 3-year PFS rate for children treated with carboplatin and vincristine. The only significant prognostic factor for this cohort of 78 patients was age, with children 5 years of age or younger having a 3-year PFS of 74% and children older the age of 5 having a 3-year PFS of 39%.[57] The use of chemotherapy to delay radiation has since been widely adopted for children age 5 and younger and is often considered for children under the age of 10. Additional chemotherapeutic agents have since been studied. The multiagent therapy using thioguanine, procarbazine, Lomustine (CCNU), and vincristine has shown promising results as have other regimens. The 5-year PFS for thioguanine, lomustine, carboplatin, vincristine (TPCV) was 48% versus 35% for carboplatin and vincristine, although this difference was not statistically significant.[58]

The toxicity of a particular chemotherapy and also the cumulative morbidity of multiple regimens must be considered. Chemotherapy may have a substantial impact on these children both during the years of treatment as well as subsequently. Chemotherapy typically delays progression, which can be beneficial in providing time for brain development, but radiation therapy is usually still required for definitive treatment. When determining the appropriate therapy, one must also consider the risks of functional loss from progression of tumor. Merchant et al reported 10-year PFS rates of 74% for conformal focal radiation.

Bithalamic low-grade gliomas carry a much poorer prognosis, more similar to high-grade gliomas, with a poor median and OS.[59] This should be taken into consideration when making management decisions for this disease.

Treatment planning for low-grade gliomas has evolved greatly. It is now recognized that these tumors are not highly infiltrative. Modern series and protocols define the GTV as visible tumor that must include enhancing and nonenhancing or cystic tumor plus a small margin of 5 mm. Standard radiation doses range from 50.4 Gy to 54 Gy. If tumors contain a cystic component, it is important to include this portion of the tumor in the GTV and to monitor the cystic component for changes during radiation therapy and adjust the plan as needed. For rare cases of disseminated low-grade glioma, radiation volumes usually encompass the entire craniospinal axis to a dose of 36 Gy followed by involved field treatment to 45 Gy to 54 Gy depending on tumor location.

HIGH-GRADE ASTROCYTOMA

Unlike adults, high-grade gliomas are relatively uncommon in the pediatric population, representing 8% to 12% of pediatric brain tumors, and although they still carry a poor prognosis, long-term DFS is seen in approximately 20% of patients.[45,60] These tumors can occur at any location in the brain; symptoms are dependent on location and MRI usually shows an enhancing mass with surrounding vasogenic edema. The vast majority of tumors are localized and spread is local, but extent of local disease likely to be more extensive than that seen for other pediatric brain tumors. Maximal safe resection with attempt to preserve function should be attempted. Radiation is standard after surgery. Chemotherapy has been studied extensively but without great success. Although temozolomide has been successful for adult tumors, it shows minimal efficacy in children.[61,62] Despite limited efficacy, at present, temozolomide is often used as a first-line chemotherapy concurrent with radiation therapy and following radiation therapy. Efforts to discover a new and more effective agent are under way.

For treatment planning, one must be careful to include areas of contrast enhancement and T2 FLAIR signal abnormality for the initial GTV. This volume plus a generous margin is usually treated to 45 Gy. The enhancing area plus a margin should receive a boost dose to bring this region to a dose of 54 Gy to 59.4 Gy. Although anatomical boundaries such as bone and tentorium should be respected when defining the CTV, these tumors often cross white matter tracts, and it is important to consider this when defining tumor margins to account for microscopic spread of disease (Figure 67-10). These volumes are large compared to other pediatric tumors but considered necessary for disease control.

DIFFUSE PONTINE GLIOMA

Diffuse infiltrating pontine gliomas (DIPG) are high-grade tumors arising in the pons of the brainstem. These tumors have a characteristic appearance on MRI of a nonenhancing T2 bright lesion that expands the pons. Biopsy is not indicated when this classic pathognomic radiographic appearance is seen; however, for some clinical trials, pathology is obtained for molecular profiling.[63] Children typically present with a short duration of symptoms that most often includes ataxia, nausea/vomiting, and cranial neuropathies. Radiation is indicated to the tumor with a margin to a dose of approximately 54 Gy. Symptoms generally resolve with treatment. Unfortunately, duration of symptom relief is usually short lived, on the order of 6 months. This disease is uniformly fatal, and the median survival for these children is 1 year. Dose escalation and altered fractionation radiation therapy failed to improve outcomes and chemotherapy has not been terribly effective.[64-66] Genetic aberrations and molecular targets are currently under investigation and will hopefully improve outcomes for this disease.[63,67]

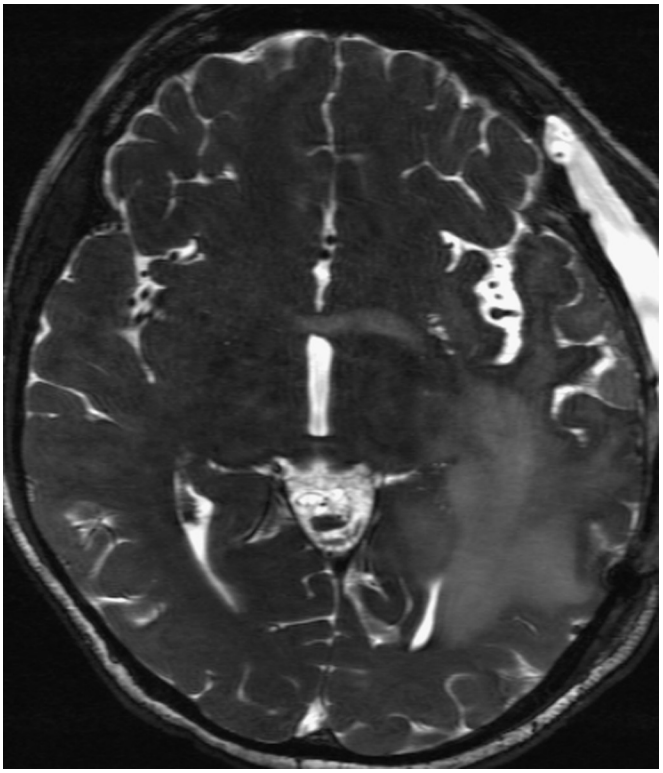

Figure 67-10 High-grade glioma showing a component of the tumor crossing the anterior commissure. Care should be taken to be sure this component crossing into the contralateral hemisphere is included in the gross tumor volume.

GERM CELL TUMORS

Pediatric intracranial germ cell tumors represent only 2% to 3% of childhood CNS neoplasms in North America, but they make up 10% to 11% of pediatric CNS tumors in Japan in the Far East.[68] These tumors occur most often in adolescents, but they can be seen in young children and adults. CNS germ cell tumors (GCTs) usually occur in the pineal gland and infundibulum and suprasellar region but may occur in other locations of the brain, such as the basal ganglia. A male predominance is seen for pineal gland tumors (5:1), but there is no sex predilection for suprasellar tumors. Disease is found in both the pineal gland and suprasellar region in 5% to 10% of cases and GCTs can occur elsewhere in the brain less frequently.

Patients typically present with symptoms of increased intracranial pressure as a result of blockage of CSF flow from the third to fourth ventricle or Parinaud's syndrome (decreased pupillary light reflex, impaired upward gaze, and convergence nystagmus) from compression of the superior colliculus of the tectum. Patients with suprasellar disease usually present with diabetes insipidus, decreased growth, or other endocrinopathy. Suprasellar tumors may also involve the chiasm or optic nerves causing visual impairment. It is not uncommon to see a patient with suprasellar GCT with a long history of symptoms before diagnosis.[69]

When a GCT is suspected by MRI findings, serum tumor markers, α-fetoprotein (AFP) and β-human chorionic gonadotropin β-HCG), should be obtained. If a lumbar puncture can be safely performed, CSF should be obtained for cytology and tumor markers. Although ventricular fluid is often obtained at time of biopsy or shunt placement, lumbar CSF 10 days to 14 days after a procedure is the gold standard.[70] MRI of the spine is also required to ensure disease is not disseminated.

GCTs are a heterogeneous group of tumors and are classified into two main groups that have prognostic and treatment implications, pure germinomas and non-germinomatous germ cell tumors (NGGCT). NGGCT include the subtypes embryonal, immature teratoma, choriocarcinoma, and yolk sac/endodermal sinus tumors. North American guidelines consider any abnormal elevation of AFP (≥10 or institutional norm) or elevation of β-HCG ≥100 to indicate a NGGCT. They children do not require biopsy for diagnosis. Mild elevation of β-HCG may be seen with pure germinomas. If tumor markers do not clearly indicate a NGGCT, biopsy is recommended to confirm diagnosis.

In North America, surgery is typically performed with the intent of obtaining tissue for diagnosis. For pineal region tumors, an increasingly common procedure accomplishing both diagnosis and relief of hydrocephalus is a third ventriculostomy. For this procedure, an endoscope is inserted through the lateral ventricles. Inspection of the lateral and third ventricles is performed to ensure no MRI-occult metastases are present. The pineal gland can be biopsied and an opening in the floor of the third ventricle is created permitting flow from the third ventricle to the prepontine space. This procedure is highly effective in relieving hydrocephalus without the need for an external drain or shunt.

Pure germinomas are highly curable tumors with DFS rates in excess of 90% for both localized and disseminated disease.[6,71,72] In the United States, chemotherapy followed by reduced-dose radiation is usually recommended for pure germinomas, although radiation alone is still considered an acceptable standard of care. Two to four cycles of platinum based therapy, usually carboplatin and etoposide is delivered. If a complete response is achieved, a dose of 21 Gy to the whole ventricles followed by a boost to 30 Gy to 40 Gy to the primary tumor region is delivered. If a complete response is not achieved, a second-look surgery is recommended (if this can be safely performed) to ensure that a nongermininomatous component is not present or higher doses of radiation may be recommended. If radiation alone is used, a dose of 24 Gy is usually delivered to the whole ventricle volume followed by a dose of 45 Gy to 50 Gy to the primary tumor bed. Patients with disseminated disease are treated in a similar manner, but CSI is used for the initial treatment volume rather than the whole ventricular volume.

Several studies have explored the use of chemotherapy followed by involved-field radiation to 30 Gy to 40 Gy.[73] Early reports showed promising results, but higher rates of ventricular relapse were later reported by Alapetite et al, resulting in a shift back to whole ventricular RT followed by an involved-field boost.[74] The current COG protocol, ACNS1123 is investigating the use of preradiation therapy chemotherapy with four cycles of carboplatin and etoposide followed by very low-dose whole ventricular radiation to 18 Gy and a boost to a total of 30 Gy to the primary tumor for localized pure germinomas following a complete response to chemotherapy.

NGGCT have a much poorer prognosis and multimodality therapy is always recommended. The addition of platinum-based chemotherapy has led to marked improvements in outcomes and recent studies show long-term disease free survival rates of 70% to 80%.[75] The standard chemotherapeutic regimen in the United States consists of six cycles of alternating carboplatin/etoposide and ifosfamide/etoposide. Patients with a complete response by MRI and normalization of tumor markers are then treated with radiation. Those who do not have a complete response should undergo a second look surgery. Although no viable tumor is found in some cases, residual tumor or mature teratoma may be present and is likely to grow at a later time. Although risks must be taken into consideration, removal is considered best if at all possible.

Radiation volumes and doses are somewhat controversial. The last COG protocol, ACNS0122, delivered CSI to 36 Gy followed by a boost to the tumor volume to 54 Gy. The results of this trial have not yet been published in manuscript form, but 5-year EFS and OS rates of, 84% and 93%, respectively, have been reported (personal communication, Stuart Goldman). International Society of Paediatric Oncology (SIOP) has reported excellent outcomes for chemotherapy and involved field RT. They found a dose less than 50 Gy to the involved field to result in inferior outcomes. The current COG protocol, ACNS1123, examines a middle ground radiation volume delivering 30.6 Gy to the whole ventricles followed by a dose of 54 Gy to the involved field following six cycles of carboplatin/etoposide alternating with ifosfamide/etoposide (identical to ACNS0122) for patients with localized NGGCT.

For treatment planning, it is important to assess carefully pre- and postchemotherapy imaging. It should be determined if tumor appeared invasive of brain parenchyma or if tumor is only displacing the adjacent brain parenchyma. These tumors are often large at diagnosis, but often regress completely with chemotherapy. It can sometimes be challenging to determine if there has been a complete response. Posttreatment MRI's almost always show some residual tissue that may be scar tissue, but this tissue should be evaluated carefully with pediatric neuroradiologists familiar with this disease to ensure residual tumor is not present. Pre- and postchemotherapy scans should also be reviewed to rule out any occult disease. A decrease in size of the infundibulum or pineal gland after chemotherapy should lead to suspicion of occult disease. If this is suspected, both regions should be included in the boost volume. The involved-field volume should also be determined at the time of planning CSI or whole ventricle treatment planning to ensure the CTV boost volume receives full dose. GCTs can involve the optic nerves and hypothalamus in areas that are not part of classic CSI or whole ventricle volumes (Figure 67-11). As the whole ventricular volume is somewhat difficult to contour consistently and is used on for all patients on the ACNS1123, guidelines to assist in contouring the whole ventricular volume are available on the QARC website (Figure 67-12).

CRANIOPHARYNGIOMA

Craniopharyngioma is a relatively uncommon brain tumor, with less than 100 cases diagnosed in the United States per year. Despite being considered a "benign" and highly curable disease, it remains one the most difficult and controversial brain tumors in terms of management. The controversy lies in the high risk of morbidity for these patients. Although complete resection is curative for these tumors, the most common adamantinomatous type of craniopharyngioma is often too adherent to critical structures to allow for a minimal-risk resection. It is critical that these cases be seen by experienced pediatric neurosurgeons and pediatric radiation oncologists, and that the risks and benefits of treatment are carefully considered in a multidisciplinary setting.

Craniopharyngiomas arise from remnants of Rathke's pouch in the sellar/suprasellar region intimate with neuroendocrine structures, the optic apparatus and the medial

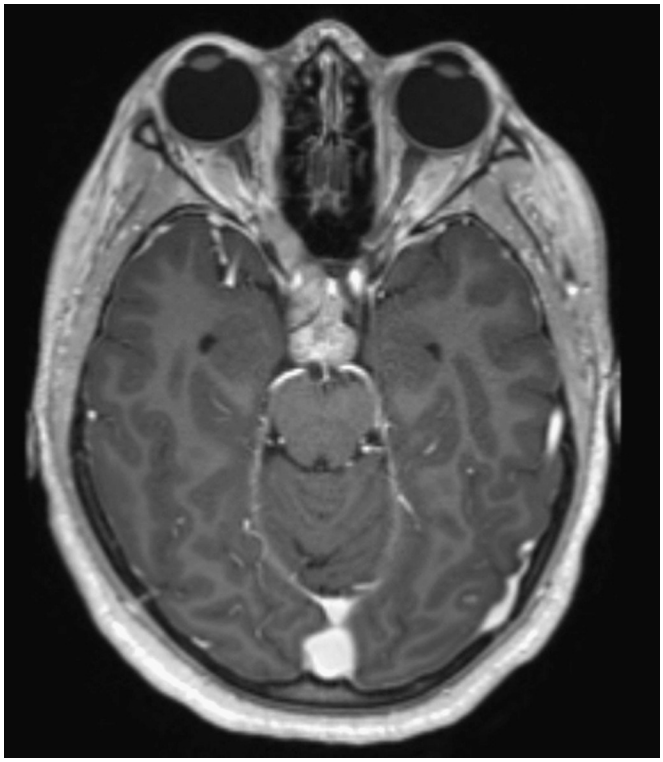

Figure 67-11 Germinoma with optic nerve involvement. Care should be taken to include this region in both the whole ventricle volume (or CSI volume) and the boost volume. The boost volumes should always be contoured at the time of initial volume planning.

temporal lobes. Complete resection is curative, but seldom achievable without great morbidity. For some young children or those with a large cystic component, cyst decompression and partial resection with close observation may be the best management. These children will require RT at some point and careful and frequent observation is required. Limited surgery followed immediately by radiation is our preference for most patients. This treatment was first shown to be an effective treatment for craniopharyngioma by colleagues at St. Georges and Royal Marsden Hospital in 1961.[76] Since their early reports, additional studies have confirmed excellent disease outcomes, with progression free survival ranging from 72% to 100%, for this combined treatment.[76-78] Although less data for IMRT and proton radiation is available, published studies have reported excellent outcomes.[78,79] Given the high likelihood of survival, minimizing late morbidity is of paramount importance. These modern modalities are therefore favored for treatment in attempt to decrease long-term morbidity (Figure 67-13). Fractionated SRS plays a role in the management of small tumors. SRS has a limited role given the close proximity of these tumors to the optic structures, but it may have a role for small solid tumor components that are not adjacent to optic structures or small recurrences.

Intracavitary radiation is another modality that can be an effective treatment option for the cystic component of craniopharyngiomas, but because of limited penetration, this treatment is not useful for treatment of the solid component of craniopharyngiomas.[80,81] For this reason, it is generally used only for cystic recurrence. For this procedure, beta emitting particles (P32 or Y90) are administered by stereotactic cannulation of the cyst or via an Ommaya reservoir in a joint procedure by a radiation oncologist and neurosurgeon.

For any tumor that has a cystic component, cyst growth, or less often reduction in cyst size, may occur during radiation therapy. Because of the cystic portion of the tumor is also targeted in treatment, it is crucial to make appropriate adjustments in the radiation plan during the course of radiation. We

Purple (WVV), blue (WVV PTV), dark blue (pre-pontine space). (Atlas is available on qarc website. http://www.qarc.org/cog/ACNS0331Atlas.pdf)

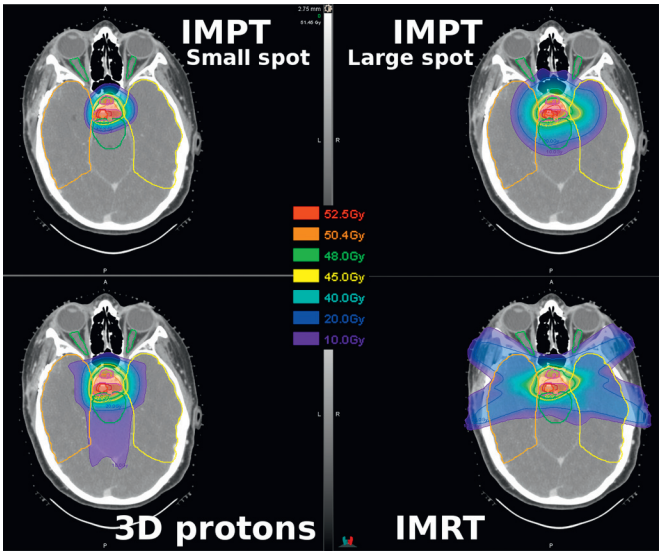

Figure 67-13 Modern modalities for localized treatment of craniopharyngioma.

recommend obtaining a CT or T2-weighted noncontrast MRI every 7 days to 14 days for cyst monitoring. If the initial MRI does not show change, subsequent MRIs during treatment are less likely to show change. The use of cone-beam CT is particularly desirable for image guidance for craniopharyngiomas because it may provide additional information about cystic changes on a daily basis.

The GTV for craniopharyngiomas includes both solid and cystic components. A small margin of 3 mm to 5 mm around the GTV should be given for the CTV volume. A dose of 50.4 Gy to 54 Gy at daily fractions of 1.8 Gy is recommended. Some series have used higher doses of radiation, but because of optic structure tolerance and lack of evidence that a greater dose provides improved tumor control, higher doses are not generally recommended.

CHOROID PLEXUS TUMORS

Choroid plexus tumors are rare and typically occur in young children, usually under the age of 2. Choroid plexus papillomas can be cured with surgery alone. Choroid plexus carcinomas carry a less favorable prognosis and in addition to maximal resection, chemotherapy and radiation are recommended.[82,83] Choroid plexus carcinoma has been associated with *p53* mutations.[84] A dose of 50.4 Gy to 54 Gy is used for the tumor bed. If the child is older and metastatic disease is present, CSI should be considered.

SPINAL CORD TUMORS

Primary spinal cord tumors are rare in children. Presenting symptoms include pain, weakness, altered sensation, sphincter dysfunction, and scoliosis.[85] Complete resection is recommended if this can be performed without loss of neurological function and is often required to relieve pressure on normal spinal cord. Pathologies include ependymoma (usually myxopapillary, WHO grade I), low-grade astrocytoma, and less often high-grade astrocytoma. Radiation is used for tumors that recur or cannot be completely resected. The recommended dose is 45 Gy to 54 Gy depending on the location in the spinal canal. A dose of 50.4 Gy is most often used in attempt to allow for durable control while minimizing, though not obviating, risk of spinal cord injury. Treatment is delivered to the visualized tumor usually with a margin of at least one vertebral body above and below the tumor. Care should be taken to provide an even dose to bone to prevent scoliosis or growth abnormality in children that have not reached their full height.

NORMAL TISSUE TOLERANCE AND SIDE EFFECTS

Toxicities related to radiation are usually divided into acute, subacute, and late effects according to the timing of the complications. Acute effects, which are usually temporary, occur during or shortly after irradiation. Subacute toxicities occur usually up to 6 months and occasionally even a year after the completion of radiation and late effects may develop after only 6 months but may also take years to manifest. A thorough discussion about the long-term side effects of cranial irradiation is a pivotal part of the initial consultation with a child and his and her parents, and it sometimes plays a role in decisions regarding the use of radiation therapy for a child. It is a good idea to first approach the parents to determine together how much information should be discussed with the child in attendance. Although some children benefit from hearing the whole discussion and knowing that nothing is being hidden from them, others may be scared or traumatized by the potential side effects of treatment.

ACUTE AND SUBACUTE TOXICITY

The most-common acute reactions to radiation for CNS tumors are nausea/vomiting, fatigue, headache, decreased appetite, temporary alopecia, and less commonly recurrence of symptoms initially caused by the tumor from swelling induced by radiation. Nausea and vomiting are usually effectively treated with antiemetics such as ondansetron or similar serotonin antagonists. For persistent vomiting despite these medications, lorazepam dronabinol or corticosteroids may be of benefit. The majority of acute toxicities resolve after the completion of chemoradiation, though fatigue, nausea, and decreased appetite may persist. When fatigue worsens several weeks after radiation, this is considered a subacute effect referred to as somnolence syndrome.[86] The most striking symptom of somnolence syndrome is marked fatigue, but headache, nausea, and vomiting may accompany fatigue. Symptoms typically peak after 4 weeks to 6 weeks and typically resolve by 4 months to 6 months after radiation. Low-dose corticosteroids or neurostimulants, such as modafinil or methylphenidate are typically used to alleviate symptoms. Duration of treatment is typically 1 months to 2 months.

NEUROCOGNITIVE TOXICITY

Cognitive impairment is among, if not the most, devastating and feared side effect in survivors of childhood primary brain tumors. This complication takes months to years to manifest and has been determined to be a failure of development rather than a decline in existing ability. The degree of impairment has been correlated to age at the time of radiation, volume of brain receiving radiation and radiation dose.[87] Radiation-induced cognitive decline is best studied in patients who have undergone radiation to the whole brain.[88] The loss in full-scale intelligence quotient (FSIQ) correlate with both dose and age at the time of irradiation. In a study of 48 patients with either acute lymphocytic leukemia or medulloblastoma, Silber et al found that the follow-up FSIQ in patients who received whole-brain radiation to a dose of 36 Gy was 8.2 points lower than the FSIQ of a patient who received 24 Gy, and 12.3 points lower than the FSIQ of a patient who received 18 Gy.[89] In contrast to

patients treated with whole-brain radiation, patients treated with involved field radiation may experience relative stability of FSIQ.[90] Merchant et al studied the cognitive outcomes in 78 patients with low-grade glioma treated with involved field radiation.[91] Fifty-five patients were evaluated on at least two occasions. The estimated FSIQ at 60 months (average 95.4) was not significantly changed from baseline (98.96). Analogous results were reported for 123 patients with ependymoma.[92] Longer follow up is needed to confirm this stability of neurocognitive function in these patients. Although Merchant et al have reported that the supratentorial brain seems more important for cognitive outcomes, more detailed neuropsychological testing is needed to determine what areas of the brain may be most critical for preserving overall cognitive function.[93]

NEUROENDOCRINE TOXICITY

Growth hormone deficiency (GHD) is the most common and best-characterized endocrine complication of radiation therapy.[94] In children, GHD limits growth and can lead to weight gain. In both children and adults, GHD alters body composition and lipid profile, decreases bone mineral density, and may affect cognitive ability and quality of life.[95,96] GHD is associated with many pretreatment variables, including tumor location and size as well as hydrocephalus.

Merchant et al performed provocative testing of GH secretion on 192 patients with primary brain tumors before and after involved-field radiation.[97] At a dose as low as 5 Gy, the 5-year risk of GHD was 23%. The cumulative dose associated with a 50% risk of GHD at 5 years was 16.1 Gy. Higher doses to the hypothalamus shortened the time to the development of GHD; patients who received greater than 60 Gy developed GHD by 12 months, whereas patients who received 15 Gy to 20 Gy developed GHD by 60 months.

Central hypothyroidism may also occur as a result to injury to the pituitary or hypothalamus from radiation or from mass effect from tumor or surgery. Although less common than GHD because of the higher dose required to induce central thyroid deficiency, rates close to 70% are seen for doses exceeding 40 Gy.[98,99] Symptoms include fatigue, lethargy, and weight gain. Replacement with levothyroxine is usually effective and well tolerated.

Radiation may affect gonadotropins. Relatively low doses of radiation can result in precocious puberty, especially in females. For doses between 18 Gy and 24 Gy, the mean age at menarche is earlier in females.[100,101] In children treated with doses between 25 Gy and 47.5 Gy, the average onset of puberty is early in both genders. It is much rarer for radiation to cause gonadotropin deficiency, but at doses greater than 50 Gy, this can be seen.[102] Merchant et al reported the cumulative risk of gonadotropin-replacement treatment at 10 years to be 14.1%. In contrast, the 10-year cumulative incidence of GnRH agonist use was 34.2%, but this is likely an overestimation of precocious puberty because some patients received growth hormone replacement.[91]

Adrenocorticotropic hormone (ACTH) deficiency causes nausea/vomiting, decreased appetite, hypoglycemia, fatigue, and hypotension. It may become life-threatening at times of stress if replacement is not given. It is rare that radiation alone results in deficiency.[98] Prolactin deficiency is rare, though hyperprolactinemia is possible.[99] Diabetes insipidus and hypothalamic obesity should not occur from radiation alone and are usually attributed to tumor mass effect or surgery.

OTOTOXICITY

Sensorineural hearing loss may occur as a result of radiation to the cochlea. Hua et al correlated mean dose to the cochlea with the risk of hearing loss.[103] They found that high-frequency hearing loss was 0% at 30 Gy, 2% at 35 Gy, 4% at 40 Gy, 5% at 45 Gy, 11% at 50 Gy, 24% at 55 Gy, and 37% at 60 Gy. Intermediate- and low-frequency hearing loss was not seen at doses less than 40 Gy. Although longer follow-up is needed, it seems that dose less than 35 Gy should minimize hearing loss from radiation therapy. This risk of ototoxicity is greater for patients who receive cisplatin-based chemotherapy, though it is unclear if this is because of independent risks of radiation and cisplatin or if there may be some synergistic effect of both therapies.[104]

VASCULAR COMPLICATIONS

Vascular complications as a result of radiation are rare, but do occur. Moyamoya syndrome may be seen after radiation.[105] Patients may present with seizures and ischemic events due to occlusion of vessels in the Circle of Willis. This syndrome is seen most often in patients with optic gliomas or craniopharyngiomas because of the tumor's close proximity to these vessels. The estimated prevalence following radiation is 3.5%, most diagnosed in patients with optic gliomas. Risk factors for Moyamoya syndrome include neurofibromatosis type 1, high dose to the circle of Willis, and young age at the time of radiation.

Brain tumor survivors are also at slightly higher risk for stroke than the general population. The 25-year cumulative incidence of stroke in brain tumor survivors is reported to be 6.9% for those who received radiation and 2.85% for those who did not receive radiation.[106]

Cavernous hemangiomas are benign vascular malformations that can develop months to years following radiation.[107] Most cavernomas are asymptomatic, but hemorrhage can occur. MRI surveillance is generally recommended, but surgical intervention is required if symptomatic hemorrhage occurs and may be indicated of if radiographic characteristics suggest that hemorrhage is imminent and may lead to morbidity.

VISUAL OUTCOMES

The optic nerves, chiasm, lenses, and retina may receive radiation dose from the treatment of CNS malignancies. Cataracts are a relatively common side effect of CSI and low doses may result in cataracts.[108] Lens replacement is generally successful. Optic neuropathy is rare at doses less than 55 Gy delivered with fraction sizes of less than 2 Gy per fraction.[109,110] The retina should not receive in excess of 45 Gy to avoid retinopathy, but this is easily accomplished for most brain tumors.

RADIATION NECROSIS AND PSEUDO-PROGRESSION

Radiation necrosis is a rare but devastating side effect of high-dose radiation (typically >55 Gy) that results in permanent death of brain tissue. Although most cases present within a year of treatment, cases have been reported as late as 6 years to 7 years after treatment.[111] It can be difficult to distinguish tumor progression from radiation necrosis or pseudoprogression by MRI and this should be considered. Decadron is often administered for patients who are symptomatic. Bevacizumab reduces vessel permeability and may lead to relief of symptoms and decreased steroid requirements.[112,113] Hyperbaric oxygen has also been investigated for the treatment of radiation necrosis.[114]

LEUKOENCEPHALOPATHY

Leukoencephalopathy is a rare but potentially devastating complication of radiation or methotrexate. Clinical symptoms

include lethargy, seizure, loss of motor function, ataxia, and spasticity. MRI will typically show extensive periventricular white matter destruction and areas of hypodensity attributed to lacunar infarcts. It is unusual to see this complication for patients treated for primary brain tumors and is best described in children with acute lymphocytic leukemia treated with brain radiation and high dose methotrexate.[115]

SECOND MALIGNANCY

Development of a second tumor following the treatment of a primary tumor is among the most devastating potential complications of radiation therapy. For patients who receive cranial irradiation, the risk is low, but increases with time from radiation. Most occur after 10 years. The Childhood Cancer Survivors Study reported 76 subsequent neoplasms among 1877 survivors of CNS malignancies at a median of 16 years from diagnosis.[116] Meningioma is the most common radiation induced malignancy for this group followed by gliomas.

CONCLUSIONS

A great deal of progress has been made in the field of pediatric radiation oncology and pediatric oncology as a whole. Recent estimates suggest that approximately 75% of children diagnosed with a brain tumor can expect a long-term DFS following modern treatment.[116] Advances in both radiation and imaging techniques and a better understanding of CNS malignancies allow for fewer long-term side effects and a greater optimism that patients will survive to live relatively healthy lives. Molecular patterns of many tumors are being discovered and we are likely seeing just the tip of the iceberg for the use of distinct genetic patterns to provide prognostic information and guide therapies. Although current treatment recommendations are still based on a tumor's location and its appearance under the microscope, future therapies will likely be dictated by genomic analyses that define the molecular characteristics of a specific tumor. This information will also reveal molecular mutations critical for the viability of tumor cells that can either be directly targeted or perhaps made more sensitive to radiation or chemotherapy. Advanced forms of radiation, such as proton radiation, are becoming increasingly available allowing more children to receive targeted treatments. However, we must be cautious, as often the technology is not as important as the as the users experience and care in its delivery. In the future, we may see a decreased role for radiation as some CNS malignancies become curable with less radiation, whereas our role for others may increase as a broadly curative modality rather than a specifically or primarily palliative measure.

CHAPTER

68 Pediatric Soft-Tissue Sarcomas

Michael W. Bishop and Matthew J. Krasin

INCIDENCE

There are 350 cases annually in the United States of rhabdomyosarcoma (RMS).
- Of those, embryonal rhabdomyosarcoma (ERMS) comprises 75% (260 cases), botryoid subtype (35 cases), and alveolar rhabdomyosarcoma (ARMS) comprises 25% (90 cases).

There are 500 cases annually of non-rhabdomyosarcoma soft-tissue sarcoma (NR-STS) in the United States. These are divided into high grade (Pediatric Oncology Group [POG] grade III), 67% (335 cases), and low and intermediate grade (POG grade I/II), 33% (165 cases).

BIOLOGIC CHARACTERISTICS

RMS
- With EMRS, there is a loss of heterozygosity chromosome 11p and RAS/NF1 pathway mutations.
- In alveolar rhabdomyosarcoma, t(2;13) or t(1;13) translocations result in *PAX-FKHR* fusion protein (80%)

There are diverse histologies in NR-STS with mixture of distinct genetic events. Examples include:
- Synovial cell sarcoma: t(X;18) and resulting fusion product *SYT-SSX*
- Alveolar soft-part sarcoma: der(17)t(X;17) and resulting fusion *TFE3-ASPL*
- Diverse genetic signatures (e.g., malignant fibrous histiocytoma)

STAGING EVALUATION

RMS
- There is the Intergroup Rhabdomyosarcoma Study Group (IRSG) clinical grouping system based on the degree of surgery, nodal involvement, and metastatic disease.
- In the TNM pretreatment staging classification, stages are based on location of primary tumor, size, invasiveness, nodal involvement, and metastatic disease.

NR-STS uses the American Joint Committee on Cancer staging system, which is based on grade, size, invasiveness, nodal involvement, and metastatic disease.

PRIMARY THERAPY

For RMS, nonmorbid "upfront" surgery is the first line of therapy.
- Radiation therapy (RT) is used for primary and metastatic sites of disease. The following are recommended doses:
  - microscopic disease: 36 Gy; microscopic nodal disease: 41.4 Gy; and gross disease: 50.4 Gy
- Local failure rates are 10% for Group I/II and 13% for Group III.

For NR-STS, the recommended course is surgical resection with or without adjuvant RT (55.8 Gy to 63 Gy) or brachytherapy (34 Gy at 3.4 Gy twice daily, high-dose rate).
- In some cases, preoperative chemoradiation (conventionally fractionated external beam RT, 45 Gy to 50.4 Gy) followed by surgery is needed.
- Local failure rates are 4% for resected and range from 40% to 80% for unresected disease.

ADJUVANT THERAPY

For RMS, vincristine, dactinomycin (Actinomycin D), cyclophosphamide (VAC)–based chemotherapy is the standard. For high-risk disease, vincristine, irinotecan, dactinomycin, cyclophosphamide, doxorubicin, ifosfamide, etoposide, or experimental agent(s) is used. With these treatments, there is a 5-year event-free survival:
- low risk (group I/II embryonal RMS): 90%;
- intermediate risk (alveolar RMS groups I-III, embryonal RMS group III): 70% to 73%; and high risk (metastatic embryonal or alveolar RMS): <30%.

In NR-STS,
- neoadjuvant chemoradiation or adjuvant chemotherapy (ifosfamide/doxorubicin) is used. There is a 5-year event-free survival:
  - Localized, resected: 75%; localized, unresectable: 45%; and metastatic: 10%.

EPIDEMIOLOGY

Soft-tissue sarcomas (STS) account for approximately 7% of all pediatric cancers. RMS comprises 40% of STS, and the other NR-STS comprise 60%.[1,2] This results in 350 patients with RMS and 500 with NR-STS (divided about 2:1 between high and low grade) available for participation in clinical trials in the United States annually. Based on prior clinical trials, 75% of children with RMS have required RT, and based on the presence of high-grade disease only, approximately two thirds of children with NR-STS receive irradiation. This yields 600 sarcoma cases annually for the study of radiation-specific clinical trial questions, training of young radiation oncologists, and study of radiation-specific long-term sequelae.

Patients with RMS have benefited from the Children's Oncology Group (COG) sarcoma studies (formerly the IRSG). The trials conducted by these groups have defined the combined modality management of children with RMS in North America and allowed the randomized comparisons of new chemotherapeutics as well as RT strategies that would not be possible without the cooperative group structure. These approaches, as well as the specifics of modern RT, are discussed in this chapter.

Treatment of children with NR-STS is less well defined. Local therapy approaches have evolved from adult paradigms, incorporating limb salvage over amputation, adjuvant irradiation, and subsequently, preoperative RT approaches.[3-6] Despite an adult parallel to draw from, little prospective

research has been conducted in the pediatric NR-STS population. A recently closed trial through COG (ARST0332) sought to address some of these deficiencies delivering both preoperative and postoperative RT in conjunction with surgery and chemotherapy to define the role of local and systemic approaches in a comprehensive clinical trial; preliminary data from this recently closed study suggests that a risk-based approach may be used with lower dose RT or RT avoidance in select patients.[7]

BIOLOGIC CHARACTERISTICS AND PATHOLOGY

Rhabdomyosarcoma

RMS is broadly classified as one of the small, round, blue cell malignancies of childhood.[8] The histologic subtypes, in order by worsening prognosis, include ERMS, the most common form (with spindle cell and botryoid comprising two favorable variants); ARMS; and undifferentiated sarcoma. Patients with undifferentiated sarcoma were previously enrolled in IRSG clinical trials in a fashion similar to ARMS. More recently, these patients have received systemic therapy similar to patients with Ewing's sarcoma and have also been included in the COG ARST0332 trial. Light microscopy often describes ERMS with spindle-shaped cells and ARMS with small, round, blue cells forming alveolar-like spaces, although tumor biopsy specimens may also look like collections of poorly differentiated cells complicating definitive diagnosis by hematoxylin and eosin staining alone. Immunohistochemical staining can include positivity for MyoD1.[9] Cytogenetic events occur in ERMS with a loss of heterozygosity on chromosome 11p and frequent mutations of the RAS/NF1 pathway,[10,11] and in 80% of ARMS with translocations between chromosomes 2 and 13 or 1 and 13. These represent loci of *PAX3* and *PAX7* (chromosomes 2 and 1) and their fusion with *FKHR* on chromosome 13. These fusion proteins act as transcription factors and are diagnostic of ARMS.[8] Other genetic abnormalities and syndromes associated with RMS include neurofibromatosis type 1 (with a prevalence of 1:200 noted on IRSG-IV), Li-Fraumeni syndrome, and Beckwith-Wiedemann syndrome.[12-14]

Nonrhabdomyosarcoma Soft-Tissue Sarcoma

The pediatric NR-STS comprise a heterogeneous group of tumors managed homogeneously largely because of the limitations in patient numbers and effective chemotherapy. The most common histologies include synovial cell sarcoma and malignant peripheral nerve sheath tumor (MPNST), although several rarer variants including rhabdoid tumor and infantile fibrosarcoma are almost exclusive to the pediatric age group.[15,16] Although many NR-STSs have no genetic signature, several histologic variants do have specific translocations or deletions[15,17] (Table 68-1).

CLINICAL MANIFESTATIONS

Rhabdomyosarcoma

The presentation of children with RMS is diverse, characterized by the site of involvement and extent of disease. The median age for children presenting with RMS is younger than 5, although a second incidence peak occurs in the mid-teens. The head and neck region is the most frequent site of involvement and is divided into favorable and unfavorable (parameningeal) sites.[18,19] This site comprised 42% of localized presentations in patients enrolled in IRSG III and IRSG IV and serves as an example of the important nature of primary tumor location.[20] Metastatic disease occurs 20% of the time at presentation, and nodal involvement is rare (<5%) except for paratesticular (25%) and extremity (24%) sites of disease, which warrant computed tomography ([CT] including paratesticular sites at <10 years of age), nodal sampling (paratesticular sites for ≥10 years of age), or sentinel node biopsy (extremity sites).[21-25]

Nonrhabdomyosarcoma Soft-Tissue Sarcoma

The presentation of NR-STS is often as a painless mass, whereas other symptoms are site specific. Approximately half of the cases arise in the extremity, and the incidence increases throughout the adolescent years and into adulthood.[26,27] Although the vast majority of soft-tissue "masses" are either not real or benign, consideration should be given to malignancy because an ill-chosen surgical approach may compromise future local therapy (Figure 68-1).

Fifteen to 22 percent of patients present with metastatic disease at diagnosis, with the lungs being the predominant

TABLE 68-1 Genetic Abnormalities: Nonrhabdomyosarcoma Soft-Tissue Sarcomas

Histology	Genetic Abnormality
Synovial cell sarcoma	t(X;18); fusion *SYT-SSX*
Clear cell sarcoma	t(12;22); fusion *EWS-ATF1*
Desmoplastic small round cell tumor	t(11;22); fusion *EWS-WT1*
Infantile fibrosarcoma	t(12;15); fusion *ETV6-NTRK3*
Alveolar soft-part sarcoma	der(17)t(X;17); fusion *TFE3-ASPL*
Low-grade fibromyxoid sarcoma	t(7;16); fusion *FUS-CREB3L2*
Myxoid and round cell liposarcoma	t(12;16); fusion *FUS-DDIT3*

site of metastatic involvement.[16,28] Clear cell sarcoma and epithelioid sarcoma carry a risk of regional nodal involvement and warrant evaluation of the draining nodal bed(s) with sentinel node sampling.[29]

STAGING

Rhabdomyosarcoma

Staging workup is similar for most patients with RMS (Table 68-2). A site-specific history and physical examination should be performed by the treating radiation oncologist at the time of presentation to define the site of primary disease, its extent, and symptoms possibly related to potential metastatic sites of involvement. Attention to cranial nerve involvement for head and neck primary sites as well as attending the examination under anesthesia for genitourinary sites (vaginal, cervix, uterus, bladder, and prostate) will assist in the multidisciplinary discussions regarding staging and local therapy approaches.

Laboratory studies include a complete blood cell count and chemistry panel, which may be suggestive of bone marrow disease (anemia) or other organ-specific dysfunction related to metastatic involvement.

Review of the pretreatment imaging is critical to ensure adequate imaging of the primary tumor as well as understanding the extent of disease. Often, standard diagnostic imaging protocols (particularly magnetic resonance imaging [MRI]) will not encompass the entire tumor, because the studies were designed for evaluation of joint or intracranial disease. Repeating these studies will facilitate better local therapy decisions and delivery. Standard diagnostic imaging should include MRI of the primary site of disease, CT of the chest (and abdomen for infradiaphragmatic presentations), bone scintigraphy, and site-specific imaging related to potential metastatic disease.[19] F-Fluorodeoxyglucose–labeled positron emission tomography (FDG-PET) may be useful in the evaluation of distal metastases, especially lymph nodes, and may eventually replace bone scintigraphy.

Bone marrow aspiration and biopsy should be performed for all patients, as well as cerebrospinal fluid cytology for patients with parameningeal, orbital, and paraspinal primary sites of disease. Lymph node sampling should be performed for patients 10 years of age or older with paratesticular primary tumors, and sentinel node mapping and sampling should be done for patients with disease of an extremity.

After staging evaluation, a clinical stage should be assigned (outlined in Table 68-3). If surgery has been performed (or

TABLE 68-2 Staging Workup and Follow-Up Evaluations for Patients with Rhabdomyosarcoma and Nonrhabdomyosarcoma Soft-Tissue Sarcomas

	Rhabdomyosarcoma	Nonrhabdomyosarcoma Soft-Tissue Sarcomas
Staging		
Clinical	Site-directed history and physical examination	Site-directed history and physical examination
Imaging	MRI of primary tumor CT of chest CT of abdomen (infradiaphragmatic tumors) Bone scintigraphy	MRI of primary tumor CT of chest
Procedures	Biopsy: primary tumor/metastasis Extremity: sentinel lymph node biopsy Paratesticular (>10 years): ipsilateral retroperitoneal lymph node dissection Head and neck: cerebrospinal fluid cytology Genitourinary: examination under anesthesia	Biopsy: primary tumor/metastasis Histology: specific sentinel lymph node biopsy
Follow-up		
Year 1	History and physical examination every 3 months, laboratory studies, MRI of primary tumor area CT of chest and other metastatic imaging every 3 months	History and physical examination, laboratory studies every 3 months, MRI of primary tumor area CT of chest every 6 months
Years 2 to 3	Every 4 months: history and physical examination, laboratory studies, MRI of primary area Every 4 months: CT of chest and other metastatic imaging	Every 6 months: history and physical, laboratory studies, MRI of primary tumor region, CT of chest

III	Gross residual disease
IIIa	After biopsy
IIIb	After gross major resection (>50% of disease)
IV	Distant metastasis

after a planned surgical resection or biopsy), a grouping should be defined (Table 68-4). These two factors plus the patient's histology are combined into a risk classification to assign patients to protocol therapy.

Nonrhabdomyosarcoma Soft-Tissue Sarcoma

The workup for patients with NR-STS is similar to that for RMS (see Table 68-2). A site-specific history and physical examination should be performed by the treating radiation oncologist at the time of presentation to define the site of primary disease, its extent, as well as symptoms related to potential metastatic sites of involvement.

Laboratory studies include a complete blood cell count and chemistry panel, the findings from which may be suggestive of organ-specific dysfunction related to metastatic involvement.

Diagnostic imaging studies include MRI of the primary site, CT of the chest, and other metastatic imaging, including bone scintigraphy, as indicated by symptoms and laboratory studies. FDG-PET may be useful in the workup of patients

EVALUATION AND DEFINITION OF RISK CLASSIFICATION

Rhabdomyosarcoma

Favorable and unfavorable sites of disease are defined as part of the staging system and are noted in Table 68-3. In addition, histology affects outcome and is related to site of disease; favorable sites of disease in the orbit and genitourinary region are four and five times as likely to be of an embryonal histology as opposed to alveolar or undifferentiated histology. This yields higher disease control rates for localized ERMS compared with ARMS (failure-free survival [FFS], 82% versus 65%).[20] Clinical group (see Table 68-4) is also prognostic of FFS in both ERMS and ARMS. Because of the strong interaction of site, histology, group, and stage, a risk classification system was devised to stratify patients for therapeutic decisions. This resulted in three strata[20,30,31]:

1. Patients with low-risk disease (ERMS, stage 1, groups I to III and ERMS, stage 2 to 3, groups I to II) whose tumor is treated by upfront with or without nodal resection at any site as well as patients with group III orbital site of disease. Patients with nonorbital group III ERMS are also considered low risk in the context of current research protocols. The FFS for this group is approximately 90%.
2. Patients with intermediate-risk disease (ERMS, stage 3, group II to III and ARMS stage 1 to 3, group I to III) are the remaining localized tumors and have variable outcomes, ranging from 30% to 85% FFS.
3. Patients with high-risk disease are those with metastatic disease and have FFS rates of 26% to 40%.

Future classification systems may adjust certain subsets of patients with low-risk disease into the intermediate group where treatment reduction yielded poorer outcomes.[32,33] The presence or absence of PAX/FKHR fusion protein has been shown to be more closely associated with outcome than histologic classification and will likely be included in future risk stratifications.[34]

Nonrhabdomyosarcoma Soft-Tissue Sarcoma

Stratification for patients with NR-STS is based on retrospective data being tested in a prospective clinical trial.[23,24] Patients with low-risk disease are those with low-grade tumors (POG grade I or II) as well as high-grade tumors (POG grade III) that are less than or equal to 5 cm in maximal diameter, with an expected overall survival (OS) above 90%. Patients with intermediate-risk disease with large (>5 cm) high-grade tumors have a 5-year OS of 56%, and patients with high-risk disease with metastatic disease fare poorly, with a 5-year OS of 15%.[26,27]

PRIMARY THERAPY

Rhabdomyosarcoma

All patients with RMS are managed in a combined modality fashion. Participation by a pediatric oncologist, pediatric surgeon, radiation oncologist, and orthopedic or otolaryngologic oncologist (if indicated) at the outset ensures optimal planning for the many therapeutic decisions necessary for this diverse and complicated disease. This multimodal approach has been the hallmark of the studies of the IRSG performed in North America. Since 1972, these trials have enrolled thousands of patients, unified the therapeutic approach across the United States, and improved OS for this disease.

IRSG I (1972-1978) and IRSG II (1978-1984) answered several important questions. Patients in group I (without RT) and group II (with RT at doses of 40 Gy to 45 Gy) were noted to fare well with a regimen of vincristine and dactinomycin [Actinomycin], VA (and omitting cyclophosphamide).[18,35] Patients in group III did not benefit from the addition of doxorubicin, whereas patients treated in the CT era (IRS-II) with parameningeal disease and specific meningeal RT guidelines fared significantly better (OS, 67% versus 45%).[18] Unfortunately, 75% of patients in group IV continued to experience progressive disease.

IRSG III (1984-1991) went on to confirm that the VA regimen is equivalent to therapy with VAC for patients in group I and resulted in a progression-free survival of 83% without RT. The addition of doxorubicin to VA did not improve outcome for group II disease, and patients with groups III/IV disease did not benefit from the addition of cisplatin or etoposide, with progression-free survival for the latter group remaining at 27%.[36]

IRSG IV (1991-1997) was the first trial to employ presurgical staging in addition to the grouping system. A randomized question was asked about systemic therapy (now standard VAC versus VAI [ifosfamide] versus VIE [ifosfamide/etoposide]) for patients with stages 1 to 3 disease. Despite the hope for improvement in overall outcomes, no benefit was seen, and VAC remains the standard of care.[37] Patients with group III disease also underwent a randomization between

standard RT (50.4 Gy/1.8 Gy daily fraction) and hyperfractionated RT (59.4 Gy/1.1 Gy twice daily fractions). Hyperfractionated RT yielded the same FFS (73%) as conventional RT, and local failure was equivalent (15% versus 12%).[38] IRSG IV, in a retrospective fashion compared with IRSG III, also clarified the management of patients with group I paratesticular disease. Patients younger than age 10 years could be evaluated by CT for retroperitoneal lymphatic involvement (without retroperitoneal lymph node dissection [RPLND]), maintaining a 90% FFS. Those 10 years old or older benefited from RPLND (100% FFS with RPLND compared with 63% with CT alone) to define nodal involvement and the need for subsequent lymphatic RT.[22,37]

IRSG V is the last of the intergroup named trials, now named with the COG nomenclature ARST. Patients with group II disease had a reduction in RT dose from 41.4 Gy to 36 Gy for positive microscopic surgical margins. Orbital primary tumors were also irradiated using a reduced dose of 45 Gy. Outcome on this low-risk trial appears equivalent to previous studies, suggesting this is a safe and effective approach, particularly when cyclophosphamide is included in chemotherapy regimens.[39,40] Another randomized question was tested for patients with intermediate-risk disease comparing VAC against VAC alternated with VTC (substituting topotecan). This did not improve outcome, with a 4-year FFS of 73% and 68%, respectively.[41] Patients with high-risk disease during this era underwent several Phase II window therapy trials incorporating new agents. The combination of vincristine and irinotecan demonstrated a 70% response rate. Although FFS remained poor (26% at 2 years), its activity was sufficient to incorporate VI into further trials for patients with intermediate- and high-risk disease.[30]

The most recent round of trials in low-risk RMS (ARST0331) further tailored and reduced therapy for patients with ERMS resected upfront (groups I/II), stage 1 to 3, and unresected (group III), stage 1 disease. The RT dose remained 36 Gy for microscopic disease and 41.4 Gy for nodal disease. Group III vaginal tumors were treated with intent to avoid or delay radiation therapy, but a 2 year FFS of 42% in this subset demonstrated the importance of RT for local control.[33] Patients with intermediate-risk disease (ERMS stages 2/3, group III and alveolar RMS stage 1 to 3, groups I to III) were randomized between VAC and VAC/VI (ARST0531), incorporating irinotecan from the prior high-risk pilot trials. Patients with high-risk disease received multiple-agent systemic therapy (ARST0431) that was later used as a backbone to incorporate new agents such as an insulin-like growth factor-1 receptor inhibitor or temozolomide (ARST08P1), seeking improvement in FFS in this poor prognosis population.

A general algorithm for the integration of chemotherapy, surgery, and RT is shown in Figure 68-2. As a first principle in nearly all North American RMS trials, only a nonmorbid surgical resection should be performed. Amputation, exenteration, or other extensive procedures are discouraged because RT will offer equivalent rates of local control with organ preservation. The timing of RT has varied across studies and disease stage. RT may be integrated after multiple weeks of chemotherapy, facilitating the time necessary to plan with modern radiotherapeutic techniques, allowing some reduction in tumor bulk, as well as potentially integrating a second-look surgical procedure. One exception to this variance is the consistent early introduction of RT in patients with parameningeal disease and intracranial extension.[42]

Nonrhabdomyosarcoma Soft-Tissue Sarcoma

The management of children with NR-STS, particularly the local therapy component, has paralleled that of adult

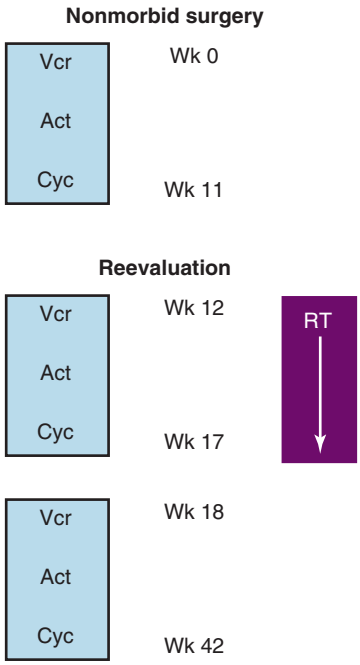

Figure 68-2 General algorithm for the delivery of multimodal therapy for rhabdomyosarcoma. *RT*, Radiation therapy; *Wk*, week; *Vcr*, vincristine; *Act*, actinomycin; *Cyc*, cyclophosphamide.

paradigms, including the move to wide local surgical excision (WLE) from amputation, the role of adjuvant RT, and most recently, the shift to preoperative chemoradiation. Compared with RMS, clinical trials in North America for children with NR-STS have been smaller, fewer, and have not resulted in well-defined prognostic groups from either a local disease control or overall outcome perspective.

The mainstay for management of children with NR-STS is surgery. Absent this modality, the outcome for patients is poor, with a fourfold higher risk of death.[43] The presence of metastatic disease predicts for subsequent disease recurrence in the majority of patients (10% EFS).[44] All patients, but particularly those with resectable primary site disease, benefit from multidisciplinary discussion before initiation of therapy. Planning the appropriate surgery in the context of tumor grade, size, location, probable surgical margin status, and the patient's age is the first critical step in the local management of patients with NR-STS. No prospective, completed clinical trials exist in the pediatric population to assist clinicians in selecting patients for specific aspects of local or systemic chemotherapy. The recent COG trial (ARST0332), stratified by risk group and local therapy approach, accrued more than 550 patients with the goal to determine the relative benefit of specific local and systemic therapeutic approaches. This multimodal approach to therapy incorporated standard-of-care approaches for NR-STS adapted for children and is outlined in Figure 68-3. More importantly, this trial provided a uniform, prospectively treated population of patients on which to evaluate prognostic factors, both clinical and biologic. The analysis of this study could lead to improved risk stratification of patients with NR-STS on future trials.

RADIATION THERAPY

Indications and Outcomes of Local Therapy

Rhabdomyosarcoma

The role of RT is to eradicate microscopic disease present after resection, treat gross disease, and consolidate visible sites of

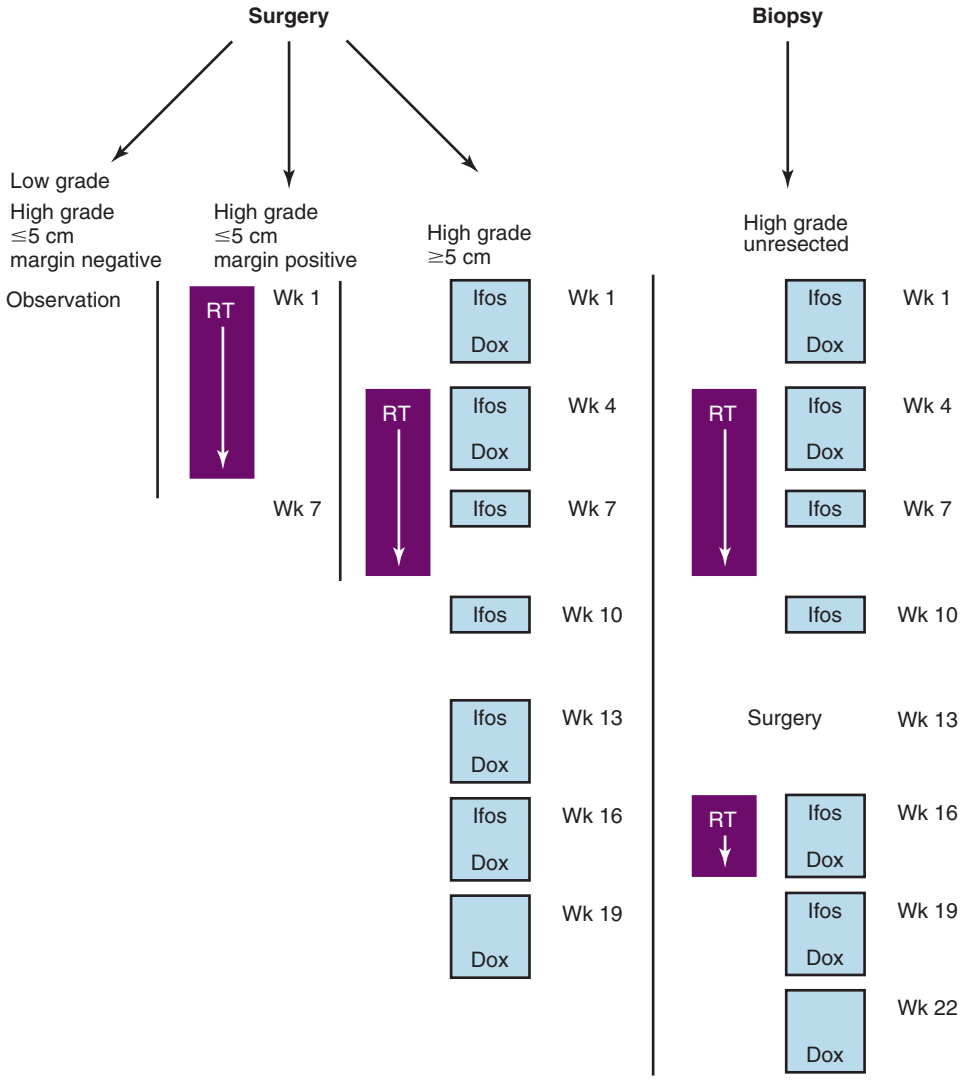

Figure 68-3 General algorithm for the delivery of multimodal therapy for nonrhabdomyosarcoma soft-tissue sarcomas. *RT*, Radiation therapy; *Wk*, week; *Ifos*, ifosfamide; *Dox*, doxorubicin.

TABLE 68-5 Indication for Radiation Therapy and Prescribed Doses for Patients with Rhabdomyosarcoma

Disease Status	Embryonal Histology	Alveolar Histology
Margin negative	No radiation	36.0 Gy
Margin positive	36.0 Gy	36.0 Gy
Node positive	41.4 Gy	41.4 Gy
Gross disease	50.4 Gy	50.4 Gy

metastatic involvement. The indications and doses, although complicated by site, can be generalized (Table 68-5). Doses are delivered at 1.8 Gy per fraction daily.

Data for the treatment of completely resected disease (group I) come from review of prior IRSG trials I to III demonstrating improvement in FFS and OS for patients with ARMS when RT is delivered (73% versus 44% and 82% versus 52%, respectively).[45] Patients with group II disease received adjuvant radiation, resulting in local failure rates of less than 10%.[46] Patients with group III disease have local failure rates of 11% to 16.5%, depending on site, size, and era of treatment.[38,41,47,48]

The parameningeal sites (middle ear, nasopharynx, paranasal sinuses, infratemporal and pterygopalatine fossae, and parapharyngeal region) require special attention to the skull base for adequate coverage of possible intracranial extension. If intracranial extension is present (Figure 68-4), then RT should be initiated within the first few weeks of the start of chemotherapy.

The orbit is a favorable site of disease involvement. Local management for this site with RT calls for delivery of 45 Gy at 1.8 Gy daily and yields excellent local control.[39,40] Despite the extremely thin and fragile nature of the bony orbit and the adjacent globe, these two structures are essentially never breached by orbital primary tumors and should be constrained out of the clinical target volume. If tumor does extend through these structures, consideration should be given that this may be parameningeal instead.

Female genitourinary tract (vulvar, vaginal, cervix, and uterus) tumors of ERMS (particularly the botryoid subtype) require adequate local therapy despite the often young age of the patients (frequently <2 years of age [Figure 68-5]). These patients should either undergo complete resection (group I) at

Figure 68-4 Coronal T1 contrast-enhanced magnetic resonance image obtained at presentation in a child with intracranial extension from a pterygopalatine fossa rhabdomyosarcoma.

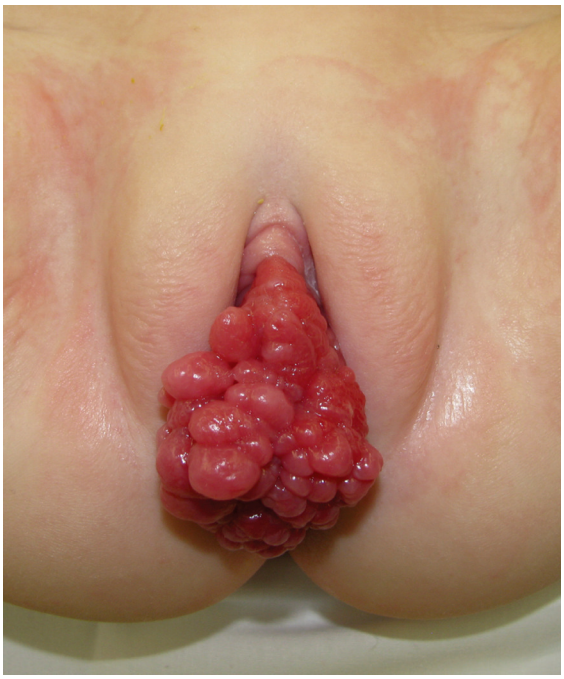

Figure 68-5 Botryoid embryonal rhabdomyosarcoma of the female urogenital tract in an infant.

diagnosis or receive adjuvant RT with either external beam or interstitial and intracavitary techniques. Absent adequate local control, high failure rates have been noted in the most recent low-risk clinical trials, prompting the call for improved local control.[33]

Paratesticular RMS is initially managed with radical inguinal orchiectomy with high ligation of the spermatic cord. RPLND, following a surgical template based on laterality, is conducted for all children 10 years of age or older.[22] Younger patients may still be managed with CT evaluation of their retroperitoneal lymphatics. Treatment of the lymphatic region is based on the discovery of microscopically or grossly involved lymph nodes.

Nonrhabdomyosarcoma Soft-Tissue Sarcoma

The best local tumor control rates are achieved in the context of microscopic disease and, as such, surgical resection—WLE or marginal—should be the goal for every patient presenting with NR-STS, including with metastatic disease. Clear surgical margins, defined as 5 mm or more of normal tissue beyond the tumor, are beneficial in cases in which RT may be avoided. Conversely, the operating surgeon should not proceed with a morbid or disfiguring resection to obtain clear surgical margins because there does not appear to be a significant reduction in local control when adjuvant radiation is delivered.[14] Preoperative RT may be employed in the context of larger (>5 cm) tumors or those deemed difficult to initially resect. This is most commonly combined with neoadjuvant doxorubicin and ifosfamide chemotherapy and given concurrently with ifosfamide chemotherapy to a cumulative dose of 45 Gy to 50.4 Gy at 1.8 Gy daily. Postoperative RT either in the form of external beam irradiation or interstitial brachytherapy may be delivered to the tumor bed after margin negative WLE (for high-grade tumors > 5 cm) or smaller high-grade tumors with involved surgical margins to doses of 55.8 Gy to 63 Gy at 1.8 Gy daily. Outcomes for either of these approaches have yielded excellent local control, with local failure occurring less than 5% of the time.[16]

Techniques

All treatment for pediatric patients with STS should be volumetric imaging based, require target volume and normal tissue delineation, and allow plan evaluation with dose-volume histograms. Conformal, intensity-modulated, and proton beam RT are all acceptable methods of radiation delivery backed by published outcome data from both cooperative group and institutional clinical trials. Patients treated on the D9803 trial with either three-dimensional conformal radiation therapy (3D-CRT) or intensity-modulated radiated therapy (IMRT) demonstrated similar rates of FFS despite superior target coverage by IMRT, and no differences in dose to critical adjacent structures.[49] Initial and postchemotherapy imaging studies are used to define the extent of disease. MRI is essential because CT provides poor soft-tissue definition for evaluating tumor extent. The definitions for gross tumor volume (GTV) and clinical target volume (CTV) are described in Table 68-6 for both RMS and NR-STS. It is important for the radiation oncologists to understand the point of origin or attachment of gross disease, which is often facilitated by examination of the patient and review of imaging at diagnosis. In tumors with an exophytic component such as bladder and prostate or female genitourinary rhabdomyosarcoma, this baseline evaluation will be valuable in helping define the GTV once significant response to chemotherapy occurs. Target volume delineation is anatomically constrained, meaning that the radiation oncologist determines the presumed infiltration of the gross tumor toward adjacent normal tissues when designing the shape of the clinical target volume. Planning volumes are institution, site, and treatment specific (e.g., photons compared to protons), but are typically 3 mm to 5 mm with some form of daily localization (cone-beam CT or fiducials) using photon techniques. Motion may be defined and managed through respiratory gating as necessary.

Treatment planners should consider adjacent normal tissues and weigh the relative risks of site-specific late effects

TABLE 68-6 Target Volume Delineation for Rhabdomyosarcoma and Nonrhabdomyosarcoma Soft-Tissue Sarcomas

	Rhabdomyosarcoma	Nonrhabdomyosarcoma Soft-Tissue Sarcomas
Gross Tumor Volume (GTV)		
Postoperative irradiation	The GTV (more appropriately defined as a CTV) will include the soft-tissue tumor bed and soft tissue contiguous with the tumor prior to surgical resection as defined by physical examination, imaging studies, operative notes, and pathology reports. The tumor bed may have "collapsed" in regions and may no longer have the same shape or extent as the presurgical, prechemotherapy volume. If bone was involved, the GTV includes the margin of bone initially involved with tumor.	Same as defined for rhabdomyosarcoma
Definitive irradiation/ preoperative irradiation	The GTV is defined as the initial tissues in contact with the tumor before therapy and the preirradiation extent of the visible mass, defined by examination and imaging studies before and after chemotherapy and physical examination. Bone involvement warrants targeting the pretherapy extent in bone. Gross residual disease (after an incomplete resection) will be targeted as a definitive irradiation case. Unresected, involved lymph nodes will be included as part of the GTV but may not form one contiguous gross tumor volume depending on tumor and nodal geometry.	Same as defined for rhabdomyosarcoma
Clinical Target Volume (CTV)	The CTV is the GTV with a 1.0-cm anatomically constrained margin of normal tissue accounting for probable pathways of microscopic disease spread. This margin may be reduced (constrained) at fascial planes, bony interfaces, or body cavities based on tumor biology. Nodal involvement is encompassed in the CTV, ideally in a contiguous volume with the GTV.	The CTV is the GTV with a 1.5-cm anatomically constrained margin of normal tissue accounting for probable pathways of microscopic disease spread. This margin may be reduced (constrained) at fascial planes, bony interfaces, or body cavities based on tumor biology. Nodal involvement is encompassed in the CTV, ideally in a contiguous volume with the GTV.

relative to one another. Every effort should be made to deliver the recommended prescribed dose of radiation because doses used in many pediatric malignancies have already been lessened significantly because of concerns of late effects. Parallel-opposed fields should be avoided in nearly all cases to reduce normal tissue exposure to high radiation doses. Even in extremity sites, treatment with circumferential irradiation using an IMRT technique (resulting in low doses to the entire circumference of the extremity as opposed to sparing a strip of skin [Figure 68-6]) has not resulted in clinically documented lymphedema with moderate follow-up.[16]

Interstitial brachytherapy may be used for NR-STS and RMS (less frequently) at the time of surgical resection. Catheters are usually placed into the operative bed transcutaneously while the resection cavity is exposed after removal of the primary tumor. Catheters are spaced at 1-cm intervals and extend 1 cm to 2 cm beyond the known tumor bed. The tumor bed may be marked with surgical clips or other radiopaque markers to define the region to be treated at the time of planning. High-dose-rate brachytherapy is delivered to a dose of 34 Gy at 3.4 Gy twice daily for NR-STS and 21 Gy at 3 Gy twice daily for RMS.

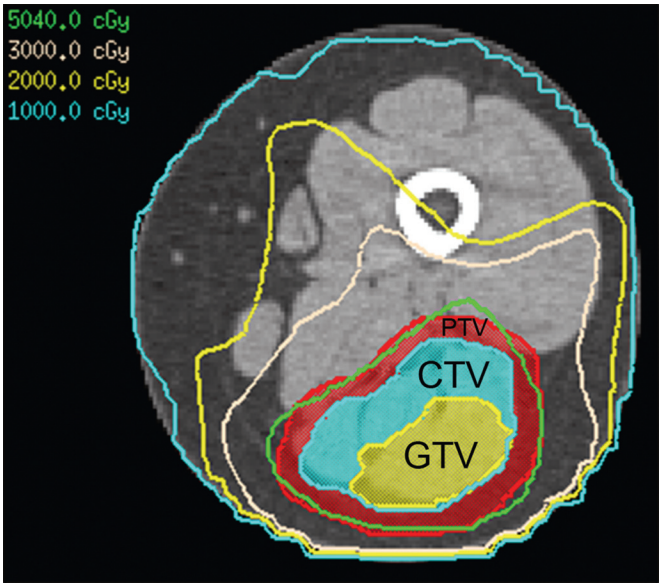

Figure 68-6 Cross-sectional image of an intensity-modulated radiation therapy plan for alveolar rhabdomyosarcoma of an extremity. *CTV,* Clinical target volume; *GTV,* gross target volume; *PTV,* planning target volume.

Timing

Rhabdomyosarcoma

The timing of delivery of radiation to the primary site of disease in patients with localized rhabdomyosarcoma has varied across the IRSG and COG clinical trials over time. Currently, for patients with low-risk disease, RT is performed after 12 weeks of every 3-weeks of chemotherapy. Patients with intermediate-risk disease also receive RT at week 12. Those with parameningeal tumors and evidence of intracranial extension receive RT near the start of treatment, primarily based on evidence of improved outcome for patients with parameningeal sites of disease irradiated earlier in the course of therapy.[42] Cranial nerve palsy and cranial base bony erosion are no longer considered high-risk features mandating early

RT.[50,51] Patients with high-risk disease (metastatic) require aggressive chemotherapy. Local control of the primary sites of disease is conducted at week 20, and metastatic sites of disease are irradiated with similar doses at the end of systemic therapy, unless symptomatic. Vincristine, cyclophosphamide, and irinotecan are given concurrently with RT whereas dactinomycin is held, owing to increased skin and mucosal toxicities.

Nonrhabdomyosarcoma Soft-Tissue Sarcoma

Postoperative RT is delivered 2 weeks or more after resection, allowing for the initiation of wound healing and stabilization of the tumor bed. Adjuvant brachytherapy should be initiated on postoperative day 5 or later to allow for adequate healing. Preoperative chemoradiation on ARST0332 (the most recent COG NR-STS trial) is initiated at week 4 immediately after the second cycle of ifosfamide/doxorubicin chemotherapy.

FUTURE DIRECTIONS

The treatment of children with STS is now well centered in the modern conformal era. All of the benefits of focal, highly conformal, modern RT can be realized in this population when the treating radiation oncologist uses available means to ensure adequate tumor dose delivery and sparing of adjacent normal tissues. The increasing use of proton therapy in the treatment of pediatric cancers will yield further opportunities for research. Cooperative group trials will continue to select patients with low-risk disease for whom radiation can be decreased or eliminated, whereas RT remains a critical component of treatment for intermediate- and high-risk disease. Less favorable populations of patients will be managed with the incorporation of new therapeutic agents to improve overall outcome.

Pediatric radiation oncologists should focus on selection of patients for RT, better delineation of target volumes, including incorporation of functional imaging into the treatment paradigm, and leading the way in understanding radiation-related treatment effects that affect how we deliver RT.

CHAPTER

69 Pediatric Sarcomas of Bone

Nadia Issa Laack

INCIDENCE
The pediatric sarcomas of bone are osteosarcoma (5.6 cases per million children per year) and Ewing's sarcoma (2.8 cases per million children per year).

BIOLOGIC CHARACTERISTICS
Osteosarcoma is associated with inactivation of the retinoblastoma gene. Ewing's sarcoma is characterized by a reciprocal translocation involving breakpoints on the *EWSR1* gene on chromosome 22q12A. The most common chromosomal translocation, t11:22 (q24;q12), is present in 85% to 90% of Ewing's sarcoma.

STAGING EVALUATION
Staging involves determining whether disease is localized or metastatic.

PRIMARY THERAPY
The primary therapy for osteosarcoma is surgical resection and multiagent chemotherapy. The 5-year survival rate is 60% to 70%. Ewing's sarcoma is treated with surgery or radiation therapy, or both, and neoadjuvant and adjuvant multiagent chemotherapy. The 5-year survival rate is 70%.

ADJUVANT THERAPY
For both osteosarcoma and Ewing's sarcoma, neoadjuvant and adjuvant multiagent chemotherapy are used.

ADVANCED DISEASE
Advanced osteosarcoma requires multiagent neoadjuvant and adjuvant chemotherapy, as well as surgical resection of the primary tumor and limited metastatic disease. The 5-year overall survival (OS) rate is 20% to 30%.

Ewing's sarcoma requires multiagent neoadjuvant and adjuvant chemotherapy, radiation therapy, or surgery, or a combination of these treatments for the primary tumor. Metastatic sites require definitive local therapy, most often with radiotherapy. The 5-year OS rate is 10% to 30%.

PALLIATION
Chemotherapy, surgery, or radiation therapy is used for palliation.

Osteosarcoma and Ewing's sarcoma are the two most-common malignant bone tumors in the pediatric and adolescent age-groups. Although osteosarcoma is more common than Ewing's sarcoma, radiotherapy is only used in rare situations. This section, therefore, is devoted largely to the discussion of Ewing's sarcoma. As with all other pediatric malignant diseases, patients should be treated on protocols and in institutions familiar with, and experienced in, the treatment of childhood tumors.

ETIOLOGY AND EPIDEMIOLOGY

In the United States, 650 to 700 children and adolescents younger than 20 years old are diagnosed with bone tumors every year. Ewing sarcoma family of tumors (ESFT) is the rarer of the two with approximately only 200 cases diagnosed each year. The incidence of Ewing's sarcoma is approximately 2.8 cases per million in children younger than 15 years of age.[1] Generally, the disease occurs in the teenage years during the adolescent growth spurt (ages 10 years to 15 years). However, approximately 30% of cases occur in the first decade of life and 30% occur in the third decade. There is a slight male predominance (1.6:1). Genome wide analysis suggests ethnic variations in susceptibility genes associated with Ewing's sarcoma but the strong Caucasian predominance is not completely understood.[2]

The cause of Ewing's sarcoma is unknown, and it does not appear to be induced by any known agents.

Osteosarcoma also is primarily a disease of adolescents and young adults; a different type of osteosarcoma linked to Paget's disease occurs in older adults. This section focuses on osteosarcoma in the younger age-group. Similar to Ewing's sarcoma, the peak incidence coincides with a period of rapid bone growth. Osteosarcoma is known to be associated with retinoblastoma gene mutations as well prior radiation therapy, particularly in children with retinoblastoma or other genetic abnormalities.[3]

PREVENTION AND EARLY DETECTION

The rate of secondary osteosarcomas has decreased with the declining use of radiotherapy in retinoblastoma patients. Some evidence suggests that limiting dose to <60 Gy can reduce risk of secondary osteosarcoma in patients receiving radiotherapy for Ewing's sarcoma. Early detection is possible with careful evaluation of persistent swelling or pain.

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

The histogenesis of Ewing sarcoma is controversial. The tumor was first described as an endothelioma of bone. Another hypothesis suggests Ewing is a primitive cell of neural origin, specifically from postganglionic, parasympathetic, and primordial cells.[4] Most recently, an alternative hypothesis suggests Ewing cells arise from mesenchymal progenitor or mesenchymal stem cells (MSC), which are found in bone marrow.[5] Previously, extraosseous Ewing's sarcoma and malignant peripheral neuroectodermal tumor (PNET) were considered separate entities from Ewing's sarcoma of bone and were treated differently; genetic studies now confirm they

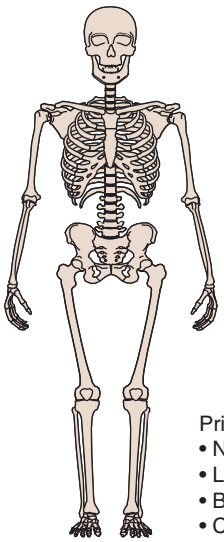

Figure 69-1 Distribution of primary sites and sites of metastases in Ewing's sarcoma.

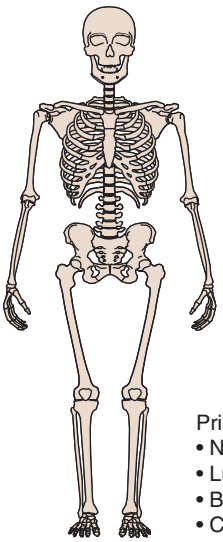

Figure 69-2 Distribution of primary sites and sites of metastases in osteosarcoma.

are from the same family of tumors, and together are termed *Ewing sarcoma family of tumors* (ESFT).[4] All exhibit identical chromosomal translocations, t11:22 (q24;q12), and more than 85% of patients share a common surface antigen, MIC2.[6-8] Ewing's sarcoma, atypical Ewing's sarcoma, and PNET of bone exist in the spectrum within this family, from the most undifferentiated tumors to those with neural differentiation. PNET can be differentiated from Ewing's sarcoma by the presence of a globular growth pattern, neuron-specific enolase (NSE) positivity, and Homer Wright rosettes.

Osteosarcoma is associated with inactivation of the retinoblastoma tumor suppressor gene (13q14), which occurs in approximately one third of cases.[9] Other genetic abnormalities include translocations, gene amplification, and abnormal *TP53* function.[10,11]

PATHOLOGY AND PATHWAY OF SPREAD

Ewing's sarcoma is an undifferentiated blue round cell tumor usually of the bone. Its pathologic appearance is a monomorphic pattern of densely packed, small, round, malignant cells with hyperchromatic nuclei and varying amounts of cytoplasm.[12] Immunohistochemical studies reveal cell-surface glycoprotein p30/32 MIC2 (CD 99) and vimentin, HBA-71, and β_2-microglobulin positivity. Occasionally, cytokeratin and NSE are positive. These studies can help differentiate ESFT from other small round cell malignant tumors of childhood. Approximately 87% of cases within the ESFT are Ewing's sarcoma of bone.[13] The remainder is PNETs or extraosseous Ewing's sarcoma.

About 75 % percent of patients with Ewing's sarcoma present with localized disease at diagnosis (Figure 69-1). Approximately 80% of children experience distant metastases if treated with only local therapy. This suggests that in the majority of cases, there are unidentifiable micrometastases present at diagnosis. The most common site of metastasis is the lung, followed by bone. Other distant sites include bone marrow, soft tissues, and rarely, the liver or central nervous system (Figure 69-1).

Osteosarcoma is derived from bone-forming mesenchyme and is described as a malignant sarcomatous stroma associated with the production of osteoid bone, its defining histopathologic feature.[12] The most common types in the pediatric population are the conventional osteosarcomas, including osteoblastic, chondroblastic, and fibroblastic types. Each type has varying amounts of osteoid formation and a different predominant component. There is no difference in outcome or treatment recommendations among these different types. Other types of less common osteosarcomas include telangiectatic, small cell, juxtacortical, periosteal, and high-grade surface sarcomas.

Approximately 90% of children with osteosarcoma present with localized disease at diagnosis (Figure 69-2). However, if only the primary tumor is treated, about 90% will experience metastatic disease.[12]

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Patients with Ewing's sarcoma present in general with localized pain, swelling, and a palpable mass. The most common primary tumor sites are illustrated in Figure 69-1. In Ewing's sarcoma, plain radiographs show a lytic, destructive lesion, most typically of the diaphysis, with or without a soft-tissue mass. Codman's triangle may form from the elevated periosteal reaction. An "onion skin" effect, derived from the development of parallel, multilaminar, periosteal reactions, is typically seen.

Patients with osteosarcoma present with similar signs and symptoms, in general, localized pain, swelling, and a palpable mass. The frequency with which osteosarcoma occurs within the different regions of the body is illustrated in Figure 69-2. Plain radiographs of patients with osteosarcoma typically show sclerotic or lytic lesions of the metaphysis. The elevated periosteal reaction may cause Codman's triangle to form. In osteosarcoma, periosteal new bone formation may be present, with the blastic component showing a bony sunburst pattern.

The evaluation for patients with Ewing's sarcoma and osteosarcoma is similar. A complete history and physical examination are performed, with particular attention to the duration of symptoms, the presence of pain, difficulty of function, neurologic symptoms, and the location and size of the mass. Studies commonly obtained to evaluate the extent of disease include routine blood work, urine analysis, bone scanning, plain radiographs, and computed tomography (CT) scanning or magnetic

TABLE 69-1 Staging Investigations at Diagnosis in Osteosarcoma and Ewing's Sarcoma

Investigation	Diagnosis	Follow-up

resonance imaging (MRI) of the primary region. A chest CT scan should be obtained to rule out lung metastases. If the chest radiograph is negative and the CT scan is positive for subtle anomalies, an excision may be needed for accurate staging and treatment recommendations. Single-institution and small multiinstitutional studies suggest fluorodeoxyglucose-positron emission tomography (FDG-PET) has improved sensitivity to bone and lymph node metastases compared to bone scan and CT.[14] An electrocardiogram and echocardiogram are included in the evaluation before chemotherapy is initiated. In the case of Ewing's sarcoma, a bone marrow biopsy is obtained. A summary of staging and follow up investigations is given in Table 69-1.

A biopsy of the primary lesion should be obtained after complete evaluation, ideally by the surgeon who will perform the definitive resection. The biopsy should be placed carefully to avoid contamination of uninvolved areas, vital structures, and hematoma development. It must not increase the extent of surgery or preclude a limb-sparing procedure or sparing of a strip of skin outside the radiation port.

Currently, there is no staging system for Ewing's sarcoma. Patients are classified as having either localized disease or metastatic disease and are treated accordingly.

In osteosarcoma, available staging systems are those of the Musculoskeletal Tumor Society and, lately, of the International Union Against Cancer and American Joint Committee on Cancer (UICC/AJCC).[15,16]

The prognosis for patients with Ewing's sarcoma is dependent on a number of factors, the most important of which is the presence or absence of metastatic disease. Data from European studies suggest histologic response to chemotherapy is the primary predictor of outcome in patients undergoing surgery.[17] This has yet to be confirmed in North American regimens although single-institution reports suggest response correlates with improved survival (Ahmed). Historically, other prognostic factors include the site of the lesion and its size and age and gender of the patient. In more recent studies, data is conflicting with no association of outcome with site or size reported in INT-154, a Children's Oncology Group (COG) study evaluating dose-intense multiagent chemotherapy.[18] However, on the recently reported COG AEWS0031 evaluating interval-compressed multiagent chemotherapy, pelvic site was associated with inferior event-free survival (EFS) and OS.[19] The French study EW93 reported poorer outcomes in axial and pelvic tumor as well as large tumor volumes, however, prognostic factors varied by type of local therapy. For surgical patients, location and histologic response correlated with survival. For radiotherapy patients, tumor volume remained significant but site did not.[17] Historically, older patients and male gender was also associated with poor survival. When accounting for histologic response in more recent studies, age and gender have not remained significant.[17] Age older than 18 was associated with poorer survival in the most recent COG study reported (AEWS0031) but histologic response was not assessed in this study.[19] Multiple retrospective studies suggest molecular biomarkers such as *p53* and *p16* may correlate with outcomes, however, prospective validation has not confirmed these findings.[20]

The prognostic features of osteosarcoma are similar, namely, the presence or absence of metastatic disease, the tumor location and size, whether complete resection of the primary tumor was possible, and the response to adjuvant chemotherapy.[21] No molecular markers have been validated in osteosarcoma.

TREATMENT OF EWING'S SARCOMA

Primary Therapy

Historically, patients with Ewing's sarcoma received treatment to the primary lesion only; cure rates were less than 20%. In the early 1960s, single-institution studies began to show an improved outcome with the addition of adjuvant chemotherapy.[22-24] Today, the standard treatment consists of local therapy and neoadjuvant and adjuvant polychemotherapy. Local therapy consists of surgery or radiotherapy or a combination of both. Concerning systemic therapy, a number of randomized trials have been performed to assess the value of different drug combinations.

The first Intergroup Ewing Sarcoma Study (IESS) investigated the use of polychemotherapy from 1973 until 1978. Patients received radiation therapy to the primary lesion and were randomized among three adjuvant chemotherapy treatment arms: vincristine, actinomycin D, and cyclophosphamide (VAC); VAC plus doxorubicin (trade name Adriamycin, so the regimen is known as VACA); or VAC plus bilateral pulmonary radiation therapy.[25] This study showed a significant improvement in all parameters with the addition of doxorubicin. Furthermore, VAC plus bilateral lung irradiation, although less effective than VACA, showed superior results to VAC alone. As a consequence of these results, doxorubicin was considered to be an essential drug in further trials.[26]

The third large intergoup study, INT-0091, investigated the addition of etoposide and ifosfamide to VACA; at 5 years, data showed a statistically significant benefit from the addition of these two drugs. In addition, local control was also significantly improved in patients on the experimental arm.[27] In the European Cooperative Intergroup Ewing Sarcoma Study EICESS-92, the value of the single agents was evaluated. In standard-risk patients (localized disease and tumor volume of <100 mL), VACA was randomized against VAIA (ifosfamide instead of cyclophosphamide). There was no significant difference in EFS rates between the groups. In high-risk patients (larger tumors or metastatic disease), VAIA was randomized

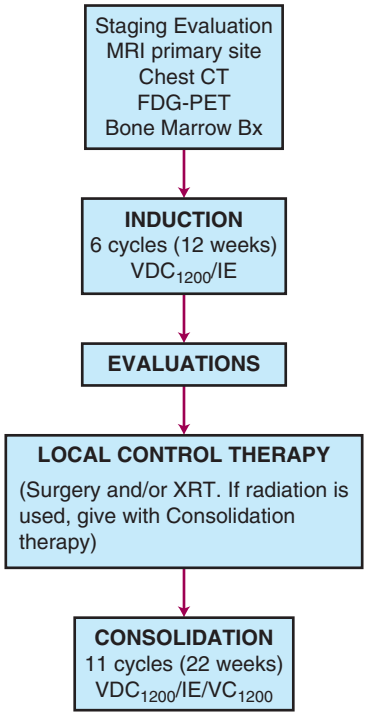

Figure 69-3 Treatment schema. *CT*, Computed tomography; *FDG-PET*, fluorodeoxyglucose-positron emission tomography; *IE*, ifosfamide-etoposide; *MRI*, magnetic resonance imaging; VC1200, vincristine-cyclophosphamide 1200 mg; VDC1200, vincristine-doxorubicin-cyclophosphamide 1200 mg; *XRT*, radiation therapy.

against VAIA plus etoposide; again, no significant difference in EFS rates was observed, but a marginal benefit was demonstrated for patients with large localized disease with the use of etoposide.[28] The most recently reported COG trial, AEWS0031, comparing vincristine, doxorubicin, cyclophosphamide, ifosfamide-etoposide (VDC-IE) dosed every 3 weeks versus every 2 weeks showed an 8% 5-year EFS benefit for interval compressed chemotherapy. This regimen remains the current standard in the United States.[19] Figure 69-3 depicts the most common treatment schema in North America. An alternative for treatment intensification used more commonly in European studies has been high-dose chemotherapy with stem cell rescue.[29] Because of its toxicity, this treatment is mainly used for very high-risk patients. In the Euro-EWING 99 trial, patients with poor pathologic response were randomized to either high-dose chemotherapy with busulfan or conventional therapy with vincristine, ifosfamide, doxorubicin, and etoposide (VIDE) give every 3 weeks. For patients with lung metastases only, high-dose chemotherapy with busulfan was compared to conventional chemotherapy and whole-lung irradiation with 15 Gy or 18 Gy, depending on the age of the patient. Results of this trial are still pending for localized patients. The results for patients with metastatic disease are discussed in this chapter.

A summary of results of different Phase III trials is given in Table 69-2.

Advanced Disease and Palliation

Children with metastatic Ewing's sarcoma at diagnosis continue to have a poor outcome despite the use of aggressive multiagent chemotherapy. The European approach in these patients is to intensify adjuvant and neoadjuvant chemotherapy using high-dose chemotherapy with busulfan or etoposide or treosulfan, and melphalan with autologous stem-cell rescue for patients with bone metastases. EuroEwing99 results using six cycles of VIDE followed by one cycle VID then local therapy. Patients then went onto high-dose busulfan and melphalan followed by stem cell rescue. Overall 3-year EFS and OS were 27% and 34%, respectively.[29] Patients with lung metastases only appear to be a more favorable subset of metastatic patients. European studies have used risk adapted strategies that are intermediate intensity compared to localized and bone metastases patients. Standard chemotherapy with whole-lung radiation has shown favorable results in the Cooperative Ewing Sarcoma Studies (CESS) and European Intergroup Cooperative Ewing Sarcoma Studies (EICESS) trials in comparison to patient with lung metastases only who did not receive whole lung radiation (5-year EFS 40% and 19%, respectively).[30] The EuroEwing99 pulmonary metastases arm evaluated the use of standard chemotherapy with whole-lung irradiation compared to high-dose chemotherapy with stem-cell rescue. The results are still pending. In the United States, metastatic patients were included on the intergroup study INT-0091 evaluating the addition of Ifosphamide/Etoposide (IE). The addition of IE did not result in and improvement in survival (5-year EFS 22%) for metastatic patients.[27] Interval compression was not evaluated in metastatic Ewing's sarcoma, however, because of the favorable results in localized patients it has been adopted for use in metastatic disease as well. In the upcoming COG study, AEWS1221, which will include all metastatic sites, interval compressed VDC-IE chemotherapy with whole lung radiation for lung metastasis patients will be the standard arm reflecting current clinical practice in the United States. Definitive treatment of metastatic sites appears to improve outcomes in metastatic Ewing's sarcoma. Definitive local treatment with surgery or radiotherapy is recommended on the upcoming COG AEWS1221 trial that is also evaluating the role of stereotactic body radiotherapy (SBRT) for bone lesions to improve feasibility of treatment. Even in patients in whom definitive local treatment of all metastatic sites is not feasible, radiation therapy can be used as a palliative local measure.

Local Therapy

Local therapy is an essential modality in the treatment of Ewing's sarcoma. With systemic therapy alone, cure cannot be obtained. Local control on modern COG studies is close to 90%. The modality of local therapy with best local control rates and functional outcome has been a matter of debate for some time. Retrospective analyses of cooperative group studies suggest that local control is improved when surgery is performed although a selection bias for more favorable tumor likely exists confounding these analyses.[31-34] Regardless of differences in efficacy, because of the risk of secondary malignancy associated with radiation, surgery is generally the recommended treatment when an oncologic resection can be obtained with acceptable morbidity. However, because Ewing's sarcoma is radiosensitive and radiotherapy is curative, radiotherapy is recommended for tumors that cannot be resected without significant morbidity. In United States, 60% to 65% of patients are treated with surgery alone, 20% to 25% are treated with radiation alone, and the remainder receives a combination of both. European studies report slightly higher rates of radiation and surgery and lower rates of surgery alone reflective of the risk-adapted approach used for higher risk tumors.[35-38] Patients on EuroEwing99 received preoperative radiation when margins were expected to be close with surgical resection and received postoperative radiation for poor histologic response.

Definitive Radiotherapy

Patients who receive radiotherapy as the only local therapy modality usually represent an unfavorably selected group of patients. They frequently present with large tumors or tumors in unfavorable locations (e.g., vertebral or pelvic tumors). In an analysis of 1058 patients with localized Ewing's sarcoma treated in the EICESS trials, 266 patients received radiotherapy alone for local treatment. Local or combined local and systemic failures in this subgroup occurred in 26% of patients, a recurrence rate that was worse than the rate following surgery with or without radiotherapy (4% to 10%).[33,34]

Bacci et al[39] performed a single-institution analysis of 512 patients treated in four consecutive trials. Treatment results in patients who received radiotherapy alone were worse than in patients who underwent surgery (local failure rates of 19% with radiotherapy alone, 11% with surgery and radiotherapy, and 9% with surgery alone). When analyzed by tumor site, radiotherapy alone was unfavorable in extremity sites but not in central tumor sites suggesting central tumor sites are problematic for surgical local control as well. Similar results were seen in a retrospective analysis of COG INT-0091 evaluating local control for pelvic tumors only. Overall local failure was 22% with no difference between surgery and radiation. Although not statistically significant, outcomes were improved in patients who received combination of surgery and radiotherapy as opposed to either surgery or radiotherapy alone (25% versus 10%, $p = 0.45$). Patients on the experimental arm (receiving IE chemotherapy) had improved local control with only 11% local failure rate for all patients.[38a]

Definitive radiotherapy is indicated is surgery is expected to leave gross disease (R2 resection). Debulking procedures do not improve local control rates and are associated with unnecessary morbidity. In the CESS and EICESS trials[33,34] and in the Bologna experience by Bacci et al,[39] patients who had intralesional resection followed by radiotherapy had the same local control rate as patients who had radiotherapy alone.

Postoperative Radiotherapy

Postoperative radiotherapy is always indicated following intralesional resections. These debulking procedures are not sufficient to obtain local control and should be avoided. Oncologic resection in Ewing's sarcoma has historically been defined by the Enneking classification.[15] Enneking et al reporting on outcomes in soft-tissue sarcoma described local failure rates of 50% for marginal resections (tumor was shelled out within the surrounding reactive zone), 25% after wide resection (resection passed through normal tissue outside the reactive zone but within the anatomical compartment), and 4% after radical excision (entire compartment resected). Although wide excisions are generally felt to ideal if possible with reasonable morbidity, with improvements in systemic chemotherapy modern surgeries are more accurately described as wide excisions. Historically COG trials recommend postoperative radiotherapy after close margins defined as margins <1 cm bone, <5 mm in muscle, and <2 mm along a fascial plane. Local control after surgery alone is approximately 90% on these studies.[18,19] In the CESS and EICESS trials, local control with surgery alone was excellent in all patients who had a wide resection according to the Enneking classification and showed a good response on histologic testing following initial chemotherapy (defined as <10% viable tumor cells in the resected specimen).[40] Only one local failure in 101 patients occurred in this subgroup. Patients with wide resection and a poor histologic testing response were at higher risk of local failure (12%). This local failure rate was improved with the use of postoperative radiotherapy (6%).[33] There was also a trend toward benefit with the use of postoperative irradiation in patients who had a marginal resection. Bacci et al[39] observed no improvement with postoperative radiotherapy following wide or marginal resection (local failure rate of 7% without postoperative radiotherapy and 6% with postoperative radiotherapy). Based on the importance of histologic response in local control reported in European studies, the current COG trial (AEWS1031) is evaluating the possibility of limiting postoperative radiotherapy after close margins (less than Enneking but still negative or R0 resections) to patients with poor histologic responses. Postoperative radiotherapy is still required for microscopic positive (R1 resection) margins.

Preoperative Radiotherapy

The systematic use of preoperative radiotherapy was incorporated into the EICESS-92 trial. The governing objective was to sterilize the tumor compartment before surgery and thereby potentially reduce the rate of dissemination during surgery. With growing experience with the use of preoperative radiotherapy, it was used in this trial when narrow resection margins were expected. More than 40% of the EICESS patients were treated with preoperative radiotherapy. In an analysis of the data from these 246 patients, however, a reduction in systemic failure could not be demonstrated.[33] On the other hand, the local control rate following preoperative radiotherapy was excellent, with only 5% of the patients experiencing local or combined local and systemic failures. However, preoperative irradiation may increase the infection rate postoperatively and may also interfere with bony union. In North America, preoperative radiotherapy remains fairly uncommon in Ewing's sarcoma for this reason.

Irradiation Techniques and Tolerance

Radiation Dose and Fractionation

The first Intergroup Ewing Sarcoma Study (IESS-I) evaluated the effect of dose on local control and showed no dose response between 30 Gy and 65 Gy. Single-institution report of the St. Jude experience showed higher rates of local recurrence in children treated with doses <40 Gy with no local failures using >40 Gy.[37] Although a clear dose-response correlation at doses above 40 Gy has not been established for definitive radiotherapy, doses between 55 Gy and 60 Gy are usually given. When surgery precedes or follows radiotherapy, the doses range between 45 Gy and 55 Gy, depending on the individual risk factors (e.g., resection margins and response). The current COG study (AEWS1031) recommends 45 Gy to prechemotherapy target volume, 55.8 Gy to postchemotherapy residual disease, and 50.4 Gy for microscopic positive margins postoperatively.

Usually, conventional fractionation with daily fractions of 1.8 Gy to 2 Gy is given. In the CESS-86 and EICESS-92 trials, hyperfractionated radiotherapy with a twice-daily dose of 1.6 Gy was also applied; after a total of 22.4 Gy had been given, a 10-day break was scheduled to permit the administration of chemotherapy. There has been no difference in local control rates between the two different fractionation groups.[40]

Target Volume

In terms of volume, previous treatment recommendations were to include the entire bone. The Pediatric Oncology Group (POG) series and other series confirmed that local failures occur generally within the high-dose irradiation volume.[38] In a randomized trial, the treatment of the whole tumor-bearing compartment showed no better results than irradiation to the tumor and an additional safety margin.[41] With reliance on MRI for target volume delineation, margins have been reduced successfully on the most recent COG studies without increase in local failure.[18] Current COG recommendations include all

T1-gadolinium enhancing tumor, all T2 signal abnormality, and all bone abnormalities to be included in the prechemotherapy gross target volume (GTV). Prechemotherapy clinical target volume (CTV) is a 1-cm expansion of this volume. Prechemotherapy GTV and CTV can be modified for pushing, noninfiltrative, borders such as paraspinal tumors pushing into the abdominal cavity or lungs that have receded after induction chemotherapy and can be modified to be restricted to fascial planes if there is no evidence of infiltration. Postchemotherapy GTV includes residual soft-tissue mass after induction chemotherapy as well as all bone abnormality present prechemotherapy. Postchemotherapy CTV is a 1-cm expansion of GTV modified for anatomic pushing borders and limited to fascial planes if there is no evidence of infiltration. Planning target volumes (PTVs) are a 0.5-cm to 1-cm expansion on CTV depending on tumor location and daily image-guidance available at the institution. Surgically contaminated areas, scars, and drainage sites must be included in the radiation fields. Circumferential irradiation of extremities should be avoided to reduce the risk of lymphedema. In growing children, growth plates must be considered. They should either be fully included in the radiation field up to 30 Gy, or they should not be included at all. A dose gradient through the epiphysis results in asymmetric growth and may lead to functional deficits. Similarly, vertebral bodies should either be fully included or spared from the radiation field. Three-dimensional conformal radiotherapy should be given in patients with Ewing's sarcoma. In selected cases (i.e., in vertebral tumors), intensity-modulated radiotherapy (IMRT) or proton therapy may be beneficial. Figures 69-4 to 69-6 show an example of treatment planning.

Irradiation of Lung Metastases

The benefit of lung irradiation in Ewing's sarcoma tumors has been shown in the randomized IESS-I trial.[25] In patients without radiologic evidence of metastases (in the era before CT became available), the best results were observed with

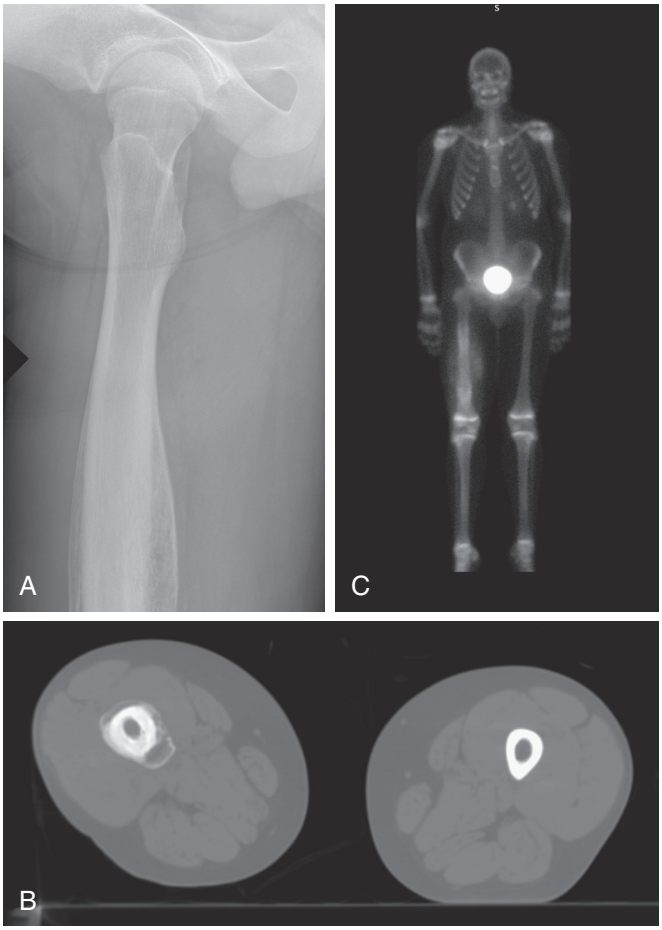

Figure 69-4 **A,** Plain radiograph; **B,** axial CT; and **C,** 99mTc bone scan of Ewing's sarcoma of right femur.

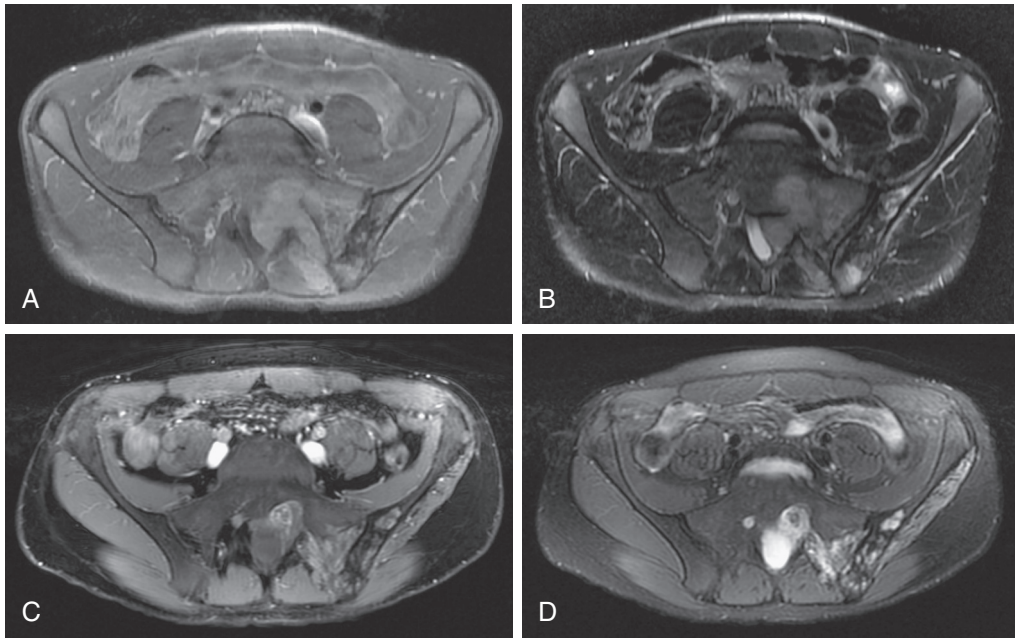

Figure 69-5 **A,** Pretreatment axial contrast-enhanced T1 MRI of a Ewing sarcoma located in the pelvis. **B,** Pretreatment axial T2 MRI of a Ewing's sarcoma located in the pelvis. **C,** Postinduction axial contrast-enhanced T1 MRI of a Ewing's sarcoma located in the pelvis. **D,** Postinduction axial T2 magnetic resonance imaging of a Ewing's sarcoma located in the pelvis.

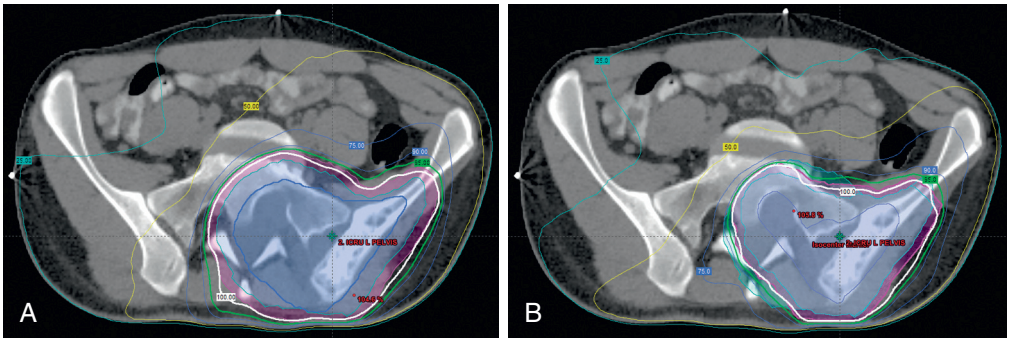

Figure 69-6 **A,** Dose distribution resulting from computed tomography (CT)-based intensity modulated radiotherapy treatment following induction chemotherapy for prechemotherapy planning target volume (PTV) receiving 45 Gy. **B,** Dose distribution resulting from CT-based intensity-modulated radiotherapy treatment following induction chemotherapy for postchemotherapy PTV receiving 10.8 Gy boost.

VACA, although VAC plus lung irradiation was significantly better than VAC alone. In an analysis of the EICESS-92 trial, patients with lung metastases alone showed a trend toward a better outcome with the use of radiotherapy.[42] The recommended dose is 15 Gy to 20 Gy in 1.5-Gy daily fractions. Opposing radiation portals should include both lungs down to the diaphragmatic recess. When possible, breath-hold treatment (treatment in deep inspiration) should be used to help to reduce the volume of irradiated liver, stomach, and upper kidneys. The inferior extent of the lung recesses is not well-seen on conventional or four-dimensional CT. If treatment cannot be performed with breath-hold technique, fluoroscopic evaluation or deep inspiration lateral chest x-ray should be used to define the inferior lung border. Doxorubicin and actinomycin D must not be given during whole-lung radiotherapy because of the increased risk of pneumonitis, and actinomycin D should also be avoided after lung irradiation because of the risk of recall pneumonitis. Lung radiotherapy is therefore best given after completion of conventional chemotherapy. Lung irradiation is not given in the context of a busulfan-containing regimen as a result of risk of significant lung toxicity.

Radiation Therapy of Bone Metastases

Radiotherapy is indicated in patients presenting with bone metastases. In an analysis of metastatic patients treated in the EURO-EWING 99 trial, there was a significant improvement in the 3-year EFS rate in patients who received local therapy to the primary tumor and to all metastatic sites compared with patients who received local therapy to the primary tumor only or no local therapy at all (39% versus 17% versus 14%).[43] In a multivariate analysis that considered patient age, volume of the primary tumor, number of bone metastases, type of therapy (i.e., high-dose chemotherapy and local therapy to the primary tumor or to extrapulmonary metastases), significant factors associated with a poor prognosis were no local therapy to the primary tumor or extrapulmonary metastases and no high-dose chemotherapy. When bone metastases are few, definitive radiotherapy can be given to all initially involved sites. Irradiation of more than 50% of the estimated bone marrow volume can result in significant myelosuppression may interfere with ability to administer the remaining chemotherapy. Therefore, in patients presenting with multiple bone metastases that preclude irradiation of all sites at the time of local therapy, radiotherapy can be either be administered at the end of therapy or may need to be selectively administered to bulky regions, lesions showing slow response to initial therapy (PET residual at the time of local therapy), or lesions with residual PET avidity at the end of therapy. Following high-dose busulfan therapy, two cases of myelopathy have been reported with the application of 50 Gy in conventional fractionation to vertebral sites. In this context, a dose reduction is necessary.

TREATMENT OF OSTEOSARCOMA

Primary Therapy

The overall current recommended approach to treatment of osteosarcoma is surgical resection of the primary tumor either by amputation or a limb-sparing procedure. Local treatment is preceded by neoadjuvant chemotherapy and followed by postoperative chemotherapy. Single-institution studies showed an improvement in OS rates among patients receiving adjuvant chemotherapy compared with historic controls.[20,44,45] Two prospective, randomized studies confirmed this, one at the University of California Los Angeles and one national multiinstitution study.[46,47] Currently, the initial chemotherapeutic agents used include methotrexate, cisplatin, doxorubicin, and ifosfamide. Pathologic response (tumor necrosis greater than 90%) is associated with improved survival in osteosarcoma.[19,20] If the primary tumor shows only minimal response to neoadjuvant chemotherapy, many believe the chemotherapy agents should be altered for the postoperative therapy, but this has not been proven. Currently, between 60% and 70% of patients with localized osteosarcoma are cured.

Because of the radioresistant nature of these tumors, radiotherapy has a limited role in osteosarcoma. Definitive irradiation is used in patients in whom complete surgical resection cannot be obtained as adjuvant therapy for close or positive margins and for palliation in patients with inoperable metastases.

Local Therapy

Surgery is the mainstay of local treatment of osteosarcoma. Surgical resection is performed either by amputation or a limb-sparing approach and has a 5% local failure rate. Although not well studied and rarely used, the addition of radiation therapy in limb-sparing approaches is a possibility and can be considered in special circumstances. Osteosarcoma is usually considered to be a radioresistant tumor. In vitro studies, however, show that it has a radiosensitivity similar to that of other human tumor cell lines.[48] Also, there have been case reports of patients with inoperable or residual tumor treated with radiation doses ranging between 50 Gy and 70 Gy who remained in continuous remission.[49] In an analysis of patients with osteosarcoma refusing surgery but receiving systemic therapy and local irradiation, the local progression-free survival rate at 5 years was 56%.[50] The survival rate was about

90% at 5 years in the subgroup of irradiated patients responding to chemotherapy. DeLaney et al reported on 41 patients with osteosarcoma who received radiotherapy with no surgery or close or positive resection margins. The respective local control rates at 5 years were 40%, 78%, and 78%, respectively.[51] Median dose was 66 Gy although doses as high as 80 Gy were used for gross disease. Because of the often unfavorable site of these tumors, 56% of patients received some or all of their treatment with proton radiotherapy. Recent reports suggest a benefit for heavier particle therapy in unresectable osteosarcoma. In a retrospective review of 78 patients with unresectable axial osteosarcoma treated with carbon ion radiotherapy, local control was 62% at 5 years and 88% for smaller tumors (<500 mL). Treatment was hypofractionated and patients received a median of 70.4 CGE in 16 fractions over 4 weeks. Although surgery is the local treatment of choice, cure can also be achieved with irradiation in inoperable tumors or patients refusing surgery.[52]

Advanced Disease and Palliation

The overall approach to metastatic disease with osteosarcoma is with multiagent chemotherapy. The overall prognosis depends on the location and number of metastases, whether complete surgical resection of all tumor tissue was possible, and the response to chemotherapy.[53,54] Patients with metastasis only in the lung or a limited number of metastases who can undergo complete surgical resection fare better; the 3-year survival rate is approximately 50%, compared with 20% to 30% for more advanced disease.

Radiation therapy to the lungs for metastases, when appropriate, can be given to a dose of 15 Gy to 20 Gy to the whole lung. The use of whole-lung radiation therapy in the setting of metastatic disease is controversial. Whole-lung radiation therapy as prophylaxis against metastatic disease is also controversial and is usually not recommended. Randomized trials of the European Organization for Research and Treatment of Cancer (EORTC) showed that prophylactic whole-lung radiation therapy compared well with chemotherapy.[55] However, no benefit was shown in the U.S. studies.[56]

Radiation therapy may be incorporated into the treatment of osseous metastatic sites not amenable to surgical resection. In an analysis of the prognosis of relapsing patients treated in the Cooperative Osteosarcoma Study Group (COSS) trials, results were best when metastases could be surgically removed. Radiotherapy of inoperable sites, though, was associated with an improved survival rate compared with that of patients who received no local therapy.[57]

The use of samarium-153 (^{153}Sm) ethylenediaminetetramethylene phosphonic acid (^{153}Sm-EDTMP) therapy has been investigated in unresectable osteosarcoma (for the primary tumor and metastases). This therapeutic beta-emitting isotope, which also emits a gamma photon to permit imaging and dosimetry, localizes to osteoblastic lesions with very high tumor to nontumor ratios.[58] Although it is not yet possible to make any definitive statements about the long-term efficacy of this treatment modality, a multimodal concept of high-activity ^{153}Sm-EDTMP in combination with external beam radiation therapy, polychemotherapy, and autologous hematopoietic progenitor cell support for unresectable osteosarcoma seems to be promising.[59,60]

It is therefore reasonable to offer radiation therapy in the treatment of osteosarcoma for (1) unresectable primary tumors or following incomplete resection, (2) patients who refuse surgery, and (3) unresectable metastatic tumors. The recommendation is to treat the tumor to the highest tolerable dose based on the surrounding structures, using a shrinking-field technique.

Treatment Planning Techniques

The treatment planning techniques used for osteosarcoma of the extremities and other sites are similar to those described for the treatment of Ewing's sarcoma.

FUTURE POSSIBILITIES AND CHALLENGES

Future challenges include maintaining a good outcome in patients with localized disease while decreasing treatment toxicity and increasing organ functionality. For patients with metastatic disease and for poor responders, the challenge is to improve the outcome. Pathologic response for patients who undergo surgery appears to be associated with survival outcomes but a reliable prognostic factor for nonsurgical patients is not available as yet. FDG^{18} PET-CT as a predictor of response is being evaluated on the currently open COG AEWS1031. Risk-adapted treatment based primarily on baseline characteristics and pathologic response when available is being evaluated in European studies but because of perceived lack of effective alternative treatment for poor responders has not been adopted in North America. Future possibilities include identifying new active agents based on molecular profiling of tumors and a better understanding of mechanism of oncogenesis.

New radiation therapy approaches to the treatment of pediatric bone sarcomas include the use of smaller margins and more conformal techniques such as intensity-modulation therapy and proton or heavy ion therapy.[51,52] Risk-adapted dose and volume constraints are being evaluated in the currently open COG AEWS1031 study for postoperative patients based on pathologic response. Risk-adapted dose and volume strategies for definitive radiotherapy patients also await validated results with noninvasive imaging such as FDG^{18}-PET.

CHAPTER

70 Wilms' Tumor

John A. Kalapurakal and Jeffrey S. Dome

INCIDENCE

Renal tumors are the fifth-most common cancer in children younger than 15 years of age. It is estimated that 7.1 per million children are affected, and 500 new cases are reported each year in the United States. The median age at presentation is 3.5 years.

HISTOLOGY OF PEDIATRIC RENAL TUMORS

Favorable histology Wilms' tumor: 80% to 85%
Anaplastic Wilms' tumor: 5% to 8%
Renal cell carcinoma: 5% to 8%
Clear cell sarcoma of the kidney: 2% to 3%
Rhabdoid tumor of the kidney: 1% to 2%
Mesoblastic nephroma: 1% to 2%

BIOLOGIC CHARACTERISTICS

WT1 (11p13), *WT2* (11p15), and genes in the WNT signaling pathway (WTX and β-catenin) are implicated in the development of Wilms' tumor. Loss of heterozygosity (LOH) at 1p and 16q and gain of chromosome 1q are associated with higher relapse rates. Children's Oncology Group (COG) protocols include LOH results in addition to tumor stage and histology for risk stratification.

STAGING EVALUATION

Staging requires a patient history, physical examination, complete blood cell count, hepatic and renal serum chemistries, urinalysis, chest computed tomography (CT), abdominal and pelvic CT or magnetic resonance imaging (MRI), and abdominal ultrasonography if the renal vein and inferior vena cava are not well visualized by cross sectional imaging.

PRIMARY THERAPY

Surgical resection (nephrectomy, tumor resection, and staging) is the primary therapy for this tumor in the United States. Preoperative chemotherapy is routinely used in Europe.

ADJUVANT THERAPY

National Wilms Tumor Study Group (NWTS) studies show vincristine and dactinomycin result in excellent cure rates for patients with localized (stages I and II) Wilms' tumor of favorable histology. Radiation therapy (RT) and doxorubicin are added for advanced local or metastatic disease (stages III and IV).

The recently completed COG protocol augmented chemotherapy for patients with LOH at 1p and 16q.

Chemotherapy is also intensified for focal and diffuse anaplastic Wilms' tumor, clear cell sarcoma of the kidney (CCSK), and rhabdoid tumor of the kidney (RTK).

The flank or abdominal radiation dose is 10.8 Gy. Higher doses are recommended in patients with gross residual tissue or for stage III anaplastic tumors and RTK (19.8).

RETRIEVAL THERAPY

Retrieval therapy is based on original stage, prior treatment, and sites of relapse and includes surgery, RT, and intensive multiple-agent chemotherapy with or without stem-cell transplantation.

Wilms' tumor, or nephroblastoma, is the most common childhood renal tumor, accounting for about 6% of pediatric malignant diseases.[1] It was first described in 1814, but Max Wilms first identified the true nature of the condition as a neoplasm with mixed cellular elements in 1899.[2] His name has become synonymous with nephroblastoma. The early advances in managing these small patients with huge tumors were made by surgeons, who reduced the operative mortality from 25% to the current rate of less than 1%. The survival of children with Wilms' tumor gradually increased from less than 10% to about 50% by the 1940s and 1950s. Postoperative RT became routine after results from Boston Children's Hospital documented an increased cure rate. The advent of effective chemotherapy (dactinomycin and vincristine) also had an impact on the survival of these children.[3] The systematic development of multidisciplinary management for Wilms' tumor resulted in a striking improvement in survival. Thus, the grim outlook at the beginning of the 20th century (90% mortality rate) has effectively inversed to a survival rate of 90% in the early 21st century. Randomized clinical trials in North America under the aegis of the NWTS and those in Europe, largely by the International Society of Pediatric Oncology (SIOP), have resulted in Wilms' tumor therapy becoming a paradigm for successful multidisciplinary integration in the treatment of cancer. Successive NWTS clinical trials have been based on postoperative therapies, whereas preoperative strategies have been the focus of SIOP investigators.[4]

Clinical risk factors such as tumor stage and histology were identified so that treatment could be modulated in intensity according to risk groups, the objective being to achieve cure with minimum complications. As a result, children with low-risk tumors now receive minimal therapy whereas those at high risk benefit from more intensive therapy. The modern survivors of Wilms' tumor enjoy a better quality of life owing to sequential reductions in the intensity of therapy.[5] Current Wilms' tumor studies in the United States and Canada are conducted by the COG.

ETIOLOGY AND EPIDEMIOLOGY

The cause of Wilms' tumor is unknown. The peak incidence is between 3 and 4 years of age. Wilms' tumor may arise as sporadic or hereditary tumors or in the setting of specific genetic disorders. The overall annual incidence of Wilms'

tumor is 7.1 per million children, and approximately 500 new cases can be expected each year in North America. Wilms' tumor is found more often in black than in white children, with a ratio of 1.25:1. Girls are affected more than boys in the same ratio.[1]

PREVENTION AND EARLY DETECTION

Prevention awaits an identified cause. Uncommon congenital anomalies (aniridia, genitourinary malformations, hemihypertrophy, or signs of overgrowth) may be seen in 13% to 28% of children with unilateral or bilateral disease, respectively.[6] Syndromes associated with a higher risk for developing Wilms' tumor include the "WAGR" syndrome (aniridia, genitourinary malformation, mental retardation), the Beckwith-Wiedemann syndrome, and the Denys-Drash syndrome (see section on molecular biology). Children with such syndromes should be screened for the development of Wilms' tumor using ultrasonographic examinations of both kidneys every 3 months until age 5 years (WAGR) or 7 years (Beckwith-Wiedemann syndrome).[6,7]

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

The biologic characterization of Wilms' tumor has provided the foundation for our understanding of key concepts in cancer genetics, including the roles of tumor suppressor genes and loss of genomic imprinting in tumorigenesis. Although Wilms' tumor was one of the original examples in Knudson's two-hit model of cancer development, subsequent research has shown that multiple genes and several genetic events contribute to the formation of this malignant disorder.[8] The molecular changes that have been described in Wilms' tumor can be classified as primary events predisposing to the development of tumor or secondary events associated with tumor progression.

WT1

Initial insights into the molecular biology of Wilms' tumor were derived from the observation that in patients with WAGR syndrome the risk for developing the tumor is more than 30%. Cytogenetic analysis of individuals with this syndrome showed deletions at chromosome 11p13, which was later found to be the locus of a contiguous set of genes including *PAX6,* the gene causing aniridia, and *WT1,* one of the Wilms' tumor genes. The *WT1* gene encodes a transcription factor that is crucial to normal kidney and gonadal development.[7] The Denys-Drash syndrome, which is characterized by pseudohermaphroditism, glomerulopathy, renal failure, and a 95% chance of Wilms' tumor development, is caused by point mutations in the zinc-finger DNA-binding region of the *WT1* gene.[7] Although *WT1* has a clear role in tumorigenesis of Wilms' tumor in patients with the WAGR and Denys-Drash syndromes, only a minority of patients with sporadic Wilms' tumor carries *WT1* mutations in the germline (<5%) or in tumor tissue (6% to 18%).[7]

IGF2/H19

The Beckwith-Wiedemann syndrome is an overgrowth disorder manifested by large birth weight, macroglossia, organomegaly, hemihypertrophy, neonatal hypoglycemia, abdominal wall defects, ear abnormalities, and predisposition to Wilms' tumor and other malignant disorders. Approximately 5% of individuals with this syndrome develop Wilms' tumor. Beckwith-Wiedemann syndrome maps to chromosome 11p15, a locus sometimes called "WT2" because it was the second locus shown to be associated with Wilms tumor.[9]

The 11p15 locus consists of several genetically imprinted genes that are in two clusters or imprinting centers. Several combinations of genetic and epigenetic alterations can give rise to Beckwith-Wiedemann syndrome, with increasing recognition of genotype-phenotype relationships.[10,11] Imprinting Center 1, which contains the *IGF2* and *H19* genes, has been most implicated in Wilms' tumor predisposition. Alterations in Imprinting Center 2, which contains the genes *CDKN1C, KCNQ1,* and *KCNQ1OT1,* are not strongly linked to Wilms' tumor development. Approximately 70% of Wilms' tumors have LOH or loss of imprinting (LOI) at the 11p15 locus.[12]

Wnt Signaling Pathway Genes (WTX and β-Catenin)

Alterations of the Wnt signaling pathway have been implicated in several human malignancies. Central to the pathway is the activator, β-catenin, which is degraded in the absence of Wnt signaling. Activating mutations in the gene encoding β-catenin *(CTNNB1)* occur in approximately 15% of Wilms' tumors.[13] Interestingly, mutations in *CTNNB1* occur mostly in tumors in which *WT1* is also mutated, suggesting that these two events cooperate in the formation of Wilms tumor. *WTX,* a recently discovered novel Wilms' tumor suppressor gene on the *X* chromosome, is inactivated in one third of sporadic Wilms' tumor cases. In contrast to the two-hit model of inactivation of *WT1, WTX* is inactivated by a monoallelic "single-hit" event that targets the *X* chromosome in tumors in males and the active *X* chromosome in tumors in females.[14] *WTX* has been shown to be a negative regulator of Wnt/β-catenin signaling.[15]

Familial Wilms' Tumor Genes

Familial predisposition to Wilms' tumor is rare, identified in only 1.5% of patients. A few families were shown to carry constitutional mutations of the *WT1* gene, but genetic linkage analysis has excluded *WT1* in most familial Wilms' tumor pedigrees. Rare pedigrees of familial Wilms' tumor recently have been associated with *BRCA2* mutations.[16] Linkage analysis has uncovered two familial Wilms' tumor loci, FWT1 (17q) and FWT2 (19q), but the causative genes remain to be identified.[8]

TP53 Mutation

Germline mutations of the *TP53* tumor suppressor gene are responsible for the Li-Fraumeni cancer predisposition syndrome (LFS).[17] Several LFS families with Wilms tumor have been identified.[18] Approximately 75% of anaplastic Wilms' tumors have detectable *TP53* mutations, whereas *TP53* mutations are uncommon in favorable histology tumors.[19] Studies are under way to evaluate whether *TP53* mutations carry prognostic significance in anaplastic Wilms' tumor.

Loss of Heterozygosity at 1p and 16q

One of the major goals of the NWTS-5 trial was to prospectively analyze the prognostic significance of LOH at chromosomes 1p and 16q. Analysis of these data revealed that the relative risks for relapse for patients with stages I to IV favorable histology tumors with LOH stratified by stage are 1.77 for LOH 1p ($p < 0.01$) and 1.39 for LOH 16q ($p = 0.05$). When the effects of LOH for both 1p and 16q were considered jointly, the relative risk for relapse in stage I and II favorable histology

disease was 2.88 ($p = 0.001$) and that for stages III and IV favorable histology disease was 2.41 ($p = 0.01$). The relative risk for death for patients with stages I and II favorable histology disease with LOH for both regions is 4.25 ($p = 0.01$), and for stages III and IV it is 2.66 ($p = 0.04$).[20]

Chromosome 1q Gain

Gain of chromosome 1q, observed in almost 30% of Wilms' tumor samples, is one of the most common cytogenetic findings in Wilms' tumor.[21] Several small studies of heterogeneously treated patients suggested an association between 1q gain and recurrence.[22,23] The association between 1q gain and adverse outcome was recently validated in an analysis of 212 patients treated on NWTS-4.[24] In this study, the 8-year event-free survival estimate was 76% (95% confidence interval [CI], 63% to 85%) for patients with 1q gain and 93% (95% CI, 87% to 96%) for those lacking 1q gain ($p = 0.0024$). The 8-year overall survival estimate was 89% (95% CI, 78% to 95%) for those with 1q gain and 98% (95% CI, 94% to 99%) for those lacking 1q gain ($p = 5.0075$). Interestingly, there was a strong association between chromosome 1q gain and LOH at 1p and 16q because some of the tumors with 1q gain had translocations between chromosomes 1 and 16.[24] Future COG studies will likely use 1q gain as one of the biological factors in the risk stratification schema.

PATHOLOGY AND PATHWAYS OF SPREAD

Initially, most pediatric renal tumors were classified as Wilms' tumor, with either favorable or unfavorable histology. After careful histopathologic examination of all unfavorable histology tumors registered in the first two NWTS studies, pathologists from the study group recognized that certain tumors represented separate disease entities. Therefore from NWTS-3 onward, CCSK and RTK were treated with distinct treatment regimens and analyzed separately from true Wilms' tumors.

Most Wilms' tumors are solitary lesions, although 6% involve both kidneys and 12% show multifocal involvement within a single kidney. The classic triphasic "favorable histology" Wilms' tumor consists of varying proportions of three cell types—blastemal, stromal, and epithelial—recapitulating various stages of normal renal development (Figure 70-1, *A, B*). Less commonly, heterologous epithelial or stromal components are identified, including mucinous or squamous epithelium, skeletal muscle, cartilage, osteoid, or fat. Not all specimens are triphasic; biphasic and monophasic patterns are frequently encountered. Favorable histologic features characterize 87% of Wilms' tumors.[25]

The histologic feature of greatest clinical significance is anaplasia, defined by the presence of greatly enlarged polyploid nuclei (see Figure 70-1, *C, D*). Anaplasia is present in approximately 8% of Wilms' tumors; it is rare in the first 2 years of life and increases in frequency to approximately 13% in children older than age 5 years. Anaplasia is far more frequent in black patients than in white patients and, as noted previously, has been strongly linked to the presence of *TP53* mutations.[19,26] The distinction between focal and diffuse anaplasia is prognostically significant.[27]

Further correlations between histologic characteristics and clinical behavior vary according to whether the tumor specimen is taken before or after chemotherapy. In patients undergoing immediate nephrectomy, blastemal-rich tumors are typically invasive and present at an advanced stage; there is not a strong correlation with outcome when correcting for stage.[28] In patients undergoing preoperative chemotherapy, blastemal subtype has a clear correlation with adverse outcome, suggesting that residual blastemal cells that persist after chemotherapy represent a treatment-resistant population.[29] Tumors that contain predominantly well-differentiated cells, either epithelial or stromal (rhabdomyomatous), are more likely to present at a low stage and not exhibit much size reduction with chemotherapy, though the prognosis is favorable.[29] Analysis of the cohort of young children with small stage I intrarenal tumors assigned no adjuvant chemotherapy provides further support for the excellent prognosis of epithelial-differentiated Wilms' tumors.[30] Although much of the past success of the NWTS has relied on accurate histologic subclassification of Wilms' tumors to define high-risk and low-risk subtypes, further risk classification is likely to depend on molecular genetic features.

The existence of precursor lesions (nephrogenic rests) is rather common. These lesions consist of abnormally persistent intrarenal embryonal nephroblastic tissue with small clusters of blastemal cells, tubules, or stromal cells. Nephrogenic rests can be subclassified by their positions within the kidney and histologic appearance: perilobar nephrogenic rests are limited to the periphery of the renal cortex, and intralobar nephrogenic rests occur randomly throughout the renal lobe. Nephroblastomatosis refers to the presence of multiple nephrogenic rests typically throughout the kidney. There are several possible fates for nephrogenic rests: most become dormant or involute spontaneously; only a small number develop clonal transformation into Wilms' tumor. The presence of nephrogenic rests within a kidney resected for Wilms' tumor indicates the need for monitoring the contralateral kidney for tumor development, particularly in young infants.[31]

The other major cellular types of kidney tumors are outlined in Table 70-1, including:

1. Mesoblastic nephroma (1% to 2% of pediatric renal tumors). This is the most common renal tumor encountered in the first month of life; the median age at presentation is 3 months. Hypercalcemia may be present. Local recurrence is rare after surgery alone; distant metastases are similarly uncommon. Survival rates are excellent after surgery alone.[32]
2. Clear cell sarcoma (2% to 3%). Once considered a Wilms' tumor variant, this tumor is now recognized as a separate entity. The tumor cells have poorly stained cytoplasm with cytoplasmic vacuolations (see Figure 70-1, *E*). Bone and brain metastases, rare in the other tumor types, are common in CCSK.[25,33]
3. RTK or malignant rhabdoid tumor (2%). This rare but extremely aggressive neoplasm predominantly affects

infants, in whom hypercalcemia may be present. Rhabdoid cells are characterized by eosinophilic cytoplasm that contains hyaline globular inclusions (see Figure 70-1, *F, G*). Metastases to the lung and intraabdominal relapses are frequent.[25]

4. Renal cell carcinoma (RCC) (5% to 8%). This type of carcinoma was not traditionally studied by the NWTS but is included in current COG studies. Pediatric RCCs are typically identified as the translocation subtypes (papillary, renal medullary, and oncocytic renal cell histiotypes), which are characterized by translocations typically involving the *TFE3* or *TFEB* genes. It is not clear that these subtypes respond to the same therapies (immunotherapies, tyrosine kinase/antiangiogenesis inhibitors, and mTOR pathway inhibitors) that have efficacy in the more classic clear cell subtype seen in the adult population. Its patterns of spread do mimic the adult counterpart (i.e., the lungs, lymph nodes, and bone).

CLINICAL MANIFESTATIONS, PATIENT EVALUATIONS, AND STAGING

Children with Wilms' tumor typically show no tumor-specific symptoms. The most common presentation is with an asymptomatic abdominal mass, although about 33% of patients present with abdominal pain, anorexia, vomiting, malaise, or a combination of these symptoms. Physical examination reveals hypertension in about 25% of patients and congenital anomalies (aniridia, genitourinary malformations, hemihypertrophy, or signs of overgrowth) in 13% to 28% of children, higher in those with bilateral disease. Up to 30% of patients have hematuria; fewer than 10% have coagulopathy.

Laboratory evaluation after physical examination should include a complete blood cell count, routine hepatic and renal chemistries, and urinalysis, noting the presence or absence of urinary protein and white or red blood cells. Imaging studies before surgery are designed to evaluate the extent of the renal mass and differentiate primary intrarenal tumors from neuroblastoma (most often arising from the adjacent suprarenal gland or retroperitoneal structures), the presence of a normally functioning, morphologically normal contralateral kidney, the presence of a patent renal vein and inferior vena cava (i.e., free from thrombosis, most often tumor thrombosis when seen), and the presence or absence of metastases in the lungs. Diagnostic imaging studies include abdominal ultrasonography (particularly useful in the detection of tumor thrombosis) and CT or MRI of the abdomen (Figure 70-2). A chest CT scan should be used to detect lung metastasis. The clinical significance of metastatic tumors detected by chest CT but not on chest radiographs remains unclear, although evidence is increasing that some of these patients do not fare well with chemotherapy with vincristine and dactinomycin alone.[34,35] MRI of the abdomen can help to distinguish between nephrogenic rests and Wilms' tumor.[36] Postoperatively, when the histology is established, a bone scan and brain MRI should be obtained for all patients with CCSK, RTK, and patients with RCC if they have symptoms to suggest bone or brain involvement.

Staging

Wilms' tumors are staged on the basis of anatomic tumor extent; therapy is currently based on stage and histology.[31] Classifications based on tumor extent have evolved over the years. After analysis of the prognostic significance of several clinicopathologic factors in NWTS-1 and NWTS-2, an NWTS staging system has been in use from NWTS-3 onward. Patients

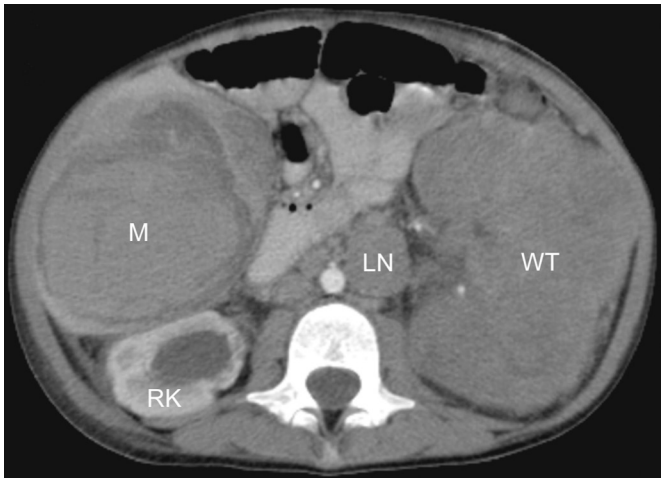

Figure 70-2 Abdominal computed tomography scan of a 4-year-old girl with a large left-sided Wilms' tumor *(WT)* measuring 10.5 × 11 × 17 cm. The right kidney *(RK)* did not show any lesions. There were multiple enlarged paraaortic lymph nodes *(LN)* and liver metastases *(M)*.

with lymph node involvement, previously included with stage II disease, are now classified as having stage III disease, and those with local tumor spill were moved from stage III to stage II disease.[37] Refinements to the inclusion criteria for stages I and II disease were introduced in the NWTS-5 study. Criteria for stage I were refined to accommodate an important subset of Wilms' tumor currently managed by nephrectomy alone. Before NWTS-5, the distinction between stages I and II in the renal sinus was established by the hilar plane, which was an imaginary plane connecting the most medial aspects of the upper and lower poles of the kidney. This criterion was difficult to apply because of tumor distortion, and thus the hilar plane criterion has been replaced with renal sinus vascular or lymphatic invasion. The latter definition includes not only the involvement of vessels within the hilar soft tissue but also vessels located in the radial extensions of the renal sinus into the renal parenchyma.[38]

The current COG staging guidelines for Wilms' tumor are shown in Table 70-2. These guidelines are essentially similar to those for NWTS-5 except for the fact that children with tumor spillage are upstaged from stage II to stage III because of the higher risk for relapse in these patients when treated with two-drug chemotherapy without RT.[39]

PRIMARY THERAPY

Primary surgical resection of Wilms' tumor remains the standard initial therapy undertaken in North America. A transabdominal transperitoneal approach is recommended to provide adequate exposure for complete locoregional staging.[40] This procedure includes biopsy of hilar and regional nodes (even if normal appearing), which remains a crucial factors in staging. Although suspicious lymph nodes are excised irrespective of location, a formal lymph node dissection is neither beneficial nor recommended.

Most Wilms' tumors that appear to involve contiguous structures actually only compress or adhere to the adjacent organs without invasion. Therefore, radical en bloc resection in these tumors, which is associated with increased surgical complications, can be avoided. However, wedge resection of infiltrated structures such as the diaphragm, liver, or psoas muscle can be undertaken if all disease can be completely removed with little operative morbidity. This procedure is advantageous because the tumor can be downstaged to stage

TABLE 70-2 Children's Oncology Group Staging of Wilms' Tumor (2010)

Stage	Description
I	Tumor limited to kidney, completely resected. The renal capsule is intact. The tumor was not ruptured or sampled before removal. The vessels of the renal sinus are not involved. There is no evidence of tumor at or beyond the margins of resection.*
II	The tumor is completely resected and there is no evidence of tumor at or beyond the margins of resection. The tumor extends beyond kidney, as is evidenced by any one of the following criteria†: • There is regional extension of the tumor (i.e., penetration of the renal capsule or extensive invasion of the soft tissue of the renal sinus). • Blood vessels within the nephrectomy specimen outside the renal parenchyma, including those of the renal sinus, contain tumor.
III	Residual nonhematogenous tumor present after surgery and confined to abdomen. Any one of the following may occur: • Lymph nodes within the abdomen or pelvis are involved by tumor.‡ • The tumor has penetrated through the peritoneal surface. • Tumor implants are found on the peritoneal surface. • Gross or microscopic tumor remains postoperatively (e.g., tumor cells are found at the margin of surgical resection on microscopic examination). • The tumor is not completely resectable because of local infiltration into vital structures. • Tumor spillage occurred either before or during surgery. • The tumor was sampled (whether Tru-Cut, open, or fine needle aspiration) before removal. • Tumor is removed in more than one piece (e.g., tumor cells are found in a separately excised adrenal gland; a tumor thrombus within the renal vein is removed separately from the nephrectomy specimen).
IV	Hematogenous metastases (e.g., lung, liver, bone, brain), or lymph node metastases outside the abdominopelvic region are present. (The presence of tumor within the adrenal gland is not interpreted as metastasis and staging depends on all other staging parameters present.)
V	Bilateral renal involvement by tumor is present at diagnosis. An attempt should be made to stage each side according to the above criteria on the basis of the extent of disease.

**For a tumor to qualify for certain therapeutic protocols as stage I, regional lymph nodes must be examined microscopically.*
†Rupture or spillage confined to the flank, including biopsy of the tumor, is no longer included in stage II and is now included in stage III.
‡Lymph node involvement in the thorax or other extraabdominal sites is a criterion for stage IV.

II and subsequent therapy reduced. Tumor extension into the renal vein and proximate inferior vena cava can, in most cases, be removed en bloc with the kidney. However, primary resection of extension into the inferior vena cava to the hepatic level or into the atrium is associated with higher operative morbidity. In these circumstances, preoperative chemotherapy decreases the size and extent of the tumor thrombus, facilitating subsequent excision.

Tumor spillage remains an important concept in the surgery of Wilms' tumor. Surgeons must be aware of any tumor-capsule violation with contamination of the peritoneal cavity during resection. The accurate assessment of a local spill from diffuse contamination is difficult; peritoneal contamination definitely increases the risk for local and abdominal recurrence, and both localized and diffuse peritoneal spill (or preoperative tumor rupture) are now considered stage III disease.[40]

Some tumors are initially judged to be unresectable or to pose too great a surgical risk because of massive size. In these cases, preoperative chemotherapy results in reduction of the tumor mass and generally renders it resectable.

RADIATION THERAPY

Flank and Abdominal Irradiation

RT continues to play an important role in the management of Wilms' tumor. Successive NWTS trials have refined the indications for RT. In NWTS-1 and NWTS-2, an age-adjusted dose schedule was used for flank irradiation, ranging from 18 Gy to 24 Gy for children younger than 18 months to 35 Gy to 40 Gy for children older than 40 months. The abdominal relapse rate was 3% to 5% for groups II and III tumors, and there was no dose-response relationship observed across these dose ranges.[41,42] NWTS-3 proved that RT could be avoided in children with stage II tumors if vincristine and dactinomycin were both given. This study also showed that children with stage III favorable histology tumors who received 10.8 Gy and vincristine, dactinomycin, and doxorubicin had tumor control similar to that of those who received 20 Gy with vincristine and dactinomycin. This was an important finding because it eliminated the need for an age-adjusted dose schedule and significantly reduced the recommended radiation dose.[43]

NWTS-1, NWTS-2, and NWTS-3 showed that delay in initiating RT beyond 10 days was correlated with poor outcome primarily in cases with unfavorable histology.[41-43] A study of the impact of RT delay on patients with favorable histology in NWTS-3 and NWTS-4 showed that a delay of more than 10 days did not significantly influence flank or abdominal tumor recurrence rates. It is currently recommended for children requiring RT that it be initiated without undue delay (within 14 days of nephrectomy) to eliminate abdominal recurrence as a variable in the analyses of outcomes in future Wilms' tumor trials.[44]

The NWTS evaluated the frequency with which tumor spill of favorable histology produced intraabdominal recurrence in NWTS-3 and NWTS-4. Flank irradiation but not doxorubicin reduced abdominal relapse rates. The odds ratio for the risk of recurrence was 0.35 for 10 Gy and 0.08 for 20 Gy when compared with those with no radiation therapy. Tumor spillage resulted in higher relapse and significantly lower survival among patients with stage II disease in NWTS-4 (i.e., those without RT). The 8-year relapse-free survival with and without spillage were 79% and 87% ($p = 0.07$), and overall survival rates were 90% and 95% ($p = 0.04$), respectively.[39]

Although diffuse anaplastic tumors are relatively resistant to chemotherapy, and presumably relatively resistant to RT, these tumors have not shown a radiation dose response between 10.8 Gy and 40 Gy.[45] The optimum radiation dose for anaplastic Wilms' tumor and other unfavorable histology tumors remains unknown. In NWTS-5, children with stage I focal and diffuse anaplasia were treated with two-drug chemotherapy (vincristine and dactinomycin) alone without flank irradiation; the approach resulted in a poor survival rate.[46] The current COG study recommends flank irradiation (10.8 Gy) with three-drug chemotherapy for these tumors. The survival

rates for children with stage III diffuse anaplastic tumors and rhabdoid tumors continue to be poor (Table 70-3). The COG study will test the value of a higher dose of irradiation (19.8 Gy) together with intensified chemotherapy (Tables 70-4 and 70-5). The COG protocol will also prospectively study whether flank irradiation could be avoided in children with stage I CCSK who have undergone lymph node sampling and central pathology review (see Tables 70-4 and 70-5).

Whole-Lung Irradiation

In children with lung metastases detected on chest radiographs, whole-lung irradiation (WLI) results in high cure rates. In NWTS-3, the 4-year relapse-free survival and overall survival were 72% and 78%, respectively, in children with favorable histology Wilms' tumor and lung metastases.[47] These results are superior to the survival rates reported by investigators from the United Kingdom Children's Cancer Study Group (UKCCSG) study in which all patients did not receive WLI.[48] In children with pulmonary metastases visible on CT but not chest radiographs, the role of WLI is unclear. In such patients treated on NWTS-3 and NWTS-4, the 4-year, event-free survival with WLI was 89% compared with 80% with chemotherapy alone, a difference that was not statistically significant.[49] The current COG protocol recommends WLI based on the response of pulmonary metastatic lesions to one course of chemotherapy with vincristine, dactinomycin, and doxorubicin. Central radiology review of chest CT will be performed before and at week 6 after chemotherapy. WLI will be omitted only in patients with favorable histology tumors with no LOH at 1p and 16q and those who have achieved a complete response to chemotherapy on chest CT central radiology review at week 6. All other children will receive WLI (12 Gy).

The current RT recommendations of the COG Renal Tumors Committee are shown in Table 70-4. There are several differences in the current COG recommendations compared with those from NWTS-5: (1) patients with local tumor spillage are upstaged to stage III and will receive flank RT; (2) patients with stage I focal and diffuse anaplastic tumors will receive flank RT; (3) the radiation dose for children with stage III diffuse anaplasia and stage I to III RTK will be increased to 19.8 Gy; and (4), in an effort to study if irradiation could be omitted in stage I CCSK, patients who have undergone nodal sampling and central pathology review will not receive flank RT.

Intensity-Modulated Radiation Therapy for Wilms Tumor

Like in other pediatric tumors, RT techniques used in Wilms' tumor continue to be critically examined. Lung and mediastinal irradiation with or without doxorubicin have resulted in a higher incidence of cardiac complications such as congestive heart failure (CHF), myocardial infarction, pericardial disease, and valvular heart disease in childhood cancer survivors.[50-52] The demonstration of a threshold dose (>5 Gy) for cardiac mortality highlights the importance of delivering a lower dose to the heart.[52] Dosimetry studies have shown several advantages for the use of whole-lung IMRT over standard anteroposterior/posterior-anterior (AP/PA) techniques. They

TABLE 70-4 Radiation Therapy Recommendations for the Children's Oncology Group Renal Tumor Protocols

Tumor Stage/Histology	RT Dose and Fields
Stages I and II FH	No RT
Stage III FH, stages I-III focal anaplasia, stages I-II diffuse anaplasia, stages I-III CCSK‡	10.8 Gy flank* RT†
Stage III diffuse anaplasia, stages I-III RTK	19.8 Gy (infants 10.8 Gy) flank* RT†
Stage IV (lung metastases, FH)	12 Gy (whole-lung irradiation in children who are not in complete remission at week 6 after induction chemotherapy)
Stage IV (lung metastases, UH)	12 Gy whole-lung irradiation regardless of chemotherapy response
Stage IV (liver metastases)	No RT if resected before chemotherapy, all others 19.8 Gy
Stage IV (brain metastases)	21.6 Gy (whole brain) + 10.6 Gy (local boost) or whole brain 30.6 Gy
Stage IV (bone metastases)	25.2 Gy (tumor + 3-cm margin)
Lymph node metastases not surgically resected	19.8 Gy
Relapsed Wilms' tumor (flank/abdomen)	12.6 Gy to 18 Gy (<age 12 mo) and 21.6 Gy in older children if previous radiation dose is ≤10.8 Gy 9-Gy boost to gross residual tumor after surgery

CCSK, *Clear-cell sarcomas of the kidney;* FH, *favorable histology;* RTK, *rhabdoid tumors of the kidney;* UH, *unfavorable histology.*

**Whole-abdomen irradiation is indicated when there is diffuse tumor spillage, intraperitoneal tumor rupture, peritoneal tumor seeding, and cytology-positive ascites. When dose is >10.8 Gy, renal shielding is required to limit the dose to the remaining kidney to <15 Gy.*

†*A boost of 10.8 Gy is to be administered to areas of gross residual tumor after surgery.*

‡*Patients with stage I CCSK will not receive flank irradiation if lymph node sampling and central pathologic review were performed.*

TABLE 70-5 Children's Oncology Group Renal Tumor Protocol Schema

Tumor Risk Classification	Multimodality Treatment
Very low-risk favorable histology Wilms' tumor: <2 years, stage I FH, tumor weight <550 g	Nephrectomy without adjuvant therapy, only if central pathology review and lymph node sampling has been performed
Low-risk favorable histology Wilms' tumor: ≥2 years, stage I FH, tumor weight ≥550 g, stage II FH without LOH of 1p and 16q	Nephrectomy, no RT, regimen EE4A
Stages I and II FH with LOH of 1p and 16q	Nephrectomy, regimen DD4A
Stage III FH without LOH of 1p and 16q	Nephrectomy, RT, regimen DD4A
Stages III and IV FH with LOH of 1p and 16q, stage IV FH slow/incomplete responders	Nephrectomy, RT, regimen M, whole-lung irradiation
Stage IV FH: complete resolution of lung metastases at week 6 with regimen DD4A (rapid early responders)	Nephrectomy, RT, regimen DD4A. No whole-lung irradiation
Stages I-III focal anaplasia Stages I diffuse anaplasia	Nephrectomy, RT, regimen DD4A
Stage IV focal anaplasia Stages II-IV diffuse anaplasia Stage IV CCSK Stages I-IV RTK	Nephrectomy, RT, regimen UH1
Stages I-III CCSK	Nephrectomy, RT, regimen I (RT omitted for stage I)

CCSK, *Clear cell sarcoma of kidney;* FH, *favorable histology;* LOH, *loss of heterozygosity;* RT, *radiation therapy;* RTK, *rhabdoid tumor of kidney.*
Regimens: DD4A: vincristine/dactinomycin/doxorubicin; EE4A: vincristine/dactinomycin; I: vincristine/doxorubicin/cyclophosphamide, cyclophosphamide/etoposide; M: vincristine/dactinomycin/doxorubicin, cyclophosphamide/etoposide; UH1: cyclophosphamide/carboplatin/etoposide, vincristine/doxorubicin/cyclophosphamide.

include superior cardiac protection, superior four-dimensional (4D) lung planning target volume (PTV) dose coverage, and superior dose-uniformity in the lungs with fewer hot spots.[53] Another report has shown that compared to standard AP-PA techniques, the use of whole liver IMRT was associated with superior 4D liver dose coverage and delivered a lower dose to the remaining solitary kidney.[54] Another important finding of these reports is the importance of using 4D simulation to accurately determine the internal target volume (ITV) of the lung and liver after consideration for maximal organ movement during respiration. A National Institutes of Health (NIH)–funded multicenter feasibility study of whole-lung IMRT has recently been completed. If feasible, whole-lung IMRT with 4D planning may replace standard techniques as the new standard of care.

CHEMOTHERAPY

Chemotherapy and Combined-Modality Treatment

Single-agent chemotherapy has been used for Wilms' tumor since the 1950s, when both dactinomycin and vincristine were found to be active. The interplay between relatively more aggressive chemotherapy and locoregional irradiation was tested in the initial NWTS studies. NWTS-1 showed that RT conferred no advantage in children younger than age 24 months with group I tumors who also received 15 months of dactinomycin.[55] NWTS-2 showed that RT could be avoided in all children with group I Wilms' tumor if they received both vincristine and dactinomycin.[56] The results of NWTS-3 showed that stage II tumors required only vincristine and dactinomycin without any RT. NWTS-3 also demonstrated an interaction between chemotherapy and RT: 10.8 Gy with three drugs (vincristine, dactinomycin, doxorubicin) was equivalent to 20 Gy with two drugs (vincristine, dactinomycin).[47] In NWTS-4, two questions were posed concerning duration of chemotherapy (6 months versus 15 months) and the delivery of dactinomycin and doxorubicin (pulse-intensive, single-dose versus 5-day course of dactinomycin or 3-day course of doxorubicin). Results showed no advantage to prolonged therapy or divided doses, which actually proved to be more toxic; the consolidated 2-year, relapse-free rate and survival results were 90% and 97%, respectively, for the patients with low- and high-risk disease (see Table 70-3). Thus, the shorter courses of the pulse-intensive regimens are now considered standard, reducing both clinic time and cost for both parents and staff.[57] NWTS-5 asked whether young patients younger than 24 months old with stage I favorable histology Wilms' tumor weighing less than 550 grams could be treated with nephrectomy only without adjuvant chemotherapy. The study was stopped early because the number of relapses observed exceeded the predefined stopping rule. However, nearly all patients with relapse were successfully treated, leading to 5-year event-free and overall survival rates of 84% and 98%, respectively.[58,59] Based on the outstanding overall survival, the question of omitting adjuvant therapy was readdressed in the recent COG studies.

Anaplastic Histology

The first NWTS trial to stratify patients with anaplastic Wilms' tumor into a distinct treatment group was NWTS-3. Both NWTS-3 and NWTS-4 called for 15 months of vincristine, dactinomycin, and doxorubicin, with randomization to receive cyclophosphamide or not. Patients with stages II to IV diffuse anaplastic tumors who were treated with cyclophosphamide had significant improvement in 4-year relapse-free survival (27% versus 55%)[45] (see Table 70-3). Patients with all stages of focal anaplastic histology or stage-I diffuse anaplastic histology had excellent outcomes, regardless of treatment regimen. Based on these results, patients with anaplastic histology were treated in prospective single-arm studies in NWTS-5. Patients with stage-I anaplastic tumors were treated with vincristine and dactinomycin for 18 weeks without RT. Patients with stages II to IV diffuse anaplastic histology were treated with vincristine, doxorubicin, cyclophosphamide, and etoposide for 24 weeks plus flank and abdominal RT. Among 2596 patients with Wilms' tumor enrolled in NWTS-5, 281 (10.8%) had anaplastic histology. The 4-year event-free and overall survival rates for stage-I anaplastic histology tumors were 70% and 83%, respectively. These results were less satisfactory

than expected and clearly inferior to results with stage-I favorable histology tumors. Therefore, the recent COG study augmented therapy for this group of patients to include doxorubicin and flank radiation. The 4-year event-free and overall survival in stages II, III, and IV diffuse anaplastic tumors after immediate operative chemotherapy and RT were 83% and 82%, 65% and 67%, and 33% and 33%, respectively.[46] These results were improved compared to historical standards and form the basis for the most COG study that recommended further augmentation of therapy for stages II to IV diffuse anaplastic tumors using a treatment regimen containing cyclophosphamide, carboplatin, and etoposide alternating with vincristine, doxorubicin, and cyclophosphamide (see Table 70-5). The study recently closed and the results have not yet been reported.

Clear Cell Sarcoma of the Kidney

Data from NWTS-1 to NWTS-4 suggested that the addition of doxorubicin to vincristine and dactinomycin improved relapse-free survival rates of patients with CCSK.[60,61] NWTS-3 demonstrated no improvement in outcomes of patients with CCSK with the addition of cyclophosphamide, though the cyclophosphamide was administered at a lower dose-intensity than is commonly employed in more recent treatment regimens.[47] NWTS-4 included a double-randomization that evaluated the effect of "pulse-intensive" dactinomycin and doxorubicin given over 1 day instead of 3 to 5 days (first randomization) and of total duration of therapy (second randomization). In patients with CCSK there was no significant difference in outcome between the standard and pulse-intensive chemotherapy regimens. However, there was a trend toward improved relapse-free survival with long duration therapy (additional 9 months) compared to standard chemotherapy with 8-year relapse free survival estimates of 88% and 61%, respectively ($p = 0.08$). However, there was no difference in overall survival, with 8-year overall survival estimates of 88% and 86% for the long- and short-duration therapy.[62] A group of patients with CCSK that fares particularly well are those with stage-I disease. A recent analysis of patients enrolled on NWTS 1-5 with stage I CCSK based on the updated NWTS-5 definition of stage I disease showed that regardless of treatment regimen, the event-free and overall survival rates were 100%.[63]

Preliminary analysis of NWTS-5 has shown promising results with the new chemotherapy regimen (vincristine, doxorubicin, cyclophosphamide, and etoposide) and RT except for patients with stage IV disease (NWTS, unpublished data). Based on these results, the recent COG study used the same regimen as in NWTS-5 for stages I-III disease, except that RT was omitted for patients with stage I disease. Patients with stage IV CCSK were treated with cyclophosphamide, carboplatin, and etoposide alternating with vincristine, doxorubicin, and cyclophosphamide, similar to patients with diffuse anaplastic Wilms' tumor (see Table 70-5).

Rhabdoid Tumor of the Kidney

Patients with RTK have been treated on NWTS trials with agents such as vincristine, dactinomycin, and doxorubicin with or without cyclophosphamide. The outcomes attained with these agents have been consistently very poor[47,64,65] (see Table 70-3). To try to improve on these results, NWTS-5 adopted a different treatment strategy consisting of carboplatin and etoposide alternating with cyclophosphamide. Preliminary analysis of patients treated with this regimen revealed an overall survival of 26%, not an improvement compared with previous studies, and thus the treatment arm was closed.[65]

The recent COG protocol evaluated whether a treatment regimen containing cyclophosphamide, carboplatin, and etoposide alternating with vincristine, doxorubicin, and cyclophosphamide improves the event-free and overall survival in these patients. The results have not yet been reported.

TREATMENT RESULTS

Treatment results are outlined in Table 70-3.

IRRADIATION TECHNIQUES

Parallel-opposed (AP/PA) treatment portals using 4-MV or 6-MV photons are recommended for flank, whole-abdomen, and whole-lung irradiation. The details regarding the planning techniques and setup for conventional RT are shown and described in Figures 70-3 to 70-5. If the lungs and either flank or abdomen have to be treated simultaneously, it is preferred that they be included as one radiation volume. However, if these two sites have to be treated sequentially, appropriate field gap calculations should be used for field matching, to avoid overlap, particularly over critical structures such as the liver and kidney.

CURRENT CLINICAL RECOMMENDATIONS

Based on the results of NWTS-5, the new COG renal tumor protocol will use LOH at both 1p and 16q in addition to tumor stage and pathologic classification for defining tumor-risk groups and assigning risk-adapted therapy (see Table 70-5). The goals of therapy in the COG study are to reduce the incidence of treatment-related morbidity in low-risk groups who have good survival rates and increase treatment intensity in high-risk tumors to improve cure rates.

OTHER STUDIES

In addition to the NWTSG, there have been randomized studies in SIOP, typically built on preoperative therapy (chemotherapy and, in defined instances, RT),[4,66-68] and the UKCCSG.[48,69]

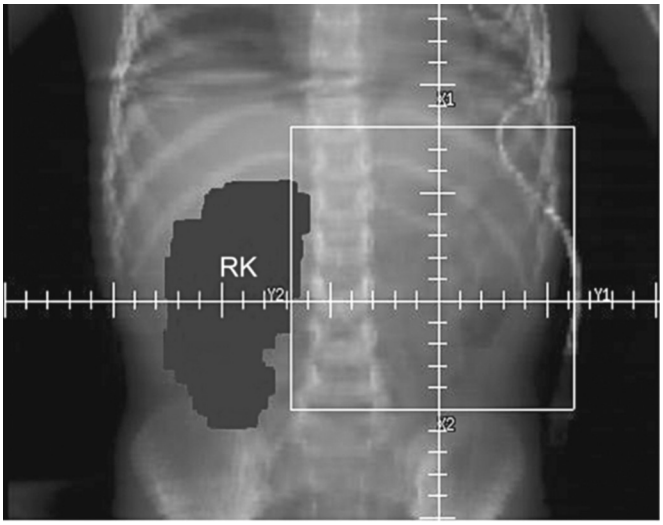

Figure 70-3 Anteroposterior left flank irradiation portal in a child with a stage-III favorable histology Wilms' tumor. The superior and inferior field margins are placed approximately 1 cm from the preoperative renal tumor volume. The medial field margin should include the entire width of the vertebral body to irradiate the lymph nodes and avoid scoliosis. The outline of the normal right kidney (RK) is shown.

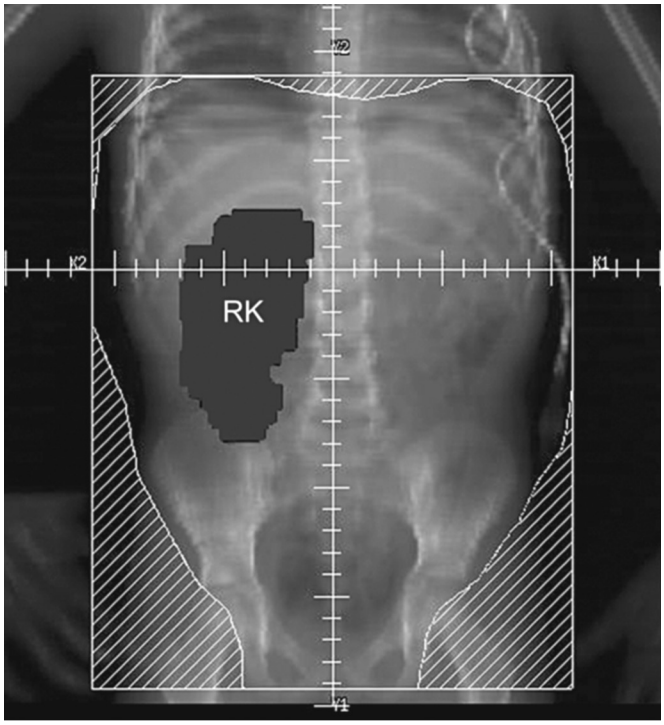

Figure 70-4 Anteroposterior whole-abdomen irradiation portal. The upper margin of the abdominal field must include the diaphragm. The acetabulum and femoral head should be excluded from the irradiated volume to decrease the probability of slipped femoral epiphysis. The outline of the normal right kidney (RK) is shown.

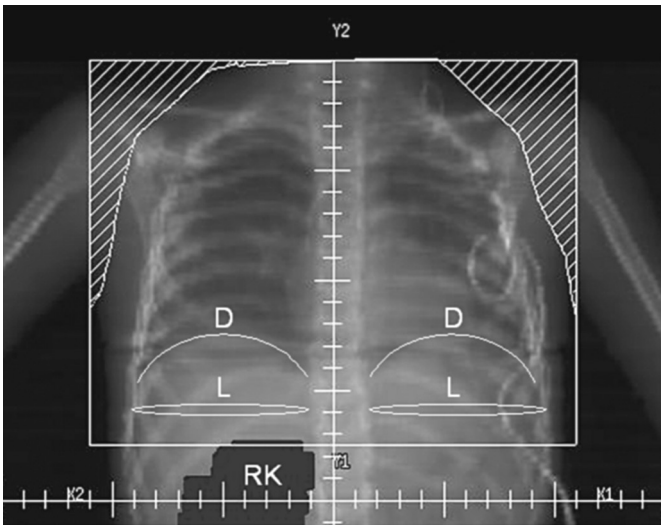

Figure 70-5 Anteroposterior whole-lung irradiation portal. The dome of the diaphragm *(D)* and the lower extent *(L)* of the costophrenic angles at the lung bases are shown. A lateral radiograph of the chest at the time of simulation or review of the sagittal and coronal images during computed tomography simulation is required to ascertain inclusion of the anterior and posterior costophrenic angles with a 1-cm margin at the inferior edge of the treatment volume. The outline of the normal right kidney *(RK)* is shown.

RETRIEVAL THERAPY

Children with relapsed favorable histology Wilms' tumor have a variable prognosis, depending on the site of relapse, the time from initial diagnosis to relapse, and previous therapy. Favorable prognostic factors include no previous treatment with doxorubicin, relapse more than 12 months after diagnosis, and intraabdominal relapse in a patient not previously treated with abdominal irradiation.[70-72] Patients with relapsed or progressive disease after initial chemotherapy with vincristine and dactinomycin and no RT were treated on a specific stratum in NWTS-5, consisting of alternating courses of vincristine, doxorubicin, cyclophosphamide, and etoposide and cyclophosphamide, plus surgery and RT. The 4-year event-free and overall survival was 71% and 81% for all patients, 68% and 81% for those who experienced relapse in the lung only, and 78% and 83% for those who had relapse in the operative bed with or without lung metastasis.[71] Patients who had experienced relapse or whose disease progressed after initial chemotherapy that included vincristine, dactinomycin, and doxorubicin plus RT were treated with alternating courses of drug pairs (cyclophosphamide and etoposide and carboplatin and etoposide), surgery, and RT. The 4-year event-free and overall survival was 42% and 48% for all patients and 49% and 53% for those who had relapse in the lung only.[72] In children who previously had not received RT, the recommended flank radiation dose is 12.6 Gy to 18 Gy (birth to 12 months) and 21.6 Gy (≥13 months). Supplemental boost fields could be added for gross residual disease (see Table 70-4). The COG protocol recommends postoperative irradiation for all children with abdominal relapse because these tumors are generally large and infiltrative and surgical resection with negative margins is unlikely.

LATE EFFECTS

As the follow-up of successfully treated children increases, data are increasingly emerging on the late consequences of treatment. The types of late sequelae and their severity depend on the age and sex of the child, extent of surgery, chemotherapy drugs, and irradiation-related factors. The most common cause for renal failure in patients with Wilms' tumors is bilateral nephrectomy, whereas the second leading cause is irradiation-induced damage or surgical complications affecting the remaining kidney. The frequency of renal failure in bilateral Wilms' tumor was 16.4% for NWTS-1 and NWTS-2, 9.9% for NWTS-3, and 3.8% for NWTS-4.[73] The incidence of scoliosis ranges from 40% to 60% with radiation doses of 25 Gy to 40 Gy. However, the rate of scoliosis should be low with the current doses of 10.8 Gy.[74,75] The cumulative frequency of CHF among patients on NWTS-1 to NWTS-4 was 4.4% at 20 years among patients treated initially with doxorubicin and 17.4% among patients treated with doxorubicin for first or subsequent relapse. Factors significantly associated with heart failure were female sex, cumulative doxorubicin dose, lung irradiation, and left-sided abdominal irradiation.[50] Women who are Wilms' tumor survivors have significantly higher rates of adverse pregnancy outcomes, such as malposition of the fetus and premature labor, with the incidence greatest after flank irradiation to doses higher than 25 Gy. Their offspring more often are premature and of low birth weight compared with control cohorts; a trend toward an increased number of congenital malformations has been noted after flank irradiation.[76,77] The cumulative 15-year risk of second malignant neoplasms was 1.6% among patients enrolled on the NWTS, after a mean follow-up of 7.5 years per patient. Higher doses of abdominal irradiation and doxorubicin increased the risk of another neoplasm.[78]

The standardized mortality ratio in an NWTS review was 24.3 within 5 years of diagnosis, 12.6 for the next 5 years, and more than 3.0 thereafter. The main cause of mortality within the first 5 years related to the original disease (91%). Beyond 5 years the mortality was equally related to the original disease (40%) and late effects of treatment (39%). The three most-common treatment-related effects contributing to mortality were second malignant neoplasms, CHF, and end-stage renal disease. The risk of death particularly from treatment-related late effects remained elevated even 20 years after diagnosis.[79]

CHAPTER

71 Retinoblastoma

Carlos Rodriguez-Galindo, Anne-Marie Charpentier, and Carolyn R. Freeman

INCIDENCE

Retinoblastoma accounts for 2.5% to 4% of all pediatric malignancies. Its incidence is two to five cases per million children per year, and there are 300 new cases per year in the United States.

BIOLOGY

There are two forms of retinoblastoma:

1. Unilateral (75%), *RB1* somatic mutations
   sporadic (90%)
   inherited (familial) (10%)
2. Bilateral (25%), RB1 germline mutations
   sporadic (in utero new mutations) (75%)
   inherited (familial) (25%)

STAGING

The staging for retinoblastomas is based on intraocular grouping, which is based on intraocular tumor burden, site and size of lesions, and presence of vitrous seeding

Retinoblastoma also can be based on systemic staging:
Locoregional: Orbit, preauricular nodes
Central nervous system (CNS) dissemination
Extra CNS metastases

The treatment principles that need to be considered for retinoblastoma include tumor burden (group and stage), laterality (unilateral or bilateral), and visual potential.

The priorities in retinoblastoma are to save patient's life, eye salvage, and vision preservation.

It is important to offer patients multidisciplinary care at state-of-the-art treatment center, which includes ophthalmologic care, pediatric oncologic, care radiation oncologic care, cccupational therapy, and psychosocial therapy.

TREATMENT MODALITIES

Treatment modalities include various forms of chemotherapy, including focal treatments (cryotherapy, thermotherapy, photocoagulation, brachytherapy), external beam radiation therapy (EBRT), and enucleation.

INTRODUCTION

Retinoblastoma is the most-frequent neoplasm of the eye in childhood, representing 2.5% to 4% of all pediatric cancers. The average age-adjusted incidence rate of retinoblastoma in the United States and Europe is 2 to 5 per million children or approximately one in 14,000 to 18,000 live births.[1,2] Retinoblastoma is a cancer of the young; two thirds of all cases are diagnosed before 2 years of age, and 95% of cases are diagnosed before 5 years of age.[1]

Retinoblastoma presents in two distinct clinical/genetic forms: (1) a bilateral or multifocal form in 25% of presenting children, characterized by the presence of germline mutations of the *RB1* gene with documented familial history in 25% of cases or the result of a new (sporadic) germline mutation in 75%; or (2) a unilateral or unifocal form in 65% to 80% of presenting children, 90% of whom do not have a family history of retinoblastoma.

ETIOLOGY AND EPIDEMIOLOGY

The incidence of retinoblastoma is higher (6 to 10 cases per million children) in Africa, India, and among children of American Indian descent in North America. The increased incidence occurs primarily in unilateral cases. In industrialized countries, an increased incidence of retinoblastoma is associated with poverty and low levels of maternal education, suggesting a role for the environment.[3,4] Human papilloma viruses (HPV) have been implicated in the pathogenesis of retinoblastoma. The viral oncoprotein E7 of high-risk HPV types has been shown to bind to and inactivate the *RB1* gene product (pRB), acting functionally to create biallelic loss of *RB1*.[5,6] High-risk HPV sequences have been detected in 28% to 36% of tumors.[6]

BIOLOGY

In 1971, based on mathematical analysis of the age at presentation of bilateral (hereditary) and unilateral (mostly nonhereditary) cases of retinoblastoma, Knudson proposed the "two-hit hypothesis," in which two mutational events in a developing retinal cell lead to the development of retinoblastoma.[7] This hypothesis was subsequently extended to suggest that the two events could be mutations of both alleles of the *RB1* gene, located in chromosome 13q14 and identified in 1986.[8,9] Its product, pRb, is a key substrate for G1 cyclin-CDK complexes, which phosphorylate target gene products required for the transition of the cell through the G1 phase of the cell cycle. The active pRb functions as a tumor suppressor and is the major gatekeeper controlling this critical point in growth regulation. The lack of pRb or its inactivation will remove the pRb constraint on cell cycle control, with the consequence of deregulated cell proliferation. Biallelic loss of *RB1* function is required for tumor development; this loss is germline and somatic for patients with bilateral disease, and somatic in a single cell in patients with unilateral disease. The *RB1* gene is a large gene, containing 27 exons over about 200 kilobases of DNA, and in patients with familial disease, mutations have been described in almost every exon.[10] New germline mutations have an overwhelming preference for the paternal allele.[5] Penetrance of the trait is greater than 90%.[11] In both hereditary and nonhereditary retinoblastoma, the second tumorigenic event is usually chromosomal in nature, often as a result of mitotic recombination errors.[12] This second hit occurs at a

much higher frequency than the first hit and is more sensitive to environmental factors such as ionizing radiation, perhaps explaining the increased risk of radiation-induced malignancies in survivors of retinoblastoma.

Additional events are required for tumor progression. Approximately two thirds of tumors have *MDM4/MDM2* amplification leading to inactivation of the *p53* pathway.[13] Next-generation sequencing studies have shown up-regulation of the proto-oncogene *SYK* in a large proportion of cases.[14] Other genes and pathways are probably also involved; studies using comparative genomic hybridization have consistently shown chromosomal gains and amplifications at 6p and 1q, and losses at 16q1. Finally, a small proportion of tumors appear to develop in the context of normal *RB1;* amplification of *N-MYC* has been described in those cases.[15]

PREVENTION, EARLY DETECTION, AND GENETIC COUNSELING

The successful management of retinoblastoma depends on the ability to detect the disease while it is still intraocular. Disease stage correlates with delay in diagnosis.[16] In developing countries, late diagnosis is associated with orbital and metastatic disease.[17] Eye assessment is encouraged in all newborns and at subsequent health visits. The consensus guidelines by the American Academy of Pediatrics and Bright Futures for Pediatric Preventive Care include health supervision visits at birth and at 3 weeks to 5 weeks of life; at 1 months, 2 months, 4 months, 6 months, 9 months, and 12 months during the first year; at 15 months, 18 months, and 24 months during the second year; and at 30 months and 3 years, 4 years, and 5 years of life. Importantly, evaluation of vision and ocular health, including red reflex examination, is a component of each visit. Mass screening is being considered, especially where the tumor is common such as in parts of South America and Asia.

Retinoblastoma is a unique neoplasm in that the genetic form imparts a predisposition to developing tumor in an autosomal dominant fashion with almost complete penetrance (85% to 95%).[18] The majority of such children acquire the first mutation as a new germline mutation, with only 15% to 25% having a positive family history. However, some families display an inheritance pattern characterized by reduced penetrance and expressivity. Also, the *RB1* gene mutation can occur at a late stage of embryogenesis, resulting in a variable expression depending on the tissue, causing mosaicisms in 10% to 15% of the patients or their progenitors.[19] Recognizing the inheritance pattern and the existence of mosaicisms, the following familial risk estimates can be made[18]:

1. *Risk for offspring of survivors of retinoblastoma:*
    1. The risk of retinoblastoma arising in the offspring of survivors of bilateral disease is 45%.
    2. In patients with unilateral disease, the risk of retinoblastoma in offspring is 2.5%. (The estimate includes offspring of the 10% of patients with unilateral retinoblastoma with a positive family history in whom the risk is similar to that of bilateral cases, 45%.)
2. *Risk for siblings of patients with retinoblastoma:* In siblings of bilaterally affected children whose parents are also affected, the risk of retinoblastoma is 45%; if the sibling is unilaterally affected, the risk is 30%. Without a family history, the risk is 2% for siblings of bilateral cases and 1% for siblings of unilateral cases.

Genetic counseling is of the utmost importance to assist parents in understanding the genetic consequences of each form of retinoblastoma and to estimate the risk in relatives. With the refinement in methods of mutational analysis over the last decade, detection rates have increased to greater than 90%.[10]

PATHOLOGY AND PATHWAYS OF SPREAD

Macroscopically, retinoblastoma is soft and friable, tending to outgrow its blood supply with resultant necrosis and calcification. Dissemination within the vitreous and retina in the form of small, white nodules (seeds) is common, sometimes making it difficult to distinguish a multicentric primary from a disseminated tumor.[20] The microscopic appearance depends on the degree of differentiation. Undifferentiated retinoblastoma is composed of small, round, densely packed cells with hypochromatic nuclei and scant cytoplasm. Several degrees of photoreceptor differentiation have been described, characterized by distinctive cellular arrangements. Flexner-Wintersteiner rosettes (clusters of low columnar cells arranged around central lumens bounded by eosinophilic membranes analogous to the external membrane of the normal retina) seen in 70% of tumors are specific for retinoblastoma. Fleurettes (composed of larger cells with abundant eosinophilic cytoplasm arranged in a distinctive *fleur de lys* pattern) are less frequent; cells exhibit ultrastructural characteristics of photoreceptor differentiation. Well-differentiated tumors composed almost entirely of fleurettes have been called *retinomas or retinocytomas.* Ultrastructurally, retinoblastoma cells demonstrate photoreceptor differentiation with the presence of the 9-0 microtubule doublet pattern, abundant cytoplasmic microtubules, synaptic ribbons, and neurosecretory granules. In cases of disseminated disease, positive cone-rod homeobox-containing gene (CRX) staining may help differentiate retinoblastoma from other common small blue round cell malignancies of childhood.[21] Guidelines for processing and evaluation of the enucleated eye have been published.[22]

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Retinoblastoma is a tumor of young children. Bilateral retinoblastoma presents at a younger age (usually before 1 year of age) than patients with unilateral disease (typically 1 year to 3 years).[18,23] Half of the cases of retinoblastoma diagnosed during the first year are bilateral, compared with fewer than 10% of those diagnosed after 1 year of age.

In more than 50% of cases, the presenting sign is leukocoria, sometimes first noticed after a flash photograph. Strabismus is the second-most common presenting sign, usually correlated with macular involvement. The differential diagnosis includes other childhood diseases that can present with leukocoria: persistent hyperplastic primary vitreous, retrolental fibrodysplasia, Coat's disease, congenital cataracts, toxocariasis, and toxoplasmosis.

Although most patients with bilateral retinoblastoma carry a germline mutation of the *RB1* gene, only 5% carry a deletion involving the 13q14 locus large enough to be detected by karyotype analysis. In those cases, retinoblastoma is part of a more complex syndrome resulting from the loss of additional genetic material. Patients with the 13q-syndrome are characterized by typical facial dysmorphic features, subtle skeletal abnormalities, and varying degrees of mental retardation and motor impairment.[24] The severity of deficits correlates with the size of the deletion; normal psychomotor development may be seen in patients in whom the deletion is restricted to the 13q14 band.

Trilateral retinoblastoma refers to the association of bilateral retinoblastoma with a typically asynchronous brain tumor.[25] The majority of tumors are pineal region primitive

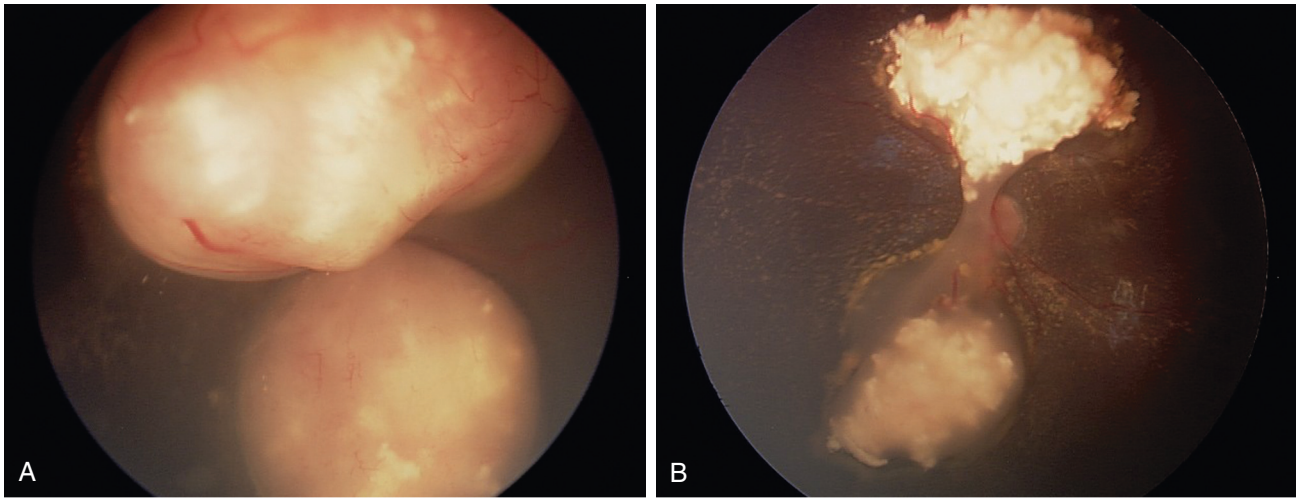

Figure 71-1 **A,** Advanced intraocular retinoblastoma in a patient with bilateral disease. **B,** Same eye after four cycles of chemotherapy.

neuroectodermal tumors PNETs (pineoblastomas); 20% to 25% of the tumors are suprasellar or parasellar. They exhibit varying degrees of neuronal or photoreceptor differentiation, suggesting an origin from the germinal layer of primitive cells. Trilateral disease occurs in 3% to 9% of patients with the genetic form of retinoblastoma and appears to be more common in familial cases. The prognosis until recently has been almost uniformly fatal. The median age at diagnosis of trilateral retinoblastoma is 23 months to 48 months; the interval between initial diagnosis of bilateral retinoblastoma and the diagnosis of the brain tumor is usually more than 20 months.[26] In recent years, with the more widespread use of chemotherapy for patients with bilateral retinoblastoma, the incidence of trilateral retinoblastoma appears to have decreased.[27] Approximately 5% of patients with bilateral disease develop pineal cysts; these appear to be a *forme fruste* of trilateral retinoblastoma.[28]

The diagnosis of intraocular retinoblastoma is usually made without pathologic confirmation. An examination under anesthesia with a maximally dilated pupil and scleral indentation is required to examine the entire retina (Figure 71-1). Endophytic tumors are those that grow inward to the vitreous cavity and may seed the vitreous cavity. Exophytic retinoblastoma grows into the subretinal space, causing progressive retinal detachment and subretinal seeding. A detailed documentation of the number, location and size of tumors, the presence of retinal detachment and subretinal fluid, and the presence of vitreous and subretinal seeds must be performed. Wide-angle real-time retinal imaging systems such as RetCam provide a 130-degree field of view and digital recording, facilitating diagnosis and follow-up.

Imaging studies that aid in diagnosis include bidimensional ultrasound, computerized tomography (CT), and magnetic resonance imaging (MRI); however, it is important to know that neuroimaging findings do not always correlate with pathology in terms of microscopic scleral or optic nerve involvement.[29] Imaging is particularly important to evaluate extraocular extension and to differentiate retinoblastoma from other causes of leukocoria. Evaluation for the presence of metastatic disease also needs to be considered in a subgroup of patients. Metastatic disease occurs in approximately 10% to 15% of patients, usually in association with advanced intraocular features, such as deep choroidal and scleral invasion, or involvement of the iris or ciliary body or the optic nerve beyond the lamina cribrosa.[30,31] In such cases, additional staging should include bone scintigraphy, bone marrow aspirate and biopsy, and lumbar puncture for cerebrospinal fluid (CSF) cytology.

TABLE 71-1 Reese-Ellsworth Grouping for Suitability for Treatment of Retinoblastoma by Radiation Therapy[32]

GROUP I. VERY FAVORABLE	
Ia	Solitary tumor smaller than 4 dd at or behind the equator
Ib	Multiple tumors, none larger than 4 dd, all at or behind equator
GROUP II. FAVORABLE	
IIa	Solitary tumor 4-10 dd, at or behind equator
IIb	Multiple tumors 4-10 dd, at or behind equator
GROUP III. DOUBTFUL	
IIIa	Any lesion anterior to equator
IIIb	Solitary tumor larger than 10 dd behind equator
GROUP IV. UNFAVORABLE	
IVa	Multiple tumors, some larger than 10 dd
IVb	Any lesion extending anteriorly to the ora serrata
GROUP V. VERY UNFAVORABLE	
Va	Massive tumors involving more than half the retina
Vb	Vitreous seeding

dd, *Disk diameter (1.5 mm).*

The Reese-Ellsworth (R-E) grouping system has been the standard for intraocular disease. The R-E system was designed to predict the outcome after EBRT. It divides eyes into five groups on the basis of the size, location and number of lesions, and presence of vitreous seeding (Table 71-1).[32] The changed paradigm for "conservative" chemoreduction (CRD) strategies for intraocular retinoblastoma has made the R-E system less predictive of ocular preservation. A new staging system (International Classification of Retinoblastoma) has been developed to provide a simpler, more user-friendly classification applicable to current therapies. The new system is based on extent of tumor seeding within the vitreous cavity and subretinal space and seems to be a better predictor of treatment success[33] (Box 71-1).

For patients undergoing enucleation, pathologic staging incorporates features known to influence outcome, guiding the therapeutic approach; such factors include choroidal and scleral involvement, optic nerve extension, and presence of

BOX 71-1 International Classification for Intraocular Retinoblastoma

GROUP A

Small tumors away from foveola and disc

- Tumors ≤3 mm in greatest dimension confined to the retina, *and*
- Located at least 3 mm from the foveola and 1.5 mm from the optic disc

GROUP B

All remaining tumors confined to the retina

- All other tumors confined to the retina not in Group A
- Subretinal fluid (without subretinal seeding) ≤3 mm from the base of the tumor

GROUP C

Local subretinal fluid or seeding

- Local subretinal fluid alone >3 to ≤6 mm from the tumor
- Vitreous seeding or subretinal seeding ≤3 mm from the tumor

GROUP D

Diffuse subretinal fluid or seeding

- Subretinal fluid alone >6 mm from the tumor
- Vitreous seeding or subretinal seeding >3 mm from tumor

GROUP E

Presence of any or more of these poor prognosis features

- More than two thirds globe filled with tumor
- Tumor in anterior segment
- Tumor in or on the ciliary body
- Iris neovascularization
- Neovascular glaucoma
- Opaque media from hemorrhage
- Tumor necrosis with aseptic orbital cellulitis
- Phthisis bulbi

BOX 71-2 International Retinoblastoma Staging System, Proposed (Treatment-Based System, Chantada)[33]

Stage 0. Patients treated conservatively
Stage I. Eye enucleated, completely resected histologically
Stage II. Eye enucleated, microscopic residual tumor
Stage III. Regional extension
1. Overt orbital disease
2. Preauricular or cervical lymph node extension

Stage IV. Metastatic disease
1. **Hematogenous metastasis** (without central nervous system involvement)
   1. Single lesion
   2. Multiple lesions
2. **Central nervous system extension** (with or without any other site of regional or metastatic disease)
   1. Prechiasmatic lesion
   2. Central nervous systems mass
   3. Leptomeningeal and cerebrospinal fluid disease

metastatic disease. A third proposed staging system developed by an international consortium of ophthalmologists and pediatric oncologists incorporates the most important elements of the older systems[34] (Box 71-2).

Growth and invasion occur as a sequence of events, and extraretinal extension occurs only after the tumor has reached large intraocular dimensions. As part of this process, retinoblastoma extends into the ocular coats (choroids and sclera), the optic nerve, and the anterior segment. Extraocular disease is the next step in this progression. Locoregional dissemination occurs by direct extension through the sclera into the orbital contents and preauricular lymph nodes. Extraorbital disease manifests as intracranial tumor, leptomeningeal dissemination, or hematogenous metastasis.

PRIMARY THERAPY: PRINCIPLES OF TREATMENT

Treatment of retinoblastoma aims to save life and preserve useful vision, with attention to the risk of late functional and carcinogenic effects, and contemporary care requires coordination between the ophthalmologist, pediatric oncologist, and radiation oncologist.[35]

Surgery

Enucleation is indicated for large tumors filling the vitreous when there is little or no likelihood of restoring vision, and when tumor is present in the anterior chamber or associated with neovascular glaucoma. The eye must be removed intact, without seeding tumor cells into the orbit.[36] For optimal staging, a long segment (10 mm to 15 mm) of the optic nerve is removed with the globe. An orbital implant is usually fitted during the same procedure, and the extraocular muscles are attached to it. A ceramic false eye is later fitted in the orbital socket. Orbital exenteration is seldom indicated. For patients presenting with orbital (extraocular) disease, judicious use of chemotherapy, surgery, and radiation therapy often provides tumor control so that orbital exenteration is now usually reserved for cases of recurrent disease after radiation therapy.

Focal Surgical Therapies

Focal treatment is used for small tumors (less than 3 mm to 6 mm), classically in patients with bilateral disease and in combination with chemotherapy. Focal therapies are central to conservative therapy (chemotherapy and focal treatment) to avoid enucleation and EBRT in unilateral intraocular disease. Photocoagulation with argon laser is used for the treatment of tumors situated at or posterior to the equator of the eye and for the treatment of retinal neovascularization occasionally seen after radiation therapy.[37] This technique is limited to tumors measuring no greater than 4.5 mm in base and no greater than 2.5 mm in height. The treatment aims to obliterate blood supply to the tumor. Two- or three-monthly sessions are usually required, achieving local tumor control in approximately 70% of cases. Cryotherapy is used for the treatment of small equatorial and peripheral lesions, measuring no more than 3.5 mm in base and no more than 2 mm in height.[38] One- or two-monthly sessions of triple freeze and thaw are performed; the resultant tumor control is usually excellent. A more recently introduced focal therapy is transpupillary thermotherapy, which applies focused heat at subphotocoagulation levels, usually with diode laser.[39] In thermotherapy, the goal is to deliver a temperature of 42°C to 60°C for 5 minutes to 20 minutes to the tumor, relatively sparing retinal vessels from photocoagulation. The use of focal treatments is especially important in conjunction with chemotherapy, where both treatment modalities appear to have synergistic effects. Sequential thermotherapy and carboplatin enhances

antitumor effect by increasing the platinum-DNA adducts; thermochemotherapy is becoming an important component of therapy for intraocular retinoblastoma.[40] In general, local control rates of 70% to 80% can be achieved. Complications of focal treatments include transient serous retinal detachment, retinal traction and tears, and localized fibrosis.

Chemotherapy

Chemotherapy is indicated in patients with extraocular disease, in patients with intraocular disease undergoing enucleation and found to have high-risk pathology, and in patients with intraocular disease in whom it is given either systemically or intraarterially in conjunction with aggressive focal therapies for ocular preservation. Agents effective in the treatment of retinoblastoma include platinum compounds, etoposide, cyclophosphamide, doxorubicin, vincristine, and ifosfamide.[35,41] Melphalan, carboplatin, and topotecan are the agents most commonly used in intraarterial administration.[42,43]

Intravitreal and Intraarterial Chemotherapy for Intraocular Retinoblastoma

Japanese investigators have pioneered the use of intravitreal and intraarterial melphalan for patients with advanced or recurrent intraocular retinoblastoma.[44] Good clinical responses in patients with progressive retinoblastoma were obtained using intravitreal melphalan followed by hyperthermia.[44] Kaneko et al initially reported the feasibility of injecting melphalan into the ipsilateral carotid artery, with documented efficacy.[44] The technique was later perfected by Mohri using a balloon catheter inflated in the distal internal carotid artery, which allowed for selective flow into the ophthalmic artery.[45] More recently, Abramson et al reported a variation of this technique that includes a direct cannulation of the ophthalmic artery using a microcatheter.[46] Using this approach, high ocular salvage rates can be achieved after the administration of 3 mg to 5 mg of intraarterial melphalan, although other agents such as topotecan and carboplatin are also used.[42,43,47] The use of this new treatment modality is being progressively incorporated into the frontline of ocular salvage for intraocular retinoblastoma. Direct administration of melphalan into the vitreous is also a promising approach for cases with vitreous disease.[48,49]

Radiation Therapy

Radiation therapy was historically the primary treatment for patients with bilateral disease. Through the early 1990s, debate focused on optimizing irradiation for localized and locally advanced intraocular disease, extraocular extension, and CNS disease (primarily trilateral, but also leptomeningeal extension). Although disease control in most local-regional presentations was excellent, the documentation of a high incidence, particularly in bilateral or hereditary retinoblastoma, of secondary malignancies continuing three to five decades after irradiation prompted a paradigm shift. Neoadjuvant chemotherapy combined with focal therapy for consolidation or focally "resistant" disease is now the standard of care for early-stage disease, unilateral or bilateral. Focal therapies as discussed, as well as radioactive plaques, are used in advanced intraocular disease requiring postchemotherapy consolidation or salvage. For cases with more advanced intraocular disease, extraocular extension, or distant metastasis, consolidative EBRT is used for local tumor control. Low-dose consolidative radiation therapy at a point when advanced intraocular or CNS disease is minimal yet "responsive" to, rather than resistant to, chemotherapy is under investigation.[50]

PRIMARY THERAPY: INTRAOCULAR RETINOBLASTOMA

Unilateral Retinoblastoma

Enucleation is curative for 85% to 90% of children who present with unilateral intraocular disease. Outcome is excellent, with good functional results and minimal long-term effects.[51] In view of the success in treating bilateral intraocular disease with chemotherapy and focal therapy, a similar "conservative" approach may be appropriate in unilateral intraocular disease, especially in young children who may later evidence contralateral disease. With the use of intraarterial chemotherapy, ocular salvage rates above 70% to 80% can be achieved for patients with intraocular unilateral disease.[43]

For patients undergoing enucleation, adjuvant treatment is indicated in patients with scleral invasion and those with tumor at the cut end of the optic nerve. Adjuvant treatment for other patients with intraocular disease is debatable. In the absence of randomized studies, available information would suggest that the use of adjuvant chemotherapy is beneficial for selected patients at higher risk of extraocular dissemination such as those with retro-laminar and choroidal involvement, and possibly those with massive choroidal involvement. Adjuvant chemotherapy is not indicated for patients with prelaminar involvement or isolated focal choroidal involvement.[35] Different chemotherapy regimens have been proposed. A 6-month treatment with vincristine, cyclophosphamide, and doxorubicin (VDC), vincristine, carboplatin, and etoposide (VCE), or a hybrid, with alternating courses of both regimens, appears to be effective. Radiation therapy is indicated only when there is transscleral disease or involvement of the cut end of the optic nerve.

Bilateral Retinoblastoma

Bilateral disease typically presents with advanced disease in one eye and relatively more localized disease contralaterally. In the past, treatment typically consisted of enucleation of the eye with more advanced disease (when little or no visual potential is apparent) and EBRT for the remaining eye. However, although associated with good tumor control, such treatment is associated with important long-term sequelae. Irradiation of the orbit during a period of rapid growth in young children results in significant reduction in orbital and zygomatic facial growth, whether symmetric (following opposed lateral radiation techniques) or asymmetric (with unilateral orbital irradiation), with dysmorphic changes apparent before puberty. As well, patients are at significant risk for secondary cancers; the standard incidence ratio (SIR) for sarcomas exceeds 100 times the expected rate and for carcinomas (e.g., breast, thyroid, lung, head and neck), at or above 10 times the expected rate.[52] This risk may be age-related and less in older children.[53]

The treatment of patients with bilateral retinoblastoma now incorporates upfront chemotherapy, either by systemic or intraarterial administration, intended to achieve maximum chemoreduction of the intraocular tumor burden, followed by aggressive focal therapies (Figure 71-2). The use of carboplatin-based multiagent chemotherapy or melphalan-based intraarterial therapy, along with consolidative local therapies, has resulted in avoidance of both enucleation and EBRT in more than 75% of patients.

For systemic therapy, the best results have been obtained with combinations of VCE.[35] When using intraarterial therapy, best responses are achieved with melphalan, alone or in combination with carboplatin and topotecan.[42,43]

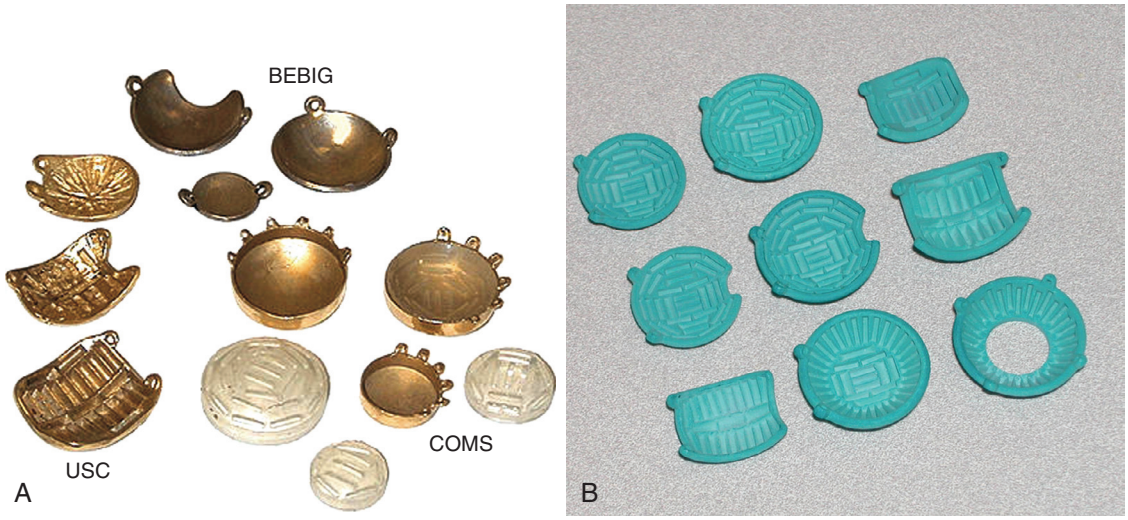

Figure 71-2 **A,** A mixture of some of the current plaques that are available today from various vendors. **B,** Prototypes showing the shapes that are possible in modern plaques.
From Astrahan M: Plaque Simulator X computer program and electronic manual [screen capture of the program written by Dr. Melvin Astrahan called Plaque Simulator X]. Image used with permission, 2010.

For systemic administration, although the three-drug regimen is the standard of care, for patients with early intraocular disease (R-E Groups I to III, International Group B), a nonintense two-drug regimen of vincristine and carboplatin has also been shown to be effective when aggressive focal consolidation is added.[35,54] With more advanced tumors, a major proportion of failures represent tumor growth as vitreous seeding or subretinal implants. Carboplatin diffuses well into the vitreous, and periocular (subconjunctival or episcleral) administration has been explored in conjunction with systemic carboplatin delivery to maximize intraocular exposure of retinoblastoma cells. However, this approach has not shown a significant impact in ocular survival.[55]

New agents with better intraocular penetration are being investigated. Topotecan is of interest with excellent intraocular penetration and preclinical and clinical efficacy.[56,57] The recent description of *MDM4* amplification as the mechanism of inactivation of the *p53* pathway in retinoblastoma has opened the door to the use of specific targeted molecular therapies. Nutlin-3 is a small-molecule inhibitor of the *MDM2-p53* interaction.[58] *MDM4* and *MDM2* bind *p53* with similar affinities, and studies have shown that nutlin-3 prevents the *MDM4-p53* interaction in retinoblastoma cells, inducing *p53*-mediated apoptosis in vitro and in vivo. Subconjunctival injection of nutlin-3 to mice with intraocular retinoblastoma resulted in significant tumor responses. The combination of nutlin-3 with a DNA damaging agent such as topotecan resulted in a synergistic effect.[13,59] Finally, targeting the SYK proto-oncogene may also offer a new therapeutic approach.[14]

TREATMENT OF EXTRAOCULAR RETINOBLASTOMA

Extraocular dissemination of retinoblastoma usually reflects delayed diagnosis and treatment. In Europe and the United States, fewer than 5% of patients present with extraocular disease, in contrast to more than 20% to 40% in less-developed countries.[60,61] Four patterns of extraocular disease have been recognized: (1) locoregional, including orbital infiltration, tumor extending into the optic nerve or to the cut end of the nerve, and lymphatic spread to preauricular lymph nodes; (2) CNS dissemination; (3) trilateral retinoblastoma; and (4) metastatic retinoblastoma.

Orbital and Locoregional Retinoblastoma

Orbital retinoblastoma occurs as a result of progression of the tumor through the emissary vessels and sclera; transscleral disease is considered to be extraocular and is treated as such. Orbital retinoblastoma is isolated in 60% to 70% of cases; lymphatic, hematogenous, and CNS metastases occur in 30% to 40% of patients with metastasis.[62] Treatment includes systemic chemotherapy and radiation therapy; with this approach, 60% to 85% of patients are cured. Failures occur predominantly in the CNS, highlighting the importance of drugs with CNS penetration. Different chemotherapy regimens have proven effective, including vincristine, cyclophosphamide, and doxorubicin, platinum- and epipodophyllotoxin-based regimens, or combinations thereof.[35] For patients with macroscopic orbital disease, upfront chemotherapy is followed by surgery, usually obviating the need for orbital exenteration. Postoperative chemotherapy and orbital irradiation (40 Gy to 45 Gy) consolidate therapy.[63] Similar management is appropriate for patients with scleral disease although good outcomes without irradiation have also been reported.[60] Patients with involvement of the optic nerve at the cut end should also receive similar systemic treatment with irradiation to the entire orbit, typically to a dose of 36 Gy with a 9-Gy to 10-Gy boost to the remainder of the optic nerve and chiasm (total 45 Gy to 46 Gy). Recent data from Argentina show disease control in 70% of cases with the use of induction chemotherapy, enucleation, and adjuvant chemotherapy together with radiotherapy (45 Gy) for patients ($N = 26$) with tumor at the optic nerve resection margin.[64] Excellent results have been described by the Children's Hospital Los Angeles group using a similar approach in nine patients with proximal optic nerve enhancement on MRI, but with more selective use of radiation. All were disease-free at 22 months of follow-up, only two of them having been given orbital radiation.[65]

The preauricular and cervical lymph nodes should be imaged carefully because 20% of patients with orbital extension have lymphatic metastases.[62] Lymphatic dissemination may not carry a worse prognosis, provided that the involved lymph nodes are also irradiated.

Central Nervous System Involvement

Intracranial dissemination occurs by direct extension along the optic nerve. Prognosis is dismal.[60,63] Treatment includes platinum-based intensive systemic chemotherapy and CNS-directed therapy. Although intrathecal chemotherapy has been traditionally used, there is no preclinical or clinical evidence to support its use. Although controversial, standard therapy includes radiotherapy consisting of craniospinal irradiation to a dose of 23.4 Gy to 36 Gy followed by a boost to 45 Gy to sites of overt or nodular disease. Therapeutic intensification with high-dose, marrow ablative chemotherapy and autologous hematopoietic progenitor cell rescue has been explored, but its role is not yet clear.[66,67] Despite such treatment, survivors are anecdotal.

Trilateral Retinoblastoma

The prognosis for patients with trilateral retinoblastoma is poor; most patients die of disseminated neuraxis disease in less than nine months.[26] The rare survivors are usually those diagnosed by screening imaging while asymptomatic and treated with intensive chemotherapy with or without craniospinal irradiation. Given the short interval between the diagnosis of retinoblastoma and the occurrence of trilateral retinoblastoma, routine screening might detect the majority of cases within 2 years. Typical treatment now consists of intensive chemotherapy followed by consolidation with myeloablative chemotherapy and autologous hematopoietic progenitor cell rescue without radiation therapy, an approach similar to that used in the treatment of brain tumors in infants.[68,69]

(Extracranial) Metastatic Retinoblastoma

Hematogenous metastases are most commonly seen in bone and bone marrow, and, less frequently, the liver. Long-term survival after conventional chemotherapy is anecdotal. However, recent reports suggest that metastatic retinoblastoma can be cured using short and intensive induction regimens usually containing alkylating agents, anthracyclines, etoposide, and platinum compounds consolidated with marrow-ablative chemotherapy and autologous hematopoietic cell rescue.[67] In the latter series, patients with hematogenous bone metastases who responded to induction chemotherapy did not always require radiation therapy.

TECHNIQUES OF IRRADIATION

In contemporary management of retinoblastoma, radiotherapy is most often used as consolidative or "salvage" therapy for disease resistant to or recurrent following chemotherapy, or as part of initial treatment for patients with extraocular spread. Consequently the target volume for radiation therapy ranges from focal to whole orbit, optic nerve and chiasm, and the technique to be used therefore is the most appropriate of several options including plaque brachytherapy, three-dimensional conformal radiation therapy (3D-CRT), intensity-modulated radiation therapy (IMRT), stereotactic radiation therapy (SRT), and proton therapy.

Plaque Brachytherapy

Radioactive plaques have been used for the treatment of ocular tumors since the 1920s, at that time using radon seeds.[70,71] Other radioactive sources have since become available including cobalt-60 in the 1950s, and more recently iodine-125 (^{125}I), iridium-192 (^{192}Ir), and ruthenium-106 (^{106}Ru).[72-76]

Plaque radiotherapy is an option for localized retinoblastoma limited to one or two lesions not involving the optic disc or macula. It can also be used in conjunction with chemoreductive therapy.

Planning for plaque placement involves identification of tumor size and location as evaluated by the ophthalmologist, together with direct visualization with the RetCam and ocular ultrasound, and sometimes MRI. The target volume includes the tumor base as projected through the sclera plus a 1-mm to 2-mm margin. Tumor height is a direct measurement from the imaging data with 1 mm added for the thickness of the sclera. The plan provides proper positioning based on the plaque's center and suture eyelets and the distance from the limbus. The surgeon provides access to the sclera underlying the typically posterior tumor, marking the center and edges of the tumor based on projection. A dummy plaque of identical configuration is used to verify positioning and the loaded episcleral plaque is sutured onto the sclera by the ophthalmologist. A lead eye shield is used to reduce exposure of personnel when ^{125}I is used. Inpatient or outpatient status depends on radiation exposure and local requirements.

The dose is prescribed at the tumor apex or extended to include overlying vitreous seeds if present. The target dose is typically 40 Gy to 45 Gy at the apex for ^{125}I at a dose rate of 40 cGy/hr to 80 cGy/hr.[72,74,75] Most of the experience with ^{106}Ru reports apical doses of 50 Gy, or sometimes 70 Gy.[73,76] The dose at the tumor base (scleral dose) approximates 120 Gy for ^{125}I and 150-200 Gy with ^{106}Ru.

Most plaques today use ^{125}I, a low-energy γ-ray emitter (27 keV to 35 keV; half-life, 60 days) that is readily available in encapsulated form, allowing custom fabrication of gold plaques of varying sizes and configured either as round or notched templates, the latter to allow placement adjacent to the optic nerve. The ^{125}I seeds can be differentially loaded within the wells of the plaque to achieve a dose distribution appropriate for the tumor. ^{125}I plaques are typically used for tumor height up to 10 mm and basal diameter ≤ 16 mm. Figure 71-3 shows some current and prototype plaques. Figure 71-4 demonstrates a case using a collimating plaque. ^{192}Ir is an alternative radioisotope (295 keV to 612 keV; half-life, 74 days), also available as sealed sources with somewhat less desirable dosimetric characteristics. Experience with ^{106}Ru has primarily been reported from Europe.[73,76] The pure β emitter provides a spectrum of β particles with energies up to 3.5 MeV; the half-life is longer than ^{125}I and ^{192}Ir at 374 days. The dosimetric profile of ^{106}Ru limits utilization to tumors with height ≤6 mm; the uniformly round plaques are typically not applied within 2 mm of the optic nerve.[73] Both ^{125}I and ^{106}Ru limit radiation exposure to patient and medical personnel while allowing one to diminish dose to the underlying orbital bones and the optic lens.

At the Wills Eye Hospital, Philadelphia, 208 tumors (141 children) were treated with plaque radiotherapy between 1976 and 1999, 71% of which had received prior treatment.[72] Tumor control was 83% at 1 year, and 79% at 5 years. For tumors treated with plaque RT as their primary treatment, recurrence at 1 year was 12%, compared to 20% for those treated for salvage after failure of prior treatment. Factors predicting for tumor recurrence were presence of tumor seeds in the vitreous, presence of subretinal tumor seeds, and increasing patient age. At 5 years, radiation-induced complications included cataract (31%), nonproliferative retinopathy (27%), papillopathy (26%), maculopathy (25%), proliferative retinopathy (15%), and glaucoma (11%). No cases of scleral necrosis were observed. In 2006, the same group published their experience using ^{125}I plaque RT for tumors recurring after chemoreduction (1994 to 2005).[74] Eighty-four tumors were treated in 71 eyes (64 patients). At 5 years, tumor control was documented in 95% of patients. Failures occurred at a median of 4 months postimplant.

A similar 5-year tumor control rate of 94.4% was reported in a retrospective analysis of 175 tumors (134 patients) treated

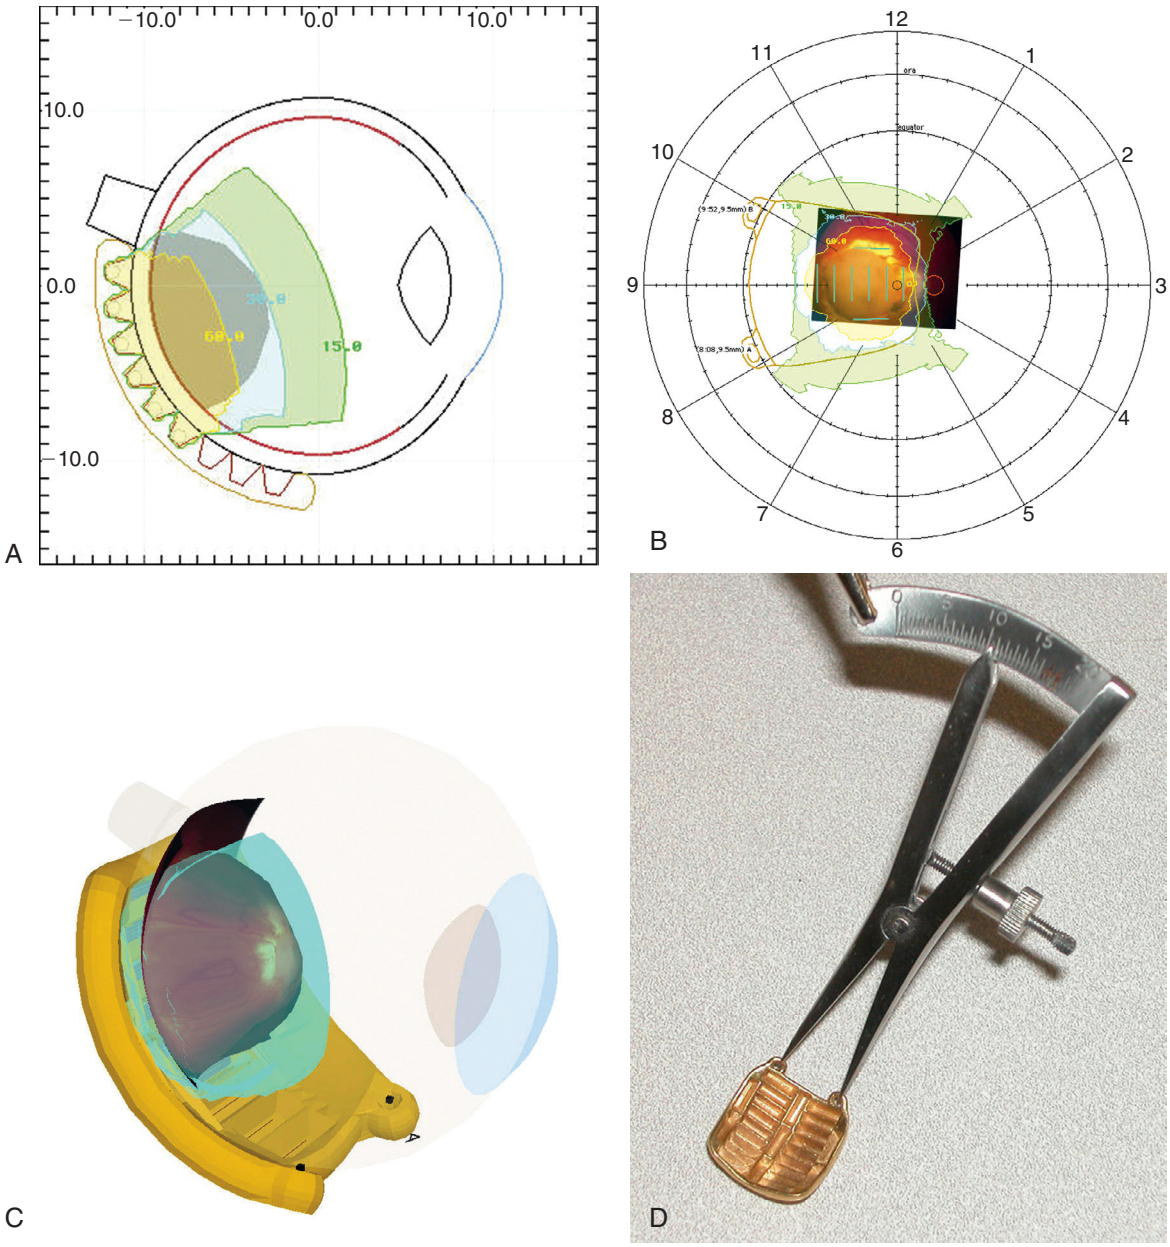

Figure 71-3 This 8-month-old child's eye had a diameter of 22 mm and required a plaque with an 11-mm radius of curvature; the dose prescribed was 30 Gy in 71 hours to the apex of the 6.7-mm high tumor. Only the seeds at the posterior end of this semielliptical, mildly notched plaque that lie under the tumor are loaded. This allows the sutures to be placed anteriorly. The perfect fit of the plaque to the eye ensures that the plaque will not lift up at the posterior end when sutured anteriorly. **A,** Retinoblastoma with a grooved plaque in which the grooves help collimate the radiation dose as shown by the isodose levels. **B,** Diagram of the retina in the same plan with suture marks in the model to help guide the team in the operating room. **C,** Three-dimensional conformal isodose map of the same plan. **D,** Measuring the actual plaque's eyelets from the same plan using Castroviejo calipers.

with ^{106}Ru plaque at the University Hospital in Essen, Germany.[73] Their estimate for eye preservation at 5 years was 86.5%. Most of the cases (119 tumors in 95 eyes) had received plaque radiotherapy as a secondary treatment.

More recently, Francis et al from the Memorial Sloan Kettering Cancer Center described their experience with plaque radiotherapy in 15 eyes after intraarterial chemotherapy (OAC).[77] Thirteen patients were treated with plaque radiotherapy as salvage therapy, of whom 12 had localized vitreous seeding. The estimate for ocular survival at 18 months was 79.4%. Of note, patients with ocular complications had a significantly shorter interval (mean, 2.5 months) between their last OAC and plaque than patients without ocular complications (mean, 6.5 months).

Stereotactic Radiotherapy

Stereotactic radiotherapy (SRT)[78-81] is an alternative to plaque radiotherapy for the treatment of locally progressive disease or as focal consolidative therapy. Compared with plaque radiotherapy, SRT is a noninvasive treatment that does not require special technical skills and that can be delivered using

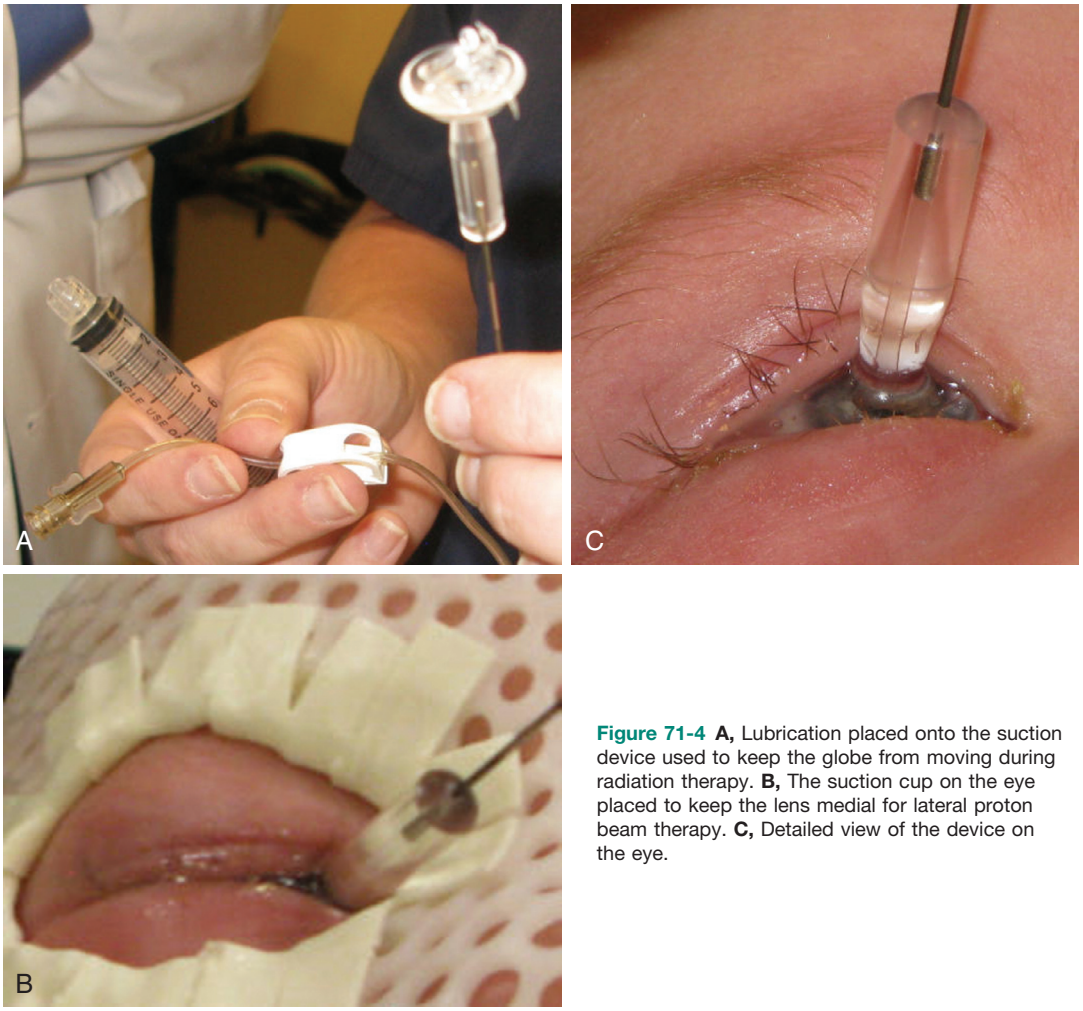

Figure 71-4 **A,** Lubrication placed onto the suction device used to keep the globe from moving during radiation therapy. **B,** The suction cup on the eye placed to keep the lens medial for lateral proton beam therapy. **C,** Detailed view of the device on the eye.

conventional fractionation. The dose within the target volume is more homogeneous and the dose to the external sclera lower, thus reducing the risk of optic nerve damage for tumors close to the optic nerve.[80]

Clinical experience in 11 children (15 eyes) treated in Switzerland with SRT with a dose of 50.4 Gy in 28 fractions showed a high local control rate of 87%, at a median follow-up of 20 months.[81] In this series, patients selected for SRT were those with recurrent retinoblastoma involving the optic nerve or macula after chemotherapy or other local treatment and potentially active residual papillary tumor not suitable for other focal therapy. Patients with diffuse subretinal or vitreous seeds, retrobulbar optic nerve invasion and other extraocular involvement were considered not suitable for SRT. Long-term side effects were observed in only four children: two cases of focal microangiopathy, one case of transient recurrence of retinal detachment and one case of bilateral cataracts. No optic neuropathy was seen.

The target volume for SRT is the GTV as seen on the planning CT (with or without MRI) to which a margin of 2 mm to 3 mm is added to obtain the planning target volume (PTV). Immobilization of the eye using a suction device (see discussion) at CT simulation and on each treatment day is critical.

External Beam Radiation Therapy

Classically, full orbital irradiation was used in children with bilateral disease; the eye with more advanced disease was enucleated and irradiation was given for the contralateral eye. Less commonly, irradiation was administered to both eyes when reasonable likelihood of disease control and visual preservation was present bilaterally. Now, however, EBRT is more typically used as consolidative therapy in conjunction with chemoreductive therapy for intraocular disease, for treatment of locoregionally extensive tumor, or as salvage therapy for disease progressing on chemotherapy.

Historically, irradiation of the retina was delivered using a single lateral field when treating one eye or parallel-opposed fields for both eyes. However, such "D-shaped" fields, by attempting to spare the lens, underdose the anterior retina from the equator to the ora serrata. Other techniques, such as a direct anterior electron or photon field technique, a two field-technique using a lateral field and an anterior field with a lens block, modified lateral field technique using oblique angles, noncoplanar arcs, IMRT, and many other techniques can also be used, each one having its advantages and disadvantages. In a dosimetry study comparing 13 techniques, Reisner et al found that IMRT best spared the orbit and lacrimal gland while ensuring a therapeutic dose to the ora serrata and vitreous.[82] Similarly, Krasin et al showed that IMRT reduced the dose to the bony orbit by more than one third in comparison to anterior-lateral photon and electron techniques, and by 23% compared with conformal techniques.[83] Doses to the temporal lobe and contralateral orbit were also reduced.

The prescription dose for retinoblastoma is classically 45 Gy at 1.8 Gy to 2.0 Gy per fraction. Foote reviewed the

Mayo Clinic experience, documenting a lack of dose-response relationship above 45 Gy, except perhaps for tumors larger than 10 DD that had a lower control rate (67%) in this series.[84] The use of lower doses of 32 Gy to 38 Gy (median, 36 Gy), was reported by Merchant et al.[85] In a series of 38 children (49 eyes) treated at St. Jude Children's Research Hospital, therapy was individualized based on presentation, with use of several treatment modalities in addition to EBRT for certain cases (laser, plaque radiotherapy, chemotherapy, etc.). Additional treatment was required after EBRT for 19 of 49 eyes, at a median time of 13.7 months. The ocular preservation rate was estimated to be 82% at 10 years for the whole cohort, but lower for patients with R-E groups III-V disease, with 7 of the 20 advanced-disease eyes requiring enucleation.

In the setting of chemoreductive therapy for group E eyes, consolidative EBRT has been tested at a reduced "prophylactic" dose of 26 Gy when initially advanced disease is yet responsive to induction chemotherapy.[50] The use of EBRT resulted in a globe salvage rate of 80% at 5 years, compared to 48% with eyes treated with chemoreductive therapy alone.

Children with retinoblastoma requiring EBRT are generally planned and treated under anesthesia, typically immobilized with a thermoplastic mask. The use of an ocular suction system integrated to a stereotactic mask enables immobilization of the eye during anesthesia and enhances precision in localization and treatment delivery. A planning CT scan should be obtained, with slices 1-mm to 2-mm thick. Coregistration with MRI is helpful, especially for SRT for focal irradiation. When treating the whole eye, the clinical target volume (CTV) encompasses the globe and the proximal 0.5 cm of the optic nerve. If the optic nerve is involved, the CTV will extend posteriorly to include the remaining optic nerve and optic chiasm. If there is extraorbital extension, the CTV will extend to the walls of the orbit. The PTV depends on the immobilization used and the availability of in-room image guidance and will therefore vary between 2 mm and 5 mm. Organs at risk (OAR) include the ipsilateral and contralateral bony orbits, the temporal lobe and whole brain, the contralateral eye and lens, the lacrimal glands, the optic nerves and chiasm, and the pituitary gland. The PTV should be adequately covered by the 95% prescription isodose. Homogeneity within the target and minimization of doses to OARs should be considered during the optimization process. The volume of the ipsilateral bony orbit receiving a dose of ≥20 Gy should be minimized because it is the suggested threshold for bone growth.

Proton Therapy

Proton therapy may be an interesting option for patients with retinoblastoma, whether for focal or whole eye treatment (Figures 71-5 and 71-6). In a retrospective dosimetric study of three cases from the M. D. Anderson Cancer Center, proton therapy was found to provide the best target coverage combined with the greatest orbital bone sparing in patients treated to a dose of 36 Gy in 18 fractions to the entire retina and vitreous cavity.[86] While providing 100% target coverage, protons were able to limit the mean orbital bone volume irradiated at ≥5 Gy to 10%, a dose low enough to potentially decrease the likelihood of orbital bone growth defects postirradiation. Krengli et al similarly described homogeneous target coverage for different intraocular tumor locations, with lens sparing and reduction of doses to bony structures.[87]

In 2011, Chang et al reported their clinical experience with three children who received proton therapy for retinoblastoma treated with chemoreductive therapy and focal therapy that were either not responding or progressing.[88] All patients responded to proton therapy but two eventually needed enucleation for recurrence. Clinical use of proton therapy for retinoblastoma has also been described by investigators from the Paul Scherrer Institute,[79] as well as the group from Boston that compared outcomes in patients treated with proton radiotherapy ($N = 55$) and photon radiotherapy ($N = 31$) between 1986 and 2011.[89] With the caveat that follow-up was shorter in the cohort treated with protons (median, 6.9 years versus 13.1 years), the 10-year cumulative incidence of radiotherapy-induced or in-field second malignancies was significantly lower with proton RT (0% versus 14%).

LONG-TERM EFFECTS OF RETINOBLASTOMA AND ITS TREATMENT

Children treated for retinoblastoma are at risk of functionally and cosmetically significant bony abnormalities that become evident by early adolescence when orbital growth is largely complete. Both enucleation, which causes orbital contraction, and radiation therapy, which induces arrest of bone growth, adversely affect orbital growth. In children treated for bilateral retinoblastoma, the impact of enucleation in orbital development is not different from that of irradiation. Patients with retinoblastoma are also at risk of chemotherapy-related complications. Carboplatin-induced ototoxicity has been rarely reported[90]; however, infants younger than 6 months of age appear to be at a higher risk of hearing loss.[91]

However, the principal concern, and the one that has motivated practice change over the past decade, is the risk of secondary malignancies, particularly in children with germline mutations of the *RB1* gene identified in long-term survivor cohorts as those with hereditary retinoblastoma who are at especially high risk. Patients with nonhereditary retinoblastoma are not inherently at increased risk. In the largest cohort study that combined data from major pediatric centers in Boston and New York City, the cumulative incidence of secondary cancers in 1601 patients treated between 1914 and 1984 and surviving more than 1 year postdiagnosis was 36% for the hereditary form and 5.7% for the sporadic/nonhereditary cohort at 50 years postdiagnosis. Exposure to radiation therapy increased the risk of second malignant neoplasms in the hereditary population 3.1-fold. At 50 years post diagnosis, the cumulative incidence of second malignant neoplasms was 38.2% following irradiation and 21% without radiation therapy.[52,92] In the sporadic cohort, the risk of second malignant neoplasms exceeded the general population only for breast cancer (2.8 times), especially among those with radiation exposure (10 times).

In a subsequent report that now included at total of 1854 patients treated between 1914 and 1996, cumulative mortality from second malignant neoplasms at 50 years postdiagnosis was 25.5% for hereditary retinoblastoma survivors and 1% for the nonhereditary cohort.[93] Among hereditary retinoblastoma survivors, the most-common secondary malignant neoplasms were sarcomas of bone and soft tissue, melanoma, and cancers of brain and other parts of the CNS. Cancers of bone and soft tissue accounted for 76.5% of all deaths from secondary cancers before an attained age of 25 years. In hereditary retinoblastoma survivors older than age 25, cancers of bone and soft tissue accounted for a smaller percentage (35.7%) of all deaths from secondary cancers and excess mortality from secondary cancers at other sites began to emerge including lung and corpus uteri. With the exception of lung cancer, the mortality rates were consistently higher among hereditary retinoblastoma survivors who were irradiated. In a Dutch population-based series standardized mortality rates (SMR) were higher for hereditary retinoblastoma survivors treated with chemotherapy in addition to radiotherapy (SMR = 60.9 as compared with 18.1 for radiotherapy alone) and lower for

those treated with surgery alone (7.95).[94] Although bone and soft tissue tumors arising in the radiation field may be difficult to treat, good treatment options exist for many other secondary malignancies and all patients need good follow up with appropriate screening to ensure early intervention.

Current treatment approaches are likely to result in a reduced risk of late sequelae as compared to those used in the past. Decreased use of EBRT is expected to result in a decreased incidence of secondary malignant neoplasms.[95] When radiation therapy is necessary, delay to treatment (on average, using chemoreductive therapy, for at least 6 or 7 months to median age 21 months) is likely to result in reduced frequency and severity of the most prevalent postirradiation side effects because effects on bone development and susceptibility to carcinogenesis appear to be greatest following radiation exposure during the first year of life.[96] Finally, newer radiotherapy techniques that allow greater sparing of orbital bone, the use of conventional fractionation schedules and lower total doses, as well as newer modalities such as protons are also likely to reduce the risk of late sequelae.[89]

TREATMENT ALGORITHMS, CONTROVERSIES, PROBLEMS, AND FUTURE DIRECTIONS

One of the challenges of retinoblastoma management is the process of accurate staging. This requires a multidisciplinary team of experienced ophthalmologists, radiologists, and pathologists. The description of the retina by the ophthalmologist during the examination under anesthesia is critical. Technology that allows panoramic imaging of the eye has proven its worth, but not to the point where detailed surgical notes are no longer needed. The experience of the pathologist is critical because the handling and evaluation of the eye globe is challenging. For this reason, it has been necessary for research protocols to include explicitly tissue-handling

guidelines meant to optimize the quality of pathological collection of retinoblastoma tissue.[22]

Once properly staged, it is important to review the most appropriate treatment approach, which may range from upfront enucleation to an eye-preserving approach with systemic or intraarterial chemotherapy and aggressive focal consolidation or radiation therapy. The use of intraarterial and intravitreal chemotherapy is becoming more common, but those approaches should only be undertaken in specialized centers. Decisions must be made in the context of a multidisciplinary team with expertise in the disease; ideally, patients should be managed at a state of the art retinoblastoma treatment center. The newer techniques of potential value in retinoblastoma make a simple chart of what to do relatively inadequate to the task. Figure 71-7 outlines current therapeutic algorithms.

CHAPTER

72 Neuroblastoma

Suzanne L. Wolden and Stephen S. Roberts

EPIDEMIOLOGY

Neuroblastoma comprises 8% to 10% of childhood cancers, with 650 cases reported annually in the United States. It is the most common extracranial solid tumor in children and the most common malignancy in infants. The tumor primarily occurs in neural crest–derived tissues, and the adrenal gland is its most common location.

EARLY DETECTION

Screening has not impacted on survival or detection of high-risk neuroblastoma. Neuroblastoma-like cells are found in normal development.

BIOLOGY, CLASSIFICATION, AND STAGING

Segmental chromosomal abnormalities including deletions of 1p36 and 11q and unbalanced gain of chromosome 17q and *MYCN* amplification are associated with a worse prognosis. Neuroblastoma contains small, round, blue cells that stain for neural features. Lymphatic spread is common, as is spread to the bones of the skull, whereas lung metastases are rare. Brain metastases are seen in 5% to 10% of cases at relapse. Children younger than 18 months of age generally have localized disease, whereas older children generally have disseminated tumors.

The International Neuroblastoma Pathology Committee (INPC) classification system is the most widely used and validated. The International Neuroblastoma Response Group (INRG) staging system is replacing the previous staging systems. Staging studies include bone marrow aspirates and biopsies, computed tomography (CT), magnetic resonance imaging (MRI), and bone scintigraphy with iodine-123–labeled metaiodobenzylguanidine (^{123}I-MIBG) (or ^{18}F-fluorodeoxyglucose–labeled positron emission tomography [FDG-PET]). Urinary catecholamines should be measured.

THERAPY

Treatment is based on risk stratification. Survival varies from 95% for patients with low-risk disease to 30% to 40% for patients with high-risk disease:

- Low-risk disease: generally treated with surgery alone with chemotherapy for progressive disease
- Intermediate-risk disease: 4 months to 8 months of chemotherapy followed by surgery and radiation therapy (21 Gy) for residual disease
- High-risk disease: surgery, induction chemotherapy with or without autologous stem-cell transplant, anti-GD2 immunotherapy, irradiation to primary site with or without metastases

Neuroblastoma comprises a range of tumors (neuroblastoma, ganglioneuroblastoma, and ganglioneuroma) that arise from primitive adrenergic neuroblasts of neural crest tissue, typically in young children. The clinical behavior, and therefore, therapy for neuroblastoma varies tremendously, depending on an array of clinical and biologic characteristics. Although some tumors regress spontaneously, others are highly malignant and often fatal.[1,2]

Significant progress in therapy has been made during the past several decades owing to an increased understanding of tumor behavior and effective risk-group stratification. Patients with low- and intermediate-risk tumors now have high survival rates with minimal intervention, and those with high-risk disease have improving survival as a result of intensive multimodality therapy.

Neuroblastoma is a fascinating and multifaceted disease. The investigation of biologic features of neuroblastoma and subsequent translation of these findings into effective therapy may serve as a model for other diseases.

ETIOLOGY AND EPIDEMIOLOGY

Neuroblastoma accounts for 8% to 10% of all childhood cancers, with approximately 650 cases diagnosed annually in the United States. It is the most-common extracranial solid tumor in children and the most common malignancy of infants. The median age at diagnosis is 17 months, and the male-to-female ratio is 1.1:1. Forty percent of patients are diagnosed when younger than 1 year of age, 89% are younger than 5 years of age, and 98% are younger than 10 years of age.[1-3]

Most primary neuroblastoma tumors occur in an anatomic distribution that is consistent with the location of neural crest tissue because the tumor arises from primitive adrenergic neuroblasts. The adrenal gland is the most common primary tumor site, accounting for 35% of cases overall. However, children younger than 1 year of age have a tumor arising from the adrenal gland in only 25% of cases. Other common sites include the low thoracic and abdominal paraspinal ganglia (30%) and posterior mediastinum (19%). Ganglia in the pelvic and cervical regions account for 2% to 3% of tumors, and in 1% the primary site is unknown.[1,4]

PREVENTION AND EARLY DETECTION

Because neuroblastomas frequently produce high levels of catecholamines, which can be detected in the urine, mass screening for the disease in infants has been performed. Extensive trials in numerous countries have shown that tumors detected by screening tend to be extremely favorable. Unfortunately, screening has not had an impact on survival or early detection of high-risk neuroblastoma.[5,6]

Microscopic neuroblastoma-like nodules frequently can be found at autopsy in infants who die of unrelated causes.[7] Furthermore, clusters of cells consistent with neuroblastoma occur uniformly in the adrenal glands of all fetuses, peaking

at between 17 weeks and 20 weeks of gestation, and then spontaneously regress by birth or in early infancy.[8] Thus, the development and subsequent regression of clusters of cells histologically identical to neuroblastoma appears to be a normal embryologic event, whereas the development of clinically detectable neuroblastoma appears to be a consequence of disruption of this normal developmental process.

The cause of neuroblastoma is not known in most cases. Prenatal or postnatal exposure to drugs, chemicals, or radiation has never been proven to be associated with an increased incidence of the disease.[1] A small fraction of neuroblastomas are familial and are usually associated with a germline mutation in the anaplastic lymphoma kinase *(ALK)* or *PHOX2b* genes. At least 20% of patients with familial neuroblastoma have bilateral or multifocal disease, which tends to present at an earlier age.[9-12]

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

Neuroblastoma is a model disease where improved genetic understanding of the tumor has allowed biology-based risk stratification and treatment. Numerous recurrent genetic changes have been identified in neuroblastoma and are correlated with disease outcome. Recent discoveries of germline mutations in the *ALK* and *PHOX2B* genes in a rare subset of patients with neuroblastoma (less than 1%) has been linked to hereditary neuroblastoma.[12-14] However, somatic *ALK* mutations are also found in 8% to 10% of neuroblastomas and may suggest biologically unfavorable disease. Most aggressive neuroblastomas contain genomic level instability, resulting in chromosomal rearrangement and unbalanced translocation. In contrast, less aggressive tumors tend to show whole chromosome losses and gains.[2,15,16] Those tumors that have loss or gain of whole chromosomes and few or no segmental chromosome abnormalities generally have an excellent prognosis, with many undergoing spontaneous differentiation or regression. In contrast, high-risk neuroblastoma is characterized by recurrent segmental chromosome abnormalities with nonrandom alterations of numerous chromosomes, particularly deletions of 1p36 and 11q and unbalanced gain of chromosome 17q.[17] The most critical genomic alteration is amplification of the MYCN oncogene, occurring in approximately 20 percent of neuroblastomas, and is associated with advanced disease, older age (>18 months), and a significantly poorer outcome.[18-21]

PATHOLOGY AND PATHWAYS OF SPREAD

Neuroblastoma is the most common of the small round, blue cell tumors of childhood. Other malignancies that can appear similar with standard pathology staining include non-Hodgkin lymphomas, Ewing's sarcoma, primitive neuroectodermal tumors, and soft-tissue sarcomas. Neuroblastoma can be distinguished from these other tumors by immunohistochemical staining for various markers including neuron-specific enolase, synaptophysin, and neurofilament. The characteristic histologic appearance is that of small, uniform cells containing dense, hyperchromatic nuclei and scant cytoplasm with neuropil. Homer-Wright pseudorosettes representing neuroblasts surrounding areas of eosinophilic neuropil are seen in up to 50% of cases.

Histologic subtypes represent different points along the maturation pathway and include (in order of increasing differentiation) neuroblastoma, ganglioneuroblastoma, and ganglioneuroma. Ganglioneuromas are considered benign and consist of mature ganglion cells, neuropil, and Schwann cells. Ganglioneuroblastomas have pathologic characteristics of both neuroblastoma and ganglioneuroma and can have an intermediate behavior as well.[22]

A variety of different pathology classification systems have been used for risk stratification. The International Neuroblastoma Pathology Committee (INPC) system is the most widely used and validated. Characteristics of this system are listed in Table 72-1. This represents a modification of the Shimada system that classifies tumors by patient age, the degree of

TABLE 72-1 Prognostic Evaluation of Neuroblastic Tumors According to the International Neuroblastoma Pathology Classification (Shimada System)

International Neuroblastoma Pathology Classification		Original Shimada Classification	Prognostic Group
Neuroblastoma			
Favorable	(Schwannian stroma-poor)	Stroma-poor (favorable)	Favorable
<1.5 year	Poorly differentiated or differentiating and low or intermediate MKI tumor		
1.5-5 years	Differentiating and low MKI tumor		
Unfavorable		Unfavorable	Unfavorable
<1.5 year	(a) Undifferentiated tumor*		
	(b) High MKI tumor		
1.5-5 years	(a) Undifferentiated or poorly differentiated tumor		
	(b) Intermediate or high MKI tumor		
>5 year	All tumors		
Ganglioneuroblastoma, intermixed	(Schwannian stroma-rich)	Stroma-rich intermixed (favorable)	Favorable†
Ganglioneuroma	(Schwannian stroma-dominant)		
Maturing		Well differentiated (favorable)	Favorable†
Mature		Ganglioneuroma	
Ganglioneuroblastoma, nodular	Composite schwannian stroma-rich/stroma-dominant and stroma-poor (schwannian stroma-rich)	Stroma-rich nodular (unfavorable)	Unfavorable†

Data from Shimada H, Ambros IM, Dehner LP, et al: The International Neuroblastoma Pathology Classification (the Shimada system). Cancer 86:364–372, 1999.
MKI, *Mitosis-karyorrhexis index.*
**Rare subtype, especially diagnosed in this age group; further investigation and analysis are required.*
†Prognostic grouping for these tumor categories is not related to patient age.

differentiation toward ganglion cells, amount of Schwann cell stroma present, whether the tumor is nodular, degree of calcification, and the mitosis-karyorrhexis index.[23]

Neuroblastoma commonly spreads via lymphatics to regional lymph nodes, often in the paraaortic chain, and less commonly to the next echelon of lymphatics, such as the left supraclavicular fossa (Virchow node) in patients with abdominal tumors. Hematogenous spread often occurs to bone marrow, bone, and less commonly, to liver. Neuroblastoma appears to have a proclivity for the bones of the skull and especially the posterior orbit, which can cause the clinical presentation of "raccoon eyes" from periorbital ecchymosis. Lung and brain metastases are rare at presentation. However, with improvements in systemic therapy, isolated parenchymal brain metastases are now occurring in about 5% to 10% patients with high-risk disease at relapse. These central nervous system relapses require craniospinal radiation therapy (RT) because of a high risk of leptomeningeal dissemination.[24]

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

The clinical presentation for neuroblastoma is highly variable because of the wide variety of disease sites. Primary tumor location and extent of disease vary with age. Most children (57%) younger than 1 year of age have locoregional disease at the time of diagnosis, whereas most children (81%) older than 1 year of age have disseminated disease. Children with abdominal tumors may present with abdominal pain, distention, or gastrointestinal disturbances but more commonly it is asymptomatic and discovered incidentally by a caregiver. Many with disseminated disease will present with fever, pain, limp, and significant irritability, especially younger children. Paraneoplastic syndromes, such as opsoclonus-myoclonus syndrome (myoclonic jerking and random eye movements) or vasoactive intestinal peptide (VIP) syndrome (intractable secretory diarrhea, with hypokalemia and dehydration caused by tumor secretion of VIP) are rare, occurring in less than 4% of patients.[25-27] The catecholamines secreted from most neuroblastomas are not likely to cause hypertension, flushing, or tachycardia.

A plain radiograph of the chest or abdomen may show a soft-tissue mass representing the primary tumor, and calcifications are present in 85% of tumors. Staging of neuroblastoma requires numerous imaging modalities. The primary tumor and regional lymph nodes should be imaged with CT or MRI. These studies should also be used to assess for metastases in the liver as well as spinal extension and resectability of the primary tumor. They also may be used to clarify the extent of bone metastases in specific locations, such as the skull.

At least 90% of neuroblastomas exhibit uptake of MIBG; thus bone metastases are primarily imaged using ^{123}I-MIBG scintigraphy. Technetium-99m (^{99m}Tc)–labeled bone scintigraphy is rarely used as a primary modality because MIBG imaging is more sensitive and specific. ^{18}F-fluorodeoxyglucose–labeled positron emission tomography (FDG-PET) can be useful in delineation of metastatic lesions in patients whose tumor is MIBG non-avid as well as in patients with low-risk disease.[28-30] Complete staging also includes two bilateral posterior iliac crest bone marrow aspirates and biopsies. A single positive result is sufficient for the documentation of bone marrow involvement.[31,32]

Because excess catecholamines are produced in most cases, urine catecholamines and their metabolites, specifically vanillylmandelic acid (VMA), and homovanillic acid (HVA) are typically measured. Urinary levels of catecholamines are often given as ratios to the urinary creatinine value.[33]

TABLE 72-2 International Neuroblastoma Staging System

Stage	Description
1	Localized tumor with complete gross excision, with or without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor (nodes adherent to and removed with the primary tumor may be positive).
2A	Localized tumor with incomplete gross excision; representative nonadherent lymph nodes negative for tumor microscopically.
2B	Localized tumor with or without complete gross excision, with ipsilateral, nonadherent lymph nodes positive for tumor. Enlarged contralateral lymph nodes must be negative microscopically.
3	Unresectable unilateral tumor infiltrating across the midline,* with or without regional lymph node involvement; or localized unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral extension by infiltration (unresectable) or by lymph node involvement.
4	Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin, or other organs (except as defined in stage 4S).
4S	Localized primary tumor (as defined for stage 1, 2A, or 2B), with dissemination limited to skin, liver, or bone marrow† (limited to infants <1 year of age).

Data from Brodeur GM, Seeger RC, Barrett A, et al: International criteria for diagnosis, staging and response to treatment in patients with neuroblastoma. J Clin Oncol 6:1874–1881, 1988; Brodeur GM, Pritchard J, Berthold F, et al: Revisions in the international criteria neuroblastoma diagnosis, staging and response to treatment. J Clin Oncol 11:1466–1477, 1993.

**The midline is defined as the vertebral column. Tumors originating on one side and crossing the midline must infiltrate to or beyond the opposite side of the vertebral column.*

†Marrow involvement in stage 4S should be minimal, that is, less than 10% of total nucleated cells identified as malignant on bone marrow biopsy or on marrow aspirate. More extensive marrow involvement would be considered to be stage 4. The MIBG scan (if performed) should be negative in the marrow.

Neuroblastoma staging has undergone several revisions over the past years. Older staging systems, including the Evans and D'Angio classification, were replaced by the International Neuroblastoma Staging System (INSS) (Table 72-2).[31] This staging system is now being replaced by the INRG staging system (Table 72-3).[32]

In 2009, the INRG Task Force introduced a new stratification schema named the INRG classification system, which is emerging as the international standard.[21] This system includes INRG stage (Table 72-3), age, histologic category, grade of tumor differentiation, *MYCN* status, presence/absence of 11q aberrations, and tumor cell ploidy (Table 72-4). Based on this classification, patients are stratified into four different risk groups: very low, low, intermediate, and high risk. Treatment strategies are based on this classification.[32] Survival varies from greater than 90% for patients with low-risk disease to about 40% for patients with high-risk disease.

PRIMARY THERAPY

The therapeutic approach for neuroblastoma varies tremendously, depending on risk group stratification. The available treatment modalities include surgery, chemotherapy, RT, biologic therapy, or immunotherapy. The following is a discussion of therapy for low-, intermediate-, and high-risk disease,

with an emphasis on the role of RT. A basic treatment algorithm for each risk group is shown in Figure 72-1.

Very-Low-Risk Neuroblastoma

Patients with very-low-risk disease have small tumors (or asymptomatic stage 4S, now called MS disease) that will generally undergo spontaneous regression or differentiation into benign ganglioneuromas. These tumors have been successfully managed with close observation without therapeutic intervention. A recently published report by the Children's Oncology Group (COG) study of observation of perinatal neuroblastoma showed event-free and overall survival rates of 97.7 and 100%, respectively.[34]

Ms disease (formerly called stage 4s disease, where "s" represents "special") is an entity unique to neuroblastoma. This stage is defined by patients up to 18 months of age at diagnosis with metastatic disease sites limited to the liver, skin, and less than 10% involvement of bone marrow.[35] Despite it being metastatic, the overall prognosis for patients with Ms disease is good, with a recent reports showing an overall survival rate of 92%.[36] Very young infants (usually less than 3 months of age at time of diagnosis), however, may have rapid tumor progression leading to massive hepatomegaly and subsequent cardiorespiratory failure, requiring immediate intervention. Chemotherapy (per the intermediate-risk group protocols) can sometimes be successful at reversing the rapid tumor progression.[37] However, in infants with rapidly progressive disease or who have failed to respond adequately to chemotherapy, low-dose irradiation to the liver should be considered. Treatment can be given efficiently because simulation and anesthesia are not necessary; the liver generally fills the entire abdomen and can be seen on a port film, and the patients are young enough to be immobilized in a papoose. The typical fractionation schedule in this setting is 1.5 Gy for three fractions, which usually leads to rapid relief of symptoms. The risk of long-term harm to the child from radiation exposure is small because of the low dose. MYCN amplification in this cohort is rare; when present these patients should be treated with intensive therapy as per a high-risk protocol.[20]

TABLE 72-3 International Neuroblastoma Risk Group Staging System*

Stage	Description
L1	Localized tumor not involving vital structures as defined by the list of image-defined risk factors† and combined to one body compartment
L2	Locoregional tumor with presence of one or more image-defined risk factors
M	Distant metastatic disease (except stage MS)
MS	Metastatic disease in children younger than 18 months with metastases confined to skin, liver, or bone marrow

Table modified from The International Neuroblastoma Risk Group (INRG) Staging System: An INRG Task Force Report. J Clin Oncol 27:298–303, 2009.
†Image-defined risk factors are surgical risks factors detected by imaging that make complete resection of the tumor unsafe at the time of diagnosis. See the primary reference for a full listing and description of these risk factors.

Low-Risk Neuroblastoma

Patients with low-risk neuroblastoma (see Table 72-3) can often be cured with surgery alone, even when only a partial resection is obtained.[38,39] Adjuvant RT was used in the past for incompletely resected tumors but has been shown to be unnecessary. Chemotherapy and RT are now reserved for progressive or recurrent disease.

Intermediate-Risk Neuroblastoma

The current treatment approach for intermediate-risk disease (see Table 72-3) consists of surgery for the primary tumor as well as standard-dose, multiple-agent chemotherapy for 4 months to 8 months. Definitive surgery may be delayed until after chemotherapy, which often makes the tumor more easily resectable.

Previously, RT was used in intermediate-risk disease; however, various studies have now shown that RT is not required as part of their initial therapy.[40]

TABLE 72-4 International Neuroblastoma Risk Group Classification System*

INRG Stage	Age (months)	Histologic Category	Grade of Tumor Differentiation	MYCN	11q Aberration	Ploidy	Pretreatment Risk Group
L1/L2		GN maturing; GNB intermixed					Very low
L1		Any, except GN maturing or GNB intermixed		NA			Very low
				AMP			High
L2	<18	Any, except GN maturing or GNB intermixed		NA	NO		Low
					Yes		Intermediate
	≥18	GNB nodular; neuroblastoma	Differentiating	NA	No		Low
					Yes		Intermediate
			Poorly differentiated or undifferentiated	NA			
				AMP			High
	<18			NA		Hyperdiploid	Low
	<12			NA		Diploid	Intermediate
M	12 to <18			NA		Diploid	Intermediate
	<18			AMP			High
	≥18						High
MS	<18			NA	No		Very low
					Yes		High
				AMP			High

Table modified from The International Neuroblastoma Risk Group (INRG) Staging System: An INRG Task Force Report. J Clin Oncol 27:298–303, 2009.

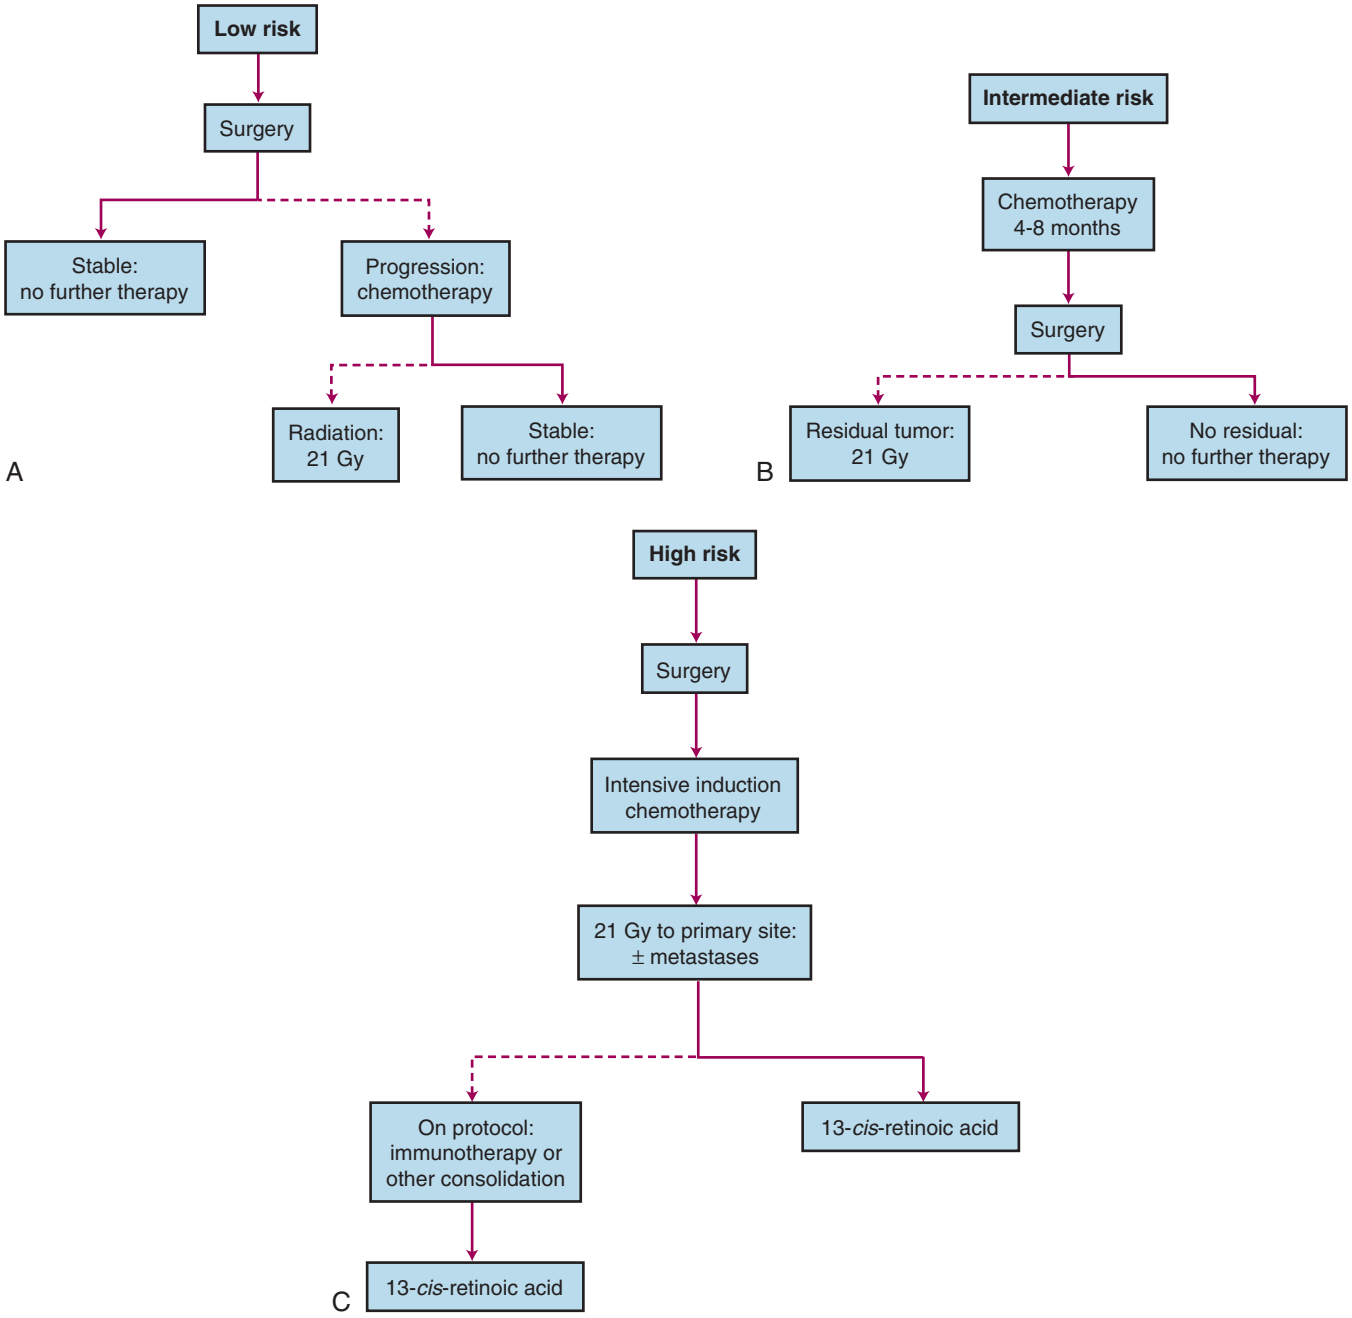

Figure 72-1 Treatment algorithm for low-risk **(A),** intermediate-risk **(B),** and high-risk **(C)** neuroblastoma.

In the COG study A3961, patients with intermediate-risk disease underwent surgery as well as chemotherapy (with cyclophosphamide, doxorubicin, carboplatin, and etoposide). The duration of chemotherapy was based on biologic risk factors for individual patients. The results of that study, published in 2010, demonstrated a 3-year overall survival of 96% among all patients, with 98% overall survival within the favorable biology group, and 93% overall survival among the patients with unfavorable biological features.[37] Importantly, these studies have shown that aggressive surgery and RT are not required to achieve excellent results. RT thus is indicated only for those with disease progression or persistent tumor after chemotherapy and second-look surgery.

High-Risk Neuroblastoma

The current therapeutic approach for high-risk disease includes intensive induction chemotherapy, surgical resection of the primary tumor, and possible myeloablative consolidation therapy with stem-cell rescue, followed by RT and biologic therapy using 13-cis retinoic acid and anti-GD2 immunotherapy to target minimal residual disease. Patients who have a complete or good partial response to induction chemotherapy have a better prognosis.[29] The induction regimens currently in use are all based on similar backbones of alkylating agents (cyclophosphamide and so on), anthracyclines (doxorubicin), and platinum compounds (cisplatin and

carboplatin). Dose and timing varies among the regimens, but published reports have shown that high-dose platinum and alkylator-based regimens have overall induction response rates (CR + VGPR + PR) of 70% to 80%.[41-46]

Consolidation therapy targets potentially resistant neuroblastoma cells using additional high-dose or myeloablative chemotherapy,[47] followed by RT. Maintenance therapy is biological and immunotherapy targeting minimal residual disease (MRD). 13-*cis*-retinoic acid is given as a monthly14-day cycles for 6 months.[47] Additionally, the COG recently reported that the addition of immunotherapy using the chimeric antibody ch14.18 directed at the neuroblastoma tumor antigen GD2, combined with the cytokines granulocyte-macrophage colony stimulating factor (GMCSF) and interleukin-2 (IL-2) significantly improved survival; 2-year event-free survival was 66% with immunotherapy compared with 46% in the control group.[48] Memorial Sloan Kettering (MSK) has also recently reported significantly improved long-term outcomes using the anti-GD2 mouse monoclonal antibody 3F8.[49,50]

The most recent COG protocol for high-risk disease, ANBL0532, included RT to the primary tumor site, regardless of the extent of surgical resection. The dose was 21.6 Gy in 1.8 Gy fractions in the case of complete resection and a boost of 14.4 Gy for a total of 36.0 Gy in the case of incomplete resection. RT was also indicated to sites of metastatic disease that demonstrated persistent MIBG avidity on the pretransplant scan. For patients with greater than five MIBG positive metastatic sites on pretransplant scan, another MIBG scan was performed 4 weeks posttransplant. RT was then limited to avid sites on that scan.

Evidence for the benefit of primary site RT comes from cooperative group trials as well as single institution series.[47] Haas-Kogan et al examined the role of RT on local control in the Children's Cancer Group study 3891. It appears that both 10 Gy to the primary site as well as 10 Gy of total-body irradiation decreased the local recurrence rate. The largest benefit was seen when patients received both local RT and total-body irradiation, for a total dose of 20 Gy. Further supporting the role of postoperative radiation therapy is a series from MSK where a total dose of 21 Gy was given in twice-daily 1.5-Gy fractions. Among 99 patients treated with irradiation to the primary site, the local failure rate was 10%.[51] Only 7 of these patients had residual disease at the primary site at the time of irradiation, and 3 of these had local recurrence, suggesting that 21 Gy is not an adequate dose for gross residual disease. Although final results are not available for the boost dose of 36 Gy in ANBL0532, this strategy may not be effective for most patients. Achieving a gross total resection of the primary tumor before RT seems to be necessary for optimal local control.

Targeted radiopharmaceuticals are also under investigation as an alternative means of delivering specific RT to metastatic tumor sites, either for refractory disease or as part of a myeloablative regimen. Targeted radioisotope therapy using MIBG for delivery of radiation in the form of iodine-131 has been tested extensively in clinical trials in patients with relapsed neuroblastoma. Efforts are currently under way by the COG to include high dose (12 mCi/kg to 18 mCi/kg) I^{131}-MIBG therapy with stem-cell rescue as primary therapy for patients with high risk disease; however, this remains somewhat controversial and the feasibility and tolerability of this approach is still under investigation.

RECURRENT DISEASE AND PALLIATION

Current approaches for treating recurrent or refractory neuroblastoma include novel cytotoxic agents and targeted delivery of radionuclides, retinoids, and other investigational agents. Cyclophosphamide and topotecan, and irinotecan and temozolomide are frequently used cytotoxic regimens.[52-55] RT plays an important role in palliation for neuroblastoma. Patients with incurable disease often live for an extended period of time. However, they often suffer severe pain and functional impairment from metastases, most commonly to bone. External beam radiation therapy (EBRT) is the most effective tool for managing painful metastases. Fractionation schemes depend on the site, field size, marrow reserves, and anticipated life span of the patient. A high-functioning child may benefit from 2-Gy fractions to 30 Gy, whereas a patient with end-stage disease may be better served by a single fraction of 7 Gy to 8 Gy.

IRRADIATION TECHNIQUES

Irradiation techniques depend on the site being treated. Most commonly, patients with high-risk disease have a primary tumor arising from the adrenal gland or abdominal paravertebral region. Radiation volume for localized neuroblastoma is determined by the surgeon's operative findings and presurgical imaging studies. Margins and normal tissue-sparing parameters vary from protocol to protocol. Based on patterns of failure data, it is important to include the paraaortic lymph nodes in the radiation field.[56] CT planning is imperative to delineate the target region as well as normal tissues, including the kidneys, liver, and in some cases, ovaries. Attention should be paid to treatment of vertebral bodies to reduce the risk of scoliosis. Simple anterior and posterior beams, as demonstrated in Figure 72-2, may be a good solution, but intensity-modulated radiation therapy (IMRT) may be better for controlling dose to adjacent organs. Proton therapy may also be considered but may lead to unacceptable kidney doses when posterior beams are used. Bone metastases are often best treated with simple opposed beams. However, more

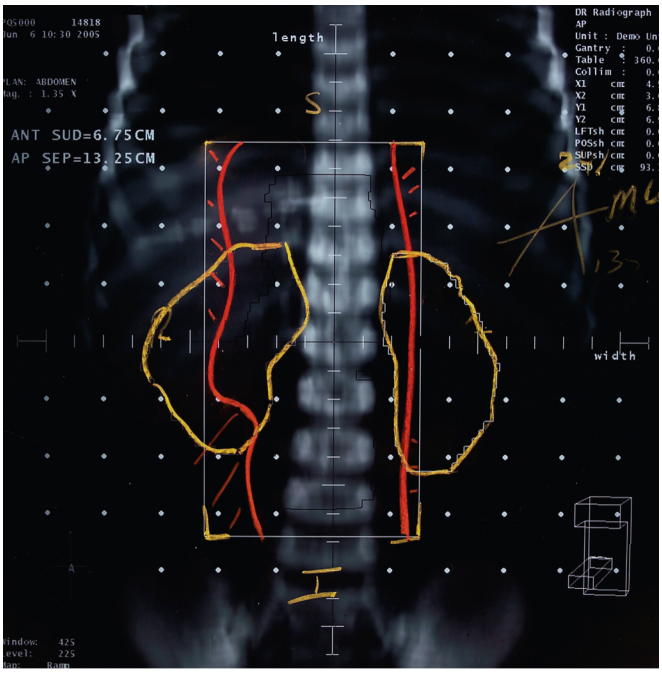

Figure 72-2 Typical anterior and posterior radiation therapy field for adrenal neuroblastoma. Generous coverage of paraaortic lymph nodes is recommended. Adequate kidney sparing is accomplished by treating postchemotherapy tumor volume.

sophisticated approaches may be needed when treating sites in the head and neck because of the complex anatomy and critical structures. Neuroblastoma is common in young children, necessitating the frequent use of anesthesia for RT. In this case, propofol is safe and well tolerated, even for twice-daily treatments.

Intraoperative radiation therapy (IORT) is not an acceptable alternative to EBRT in the context of initial therapy. A report from the University of California–San Francisco showed reasonable local control after complete resection but not after subtotal resection and a high rate of severe aortic complications in patients receiving IORT.[57] In the setting of local relapse following prior EBRT, MSK reported a relatively favorable 50% rate of local control and low rate of complications for 44 patients who underwent subsequent surgery and reirradiation with IORT for locally relapsed neuroblastoma.[58]

LATE EFFECTS

Consideration for long-term complications is critical when treating neuroblastoma. Patients treated years ago with higher doses of radiation frequently suffered from spinal deformities secondary to surgery and RT. Orthopedic problems from RT are less severe with a dose of 21 Gy but should still be considered when designing treatment fields. As a general rule, it is desirable to limit as much of each kidney as possible to doses less than 15 Gy to 18 Gy to prevent major impairment in renal function. One must also inform parents about the low risk of diabetes mellitus and second malignancies. A prospective trial is currently under way at MSK testing a stepwise reduction in radiation dose from 21 Gy to 18 Gy to 15 Gy. It is likely that even small dose reductions in this range will result in lower risks of spinal growth abnormalities and diabetes mellitus. A recent study of long-term survivors of high-risk neuroblastoma shows that the majority have late complications of therapy, including hearing loss, hypothyroidism, ovarian failure, musculoskeletal abnormalities, and pulmonary dysfunction. However, most complications were considered to be of mild-to-moderate severity.[59] All members of multimodality teams that care for patients with neuroblastoma patients must be mindful of late effects and strive to minimize complications while ensuring the best chance for cure.

EPIDEMIOLOGY

Acute leukemias (acute lymphoblastic leukemia [ALL] and acute myelogenous leukemia [AML]) and lymphomas (Hodgkin's and non-Hodgkin's [NHL]) together represent approximately 40% of malignancies in children.

The annual incidence of new cases in the United States in children younger than age 15 years for ALL is 2500 to 3500; AML, 500; and NHL, 500.

BIOLOGY, CLASSIFICATION, AND STAGING

ALL is classified by:

- Immunophenotype: B-cell progenitor, T-cell progenitor, non-B cell, and non-T cell
- Morphology and immunologic markers
- Cellular DNA content (ploidy)
- Cytogenetics (presence of specific translocations, trisomies, and other chromosomal or genetic aberrations)

Staging involves evaluation of bone marrow, cerebrospinal fluid, and evaluation of extramedullary sites.

AML is classified according to the French-American- British (FAB) morphology. Staging is as for ALL.

NHL is classified by the World Health Organization (WHO) Classification of Tumors of the Haematopoietic and Lymphoid Tissues. The major subtypes are lymphoblastic lymphoma, Burkitt's lymphoma, and large cell lymphoma. Large cell lymphomas can be of B-cell origin or T-cell origin.

Staging involves examination of bone marrow and cerebrospinal fluid as well as radiographic and nuclear imaging for nodal and extranodal sites.

THERAPY

The primary treatment of leukemias and lymphomas includes systemic chemotherapy. The intensity of therapy for leukemia and the duration of therapy for lymphoma are determined by risk stratification according to biologic and clinical features.

Therapy for ALL involves induction chemotherapy, intensification or consolidation, central nervous system (CNS) therapy, and maintenance therapy.

Therapy for AML includes induction chemotherapy based on the FAB classification. Intensification or consolidation may be with bone marrow transplant.

Therapy for NHL involves chemotherapy based on the biologic and clinical features of histologic subtype and clinical stage.

INDICATIONS FOR RADIATION THERAPY

ALL:

- Cranial irradiation for CNS prophylaxis in selected patients with high-risk disease
- Cranial irradiation for treatment of children with CNS involvement at diagnosis or relapse
- Testicular irradiation for relapse in the testes
- Total-body irradiation as part of the myeloablative regimen in stem-cell transplantation

AML:

- Primary use is total-body irradiation for stem-cell transplantation.

NHL:

- Total-body irradiation for some patients is part of the myeloablative regimen in stem-cell transplantation in patients with lymphoblastic lymphoma.

LATE SEQUELAE

Late sequelae include neurocognitive disorders, endocrinologic problems, growth delay, and induction of secondary malignancies.

TREATMENT OF RELAPSE AND PALLIATION

Local radiation therapy (RT) can be used to palliate symptomatic recurrences in leukemias and lymphomas. Relapses in the testes and CNS are treated by intensive systemic chemotherapy with RT. Treatment of relapse often includes bone marrow transplantation with total-body irradiation as part of the myeloablative regimen.

ACUTE LYMPHOBLASTIC LEUKEMIA

ALL is the most-common malignancy in children, accounting for one fourth of all childhood cancers. The advances in the treatment of ALL since the 1940s represent one of the most tremendous success stories in modern medicine. The early successes resulted from the identification of single-agent chemotherapy and then the development of combination chemotherapy, recognition of the need for CNS preventative therapy, and maintenance chemotherapy. Concurrent with these developments, new understanding of immunophenotyping, molecular characterization, and treatment responses allowed for the definition of risk groups to tailor therapy.

Epidemiology

ALL accounts for 75% of childhood leukemia and is diagnosed in 2500 to 3000 children in the United States annually[1,2] with a peak age incidence between 2 years and 5 years. The incidence of ALL is higher among boys than girls. This difference is more pronounced in pubertal children[3] and particularly evident in cases of T-cell ALL. In the United States, ALL occurs more commonly among white children than among black children.[4]

Etiology

A single etiology of ALL has not been identified; however, predisposing risk factors include genetics, environmental factors, viral infection, and immunodeficiency. Genetics appears to play a role in the cause of ALL in some children as evidenced by the association between specific chromosomal abnormalities and childhood ALL. The most-common constitutional chromosomal abnormality associated with childhood leukemia is trisomy 21 or Down syndrome[5]; less-common chromosomal abnormalities include Kleinfelter's syndrome and trisomy G syndrome.[6] The majority of cases of leukemia in children cannot be attributed to any known factor.

ALL is believed to develop from the malignant transformation of a single abnormal progenitor cell that then expands indefinitely. In pediatric ALL, evidence suggests that it occurs in committed lymphoid precursors. In contrast, in Philadelphia chromosome–positive ALL and in pediatric AML this event may occur earlier because mutations are observed in multiple cell lineages.[7,8] The sequence of events resulting in malignant transformation is likely to be multifactorial. Leukemia can develop along any point in the normal stages of lymphoid development, which reflects the fact that ALL is a biologically heterogeneous disorder.

Classification and Immunophenotyping

ALL is divided into two distinct subtypes based on the expression of cell surface markers. B-ALL, representing approximately 85% of cases and T-ALL, making up approximately 15% of cases. B-ALL is characterized by the expression of CD79a, CD19, HLA-DR, and other B cell-associated antigens. Ninety percent of precursor B-cell ALL cases express the CD10 surface antigen. Patients with B-cell precursor ALL whose lymphoblasts express CD10 on their cell surfaces have a more favorable prognosis than those who do not, primarily owing to the strong association of CD10 negativity with rearrangements of the *MLL* gene on chromosome 11.[9,10] In approximately 1% to 2% of cases of ALL, the cells express surface immunoglobulin.

Ten to 15 percent of children will have ALL that is of T-cell origin. T-ALL is characterized by the expression of cytoplasmic CD3 and surface expression of T-cell antigens including CD2, CD5, and CD7. In contrast to B-cell precursor ALL, T-cell ALL is more frequently associated with older age at diagnosis, a higher presenting leukocyte count, and bulky extramedullary disease. Extramedullary involvement can include an anterior mediastinal mass, lymphadenopathy, hepatosplenomegaly, and overt CNS involvement.[11]

Cytogenetics

Advances in cytogenetics have led to an increasing understanding of the biology of ALL.[12] Cytogenetic abnormalities identified in ALL include abnormalities in chromosomal number (ploidy) as well as those in chromosomal structure. Ploidy is determined either by counting the modal number of chromosomes in a preparation of a metaphase karyotype or by measuring DNA content by flow cytometry. Hyperdiploidy exists when there are more than 46 chromosomes. Most cases of ALL are diploid or hyperdiploid. Ploidy in childhood B-lineage leukemia has prognostic significance.[13-15] Children with higher ploidy, greater than 50 chromosomes, have a better prognosis than other children with ALL, including those with 47 to 50 chromosomes; those with 51 to 65 chromosomes (higher hyperdiploid) with specific trisomies (including chromosomes 4, 10, and 17) appear to have an especially favorable prognosis.[16-18] Those patients who have hyperdiploid leukemia with favorable trisomies also tend to have other favorable prognostic features (see discussion in this chapter). Hypodiploidy (modal chromosomal number less than 44) is associated with inferior outcomes, especially among those with near-haploid ALL, with 24 to 28 chromosomes.[19-21]

Structural chromosomal abnormalities occur in ALL leukemia cells. The most common of these abnormalities are translocations. Translocations lead to alterations in the regulation of oncogenes. The activation of oncogenes and the loss of tumor suppressor genes are examples of the altered regulation believed to be involved in the evolution of leukemia. The most frequently identified translocation in ALL is t(12;21) and leads to the TEL-AML1 fusion protein. This occurs in approximately 20% of cases (nearly exclusively in those with B-lineage phenotype) and is associated with a favorable prognosis.[22,23] In contrast, t(9;22) and t(4;11) translocations are associated with early treatment failure.[15,24]

The t(9;22)(q34;q11) translocation results in the formation of the Philadelphia (Ph) chromosome and is found in 5% of childhood ALL. Children with Ph chromosome–positive ALL have a poor response to standard therapy but may fare better with intensive regimens that include the use of a tyrosine kinase inhibitor such as imatinib.[25-29]

Other unique chromosomal translocations have been observed in childhood ALL. The role of these and all translocations in the development of leukemia remains speculative. Some translocations that result in altered gene expression appear to confer a proliferative advantage for the leukemic cells. When patients with ALL are in remission, the cytogenetic abnormalities just described are not detectable. When relapse occurs, reappearance of the original cytogenetic abnormality confirms that there is a recurrence of the original leukemia.

Presentation and Evaluation

The presenting signs and symptoms of ALL are related to the degree of bone marrow infiltration as well as the extent of extramedullary involvement. These can include fever, petechiae, lymphadenopathy, and bone pain. Hepatosplenomegaly is found in two thirds of patients. Children with T-cell ALL have some distinctive features. T-cell ALL more frequently occurs in older boys, presents as high initial white blood cell (WBC) counts, and often has a mediastinal mass at diagnosis. The definitive diagnosis is made by bone marrow aspiration, although a bone marrow biopsy may be required in some cases and allows for morphologic assessment, immunophenotyping, karyotyping, and molecular evaluations such as reverse transcriptase/polymerase chain reaction and fluorescent in-situ hybridization for chromosomal characterization.

At the time of initial diagnosis the evaluation of patients includes cerebrospinal fluid examination, evaluation of uric acid levels, liver function tests, renal function tests, coagulation screening, chest radiography, evaluation for infection, and echocardiography (Box 73-1). Manifestations of CNS involvement such as headache, lethargy, papilledema, and cranial neuropathies (most often the third, fourth, sixth, and seventh) are infrequently present at diagnosis. CNS involvement is divided into three categories based on the number of white blood cells (WBCs) and the presence of lymphoblasts on the Cytospin. CNS-1 is defined as no evidence of lymphoblasts in the cerebrospinal fluid. CNS-2 is defined as fewer than five WBCs per microliter with blasts present in the Cytospin, and CNS-3 is defined as five or more WBCs per microliter with blasts in the Cytospin or the presence of cranial nerve palsy. CNS-3 involvement of the CNS at diagnosis is found in less than 5% of children with ALL.[30]

Expression of myeloid antigens on leukemic cells
Serum immunoglobulins
Nutritional status
Rapidity of response

Prognostic Factors

Several clinical and biologic factors determined at diagnosis have been identified and shown to have prognostic significance (Box 73-2). These prognostic factors are used to assign patients to risk strata that tailor the treatment. These factors have been integral in the development of all modern therapeutic trials. Although many of these factors have shown prognostic importance, not all are currently used to determine risk stratification.

The presenting leukocyte counts and age at diagnosis are uniformly accepted as prognostic features. Children with the highest initial WBC count have a poorer prognosis.[31,32] Infants younger than 1 year of age have the worst prognosis, and adolescents also have a poorer event-free survival than younger children, except those younger than age 1 year.[33,34] Children older than 10 often have other poor risk features including T-cell phenotype.[34] Infants with ALL have shown the worst outcome, with an event-free survival of 10% to 20%.[33] Infants also have other poor-risk features, including high presenting WBC count, presence of CNS leukemia, massive organomegaly, and a poor day 14 response to induction chemotherapy.[33] Infant ALL has unique biologic features, including chromosomal abnormalities that are associated with a worse prognosis. Structural abnormalities of chromosome 11, such as rearrangement of band q23, within the *MLL/ALL1* gene are often present.[35,36] The t(4;11) translocation is commonly seen, and many have leukemia cells that coexpress myeloid markers (CD15).[33,35,37] This finding suggests that infant ALL arises in a multipotent precursor cell. Chromosomal abnormalities in the leukemia cells also have prognostic significance. The presence of the Ph chromosome and of *MLL* rearrangements (even in noninfant patients) is associated with a higher risk of relapse.

Recent studies using genomic profiling have identified a biologically distinct subset of patients with a high risk of relapse. These patients have a gene expression signature similar to patients with BCR-ABL-positive ALL but lack the BCR-ABL translocation.[38]

T-cell immunophenotype and the presence of CNS disease at diagnosis are also considered high-risk features. Early responses to initial therapy are also prognostic. These include the time to achieve remission and the decrease in peripheral blast count after administration of corticosteroids, when longer time to remission or poor response to initial corticosteroid therapy is associated with worse outcomes. Rapid morphologic clearance of blasts in the marrow 7 days to 14 days after the initiation of multiple-agent chemotherapy has been associated with more favorable outcomes.

Nearly all current leukemia protocols include measurements of minimal residual disease at the end of induction chemotherapy. Multiple-parameter flow cytometry and polymerase chain reaction assays of leukemia-specific gene arrangements have been used to assess submicroscopic levels of minimal residual disease soon after the initiation of therapy.[39-42] High levels of minimal residual disease at the end of the first month of therapy and other early time points has been associated with a high risk of subsequent relapse.[43-47]

On most protocols, children with high levels of minimal residual disease at the end of remission induction are now considered to be high or very high risk (regardless of other presenting features) and receive intensified therapy.

As therapy for ALL has become more intensive and the outcomes have improved, many of these factors have lost statistical significance as prognostic factors. In addition, the definitions of high leukocyte counts and age varied among cooperative groups. To allow comparisons of results, the National Cancer Institute held a workshop to develop a uniform set of prognostic factors.[48] The age and WBC count criteria for childhood ALL agreed on at the Cancer Treatment and Evaluation Program/National Cancer Institute Workshop are shown in Table 73-1.

Treatment

The foregoing prognostic indicators are used to stratify children with ALL into risk groups. The stratification is dependent on prompt, accurate evaluation and sophisticated techniques. To accomplish this, as well as to treat patients with the increased intensity of current therapy, evaluation and treatment is most appropriately carried out in recognized pediatric oncology centers. The treatments for the different risk groups vary in intensity and by institution. However, the framework for all risk groups includes four key elements: remission induction, CNS preventative therapy, consolidation, and maintenance (Figure 73-1).

Induction treatment is designed to achieve complete remission, defined as no evidence of leukemia. Peripheral blood cell

counts must be within the normal range, and the bone marrow must be of normal cellularity and contain less than 5% lymphoblasts. There should be no evidence of CNS disease on examination of the cerebrospinal fluid, and there must be no extramedullary disease. Remission can be achieved in 85% of children with ALL using vincristine and a glucocorticoid; however, the addition of l-asparaginase or the addition of an anthracycline will improve the remission induction rate to 95%.[49] In general, most current regimens use a three- or four-drug induction phase, including vincristine, a corticosteroid, and L-asparaginase plus or minus an anthracycline.

TABLE 73-1 Uniform Age and White Blood Cell Count Criteria for B-Precursor Acute Lymphoblastic Leukemia Standard and High-Risk Cohorts*

Risk	Definition	4-Year Event-Free Survival (%)	B-Precursor Patients (%)
Standard	WBC count <50,000/μL Age 1.00-9.99 year	80.3	68
High	WBC count ≥50,000/μL *or* Age ≥10.00 year	63.9	32

From Smith M, Arthur D, Camitta B, et al: Uniform approach to risk classification and treatment assignment for children with acute lymphoblastic leukemia. J Clin Oncol 14:20, 1996. Reprinted from the Am Soc Clinl Oncol.
**Adopted at the Cancer Treatment and Evaluation Program/National Cancer Institute Workshop.*

The prevention of CNS disease is one of the major elements of successful ALL treatment. The approach to CNS prophylaxis has evolved over the decades since it was first incorporated into ALL therapy in the 1970s. Craniospinal irradiation and cranial irradiation plus intrathecal methotrexate reduced the relapse rate in the CNS from 50% to less than 10%.[50] To avoid the myelosuppression and the effects on spinal growth, intrathecal methotrexate was substituted for spinal irradiation as part of the standard CNS preventative therapy. Intrathecal therapy has been shown to successfully prevent CNS relapse in patients with standard-risk disease and avoids the neurocognitive sequelae and secondary tumors that can result from cranial irradiation. Intrathecal chemotherapy in conjunction with intensive systemic therapy has also provided adequate CNS prevention for some children with high-risk features.

Children with an increased risk of CNS relapse include those with other high-risk features such as high initial WBC count, T-cell phenotype, very young age, t(4;11), the presence of the Ph chromosome, and lymphomatous presentation. For patients with these features, cranial irradiation (see discussion in this chapter) is generally incorporated into the treatment protocol, although many current protocols are intensifying intrathecal therapy and omitting cranial irradiation for some patients. Children with infant ALL are treated with intensive chemotherapy to avoid the late sequelae of cranial irradiation in this age group. The CNS-directed therapy for patients with CNS-3 is not preventative but therapeutic.

Once complete remission has been achieved, consolidation and maintenance therapy are used to provide continued

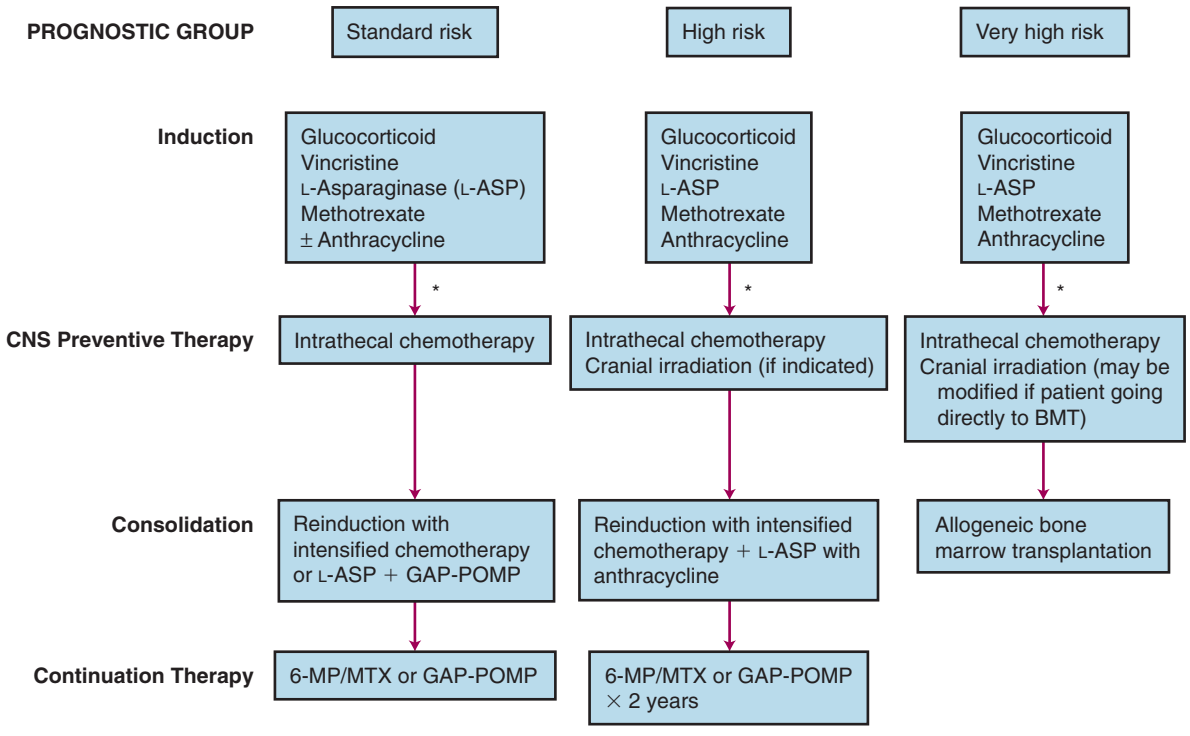

Figure 73-1 **Treatment algorithm for acute lymphoblastic leukemia.** *6-MP,* 6-mercaptopurine; *BMT,* bone marrow transplant; *CNS,* central nervous system; *MTX*, methotrexate. *GAP-POMP* (GAP refers to the schedule of mercaptopurine administration given on 14 days of each 21-day cycle, thus a 7-day GAP) repeats a 3-week cycle until 2 years of continuous complete remission: vincristine, prednisone, mercaptopurine, methotrexate; high-dose cycle; vincristine, mercaptopurine, high-dose intravenous and intrathecal methotrexate.

cytoreduction of the leukemic cell burden without permitting the emergence of drug-resistant clones. Components of the consolidation phase vary according to risk group, with more intensive treatments used for patients classified as high or very-high risk. The continuation phase consists of less-intensive, low-dose chemotherapy. Nearly all regimens include weekly methotrexate and daily 6-mercaptopurine during this phase. Some protocols also use intermittent pulses of vincristine and corticosteroid in addition to methotrexate and 6-mercaptopurine.[51] Total duration of therapy is typically 2 years to 3 years. On some regimens, boys receive a longer maintenance phase than girls.

Indications for Radiation Therapy

The role of RT in the treatment of childhood ALL has diminished in recent years. Improvements in the efficacy of chemotherapy administration and a clearer understanding of the prognostic factors have been responsible for this changing role. However, RT remains an important modality in ALL in specific situations. These include prophylactic cranial irradiation in select groups of patients with high-risk disease, therapeutic CNS treatment for patients with meningeal leukemia, treatment of testicular disease, and total-body irradiation for some patients for whom stem-cell transplant is recommended.

In most regimens, CNS prophylaxis for patients at lower risk is achieved with systemic and intrathecal chemotherapy without cranial irradiation. Children with high-risk features are at an increased risk of CNS relapse and, historically, have received prophylactic cranial irradiation. These features include a presenting WBC count of 50,000/μL or greater; those with WBC counts over 100,000/μL are at particularly high risk of CNS relapse. Additional high-risk features that are indications on some treatment protocols for cranial irradiation are T-cell phenotype, Ph chromosome–positive ALL, and the presence of t(4;11). Infants younger than age 12 months with 11q23 abnormalities are at high risk of CNS relapse but because of their young age are usually treated without cranial irradiation, using intensified systemic and intrathecal chemotherapy to treat the CNS. Historically, the standard dose for high-risk ALL cranial prophylaxis had been 1800 cGy; however, published trials from the Berlin-Frankfurt-Munster group used 1200 cGy in patients with CNS-1 disease with good results.[52] The standard dose for prophylactic cranial irradiation in those patients with high-risk disease still treated with irradiation is now 1200 cGy.

Currently, fewer than 20% of children with ALL are treated with prophylactic cranial irradiation. Investigators are continuing to evaluate whether cranial irradiation can be eliminated in a greater proportion of patients, especially in young children in whom the toxicities from irradiation are the most significant. Some protocols have omitted cranial irradiation entirely, using strategies that intensify the use of intrathecal chemotherapy and CNS-penetrant systemic chemotherapy, such as high-dose methotrexate.[53,54] In one such study from St. Jude Children's Research Hospital, the 5-year cumulative risk of isolated CNS relapse was 2.7% and that of any CNS relapse (isolated or combined with bone marrow) was 3.9%, although the risk of relapse was higher in some patients with high-risk disease subsets.[54]

Children who present with CNS-3 disease at diagnosis, regardless of the other features of their disease, are deemed at high risk and are considered to have meningeal leukemia. The treatment of these patients varies, and some protocols continue to employ craniospinal irradiation or cranial irradiation in addition to intrathecal chemotherapy. Irradiation is not administered until the patient is in remission, including clearance of the cerebrospinal fluid. After achievement of complete remission, 1800-cGy cranial irradiation has been administered early in the therapy.[52]

Isolated CNS relapse is rare with the current approach to ALL treatment. The treatment depends on the time from first remission as well as the extent of prior CNS therapy. Patients with an isolated CNS relapse occurring 18 months or more after initial diagnosis have an event-free survival of approximately 80% when treated with intensive systemic chemotherapy and cranial or craniospinal irradiation. A dose of 1800 cGy to the cranial field has been shown to be effective in such patients.[55] Patients with earlier CNS relapses, or those with T-cell phenotype or a history of cranial irradiation prior to CNS relapse, may be considered for stem-cell transplant once a second remission is achieved. In that situation the total dose of craniospinal irradiation may need to be modified depending on timing of the transplant.

Cranial nerve palsies can be seen in patients with meningeal leukemia. Urgent RT to the base of the skull initially to reverse the palsy is often given, with full cranial irradiation given at the scheduled time for CNS treatment. Doses between 1000 cGy and 1200 cGy are used. Although the use of higher doses has been reported, no dose response was observed for higher doses.[56]

The technique for cranial irradiation must ensure coverage of the cranial meninges as well as other areas of potential access to the CNS such as the cribriform plate, the posterior retina and posterior globe of the eye, the exit regions of cranial nerves III, IV, V, and VI, and the inferior extent of the temporal meninges. The cribriform plate should be identified by following the anterior clinoids anteriorly and locating the superior orbital plate. The field extends to the C1-C2 interspace unless a clinical field arrangement is used, in which case the field would be brought to the C2-C3 interspace. To ensure adequate dose to the meninges, the entire calvaria is covered and the energy should be 4 MV or 6 MV photons. Custom blocks are used to shield normal tissues. Parallel opposed lateral fields are used. Immobilization is critical to ensure precise treatment and reproducibility and use of immobilization devices is recommended when possible. Sedation may be required for younger patients who are unable to fully cooperate.

Testicular Leukemia

Testicular involvement that is clinically apparent at diagnosis is infrequent; however, occult disease is found in 25% of boys.[57] Overt involvement is manifest as painless testicular enlargement, which may be unilateral or bilateral. Testicular biopsies during maintenance or at the conclusion of all therapy have been abandoned because the biopsy results did not accurately predict eventual relapse.[13,58,59] Some protocols have used prophylactic bilateral testicular irradiation, although this approach has not been widely used because the current systemic therapy protocols have lessened the rate of testicular relapse and testicular irradiation causes permanent sterility.[60,61]

Testicular relapse occurs in less than 5% of cases in the current era of intensive therapy.[62,63] Both systemic therapy as well as local RT directed at the testes are used to treat testicular relapse. Reinduction therapy is needed as well as CNS-directed treatment. Bilateral testicular irradiation is used to doses of 2400 cGy to 2600 cGy in 200-cGy fractions.[64] The treatment is delivered with the child supine in the frog-leg position with the soles of the feet touching. The penis is taped or secured out of the RT field. A bolus dose may be needed to ensure adequate dose to the testes or electron boost therapy can be used. Radiation is delivered to the entire scrotal contents.

Late Sequelae

With dramatic improvement in the outcome of children with ALL, the late effects of therapy on the survivors have become increasingly apparent. The late effects are multifactorial and are related to both chemotherapy and RT and vary with each child, based on underlying clinical factors. A multidisciplinary approach is needed because the late sequelae involve many organ systems and vary in severity. The following discussion focuses on those late effects chiefly related to RT.

The CNS sequelae are of particular concern. Neurocognitive functional impairment has been observed in ALL survivors. Lower doses of cranial irradiation, for example, 1200 cGy rather than 1800 cGy in patients with high-risk disease, and the elimination of cranial irradiation from patients with standard-risk disease should help lessen the late sequelae. However, in a prospective randomized trial comparing 1800 cGy with no cranial irradiation, all patients received intrathecal and intravenous methotrexate and the patients who underwent irradiation had no worse neurocognitive effects.[65] Children irradiated when younger than 8 years of age and particularly when younger than 5 years of age appear to experience the most severe neurocognitive sequelae. Leukoencephalopathy is a devastating and fortunately uncommon event in the current era. It is characterized by multifocal demyelination. Although this occurs most commonly in patients who have received higher cumulative doses of RT as well as higher cumulative doses of intrathecal and systemic methotrexate (e.g., those with recurrent meningeal leukemia), this severe form of neurotoxicity has been observed in children who received no cranial irradiation.[66,67]

Neuroendocrine sequelae involving the hypothalamic-pituitary axis have been observed in ALL survivors treated with cranial irradiation. Most commonly seen is growth hormone deficiency, which appears to be dose related in that children treated with 1800 cGy have reduced growth hormone levels compared with healthy controls but not as low levels as those treated with 2400 cGy.[68] However, growth delay and short stature have also been seen in unirradiated ALL survivors, suggesting that the cause is likely to be multifactorial.

The risk of second tumors in ALL survivors is estimated to be between 3% and 12% at 5 years to 24 years after the initial diagnosis.[69,70] Second solid tumors have most commonly occurred in patients treated with cranial irradiation and are within or near the RT field. However, there are reports of ALL patients not irradiated who developed secondary CNS tumors.[71] The most common hematopoietic tumors are AML and myelodysplastic syndrome.[69,70]

Testicular irradiation results in sterility. Some studies have shown elevated follicle-stimulating hormone and luteinizing hormone levels, decreased testosterone levels, and delays in sexual maturation, suggesting that the endocrine function of the testes may be adversely affected at doses of 2400 cGy and higher.[72,73] Supplemental or replacement androgens may be required.

ACUTE MYELOGENOUS LEUKEMIA

AML comprises a group of hematologic malignancies that arise from the precursors of the myeloid, monocytoid, erythroid, and megakaryocytic cell lineages. AML represents 15% to 25% of childhood leukemia but accounts for over 30% of deaths from leukemia. The classification used in AML is the FAB schema, which defines seven subtypes of AML (M1 to M7), characterized by morphologic, histochemical, immunophenotypic, and cytogenetic features (Table 73-2). An M0 subtype has been used for an acute undifferentiated leukemia.[74]

TABLE 73-2 Morphology of Acute Myelogenous Leukemia: French-American-British (FAB) Classification System

FAB Type	Name
M1	Acute myeloblastic: no maturation
M2	Acute myeloblastic with maturation
M3	Acute promyelocytic: hypergranular type
M3v	Acute promyelocytic: microgranular variant
M4	Acute myelomonocytic
M4Eo	Acute myelomonocytic with eosinophilia
M5a	Acute monocytic
M5b	Acute monocytic with differentiation
M6	Acute erythroleukemia
M7	Acute megakaryoblastic

In 2002 the WHO proposed a new classification system incorporating cytogenetic information correlated with outcome. This was expanded in 2008 with additional cytogenetic abnormalities linked to AML classification. This cytogenetically based classification provides biologic and prognostic information that informs treatment of patients. Children with t(8;21), inv(16), t(15;17), and those with translocations of the MLL gene make up almost half of the cases of AML and are classified as "AML with recurrent cytogenetic abnormalities."[75]

Children with AML present with a broad range of signs and symptoms. Fever is present in one third of patients, owing to the release of pyrogens from leukemic cells or from macrophages and lymphocytes reacting to the proliferating leukemic blasts or from secondary bacterial infections from neutropenia. Pallor, headache, tinnitus, fatigue, and congestive heart failure can be present if anemia is severe. Bleeding from thrombocytopenia or from disseminated intravascular coagulation can occur. Bone pain is a frequent complaint. Hepatosplenomegaly as a result of organ infiltration is present in approximately half of children at diagnosis.

Treatment of AML involves first stabilization of the patient at diagnosis, aggressive supportive care to treat potential complications such disseminated intravascular coagulation, infectious complications, tumor lysis syndrome, and hyperleukostasis. Induction of remission involves multiagent chemotherapy. Induction is followed by postremission consolidation and intensification and CNS prophylaxis. The postremission consolidation consists of varying number of courses of intensified chemotherapy with or without allogeneic stem-cell transplantation. Maintenance is not part of AML therapy with the exception of acute promyelocytic leukemia for which maintenance therapy does improve event-free and overall survival. Induction therapy for AML most commonly includes cytarabine coupled with an anthracycline plus or minus additional agents such as etoposide, thioguanine, or dexamethasone.[76,77] Treatment of M3 AML, a disease characterized by promyelocytic morphology and the presence of t(15;17), includes all-trans-retinoic acid in addition to cytotoxic chemotherapy.

Postremission therapy, particularly with increased dose intensity of cytarabine, resulted in lower relapse rates and longer remission duration.[78,79] CNS chemoprophylaxis is used for all patients. Children with the highest risk of a CNS relapse are those with M4 or M5 AML or with high presenting peripheral blast counts. CNS relapse is generally followed by bone marrow relapse. With the use of prophylaxis in all patients with AML, the incidence of CNS relapse is 5%.[78,80]

TABLE 73-3 Non-Hodgkin's Lymphomas in Children

Subtype	Proportion of Cases (%)*	Phenotype	Common Site of Primary Tumor	Translocation
Burkitt's	39	B cell	Abdomen or head/neck	t(8;14)(q24;q32) t(2;8)(p11;q24) t(8;22)(q24;q11)
Lymphoblastic	28	T cell	Mediastinum or head/neck	t(1;14)(p32;q11) t(11;14)(p13;q11) t(11;14)(p15;q11) t(10;14)(p24;q11) t(7;19)(q35;p13) t(8;14)(q24;q11) t(1;7)(p34;q34)
Large cell	26	B cell, T cell, indeterminate	Mediastinum, abdomen, head/neck, or skin	t(2;5)(p23;q35)†

**Other histologies account for approximately 7%.*[93]
†Anaplastic large cell lymphoma (ALCL) histologic subtype.

Extramedullary disease outside the CNS can also occur, such as the development of chloromas, most commonly in M4 and M5 subtypes. There was no benefit to the use of local RT to treat chloromas, in addition to systemic therapy in children.[81] If a chloroma is causing significant morbidity, such as vision loss or spinal cord compression, RT is indicated.

Because the use of intensified chemotherapy has improved the event-free survival in children with AML, this raised the question as to whether even greater dose intensification, such as with myeloablative therapy and stem-cell rescue, could improve the event-free survival even more. Randomized trials have shown that children with AML who undergo allogeneic stem-cell transplants from human leukocyte antigen–matched siblings have an improved relapse-free survival.[82-88] Postremission consolidation therapy with allogeneic bone marrow transplantation has become the standard of care for children with high-risk AML based on the presence of certain molecular features or a poor response to initial therapy. Total-body irradiation is sometimes used as a part of the myeloablative regimen for bone marrow transplantation.

NON-HODGKIN'S LYMPHOMA

Lymphomas in children comprise the third-most common malignancy of childhood, superseded only by ALL and brain tumors. In children younger than age 15 years, 60% of cases are NHL. If one includes children through age 18, Hodgkin's disease is slightly more frequent.[89] NHL is diagnosed annually in the United States in approximately 500 children. The median age at diagnosis is 10 years; NHL is less frequent in children younger than age 3 years. There is no bimodal age distribution; the frequency increases with increasing age. For unknown reasons, NHL is more common in the white population than in blacks and two to three times more frequent in males than in females.[1] Specific populations at increased risk of developing NHL include children with congenital immunodeficiency disorders such as Wiskott-Aldrich syndrome, ataxia-telangiectasia, and X-linked lymphoproliferative syndrome.[90]

In contrast to NHL in adults, NHL in children is primarily aggressive, with diffuse tumors and frequently extranodal presentation. There are three main subtypes: Burkitt's, lymphoblastic, and large cell (diffuse large B-cell lymphoma and anaplastic large cell lymphoma)[91] (Table 73-3). The staging system used in childhood NHL is the Murphy/St. Jude's Children's Research Hospital staging system, which incorporates extent of disease and clinical patterns[92] (Table 73-4). Treatment of childhood NHL is based on the stage, immunophenotype, and histology.

TABLE 73-4 Staging of Non-Hodgkin's Lymphoma in Children

Stage	Description
I	Involvement of a single extranodal site or single anatomic nodal site, excluding the mediastinum or abdomen
II	Involvement of a single extranodal site with regional nodal involvement Two or more nodal areas on the same side of the diaphragm Two extranodal sites with or without regional nodal involvement on the same side of the diaphragm A primary gastrointestinal tract tumor, usually ileocecal, with or without mesenteric node involvement that is completely resected
III	Two single extranodal sites on opposite sides of the diaphragm Two or more nodal groups above and below the diaphragm All primary intrathoracic tumors All extensive (unresectable) intraabdominal primary tumors All paraspinal or epidural tumors
IV	Any of the preceding stages with initial involvement of the bone marrow, central nervous system, or both

Burkitt's lymphoma makes up 39% of childhood NHL and is of mature B-cell immunophenotype. These lymphomas present in the abdomen or in the head and neck. The epidemiology of Burkitt's lymphoma is of great interest because of its major differences in incidence and clinical features based on geography. For example, it is the most-common childhood malignancy in equatorial Africa, yet is rare in Japan.[94] In Africa, the endemic subtype occurs and is characterized by younger age at diagnosis and frequent involvement of the jaw, abdomen, orbit, and paraspinal area.[94] The sporadic subtype, which occurs in the United States and Western Europe, is characterized by older median age at diagnosis and frequent involvement of the abdomen, nasopharynx, and bone marrow. These tumors are characterized by translocations that result in the juxtaposition of the *CMYC* gene and an immunoglobulin gene; there are breakpoint differences within these translocations that have also been reported to vary with geography.[94] The association of Epstein-Barr virus with Burkitt's lymphoma varies with geography; Epstein-Barr virus is highly associated with the endemic (African) subtype.[94]

The treatment of Burkitt's lymphoma uses cyclophosphamide-based chemotherapy, with the addition of agents including vincristine (Oncovin), prednisone, doxorubicin (Adriamycin), and methotrexate. Children with advanced-stage Burkitt's lymphoma have an improved outcome with the addition of cytarabine or high-dose methotrexate. Children with bone marrow or CNS involvement have an improved outcome, with more intensive regimens resulting in an 80% to 90% event-free survival even for patients with advanced-stage disease.[93,95-98] Current trials are examining the benefits of incorporating an anti-CD20 monoclonal antibody (rituximab) into a conventional multiagent chemotherapy regimen.[99]

Lymphoblastic lymphomas make up approximately 29% of childhood NHL. Children with lymphoblastic lymphoma typically present with advanced-stage disease (i.e., mediastinal mass which in some cases is associated with bone marrow involvement); however, some children do present with limited-stage disease. These lymphomas share morphologic, immunophenotypic, and cytogenetic features with ALL. The majority (~90%) are characterized by a T-cell immunophenotype and are designated as precursor T-lymphoblastic leukemia/lymphoma in the WHO classification system; the remainder have a precursor B-cell immunophenotype.[91] The distinction between ALL and lymphoblastic lymphoma is made arbitrarily on the basis of degree of bone marrow involvement. Those with greater than 25% replacement of the marrow by lymphoblasts are considered to have ALL, whereas those with a lesser degree of involvement are considered to have advanced stage (IV) lymphoblastic lymphoma. Whether there is a biologic distinction between lymphoblastic leukemia and lymphoblastic lymphoma is somewhat controversial; however, there appear to be subtle differences in the molecular biology, cytogenetics, and immunophenotypic markers between these two entities.[92,100,101] The treatment of lymphoblastic lymphoma in children uses multiple-agent chemotherapy comprising drugs similar to those used for T-cell ALL, which include vincristine, prednisone, L-asparaginase, doxorubicin, cytarabine, cyclophosphamide, and high-dose methotrexate. Recent studies have indicated that high-dose methotrexate may not be necessary in some patients if sufficient intrathecal chemotherapy is given.[102,103] The total duration of therapy generally ranges from 2 years to 3 years, although shorter durations have been attempted. With contemporary treatment protocols, between 80% and 85% of patients are long-term event-free survivors.[104-106] Current trials are incorporating minimal residual disease technology into treatment stratification and planning based on results from a recent COG trial.[107]

Large cell lymphomas represent approximately 27% of childhood lymphomas. Forty to 50 percent are T-cell anaplastic large cell lymphomas (ALCL), CD30+ and often associated with t(2;5)[108]; 30% to 40% are diffuse large B-cell lymphomas (DLBCL), which include the mediastinal large B-cell lymphomas (MLBCL); and the remainder are nonanaplastic mature T-cell lymphomas.[109] Historically, the treatment of childhood NHL in the United States has been based on histology. However, there has been a shift toward using an immunophenotype-directed approach, which has been the standard practice in Europe for many years. With this approach, children with DLBCL are treated with regimens for children with Burkitt's lymphoma and achieve a comparable outcome.[96] The MLBCLs have a slightly poorer prognosis than the DLBCLs.

Those patients with ALCL are treated with either cyclophosphamide, hydroxydaunomycin (doxorubicin), vincristine (Oncovin), and prednisone (CHOP)-based regimens or regimens derived from Burkitt's lymphoma regimens.[110-113] A randomized comparison of ACOP versus APO (doxorubicin [Adriamycin], vincristine [Oncovin], prednisone with or without cyclophosphamide) showed no significant difference in outcome.[113,114] The optimal approach for treatment of ALCL in children has not been established. Approximately 70% of children are long-term event-free survivors regardless of approach.[111,112] Single-agent vinblastine has been shown to be active in children with recurrent ALCL.[115] However, when it has been incorporated into frontline multiagent regimens, there has been no improvement in long-term event-free survival.[116] Targeted therapeutic approaches are currently being studied.[117,118]

The role of local RT in the management of NHL in children has been more limited because of the improved outcomes with more effective chemotherapy. In a prospective randomized trial evaluating the need for local RT in early-stage NHL,[119] no benefit was found for the addition of local RT. A second trial,[120] built on the results of the first, confirmed this. Although children with primary lymphoma of bone were not randomized in the first trial and all received local RT, in the second trial RT was not given and there were no local relapses. Based on these results, the current management of localized NHL of bone includes chemotherapy but does not use consolidative local RT. Children with advanced-stage lymphoma do not benefit from involved-field RT.[121]

Cranial irradiation has been eliminated as a component of CNS prophylaxis in the management of children with NHL.[97,105,106] RT is used for some cases of relapse or refractory disease and as a palliative modality. Children with persistent disease after chemotherapy or who experience relapse are often considered for high-dose chemotherapy protocols with stem-cell rescue if they have chemosensitive disease.[122] Consolidative RT can be considered either before or after transplant in some cases. There are no prospective randomized trials in pediatrics to confirm the benefit of this approach.

Urgent RT is rare, but there are occasions when it is considered. Mediastinal masses in children can cause significant airway compromise or superior vena cava compression. If a tissue diagnosis cannot be established to allow administration of systemic therapy, urgent RT may be considered. It should be noted that if one treats empirically with systemic therapy for the most likely diagnosis, the correct treatment is given in the vast majority of cases.[123] Radiation oncologists are often called to be aware of children with newly diagnosed mediastinal masses. If RT is given, only a few fractions are needed to achieve stabilization and allow appropriate systemic therapy to be initiated once a histologic diagnosis is made.

Encouraging progress has been made in the treatment of childhood leukemias and lymphomas. However, many children continue to succumb to disease despite aggressive therapy and many children experience significant treatment-related short- and long-term sequelae. Oncologists and radiation oncologists need to strive for improvements in treatment while minimizing the late effects of therapy. Continued research in the biology of these malignancies coupled with a search for new biologic and clinical prognostic factors will help to achieve this goal.

CHAPTER

74 Pediatric Hodgkin's Lymphoma

Kenneth B. Roberts, Kara M. Kelly, and Louis S. Constine

EPIDEMIOLOGY AND BIOLOGIC CHARACTERISTICS

Relative to adult Hodgkin's lymphoma (HL), pediatric Hodgkin's lymphoma has:

- Distinct features in relation to geographic distribution, gender, association with Epstein-Barr virus (EBV), and histological subtype;
- Relatively higher incidence in developing countries and in males;
- Nodular lymphocyte predominant subtype is more frequent.

STAGING EVALUATION

- All patients: history and physical examination; complete blood count; blood chemistries; upright posteroanterior and lateral thoracic radiographs; computed tomography (CT) of the neck, chest, abdomen, and pelvis; functional nuclear imaging studies with ^{18}fluoro-2-deoxyglucose [FDG] positron emission tomography [PET]);
- Bone marrow biopsies in selected patients with clinical stages III and IV disease or B symptoms;
- Staging laparotomy is rarely appropriate, but biopsy of specific sites with equivocal findings by clinical staging should be considered where results will alter therapy;
- Two thirds of children are stage I or II, and one third have B symptoms.

PRIMARY THERAPY

- Risk-adapted therapy based on some of the following presenting features at diagnosis:
  - B symptoms, mediastinal and peripheral lymph-node bulk, extranodal extension of disease to contiguous tissues, number of involved nodal regions, Ann Arbor stage, and gender;
- Response to chemotherapy:
  - Profound prognostic factor;
  - Reduction in therapy may be based on rapidity and the degree of response to chemotherapy;
  - Augmentation of therapy may be based on lack of or insufficient response to chemotherapy;
- Toxicity
  - Children have a relatively increased risk, compared with adults, for long-term cardiopulmonary compromise, musculoskeletal growth impairment, and subsequent malignant neoplasms;
  - Late effects experience (e.g., second cancers, cardiopulmonary effects) from the legacy of archaic extended field high-dose radiotherapy technique have limited bearing on modern clinical practice;
- Chemotherapy:
  - Common regimens:
    - doxorubicin, bleomycin, vinblastine, dacarbazine (ABVD)
    - vincristine, doxorubicin, methotrexate, prednisone (VAMP)
    - vincristine, etoposide in boys, procarbazine in girls, predinsone, doxorubicin (OEPA/OPPA)
    - mechlorethamine, vincristine, procarbazine, prednisone (MOPP)
    - MOPP substituting cyclophosphamide for mechlorethamine (COPP)
    - bleomycin, etoposide, doxorubicin added to COPP (BEACOPP)
    - mechlorethamine, doxorubicin, vinblastine, vincristine, bleomycin, etoposide, prednisone (Stanford V)
    - doxorubicin, bleomycin, vincristine, etoposide, prednisone, cyclophosphamide (ABVE-PC)
  - Early stage favorable disease most commonly uses ABVD or derivative chemotherapy; VAMP and OEPA/OPPA are alternatives
  - Intermediate- or high-risk disease use dose dense combinations derived from both ABVD and MOPP (nitrogen mustard, vincristine, procarbazine, and prednisone) along with the addition of etoposide; ABVE-PC, OEPA/OPPA with COPP are examples of this.
- Radiotherapy:
  - Use of low-dose radiation therapy (RT) following chemotherapy is response based. RT used for slowly responding, bulk, residual, or recurrent disease is the emerging standard across all stages;
  - Ongoing concerns about the incremental toxicity of RT, particular secondary cancers, remain a stimulus for investigations of chemotherapy alone;
  - Shift to involved-node or involved-site RT from traditional involved field volumes
- Results
  - Chemotherapy alone: long-term event-free survival (EFS) ranges from 85% to 100% in patients with localized favorable disease and 70% to 90% in those with advanced or unfavorable disease;
  - Incremental improvements in EFS with addition of involved field RT are in range of 5% to 10%. Rapid response to chemotherapy predicts for negligible benefit from RT.
  - The subset of patients who relapse after initial therapy have a high chance for long-term disease remission with second-line therapies.

INTRODUCTION

Given the high cure rates in treating children with HL, the ongoing challenge has been the development of less toxic therapy. In this regard, the progress in HL management in children has often presaged that in adult patients. Although many similarities between pediatric and adult HL exist, there are a number of distinctions that suggest different biologic processes, though this remains controversial. Differences associated with age include gender ratio, the proportion of patients with the most common histologic subtypes, the underlying biology (e.g., the role of EBV), and the potential for cure.[1] Pediatric HL has an excellent prognosis with high survival rates.[1,2] Given the high cure rates, HL, particularly in children, has provided much of the knowledge base we have about late toxicities of RT and cytotoxic chemotherapy. Because of the increased vulnerability of children to the adverse effects of therapy, the management of pediatric HL has led the way in the evolution of treatment strategies that consider both the toxicity and efficacy of therapy.

Historically, the desire to avoid the musculoskeletal hypoplasia that occurred following high-dose extended field RT, and leukemogenesis and infertility associated with certain alkylating agents led to a more rational combined modality therapy. Subsequent observations of cardiovascular dysfunction and increased risk of secondary cancers have played additional roles in modifying therapeutic approaches. The first generation of combined-modality therapy regimens used cycles of chemotherapy to replace a portion of the RT in children staged with laparotomy.[3-8] Second-generation regimens used doxorubicin-containing combinations to replace or reduce offending alklylating agents. Concurrent with advances in diagnostic imaging, investigators eventually abandoned surgical staging after demonstrating efficacy of the combined-modality treatment approach.

In time, risk-adapted trials evolved that prescribed fewer cycles of multiagent chemotherapy and lower radiation doses and treatment volumes for patients with favorable clinical presentations.[9,10] The definition of risk groups for disease stratification can vary in different trials and has changed with therapeutic advances. In some trials, gender-related predispositions also influence the treatment algorithm. For example, following cumulative doses of alkylating agent chemotherapy used in primary treatment regimens, boys exhibit a greater sensitivity to gonadal toxicity compared to girls, who generally maintain ovarian function unless chemotherapy is combined with abdomino-pelvic radiotherapy.[11] Conversely, young women treated with thoracic RT have a markedly increased risk of a breast cancer that is not observed in their male counterparts; however, current approaches with more restricted RT volumes are decreasing this risk.[12-14]

Because of the spectrum of prognostic factors in pediatric HL, and the unique developmental and gender-related predispositions to therapy effects, no single treatment method is ideal for all patients. Contemporary treatment for children and adolescents with HL uses a risk-adapted approach that considers presenting risk features at diagnosis. Therapy duration and intensity are selected to maintain long-term remission with minimal treatment-related morbidity. Moreover, the response to initial chemotherapy is itself an important prognostic factor and now a trigger to reduce or augment therapy.[7,15,16] The Children's Oncology Group (COG) intermediate-risk group Phase III trial AHOD0031 was the first HL trial to demonstrate that a rapid interim response to chemotherapy would allow for the elimination of involved field RT.[17]

Consequently, the evolution of therapy for pediatric HL has served as a model for other cancers. Pediatric HL management has also been early to adopt improved risk stratification and more recently response-based strategies that titrate the aggressiveness of therapy to improve the therapeutic ratio. Ongoing investigations aim to identify subgroups of HL that may be treated with reduced volume and dose of irradiation or with chemotherapy alone. The concerns about RT are to a certain extent the legacy of the significant late complications (second malignancies, cardiopulmonary dysfunction, and musculoskeletal hypoplasia) observed following archaic extended field high-dose RT techniques that have limited bearing on modern clinical practice. Nevertheless, children are more susceptible to late effects of therapy, and the trends in clinical trials have been to strive to reduce adjuvant RT despite many individual trials showing a small improvement in disease-free survival (DFS) from involved field RT and even a meta-analysis showing a small survival advantage in patients who are in early-stage disease.[18] With better risk- and response-adapted therapies, there is a general decline in RT for the upfront management of pediatric HL. RT remains important, however, to (1) complement chemotherapy when there is slowly responding, residual, or possibly initial bulky disease; (2) reduce chemotherapy intensity in selected patients where the predicted late toxicity risk for RT is small; and (3) help manage relapsed disease.

ETIOLOGY AND EPIDEMIOLOGY

Pediatric HL, accounts for 5% to 6% of childhood cancers and exhibits distinctive epidemiologic features. The childhood form, which presents in patients younger than 15 years of age, is associated with a marked male predominance, increasing family size, and decreasing socioeconomic status.[19-21] In developed countries, HL is rarely diagnosed in children younger than 5 years of age. The young adult form, which presents in patients ages 15 years to 34 years, is associated with a higher socioeconomic status in industrialized countries. Overall, the incidence is highest in developed countries (North America and Europe) and rare in Asian populations; in childhood, however, some developing regions have relatively higher incidences.[22] In adolescents, the incidence between males and females is roughly equal, and most older adolescent patients are white.[21] The risk for young adult HL decreases significantly with increased sibship size and birth order.[23,24] Specifically, the risk of HL in young adults is lower in individuals with multiple older, but not younger, siblings. Histologic subtypes also vary by age at presentation. Mixed cellularity subtype (more commonly associated with EBV) is more common in HL of childhood and the elderly, whereas nodular sclerosing subtype is more frequently observed in adolescents and young adults.

Although underappreciated because of the rarity of HL, there is a genetic predisposition that may be important to better advise families as well to help elucidate the underlying etiology of this disease. First-degree siblings of HL patients younger than 40 years of age have a 3-fold increased risk for HL.[25] Other studies report that siblings have as high as a increased incidence that may be a 9-fold increased risk in same-sex siblings.[26] Parent-child dyads have been observed. Moreover, a 99-fold increase risk in identical twins, but not in dizygotic twins has been reported.[27] More recent genetic correlative studies and exon sequencing has linked the genetic susceptibility for HL with various chromosomal loci, human leukocyte antigen (HLA) subtypes, and single nucleotide polymorphisms.[28-31] In this regard, there may be interactions with specific HLA loci and viral pathogenesis. The nodular lymphocyte predominant variant—thought to be more akin to a low-grade B cell non-HL with a lengthy time to diagnosis and time to relapse—also has a familial pattern of inheritance in some instances, linked to mutation in the ataxia

telangiectasia gene.[32,33] Increased risk for nodular lymphocyte predominant HL has also been observed in individuals with autoimmune lymphoproliferative syndrome (ALPS), a disorder associated with defects in fas-mediated apoptosis.[34]

Pediatric HL exhibits epidemiologic features similar to that seen with paralytic poliomyelitis. Delayed exposure to an infectious agent might increase the risk of the young adult form of HL, whereas early and intense exposure to an infectious agent might increase the risk for the childhood form of HL.[23] Data also indicate an association between nursery school or daycare attendance and reduced risk of HL among young adults, supporting a model in which childhood exposure to common infections promotes maturation of cellular immunity.[35] The presence of high-antibody titers to EBV, in situ hybridization evidence of EBV genomes in Reed-Sternberg cells, and EBV early RNA1 and RNA2 (EBER1 and EBER2-Epstein-Barr Early Ribonucleoprotein 1) sequences provide evidence that enhanced activation of EBV may play a role in the development of HL.[36,37] The incidence of EBV-associated HL varies by age, sex, ethnicity, histologic subtype, regional economic level, and underlying immune function.[38,39] Approximately 30% to 40% of patients with HL have associated EBV.[38] In one series of childhood HL, EBV early RNA1 was expressed in the malignant Reed-Sternberg cells in 58% of cases.[40] More specifically, an association with EBV is greater in populations of lower socioeconomic status, cases of mixed cellularity HL, and cases occurring in both young children and in the elderly.[36] Finally, there is an increased incidence of EBV-associated HL in patients with primary immunodeficiency disorders such as common variable immunodeficiency as well as with secondary immunodeficiency (e.g., HIV infection and immunosuppression for solid organ transplantation).[41]

PATHOLOGY AND PATHWAYS OF SPREAD

The pathologic features of HL are similar in adults and children; however, the distribution of the histological subtypes defined by the World Health Organization may vary by age at presentation.[42,43] Nodular lymphocyte-predominant Hodgkin's lymphoma (nLPHL) makes up almost 10% of pediatric cases. This histological subtype usually presents as clinically localized disease and is more common among male and younger patients. In contrast to classical HL, which is CD-15 and CD-30 positive, nLPHL is an indolent B cell neoplasm with histopathology notable for lacunar or Reed-Sternberg–like giant cells that are CD-20 positive and usually CD-15 and CD-30 negative.

Nodular sclerosing HL represents the most common histologic subtype in pediatric cases under the rubric of classical HL, affecting approximately 70% of adolescents and children.[44] Nodular sclerosing HL most commonly involves the lower cervical, supraclavicular, and mediastinal lymph nodes. The bulky growth of some involved nodal regions (particularly in the mediastinum) may be associated with persistent radiographic abnormalities even when the patient has fully responded to therapy. The other classical form, mixed-cellularity HL is observed in approximately 15% of patients, is more common in children aged 10 years or younger, and more frequently presents as advanced disease with extranodal involvement.[44] Lymphocyte-depleted HL is rare in children but relatively more common in patients infected with human immunodeficiency virus (HIV).[45] Lymphocyte-depleted disease in patients who are HIV-positive is often associated with EBV. Lymphocyte-rich classical Hodgkin lymphoma (LRHL) makes up approximately 5% of all HL and closely overlaps with the nodular lymphocyte-predominant subtype in presenting clinical features and prognosis.[46] The median age at presentation for LRHL (32 years) is, however, higher than for NLPHL, and there is a slightly higher incidence of mediastinal involvement and stage III disease at presentation.[47]

STAGING, CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND PROGNOSTIC FACTORS

Staging

Physical examination and diagnostic imaging evaluations are used in pediatric patients to designate a clinical stage according to the Ann Arbor staging system.[48] This historical staging system is based on anatomical groups of regional lymph nodes as delineated at the 1970 Ann Arbor symposium. It was subsequently revised at the Cotswolds meeting in 1989, although not all recommendations are in current usage.[49] This staging system persists to date with stage I identifying disease confined to one nodal region. Stage II signifies disease confined to two or more regions, but on one side of the diaphragm. Stage III indicates nodal disease that is on both sides of the diaphragm, whereas stage IV is diffuse or disseminated disease that includes extranodal sites. A special subset of stages I and II disease may be designated as extralymphatic or extranodal with the "E" suffix, which historically had been interpreted to be a disease distribution that could be encompassed within a reasonable radiation treatment portal; this operational definition has current difficulties because the role of RT is being curtailed but still is needed for prognostic purposes to designate early stage. Largely ignored from the Cotswold recommendations in current practice is the suffix "X" to designate bulky disease (greater than 10 cm maximum dimension) and a category of response to therapy, unconfirmed/uncertain complete remission (CR[u]), introduced to accommodate the difficulty of persistent radiological abnormalities of uncertain significance before the current use of metabolic imaging.

Lymphoma staging continues to be unique with the inclusion of prognostically significant constitutional symptoms. The absence of symptoms is labeled with the suffix "A," whereas "B" symptoms included in the staging assignment are unexplained fever with temperatures taken orally that are higher than 38°C, unexplained weight loss of 10% within 6 months preceding diagnosis, and drenching night sweats. At one time pruritus had been included as a B symptom but was dropped many decades ago.

In the past, pathologic staging, based on the findings of a staging laparotomy, including splenectomy, was routinely used to assess infradiaphragmatic disease. The increasing use of systemic therapy in children and the development of more accurate diagnostic imaging modalities led to the routine use of clinical staging and abandonment of surgical staging except to assess equivocal findings. Currently, surgical staging—most typically nodal sampling without splenectomy—is pursued only if the anticipated findings will significantly alter the treatment plan.

Clinical Manifestations

Pediatric patients most commonly present with painless cervical or supraclavicular lymphadenopathy. Mediastinal lymphadenopathy occurs in up to 66% of patients and may be associated with a nonproductive cough or other symptoms of tracheal or bronchial compression. Axillary or inguinal lymphadenopathy is less frequently seen as the first presenting sign. Primary infradiaphragmatic disease is rare in pediatric patients and occurs in fewer than 5% of cases. Splenic involvement occurs in 30% to 40% of pediatric patients with HL, whereas hepatic involvement is exceedingly rare. The pulmonary parenchyma, chest wall, pleura, and pericardium are the most

commonly involved extranodal sites of disease. Bone marrow involvement at the time of initial presentation of HL is also uncommon in children. Approximately 65% of children have stages I and II disease and 35% have stages III and IV disease (Table 74-1).

Nonspecific systemic symptoms are often associated with lymphadenopathy and may include fatigue, anorexia, mild weight loss, and pruritus. The prognostically significant B symptoms have already been defined and occur in approximately 33% of patients (see Table 74-1). Laboratory changes observed at presentation are nonspecific but may provide clues about the extent of disease. Hematological abnormalities may include anemia, neutrophilic leukocytosis, lymphopenia, eosinophilia, and monocytosis. Anemia may be associated with the presence of advanced disease and may result from impaired mobilization of iron stores or less commonly from hemolysis. Several autoimmune disorders have been reported in patients with HL including nephrotic syndrome, autoimmune hemolytic anemia, autoimmune neutropenia, immune thrombocytopenia, and autoimmune lymphoproliferative disorder.[53] These conditions typically remit as the lymphoma is responding to therapy. Several acute phase reactants including erythrocyte sedimentation rate, serum copper, ferritin, and C-reactive protein levels may be elevated at diagnosis and useful in follow-up evaluations.

Patient Evaluation

Posteroanterior and lateral thoracic radiographs should be performed as soon as HL becomes part of the differential diagnosis to assess mediastinal involvement, airway patency, and other intrathoracic structures. This is particularly important if sedation is planned for diagnostic procedures. An excisional lymph node biopsy is the preferred diagnostic procedure because it permits evaluation of the malignant Hodgkin Reed-Sternberg cells within the background of characteristic architectural changes of the specific histological subtypes. All nodal regions, including Waldeyer's ring, should be assessed by careful physical examination. Historically, an upright chest radiograph was also important to assess mediastinal bulk that is defined by mediastinal lymphadenopathy measuring 33% or more of the maximum intrathoracic cavity. Whether or not this definition for bulk mediastinal adenopathy may be replaced by CT-based mass dimensions or volumes is currently under debate. CT is most frequently used to evaluate the nodal regions in the neck, axilla, thoracic and abdominal cavities, and pelvis. Administration of both oral and intravenous contrast agents is required for CT to accurately distinguish lymphadenopathy from other infradiaphragmatic structures. Organ size is an unreliable indicator of lymphomatous involvement in the liver or spleen because tumor deposits may be less than 1 cm in diameter and not visualized by diagnostic imaging modalities. Increased size of either organ can, of course, be caused by nonmalignant causes. The presence of hypodense lesions by CT or abnormal functional avidity PET scanning provides stronger evidence of tumor infiltration in these organs.

Functional nuclear-imaging studies are appropriately used in patients with HL as a diagnostic and monitoring modality. FDG-PET scanning has become a standard part of the staging

work-up and assessment of response to therapy. Fused positron emission tomography/computed tomography (PET-CT) offers the advantage of integrating functional and anatomic tumor characteristics. Residual or persistent FDG avidity appears to be useful in predicting prognosis and the need for additional therapy in posttreatment evaluation.[54-58] Moreover, PET may be useful in evaluating abnormalities that become clinically manifest or appear on imaging to assess recurrence.[59] The utility of PET for follow-up is being studied because other reports suggest low rates of diagnosing relapsed disease and problems with a high degree of false-positive findings.[60-62] Because extranodal disease involving the bones and bone marrow is relatively uncommon in children, these staging evaluations can be omitted in patients presenting with localized and asymptomatic disease. Bone pain should be evaluated with plain radiographs; magnetic resonance (MR) may also be necessary in this situation for questions about focal bone involvement. PET scanning is supplanting technetium-99 bone scans for skeletal evaluation, which historically have also been performed when there was an elevated serum alkaline-phosphatase concentration beyond that expected for age, or extranodal disease identified by other staging evaluations. A bone marrow biopsy should be performed in any patient with clinical stage III or IV disease or B symptoms, although this standard recommendation is being reconsidered when PET imaging shows no bone or bone marrow involvement.[63] Because the pattern of infiltration in the bone marrow may be diffuse or focal and is often accompanied by reversible marrow fibrosis, a bone marrow aspirate alone is inadequate to assess the marrow for disease.

Prognostic Factors

The identification of prognostic factors has taken on importance as a determinant of risk- and response-adapted treatment algorithms. Many prognostic factors have been identified from adult trials. Regardless, this effort is complicated by several concepts. First, prognostic factors are in flux as more effective or higher intensity therapy may negate adverse risk factors previously demonstrated.[64] Second, various risk-stratification schemes have been used by different institutions and cooperative groups to allocate patients to various treatments regimens making comparisons of patient populations challenging. Most data are based on reports that primarily include adults. Although there is overlap in the biology and response to therapy of pediatric and adult forms of HL, there is divergence in prognostic groupings just as there are differences in treatment regimens. Even among pediatric protocols and cooperative groups there is a lack of standardization in prognostic factors. See Table 74-2. Third, there is an evolving understanding that early response to systemic therapy may be an important prognostic factor that may be used to guide further treatment decisions.[57] While this concept is under investigation in adults with HL, response-based therapy has recently developed firm roots in pediatric HL treatment paradigms.[17] Thus, there is much variability in classifications of patients with HL into favorable, intermediate, and unfavorable/advanced strata.

Dating from the time that early-stage HL was treated with subtotal or total nodal irradiation including splenic irradiation—often termed extended field radiotherapy (EFRT)—numerous adverse prognostic factors in stages I to II disease have identified those patients who benefit from combined-modality therapy.[73-76] In pediatric management, EFRT was abandoned in favor of primary chemotherapy and reduced dose involved field RT in the 1970s and 1980s to reduce late effects of full dose EFRT. This switch in adult management of early-stage disease did not occur until the mid-1990s. Regardless, the concept of risk-adapted therapy was first developed in which the presence of poor prognostic factors drive more intensive therapy; at the same time, favorable factors identify a population appropriately treated with less intensive therapy designed to maintain high cure rates with fewer acute and late side effects. Prognostic factors identified in these analyses include the number of involved lymphoid regions, the size of individual nodes, the extent of mediastinal disease, patient gender and age, the presence of B symptoms or pruritus, histology, erythrocyte sedimentation rate (ESR), and overall tumor burden as measured by number of sites and disease bulk.

Even for pediatric management, it is relevant to note that the adult cooperative groups have refined favorable versus unfavorable groupings. For instance, the European Organization for Research and Treatment of Cancer (EORTC) and

Groupe d'Etudes des Lymphomes de l'Adulte (GELA) specify the following as unfavorable factors: age >50 years, ESR ≥ 50 in the absence of B symptoms, ESR ≥ 30 with B symptoms, ≥4 sites of involvement or bulky mediastinal involvement.[77] For the German Hodgkin Lymphoma Study Group (GHSG), the following are considered unfavorable factors: ESR ≥50 in the absence of B symptoms, ESR ≥ 30 with B symptoms, ≥3 sites of involvement, extranodal involvement, or bulky mediastinal mass.[78]

For pediatric practice, adverse prognostic features have included advanced stage, B symptoms, extranodal extension, peripheral or mediastinal bulky disease, hilar adenopathy, and three or more involved nodal regions. Based on the most recent intermediate risk COG protocol AHOD0031, a preliminary prognostic scoring system has been proposed, with the acronym CHIPS for Childhood Hodgkin International Prognostic Score. Based on a multivariate analysis, four predictors—stage IV, large mediastinal adenopathy, albumin <3.5, and fever—were identified as predictive of adverse EFS.[79] This simple scoring system needs further validation, particularly as treatment algorithms change, prognostic factors may change and become more difficult to identify. But for the present, several prognostic factors continue to influence the success and choice of therapy for pediatric practice:

1. *Stage of disease:* Stage persists as the most important prognostic variable. Patients with advanced stage disease, especially stage IV, have a poorer outcome than patients with early-stage disease.[80]
2. *B symptoms:* These constitutional symptoms likely result from cytokine secretion, and correlate with biologic aggressiveness. Thus, unexplained fevers, drenching night sweats, or significant weight loss with definitions noted in the Ann Arbor staging classification system[48] continue to have prognostic importance and in turn influence management decisions. The presence of B symptoms has correlated with a higher likelihood of systemic disease, including occult subdiaphragmatic disease when staging laparotomies were once performed. Evidence suggests that fevers and weight loss have more prognostic significance than night sweats alone.[81]
3. *Bulk:* The bulk of disease combines the number of disease sites and the volume of involvement at each site. Patients with several sites of involvement, defined variably as either three or four or more sites of disease, fare less well.[82] This prognostic factor may also influence treatment selection as to the reduction or elimination of RT after primary chemotherapy for patients with early-stage HL.[83,84] Moreover, the presence of large mediastinal adenopathy or bulky disease in nonmediastinal sites has been another consistent risk factor. A variety of definitions of large mediastinal adenopathy have been reported in the literature.[85] The most commonly used definition is based on a measurement of the maximum width of the mediastinal mass on standing posteroanterior (PA) chest radiograph, compared with the maximum intrathoracic diameter. A ratio greater than one third is defined as "bulky." Other reports have used a ratio with the intrathoracic width at T5-6 as the denominator,[86] whereas still others use absolute measurements,[87] surface area calculations, or volume measurements. In the absence of a chest x-ray, CT-based measurements of mediastinal masses have not reached a consensus recommendation, but some commentators have suggested that 10-cm maximal diameter may be reasonable. Bulky disease in nonmediastinal sites has similarly been classified with varying definitions. Some protocols define bulky as ≥10 cm, while others use ≥5 cm[88] or ≥6 cm.[17,89,90] In Europe, the EuroNet Pediatric Hodgkin Lymphoma Group uses a volumetric definition of bulk. This was initially assessed by a definition of 50 mL,[64] but subsequent experience has found a 200-mL volume definition to be more prognostically discriminatory and is now used in their EuroNet PHL C2 trial to stratify patients.[91] Moreover, volume of a given site of disease is estimated by a simple formula estimating an ellipsoid where $V = (xyz)/2$ where x, y, and z are the diameters of the mass in three dimensions. This becomes much more complex when measuring mediastinal masses where adding multiple ellipsoids of disease to avoid counting normal structures is the procedure.
4. *Laboratory studies*, including the ESR, hemoglobin level, and serum albumin, have been reported to predict worse outcomes.[76] This could reflect disease biology or bulk. In adult cooperative group trials, ESR has been an important stratification factor in treatment protocols. Low hemoglobin and albumin levels have been found to be important factors in an International Prognostic Score.[92]
5. *Histologic subtype* has importance. As already noted, patients with NLPHL are biologically different and generally have improved DFS and overall survival (OS) relative to classical HL; separate protocols with minimal therapy are under way for patients with early-stage NLPHL. Patients with lymphocyte depleted Hodgkin's lymphoma (LDHL) fare poorly. Mixed reports suggest better or poorer outcome of other histologies that may be related to other prognostic factors as well. Some reports suggest that the mixed cellularity subtype of classical HL may have better prognosis than nodular sclerosis subtype in the pediatric age group.[93]
6. *Age* is a significant factor with survival rates for children with HL approaching 85% to 95%, and higher than adults stage for stage. In a report from Stanford, the 5-year and 10-year survival rates for children with HL ≤ 10 years of age was 94% and 92%, respectively, compared with 93% and 86% for adolescents (aged 11-years to 16-years old) and 84% and 73% for adults.[21]
7. *Rapidity of response to initial chemotherapy* is an important prognostic variable. Early-response to therapy was initially observed in patients with advanced stage HL treated on Pediatric Oncology Group (POG) 8725, where 93% of patients who attained a complete response (CR) after three cycles of chemotherapy remained disease free.[7] This was also confirmed for lower stage patients[16] and afterward incorporated in the latest COG front-line trials. Early CR to therapy has also been successfully incorporated into the German trials with low-risk patients who achieve CR after two cycles of oncovin, etoposide, prednisone, and Adriamycin (OPEA)) not requiring further RT.[69,94] Response-based therapy is currently the paradigm on which modern pediatric trials are based.

PRIMARY THERAPY

Risk-Adapted Treatment Approach

Contemporary treatment for children and adolescents with HL involves a risk-adapted and now a response-adapted approach based on the patient's presenting features at diagnosis[50,51,70,71,95-98] and re-evaluation after one or two cycles of chemotherapy. Factors included in the risk assessment may vary across studies; but they most often include the presence of B symptoms, mediastinal and peripheral lymph node bulk, extranodal extension of disease to contiguous structures, number of involved nodal regions, Ann Arbor stage, and gender. A favorable clinical presentation is typically characterized as localized (stages I and II) nodal involvement in the absence of B symptoms and bulky disease. Although the historical definition of mediastinal bulk has been based on the ratio greater than one third between the transverse dimension

of the mediastinal mass to the intrathoracic cavity on an upright chest radiograph, some trials have moved to use a simple size criteria on cross-sectional imaging as used for peripheral lymph node bulk. That definition, however, is highly variable across studies ranging from 4 cm to 10 cm as a minimal threshold. Moreover, there is additional subjectivity in the definition of bulk when there are multiple matted or adjacent nodes, contributing to confusion on such risk stratification in practice. Fewer than three or four involved nodal regions are considered favorable. In some risk-adapted treatment protocols, patients with localized disease presenting with unfavorable features are designated intermediate in risk and treated similarly to those with advanced-stage disease; whereas in others a therapy intermediate in intensity is prescribed. The criteria for unfavorable clinical presentations has also differed among studies, but most often it is comprised of the presence of B symptoms, bulky lymphadenopathy, hilar lymphadenopathy, more than three to four involved nodal regions, extranodal extension to contiguous structures, or advanced-stage (IIIB-IV) disease. The results of contemporary trials indicate that children and adolescents with early-stage or favorable presentations of HL are excellent candidates for reduced therapy.[50,51,96,98] Ongoing trials are evaluating whether intensification of therapy improves outcomes in patients with intermediate- and high-risk presentations.

Although not widely used to guide therapy assignment in pediatric trials, other factors such as gender, age at diagnosis, and histology are most definitely considered in individual patients. The trials organized by the German-Austrian Pediatric Oncology Group (GPOH) and one trial by the Children's Cancer Group (now integrated in the Children's Oncology Group [COG]) have been unique in their aims to prospectively evaluate gender-based therapy.[50,99] Long-term follow-up of the GPOH 90 and 95 studies demonstrate that the substitution of etoposide for procarbazine in the OPPA regimen does not compromise DFS and provides less potential risk for gonadal toxicity.[50,70] Although age at presentation has not been used as a criterion to assign therapy in prospective trials, reports describing outcomes after treatment with chemotherapy alone stress the benefits of this approach in younger children at higher risk of radiation-related toxicity.[51,97]

Prognostic groupings now dictate the intensity of therapy with the goal of matching up just enough cytotoxic therapy to yield a high chance for cure while minimizing those exposures responsible for late complications. Within the last cycle of COG trials, patients were allocated into a favorable group if they had stage IA or IIA disease without bulk. Unfavorable patients were those with stage IIIB or IVB disease. The heterogeneous group of patients in between were deemed intermediate risk. See Table 74-2. The upcoming cycle of COG trials beginning in 2014 will categorize patients either into low- or high-risk strata; high risk will include those patients with stage IIB disease with bulk, IIIB, IVA, and IVB disease. In Europe, the GPOH has merged into a geographically broader EuroNet cooperative group in which patients will be categorized as follows[91]:

1. TG-1: patients of stages I A/B and II A without bulk ≥200 mL and without ESR ≥ 30 mm/hr
2. TG-2: patients of stages IEA/B, IIEA, II B, or III A and patients of stages I A/B and II A with bulk ≥200 mL or ESR ≥ 30 mm/hr
3. TG-3: patients of stages IIEB, IIIEA/B, III B, or IV A/B

Finally, a collaborative group of investigators from St Jude's, Stanford, and Harvard have defined a favorable early-stage cohort that may be treated with minimal therapy; patients with stages I to IIA disease without mediastinal bulk, no extranodal disease, and less than three sites of disease.[83]

A summary of trials in children with early- and intermediate- and advanced-stage HL is provided in Tables 74-3 and 74-4.

Response-Based Therapy

The response to chemotherapy, either early in its course or at its completion, is known to be an important prognostic factor in HL.[15] This has led to a hypothesis that modifications in therapy may be based on the initial response to chemotherapy in a similar fashion to the management of acute lymphoblastic leukemia. Based on rapidity of a complete response to chemotherapy, a reduction or augmentation of therapy may be possible, a concept under cautious investigation in clinical trials. Response-based approaches titrate the overall duration of chemotherapy or the need for RT by assessing the early response to chemotherapy. Two Pediatric Oncology Group trials from the USA (POG 8725 and 8625) comparing chemotherapy alone versus chemo-radiotherapy supported this idea that a rapid early response (RER) to chemotherapy reflects the chemosensitivity of a patient's HL and is a predictor of good long-term control.[7,16] The implication is that treatment can be reduced in intensity or duration for those with RER to mitigate toxicity or increased for those with a slow early response (SER) to improve disease control.

The augmentation in therapy for SER can be either an increased RT dose, additional chemotherapy, or both. The French Society of Pediatric Oncology MDH90 treated 202 children with stage I or II HL with four cycles of vinblastine, bleomycin, etoposide, and prednisone (VBVP). Good responders received 20 Gy IFRT alone, whereas poor responders were given an additional one to two cycles of OPPA and then either 20 Gy IFRT (good responders at second evaluation) or 40 Gy IFRT (poor responders). The 5-year OS and EFS were 97.5% and 91.1%, respectively.[98] In the German trial, GPOH HD-95, patients with early-stage disease who had a complete response to chemotherapy (two cycles OPPA for girls or two cycles OEPA for boys) did not receive adjuvant RT. OPPA/OEPA chemotherapy alone produced a 5-year DFS of 88%, which was not significantly different from that observed in patients who received RT (92%).[70] In this German trial, higher-risk patients who received RT were prescribed radiation doses of up to 35 Gy if complete response was not achieved. The use of higher-dose RT with simple anterior-posterior beams is certainly known to cause undesirable musculoskeletal toxicities and the potential for increased cardiopulmonary injury and secondary cancers, such that augmentation of chemotherapy or more conformal RT may be better approaches for nonresponders. POG 9425 administered three versus five cycles of doxorubicin, bleomycin, vincristine, etoposide, prednisone, and cyclophosphamide (ABVE-PC) chemotherapy and 21-Gy regional RT for rapid and slow responders, respectively.[68] Two-year EFS was 88.2%, with no statistical difference between early and slow responders. These studies suggest that interim or early response-adapted therapy may be useful in identifying patients with favorable disease, who can be treated with lower RT doses or abbreviated chemotherapy.

The recent COG intermediate-risk HL study AHOD0031 was a response-based paradigm in which chemotherapy was intensified enough to safely eliminate RT for some patients. Although the results are detailed, children with stages IA and IIA with bulky disease, IB, IIB, IIIA, or IVA disease received two cycles of ABVE-PC prior to response evaluation with CT imaging. Those with RER defined as at least a 60% reduction in the sum of the product of the perpendicular diameters of up to six target lesions, and who proceed to a complete response with at least an 80% reduction in disease

(Adverse disease features comprise one or more of the following: hilar adenopathy; involvement of >4 nodal regions; mediastinal tumor with diameter ≥one-third of the chest diameter; node or nodal aggregate with a diameter >10 cm.)

cross-sectional area and normalization of metabolic abnormalities on gallium or FDG-PET after an additional two cycles of the same chemotherapy, were randomized to 21-Gy IFRT or no additional treatment. On the other hand, patients with SER to two cycles of chemotherapy are randomized to either standard therapy (an additional two cycles of ABVE-PC + 21 Gy IFRT) or intensified therapy (standard therapy plus two additional cycles of chemotherapy—dexamethasone, etoposide, cytarabine, and cis-platinum [DECA]—prior to IFRT). This trial showed that an excellent response to chemotherapy allowed for selection of patients who may avoid RT, but chemotherapy intensification among those with SER was not helpful in this instance. However, analysis is still under way to be confident that select subgroups, such as those who present with bulk mediastinal disease and hematologic abnormalities (e.g., anemia, elevated ESR), do not retain a benefit in EFS from IFRT. Two other pediatric trials have sorted out situations when favorable prognosis patients may have RT withheld after a good response to initial chemotherapy[69,83]; however, another COG trial, AHOD0431 (for the most favorable patients) found that AV-PC chemotherapy for three cycles was not sufficiently intensive to allow for RT to not be given when response was adjudicated by CT scan criteria only.[126]

Although most completed trials have used CT, with or without gallium or PET to determine response, it is becoming increasingly clear that PET scanning after the initial (one or two) chemotherapy cycles will better identify good-prognosis patients and facilitate treatment intensification.[15,57,127,128] When RT can be omitted among patients with a good response to chemotherapy, PET assessment appears to be important. The corollary problem is how to define a response by PET criteria as low levels of residual FDG activity after therapy are common. Another unresolved problem is the interpretation of splenic or hepatic involvement by HL given the physiologic uptake of FDG in these organs. A consensus panel has promulgated PET-based response criteria known as the International Harmonization Project, using mediastinal blood pool as a reference visual threshold to determine residual FDG uptake.[129,130] However, more recently a visual five-point score known as the Deauville criteria has been shown to improve prediction of outcome that is reproducible enough in adult advanced-stage HL to serve as a standard reporting criterion in clinical trials and practice.[131,132] Moreover, a preliminary analysis of this Deauville criteria in a pediatric cohort has suggested that more sensitive response criteria uses liver uptake rather than blood pool as a threshold indicator of interim response to chemotherapy.[133]

Chemotherapy Regimens and Radiation Therapy

MOPP and Derivative Chemotherapy

The prototype alkylator combination that provided the first effective systemic therapy for HL was MOPP.[134] Follow-up studies of MOPP-treated survivors confirmed that secondary acute myeloid leukemia (s-AML) and infertility resulted from the alkylating agents in the regimen and exhibited a dose-dependent relationship.[135] Subsequently, investigators developed a variety of MOPP-derivative regimens in an effort to reduce the risk of secondary leukemogenesis and gonadal toxicity.

The risk of secondary leukemia following alkylating agent chemotherapy peaks in frequency in the first 5 years to 10 years after treatment and plateaus to less than 2% after 10 years from diagnosis.[136] Older age at treatment, history of splenectomy, presentation with advanced disease, treatment with high cumulative doses of alkylating agents, and history of relapse have been reported to predispose to this complication.[136-141] Some alkylating agents are more potent leukemogens than others; the 15-year cumulative incidence of s-AML is 4% to 8% after MOPP-based therapy compared to less than 1% with cyclophosphamide, Oncovin (vincristine), procarbazine, prednisone (COPP)-based therapy that substitutes cyclophosphamide for nitrogen mustard.[142] Pediatric protocols that limit the total dose of alkylating agents or substitute other less-leukemogenic drugs, such as cyclophosphamide, for mechlorethamine, have been associated with low incidence rates of s-AML.[142]

Gonadal injury is common in pediatric patients treated with MOPP and its derivative combinations. Azoospermia is typically irreversible in men treated with six or more cycles of MOPP-like therapy.[135,143] However, germ cell function may be preserved if treatment is limited to no more than three cycles of alkylator therapy.[144] In contrast, most young women will maintain or resume menses after a temporary period of amenorrhea following treatment including alkylating agents.[143] Ovarian transposition and shielding reduces the incidence of gonadal injury in young women requiring pelvic radiation, but these patients will experience a higher risk of premature menopause.[145] The radiation oncologist should also be aware of the age dependency in risk for ovarian failure.[146] Younger females tolerate a modestly higher radiation dose related to the gradual decline in oocyte numbers associated with aging.

ABVD and Derivative Chemotherapy

The ABVD combination provided a systemic therapy that produced superior DFS compared to MOPP and was not associated with an excess risk of secondary leukemia or infertility.[4,147] However, follow-up of patients treated with the ABVD regimen established its association with cardiopulmonary toxicity that was enhanced with the addition of thoracic radiation.[4] Many ABVD derivatives soon followed, aiming to reduce the risk of these sequelae.

Anthracycline agents are an important component of chemotherapy regimens for children with HL because of their significant lympholytic effects. In adults the cumulative incidence of cardiomyopathy increases significantly after anthracycline dose exceeds 550 mg/m^2; children are at increased risk of cardiac dysfunction at lower cumulative doses.[148-151] Other risk factors for anthracycline toxicity identified in studies of childhood leukemia survivors include younger age at treatment (especially younger than 5 years old) and female gender. Combination treatment with chest radiation or other cardiotoxic agents such as amsacrine or cyclophosphamide may also enhance risk of cardiac dysfunction.[150,152-155] Because treatment protocols for pediatric HL frequently include chest radiation or other chemotherapeutic agents with potential cardiotoxicity, most regimens limit cumulative doses of anthracycline agents to below 250 mg/m^2, particularly for patients with favorable-risk disease presentations.

Bleomycin in the ABVD regimen increases the risk of pulmonary toxicity that is most commonly manifested as pulmonary fibrosis and chronic pneumonitis.[156] Thoracic radiation may augment this risk. Patients at highest risk of pulmonary complications are those treated with cumulative bleomycin doses exceeding 400 U/m^2, that far exceed doses used in pediatric regimens for HL. Contemporary protocols use bleomycin doses in the range of 60 U/m^2 to 100 U/m^2; these cumulative exposures are usually associated with asymptomatic pulmonary restriction and diffusion deficits in long-term survivors, some of which will improve over time.[157,158] Serial monitoring of pulmonary function during therapy and withholding bleomycin doses in patients exhibiting significant declines in pulmonary function (20% or more from baseline) may reduce the risk of further pulmonary injury and does not appear to compromise disease control.[106]

Chemotherapy Combinations Including Etoposide

Etoposide has been increasingly incorporated into treatment regimens for pediatric HL over the last few decades. This agent is used in risk-adapted regimens for favorable patients as an effective alternative to alkylating agents in an effort to reduce gonadal toxicity.[68,71,97,98,103,113] Etoposide has been added to alkylating and anthracycline chemotherapy in regimens for advanced and unfavorable patients to enhance treatment response. For example, the previously mentioned dose-intensive ABVE-PC regimen used in recent U.S. cooperative groups yields excellent survival outcomes in intermediate- to high risk patients.[68] Balanced with this survival advantage is an excess risk of s-AML seen with topoisomerase-II inhibitors like etoposide and doxorubicin that differs in epidemiology and biology from alkylator-related s-AML.[159] Secondary AML that occurs in association with topoisomerase-II inhibitors is characterized by a brief time of onset from primary diagnosis, absence of a preceding myelodysplastic phase, monoblastic and myelomonoblastic histology, and translocations involving the *MLL* gene at chromosome band 11q23. Studies of childhood patients with leukemia suggest that intermittent weekly or twice weekly dosing schedules may result in transforming mutations of myeloid progenitor cells by epipodophyllotoxins.[160] A relationship between leukemogenic activity and cumulative epipodophyllotoxin dose could not be established in an evaluation of s-AML cases developing in patients treated with multiagent chemotherapy regimens including epipodophyllotoxins, alkylating agents, doxorubicin, and dactinomycin for pediatric solid tumors.[159] However, the risk of s-AML following treatment with regimens that restricted etoposide doses to 5.0 g/m^2 or less did not exceed that associated with other agents used in solid tumor regimens.[159] Pertinent to this discussion is the report of an increased incidence of second malignancies observed in children treated with ABVE or dose-intensified ABVE with prednisone and cyclophosphamide and the cardiopulmonary protectant dexrazoxane.[161] In these Pediatric Oncology Group trials, patients were randomly assigned to receive dexrazoxane to evaluate its potential to decrease cardiopulmonary toxicity. Unexpectedly, 10 patients developed SMN with AML/myelodysplastic syndrome (MDS) accounting for 8 of the 10 cases. Six of the 8 cases of AML/MDS and two solid tumors occurred in children randomized to receive dexrazoxane. The authors speculated that the use of multiple topoisomerase II inhibitors (dexrazoxane, etoposide, and doxorubicin) may have potentiated carcinogenesis. Collectively, most data support the relative safety of using limited doses of etoposide, but reports of s-AML in patients receiving etoposide for treatment of favorable pediatric HL raise concerns about whether this agent should be avoided in favorable disease presentations.[98]

Gender-Based Therapy

The German Paediatric Oncology and Haematology Society (GPOH) has explored the use of not only risk-adapted, but also gender-adapted therapy featuring the OEPA regimen for boys to limit the amount of alkylators, whereas girls received OPPA, substituting procarbazine for etoposide. Procarbazine is especially problematic in boys as a cause of infertility.[11,162] Although this has not caught on in North America as a strategy to limit late effects, the CCG 59704 high-risk study did include a successful gender-based consolidation phase. All patients received the escalated BEACOPP regimen pioneered by the GHSG as a backbone, having documented efficacy in adult trials with unfavorable features. All patients with a slow response received four additional cycles of BEACOPP and IFRT. But for rapidly responding males, two cycles of ABVD with IFRT were given while females received four cycles of COPP/ABV without radiotherapy particularly to avoid the risks for breast cancer and infertility with mantle and pelvic fields respectively. The concept of gender-based use of RT has been abandoned for now, though it remains quite reasonable as females seem to be particularly predisposed to secondary radiation-related cancers.[163-165]

Radiotherapy Considerations

The curability of pediatric HL and the vulnerability of the developing child to both RT and chemotherapy are critical issues in appropriately integrating radiation into the complex treatment algorithms currently used. Most newly diagnosed children will be treated with risk-adapted chemotherapy alone or combined-modality therapy including low-dose, involved-field RT. Full-dose, extended-field RT using techniques that were once standard for adults and even children has been long abandoned because of concerns primarily relating to growth inhibition, cardiovascular toxicity, and second malignant neoplasms. Historically, the results of treatment with RT alone for early-stage disease were superior at institutions that treated many patients with HL. Although different institutions and radiation oncologists may use slightly different treatment techniques, underlying principles, and in fact, most of the technical details remained constant.[166] However, currently in the United States, most adults with HL are treated in the community setting. Because most children are treated at academic or tertiary care hospitals often on institutional (or multiinstitutional) studies, the radiation oncologist should confirm all aspects of the diagnostic workup and staging; they must also understand study requirements to deliver appropriate RT. Supportive of this premise, up-front centralized review of patients entered into the GPOH-HD 90 study altered the treatment approach in a large number of children.[167] Similarly, prior Pediatric Oncology Group trials observed inferior outcomes related to major deviations in radiation protocol compliance.[168] These data support the need for prospective central review of RT in current COG HL protocols.

In contemporary trials, there is a considerable impetus to minimize RT when possible in children with HL to remove the associated late risks of therapy that include secondary malignancy, cardiovascular complications, and hypothyroidism among others. Secondary malignancy is the most compelling concern as children are more susceptible than adults for this problem despite the reduction in RT dose and volume relative to the historical use of extended field RT.[165] Moreover, young females getting low dose involved field RT to the chest are particularly at risk for breast cancer.[164,165] The risk for subsequent coronary artery disease, valvular heart disease, and heart failure after treatment for HL is multifactorial with both anthracycline and radiations exposures playing a role.[169] However, risk related to RT is radiation dose and volume dependent, and the risk is decreased with doses in the 20-Gy to 25-Gy range.[170] In turn, efforts within the Radiation Oncology community to make the use of low-dose RT safer include more conformal dose distributions with three-dimensional conformal techniques including intensity-modulated radiotherapy (IMRT) and proton RT, deep inspiration breath-hold techniques to improve radiation targeting, and a reduction in the volume of RT with involved-node radiotherapy (INRT) or involved-site radiotherapy (ISRT).

It is hoped that response-adapted therapy may identify patients with favorable-risk pediatric HL who can be treated with chemotherapy alone without significantly reducing DFS. In the past, chemotherapy-alone regimens for advanced-stage disease used higher cumulative doses, predisposing survivors to greater risks of acute and late toxicity associated with alkylating agents, anthracyclines, and bleomycin. These protocols

were designed with the hopes of avoiding toxicities because of RT. However, RT remains an effective agent in HL, and a danger continues to be engendered when systemic therapies are overemphasized and their own set of complications are underappreciated. Current protocols strive to carefully balance chemotherapy exposures along with RT details of dose and volume to limit long-term risks. Importantly, response-based paradigms now allow patients with a rapid response to systemic therapy to minimize the use of RT. The data suggest that children with HL may require RT for both early and advanced disease when the chosen chemotherapy program is insufficiently intensive, when there is a slow response to chemotherapy, when there is residual disease at completion of therapy, possibly when there is bulky disease at presentation, and selectively for relapsed lymphoma. Identification of prognostic features including response features that dictate integration of RT to optimize disease control is a focus of many ongoing pediatric trials.

There is considerable impetus to minimize RT exposures in HL because of late effects, particularly secondary malignancies. Some of the concern results from the historic use of extended field, high-dose radiotherapeutic practices that are no longer representative of modern RT. For example, the Late Effects Study Group analyzed patients treated from 1955 to 1986, before the widespread use of customized lung shielding, megavoltage linear accelerators, or CT-based image guided RT planning.[138] Both the RT doses and volumes are now significantly reduced in managing pediatric HL. As a result, the risk of late effects may be overestimated when analysis are based on past, antiquated techniques. As an example, several studies reveal a marked decrease in the risk for secondary breast cancer when RT volumes and doses are reduced.[14,163,171] But, an important confounding factor leading to reduction in breast cancer risk related to RT occurs from akylating agent chemotherapy or pelvic radiotherapy obstensibly because of ovarian failure and the consequential loss of hormonal influence on the neoplastic process. Nevertheless, the transition from extended-field RT to IFRT significantly reduces the dose to breast and lung tissue,[172] and has been predicted to result in a substantial reduction in secondary cancer risk.[13] Thyroid cancer may be one exception to the general concept that higher radiation doses correlate with higher risk for secondary cancers.[173] In this case, an update to the Late Effects Study Group has shown a nonlinear relationship of dose and cancer incidence with a maximum risk associated with radiation doses in the range of 15 Gy to 25 Gy and decreasing risk with higher doses greater than 29 Gy. Yet despite the use of lower radiation doses, children with HL still continue to harbor an increased risk for secondary solid-type malignancies relative to the general population risk from the use of RT, especially breast cancer in females.[164,165]

Volume

Treatment volumes are continuing to evolve with a current transition in progress from involved field to involved nodal or involved site RT.[174] When RT is indicated, meticulously and judiciously designed fields are necessary for maximum success in terms of both disease control and minimal tissue damage. Until recently, an anatomic region was targeted, designed in terms of lymph node distribution, patterns of disease extension into regional areas, and consideration for match-line problems should disease recur. An understanding of involved field principles remains important to understand the historical results of combined-modality therapy and potential side effects for follow-up purposes. Involved fields typically included not just the identifiably abnormal lymph nodes, but the entire lymph node region containing the involved nodes (Table 74-5). These traditional definitions of lymph node regions have operational details that date to a time when treatment planning technology required the use of simple parallel opposed fields with boundaries that dated to the use of lymphangiography rather than modern cross-sectional imaging. Successful outcomes had cemented field design concepts that have only recently been changed in response to the understanding of late effects.

TABLE 74-5 Historical Involved Field Radiation Guidelines

Involved Node(s)	Radiation Field
Cervical	Neck and infraclavicular/supraclavicular†
Supraclavicular	Neck and infraclavicular/supraclavicular with or without axilla
Axilla	Axilla with or without infraclavicular/supraclavicular
Mediastinum	Mediastinum, hila, infraclavicular/supraclavicular*†
Hila	Hila, mediastinum
Spleen	Spleen with or without para-aortics
Para-aortics	Para-aortics with or without spleen
Iliac	Iliacs, inguinal, femoral
Inguinal	External iliac, inguinal, femoral
Femoral	External iliac, inguinal, femoral

**Prechemotherapy volume is treated except for lateral borders of the mediastinal field, which is postchemotherapy.*
†Upper cervical region not treated if supraclavicular involvement is extension of the mediastinal disease.

However as past is prologue, a discussion of involved field RT remains relevant despite the current move toward more restricted fields (See Table 74-5). For example, the cervical and supraclavicular lymph nodes have generally been treated when abnormal nodes are located anywhere within this area; this is consistent with the anatomic definition of lymph node regions used for staging purposes. However, the hila have usually been irradiated when the mediastinum is involved, despite the fact that the hila and mediastinum are separate lymph node regions. Similarly, the supraclavicular fossa (SCV) has typically been treated when the axilla or the mediastinum is involved, and the ipsilateral external iliac nodes have often been treated when the inguinal nodes are involved. However, in both situations care would have been taken to shield relevant normal tissues to the degree possible, such as the breast in the former situation and ovaries in the latter. Moreover, the decision to treat the axilla or mediastinum without the SCV, and the inguinal nodes without the iliacs, might have been appropriate depending on the size and distribution of involved nodes at presentation. In a young child (younger than age 5 years), consideration would be given to treating bilateral areas (e.g., both sides of the neck) to avoid growth asymmetry. However, this is less of a concern with low radiation doses, and unilateral fields are usually appropriate if the disease is unilateral. Efforts to exclude unnecessary normal tissues are always important, such as breast tissue in a child with isolated mediastinal disease and no axillary involvement.

Treatment of involved supradiaphragmatic fields or a mantle field has required precision because of the distribution of lymph nodes and the critical adjacent normal tissues. These fields could be simulated with the arms up over the head or down with hands on the hips. The former pulls the axillary lymph nodes away from the lungs, allowing greater lung shielding. However, the axillary lymph nodes then

move into the vicinity of the humeral heads, which should be blocked in growing children. Thus, the position chosen involves weighing concerns regarding lymph nodes, lung, and humeral heads. Attempts are consistently made to exclude or position breast tissue under the lung and axillary blocking.

When the decision is made to include some or all of a critical organ in the RT field, such as liver, kidney, or heart, normal tissue constraints, depending on the chemotherapy used and patient age, are critical. Thus, the width of a mediastinal field is generally based on the postchemotherapy residual disease, whereas the cephalad-caudad dimension respects the original disease extent. Humeral head blocks are appropriate unless bulky axillary adenopathy is thereby shielded. Laryngeal and occipital blocks have also been used unless disease is located in the vicinity of these structures; these blocks can be placed at the beginning of treatment or after some portion of it. Depending on the response of the disease to chemotherapy and the dose administered, field reductions might be considered. The entire heart or lungs are rarely treated above doses of 10 Gy to 16 Gy, depending on the distribution of disease and chemotherapy used.

When the subdiaphragmatic region has been treated, a treatment-planning CT is essential to devise the shielding. When treating the pelvis, special attention must be given to the ovaries and testes. The ovaries may be relocated or transposed and marked with surgical clips, laterally along the iliac wings or centrally behind the uterus. In this manner appropriate shielding may be used. The testes might still receive 5% to 10% of the administered pelvic dose, which is sufficient to cause transient or permanent azoospermia, depending on the total pelvic dose. The greatest shielding can be afforded to the testes if the patient is placed in a frog-legged position with an individually constructed testes shield. If multileaf collimation is available, the multileaf can be placed over the testes, additionally decreasing the transmitted dose.

Even though IFRT has been a standard treatment volume in recent studies, there is a clear shift to what is alternatively termed either INRT or ISRT. The rationale for this volume reduction derives from reconsideration of the anatomic definitions of lymph node regions and the patterns of recurrence in HL. Clinical definitions of lymph node regions are historic and based on anatomic or bony landmarks without the benefit of CT scanning to identify the location of nodes. The EORTC-GELA has introduced the concept of INRT.[175,176] This uses all available clinical information including pre- and postchemotherapy imaging with CT and FDG/PET scans to define the treatment field according to the prechemotherapy extent of disease. The concept is based on evidence that recurrence occurs most often in initially involved lymph nodes[177,178] suggesting that chemotherapy is adequate to treat disease contained within radiologically normal lymph nodes, while RT is needed only to treat sites of macroscopic enlargement. In a study of patients with early-stage HL, PET identified presumptively involved lymph nodes that were radiographically occult on CT scan. Therefore, evaluation with FDG/PET scan before chemotherapy may help to delineate the complete extent of clinical disease.[175] Initial clinical data with the use of INRT is only just emerging. Campbell et al reviewed clinical outcomes of patients with limited stage HL treated with EFRT, IFRT, and INRT ≤ 5 cm. No marginal recurrences or locoregional failures occurred with INRT.[179]

Various European trials are actively incorporating and testing INRT along with reported guidelines.[180] In the EORTC/GELA H11 trial for early-stage, unfavorable-prognosis HL, INRT was adopted in both the standard and experimental arms. Meanwhile, the German Hodgkin's Study Group (GHSG) is enrolling patients in a randomized trial with unfavorable-prognosis, early-stage disease (HD17) comparing IFRT versus INRT.

Recently, a new set of field designs, the involved site (ISRT), have been developed, published, and endorsed by the steering committee of the International Lymphoma Radiation Oncology Group (ILROG).[181] This represents the first effort by an expert group of radiation oncologists, having experience with lymphoma management, recognizing a need to promulgate a "modernized" version of IFRT. These new field designs take into account modern technology, including the use of staging PET/CT scans, three-dimensional and four-dimensional treatment planning with CT scanners, conformal treatment techniques, and the use of image guidance. These fields are expected to be somewhat smaller than the traditional IFRT, but larger than INRT especially recognizing the difficulty of staging PET-CT scans not being performed in the patient position used during eventual treatment planning and RT delivery. Regardless, in the years to come it is expected that these ISRT concepts will be applied to pediatric protocols and become more standardized in practice. Finally, as previously noted, RT for unfavorable and advanced HL is variable and protocol dependent. Although IFRT has been a standard when patients are treated with combined-modality therapy, restricting RT to areas of initial bulk disease (generally defined as 5 cm to 6 cm or more at the time of disease presentation), slowly responding sites, or postchemotherapy residual disease (generally defined as 2 cm to 2.5 cm or more, or residual PET avidity) is under investigation.

Dose

In the setting of combined therapy, certainly the intensity of the chemotherapy is important to consider in the choice of the RT dose and volume. In general, doses of 15 Gy to 25 Gy are typical with shrinking fields and boosts individualized. In the tables summarizing recent clinical trials (see Tables 74-3 and 74-4), the RT doses selected to complement the chemotherapy regimen are provided. Doses of more than 25 Gy are uncommon in the pediatric setting. Of interest are the results of the GPOH HD-90 trial, in which doses of 20 Gy to 25 Gy were administered in combination with OPPA or OEPA, with or without COPP. The radiation doses administered were 20 Gy to 25 Gy, with a local boost of 5 Gy to 10 Gy for insufficient remission following chemotherapy. Tumor burden, indicated by bulky disease or number of involved nodes, proved not to be prognostically significant because of the relatively high doses used for bulk disease.[64] In the GPOH-95 trial, the safety of lowering the standard radiation dose to 20 Gy was demonstrated, although boosts to residual large masses were still allowed.[69] Most current treatment approaches for children include radiation doses at the lower end of the 20-Gy to 25-Gy range. Indeed within the COG, radiation dose has been standardized to 21 Gy in 14 fractions.

Treatment Approaches

Chemotherapy Alone Versus Combined with Radiation Therapy

Noncross-resistant combination chemotherapy alone is well established as an effective modality for the treatment of pediatric HL.[7,8,95,112,113,115,116,123,125,182] This treatment approach eliminates the risk of radiation-induced growth complications, thyroid and cardiopulmonary dysfunction, and solid tumor carcinogenesis. However, the higher-cumulative doses of anthracyclines, alkylating agents, and bleomycin chemotherapy increase the risk of cardiopulmonary, toxicity infertility, and leukemogenesis and may be less effective as combined-modality therapy for treatment of bulky nodal disease. Chemotherapy alone trials have been limited by their small

numbers of patients, nonrandom treatment assignments, lack of long-term follow-up related to disease control, and late-treatment sequelae. Despite these deficiencies, identification of clinical factors predicting an optimal outcome following treatment with chemotherapy alone remains an important objective of many ongoing trials because of the desire to avoid late RT sequelae. As already noted, the early response to chemotherapy of sufficient intensity appears to be the one factor allowing for the elimination of RT.[17,83]

Investigators from North American pediatric cooperative groups have undertaken three longitudinal controlled trials to evaluate chemotherapy alone versus combined-modality therapy in pediatric HL.[6,7,51,66] The first two trials failed to show a statistically significant advantage in EFS or OS with the addition of RT to noncross-resistant chemotherapy. The Children's Cancer Group compared 12 cycles of alternating MOPP/ABVD to 6 cycles of ABVD plus low-dose (21 Gy) radiation.[6] EFS and OS suggested a survival advantage for the combined-modality group (90% 4-year EFS) over the chemotherapy-alone group (84% 4-year EFS), but this difference was statistically insignificant. In a Pediatric Oncology Group trial, adding low-dose radiation to four cycles of alternating MOPP and ABVD chemotherapy did not improve DFS or OS.[7] However, statistical and quality-assurance issues produced problems with interpretation of these data. Moreover, the findings of both studies are irrelevant to present-day practice because the treatments evaluated included the more leukemogenic MOPP-based therapy and an excessive number of treatment cycles.

Using an antiquated hybrid regimen, the Children's Cancer Group compared chemotherapy alone with COPP/ABV to combined-modality therapy including low-dose IFRT.[51,66] Clinical risk features including the presence of B symptoms, hilar lymphadenopathy, mediastinal and peripheral lymph node bulk, and the number of involved nodal regions determined treatment assignment. Patients who achieved a complete response to chemotherapy were eligible to be randomized to receive low-dose, IFRT or no further therapy. The trial was prematurely terminated because patients treated with chemotherapy alone had a significantly higher number of relapses. As updated with a median follow-up of 7.7 years, those patients receiving IFRT had a statistically improved EFS of 92.5% at 10 years compared to 83.5% for chemotherapy alone ($p = 0.004$).[66] OS was the same the result of effective retrieval therapies that often included high-dose chemotherapy with an autologous stem cell transplant. Risk factors for relapse included nodular sclerosis subtype, B symptoms, and bulk disease. Ten-year EFS was 83.5% for patients with nodular sclerosing histology compared with 96% for patients with other histologies. Patients with B symptoms at diagnosis had a 10-year EFS of 71.7% compared with 87.5% for patients without B symptoms ($p < 0.001$). And finally, patients with bulk disease had a 10-year EFS of 75.6% compared with 87.2% for patients with no bulk ($p < 0.001$).

European experience in pediatric HL with end of treatment assessment using CT or MRI scan criteria also suggests that elimination of RT may be detrimental in certain patient subsets. In a nonrandomized trial that omitted radiation for patients achieving a CR with chemotherapy, German-Austrian investigators reported a similar advantage for patients treated with radiation consolidation following combination chemotherapy in the GPOH-HD 95 trial.[69] In this study patients treated with RT after partial response to combination chemotherapy defined as more than 75% volume reduction received 20 Gy using a "reduced involved-field" along with an additional 10-Gy or 15-Gy boost to larger residual masses. In the early stage (TG1) patients, there was no detriment to omitting RT for those patients not in CR; the progression-free survival (PFS) at 10 years was 97% for CR patients not receiving RT compared to 92% for those receiving RT ($p = 0.21$). PFS was unsatisfactory for nonirradiated intermediate risk patients (TG2) at 68.5% compared to those who received RT who had a PFS of 91.4% ($p < 0.0001$). The TG3 advanced risk group patients had a nonsignificant trend favoring the receipt of RT with a 10 year PFS of 88.7% versus 82.6% without RT.

Contemporary practice now allows for interim assessment of response to chemotherapy incorporating both PET and anatomical criteria. RT may be reduced or eliminated after sufficiently intensive chemotherapy producing a rapid early response, even with initially bulky masses. The landmark COG AHOD0031 trial of intermediate-risk patients has already been mentioned. Final published results are eagerly awaited. Thus, the standard of care is shifting and no longer is involved field RT given across all stages of pediatric HL.

The results of chemotherapy-alone regimens in carefully selected patients document excellent efficacy of this treatment approach particularly in children with early-stage favorable HL and those with a rapid-early response to chemotherapy with intermediate-risk disease. Circumstances where RT may have particular toxicity, such as in young children, may warrant chemotherapy alone. The incremental value of adjuvant RT is small, but its importance lies in the avoidance of relapse therapy that often includes high-dose chemotherapy with an autologous stem-cell transplant. At the same time, there is an appreciation that safe radiation volume reductions using ISRT[181] are appropriate to reduce side effects and normal tissue exposures. As noted previously, European studies of adult HL are evaluating INRT as a shift away from targeting anatomic compartments.[175-178] PET imaging is proving particularly useful not only for response assessment but also RT planning.[183] By the same token conformal techniques such as IMRT or proton radiotherapy are also under investigation in HL.[175,184-190] Figures 74-1 and 74-2 are examples of the use of IMRT to ensure coverage of involved regions. In the first case, the mediastinal disease has extensive anterior chest wall extension, whereas the second case depicts splenic IMRT with AP-PA mantle fields. In these examples, radiation exposure to normal tissues (lung, heart, and kidney) was minimized to reduce toxicity, not readily accomplished by standard AP-PA beam arrangements.

Risk-Adapted Therapy: Favorable Risk Disease

Favorable risk has variable definitions across various studies as already noted, but generally includes patients with stages I and II disease without adverse prognostic features. These unfavorable features may be B symptoms, extranodal extension, peripheral or mediastinal bulky disease, hilar adenopathy, and three or more nodal regions involved. Treatment typically involves two to four cycles of chemotherapy and low-dose, IFRT. But in some instances, RT has been reduced or eliminated based on a favorable response to chemotherapy.[51]

The GPOH HD-95 trial used OEPA in boys and OPPA in girls, with RT successfully omitted in patients achieving a CR to chemotherapy, as already noted. The criteria for CR did not entail metabolic imaging, but rather volume reduction of ≥95% with ≤2 mL of the initial volume remaining. An unconfirmed CR that triggered low-dose RT occurred if volume reduction was ≥75% or <b2 mL, occurring in less than 30% of the favorable cohort. One caveat to note is that patients with nLPHL were included in this trial.[69,70] These results were confirmed in the GPOH-HD 2002 study that excluded nLPHL patients.[94] In the GPOH-HD2002 study, all patients received

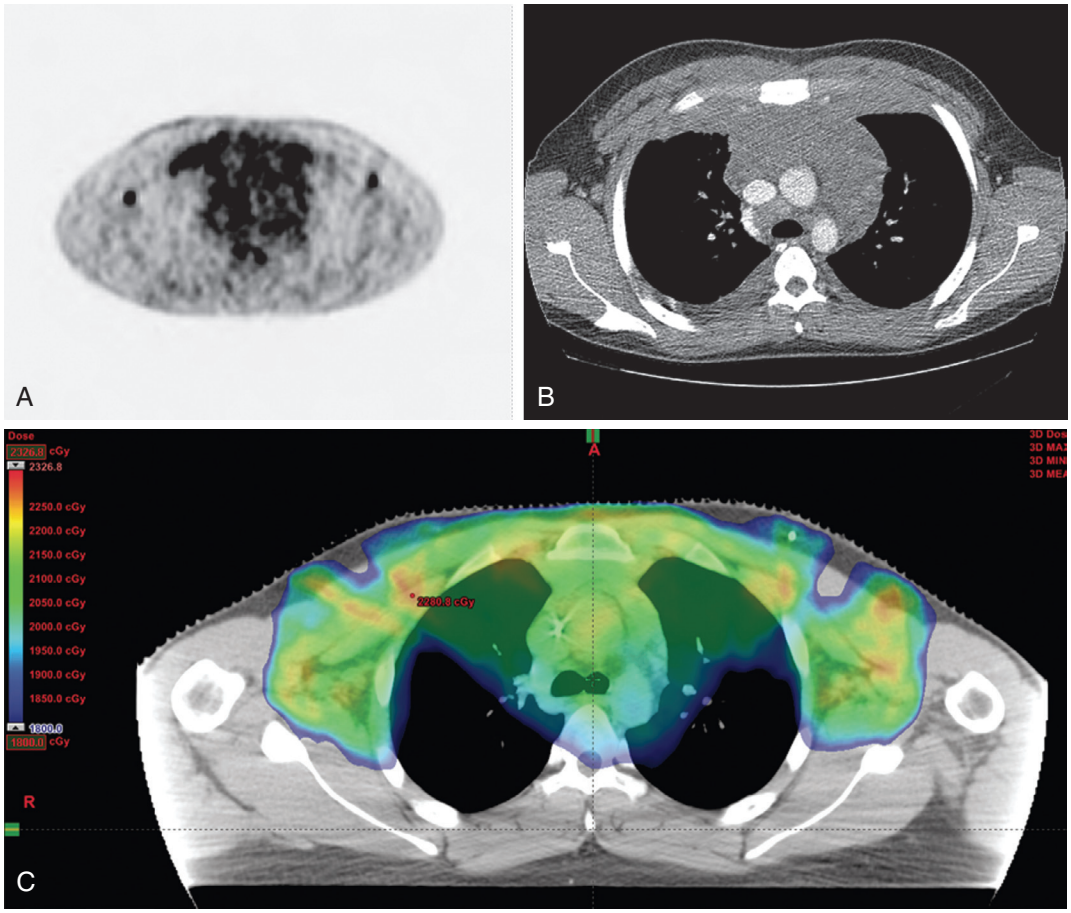

Figure 74-1 Use of intensity-modulated radiation therapy (IMRT) is not standard in Hodgkin's lymphoma but may be preferred in special circumstances. In this case, IMRT was used to treat extensive anterior chest wall involvement at diagnosis. This 18-year-old male with stage IVB nodular sclerosing Hodgkin's lymphoma presented with fevers, sweats, chest pain, purities, and right supraclavicular adenopathy. Staging showed neck, bilateral axillary, and bulky mediastinal adenopathy. Panel A and B shows extensive anterior chest wall involvement on positron emission tomography (PET) and computed tomography (CT) imaging, respectively. After a complete response to ABVE-PC chemotherapy for four cycles, the patient underwent involved field radiotherapy to 21 Gy in 14 fractions. Standard anteroposterior and posteroanterior (AP-PA) fields would have included too much lung. Instead, an IMRT plan yielded a better dose distribution with lower risk for pulmonary toxicity while insuring good coverage of initial sites of involvement. Panel C shows the IMRT dose distribution in a color wash superimposed on an axial CT scan postchemotherapy at the level of the carina. Two years following therapy, patient remains free of lymphoma and is a competitive swimmer in college.

IFRT to 19.8 Gy except patients in the early stage (IA/B and IIA without extranodal involvement) disease category who achieved a CR after induction therapy as defined in GPOH-HD 95. In contrast to North American practice, regions defined as a partial response by anatomic criteria (<75% volume reduction) received a boost to 30 Gy while residual masses greater than 100 mL were boosted even higher to 35 Gy.

Several North American investigators have observed excellent treatment results in combined modality trials for favorable risk HL. Investigators from St. Jude's, Stanford, and Harvard reported treatment results using a nonalkylator regimen, VAMP for children with clinical I/II, non-bulky HL.[108] Patients received four cycles of VAMP chemotherapy and response-based IFRT after two cycles of chemotherapy in which the radiation dose varied from 15 Gy to 25 Gy. At a median follow-up of 9.6 years, 5-year and 10-year EFS rates were 92.7% and 89.4%, respectively.[108] In a follow-up trial, the same investigators limited VAMP chemotherapy alone to a favorable group with less than three nodal sites of disease and no extranodal sites with a CR after one cycle of chemotherapy.[83] The 2-year EFS for patients who did not require RT was 89.4% compared with 92.5% for those who were not deemed in CR and received low-dose IFRT ($p = 0.61$). These results need to be contrasted with more mature adult experience with another minimal therapy approach that includes ABVD for two cycles and 20-Gy IFRT for similar favorable risk patients in which the PFS was 95.1% at 5 years and 86.5% at 8 years.[84]

In contrast to adult trials, there has been remarkably little study of ABVD in pediatric HL. The Pediatric Oncology Group (POG)[111] evaluated the feasibility of combined-modality therapy using four courses of DBVE followed by IFRT to 25.5 Gy to treat stages IA, IIA, and IIIA HL. At a median follow-up of 8.4 years, remarkably good 6-year OS and EFS rates were 98% and 91%, respectively, with almost (98%) all patients achieving remission after completion of therapy. This regimen (DBVE) was used by the POG/COG to support reduction of chemotherapy via an early-response–based treatment algorithm. Patients received only two courses of ABVE if they achieved an early CR, which occurred in 45% patients, whereas

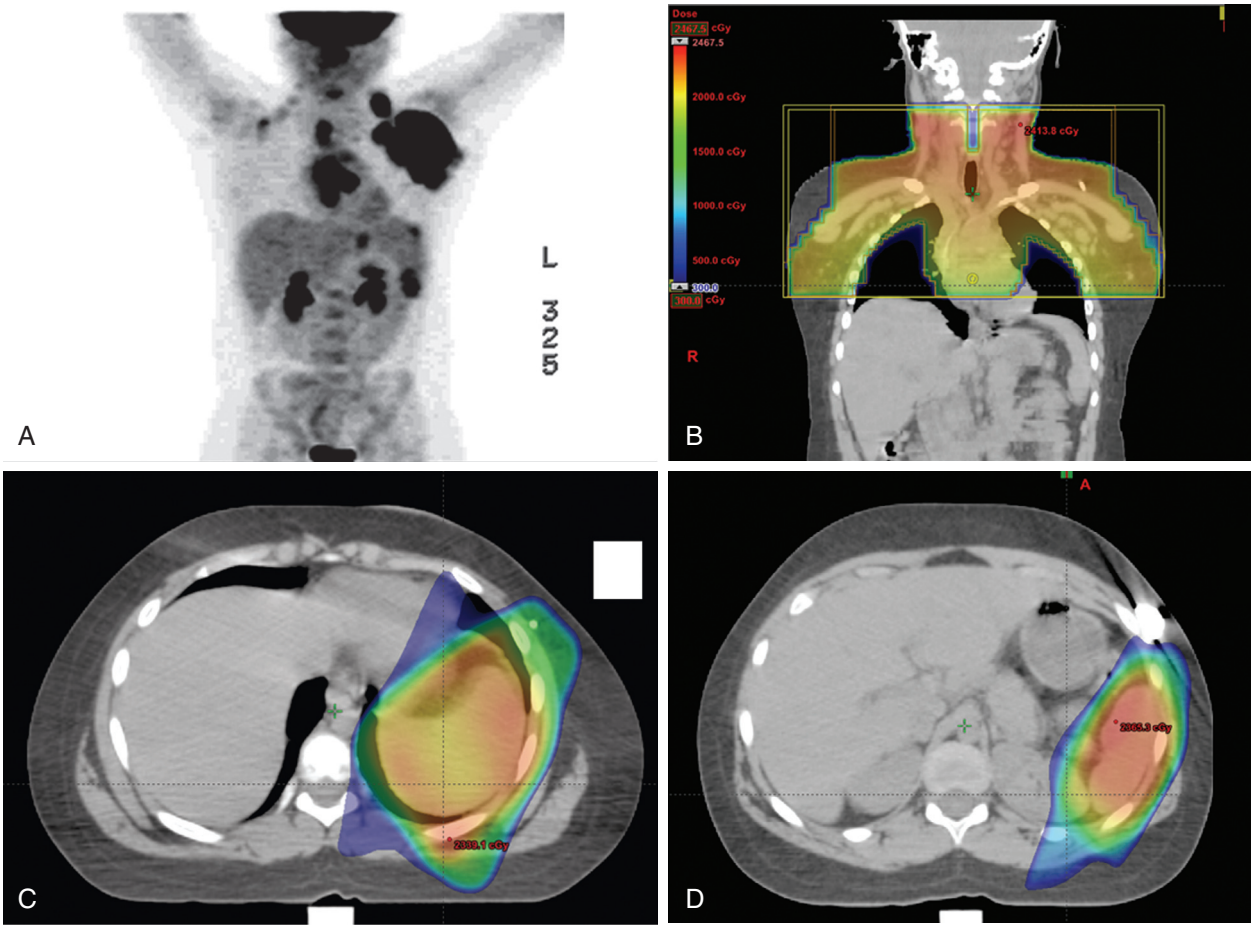

Figure 74-2 Use of non-standard IMRT to treat spleen along with anteroposterior and posteroanterior (AP-PA) mantle field. A 12-year old presented with stage IIIAS lymphocyte predominant Hodgkin's lymphoma with bulky right axillary adenopathy. On staging evaluation, PET scanning shown in Panel A showed bilateral neck and axillary adenopathy, bulky mediastinal disease, as well as multiple splenic nodules. After a complete response to ABVE-PC chemotherapy for four cycles, involved field radiotherapy to 21 Gy in 14 fractions was initiated. The supradiaphragmatic disease was well covered by standard APPA fields as shown in Panel B. APPA or oblique fields to the spleen would have treated too large a volume of the heart or kidney. Instead, a four-field IMRT field along with shallow breathing and appropriate margin for respiratory motion was devised. Panel C and D show superior and inferior aspects of the spleen treatment with the dose distribution shown with a color wash superimposed on the treatment planning CT scan. IMRT technique successfully minimized dose to the heart and left kidney.

four courses of ABVE were given to slow responders. All patients received 25.5 Gy IFRT, resulting in 5-year OS and EFS of 98% and 88%, respectively. With the desire to minimize the use of any RT, the COG AHOD0431 single-arm study already mentioned, stages IA and IIA patients who achieved a CR after three cycles of AVPC received no further therapy. Those with a partial response (PR) received 21-Gy IFRT. The 2-year EFS rate was 80% for those who did not receive RT versus 88% for patients achieving PR (and receiving IFRT) (p = 0.11). The 2-year OS rate was 100%. Of the evaluable patients with FDG-PET results after one cycle of chemotherapy (PET1), the 2-year EFS rates for CR patients who had a positive/equivocal PET1 versus a negative PET 1 were 65% versus 87%, respectively (p = 0.005). The 2-year EFS rates for PR patients who had a positive/equivocal PET1 versus a negative PET1 were 82% versus 96%, respectively (p = 0.047).[126,191] These preliminary results suggest that CT response alone is not adequate to identify patients who can be treated without RT after minimal therapy such as AVPC chemotherapy for three cycles.

Risk-Adapted Therapy: Intermediate-Risk Disease

In risk-adapted treatment regimens, localized disease presenting with unfavorable features are often grouped into an intermediate-risk category and includes those with localized (stages IA, IIA) disease with unfavorable features and those with stage IIIA disease. The GPOH-HD84 study was the first study to match this group of patients with chemotherapy whose intensity was midway between that of favorable and unfavorable/advanced patient cohorts. Building on this concept, the GPOH-HD 2002 study reported a 5-year EFS rate of 88% with two cycles of OEPA for boys and OPPA for girls. This was followed by two cycles of COPP for girls and cyclophosphamide, vincristine, prednisone, and dacarbazine (COPDAC) for boys to spare fertility by reducing alkylator exposure. Deletion of RT appears to have been detrimental with reduced EFS for this group as already discussed.

The COG has developed an approach of using dose-dense chemotherapy to support response-adapted therapy.

An intensive regimen of doxorubicin, bleomycin, vincristine, etoposide, prednisone and cyclophosphamide (ABVE-PC) chemotherapy was used for patients with both intermediate- and high-risk disease in the POG9425 study. Patients with a RER to three cycles of ABVE-PC received 21 Gy of regional field RT (mantle, para-aortic, or pelvis). Slow early responders (SER) received an additional two cycles of ABVE-PC and then received IFRT to 21 Gy. The 5-year EFS rates were 86% for RER patients and 83% for SER patients ($p = 0.85$) and the 5-year OS rate was 95%.[68]

In the recently completed COG AHOD 0031 study, patients received two cycles of ABVE-PC followed by response assessment. Patients with RER received two additional cycles of ABVE-PC followed by a second response assessment. Those with a CR as defined by an 80% reduction in cross-sectional area of disease and resolution of metabolic uptake on gallium or FDG-PET were randomized to 21-Gy IFRT or no further therapy. Patients who did not have a CR constituted a third of the RER cohort and all received IFRT—a subtlety in the results of this trial that may be underrecognized. All SER patients were randomized to either two additional cycles of ABVE-PC or dexamethasone, etoposide, cisplatin, and cytarabine (DECA) followed by an additional two cycles of ABVE-PC. All SER patients received 21-Gy IFRT after chemotherapy. Three-year EFS rates were 87.1% for RER patients versus 77.8% for SER patients ($p = 0.0001$). The 3-year OS rate for RER patients was 98.7% versus 96.9% for SER patients ($p = 0.02$). The 3-year EFS rate was 87.9% for RER/CR patients randomized to receive IFRT versus 85.4% for those randomized to no IFRT ($p = 0.07$). These results suggest that early response to chemotherapy defined by early reduction (60%) in tumor size—based on CT after two cycles can be a powerful predictor of outcome and help optimize subsequent treatment Moreover, the inclusion of a PET analysis after two cycles of ABVE-PC chemotherapy might more definitively help define a cohort of patients who do not benefit from IFRT, even in the presence of initial bulky disease.[192]

Risk-Adapted Therapy: Unfavorable Risk Disease

The criteria for the unfavorable prognostic group is also quite variable from one clinical trial to another, but typically include the presence of B symptoms, bulky lymphadenopathy, hilar lymphadenopathy, involvement of three or more nodal regions, extranodal extension to contiguous structures, or advanced stage (IIIB-IV). RT for unfavorable and advanced HL is also variable and protocol dependent. Suffice it to say, IFRT remains the standard in patients with advanced pediatric HL in good part because of the CCG 5942 results,[66] but restriction of RT volumes to regions of initial bulky disease or post-chemotherapy residual disease is under investigation.[51,94]

For patients with unfavorable or advanced disease, two primary treatment approaches have been used. First, a conventional treatment approach involves outpatient chemotherapy on a twice-monthly schedule for 6 months to 8 months. In adults the use of ABVD therapy for early unfavorable or high-stage HL has reported PFS in the range of 65% to 75% (which is low by pediatric standards).[193-195] In a limited Children's Cancer Study Group pilot trial, CCSG 521-P, ABVD for six cycles produced an 87% EFS and the same OS rate at 3 years. The principal problem, however, was a high serious pulmonary toxicity rate of 9%, predominantly occurring before RT was given.

An alternative strategy used dose-dense chemotherapy to reduce the theoretic risk of developing resistant disease but may also increase the risk for acute and late side effects. The C59704 trial, employing BEACOPP followed by gender-based consolidation, has some of the best disease control results for this high-risk group. A high 5-year EFS rate of 94% was achieved while the 5-year OS rate was 97%.[196] The GPOH, building up on their original experience with the OPPA/COPP regimen, showed that six cycles OEPA/COPDAC together with 20-Gy to 30-Gy IFRT also produced reasonably good results with a 5-year EFS rate of approximately 87%.[94]

Results of the COG AHOD0831 trial will be of interest, but none have yet been reported. This trial treated patients with stages IIIB and IVB disease with ABVE-PC for five cycles with higher doses of cyclophosphamide than the intermediate risk 0031 trial along with response assessment after cycles 1 and 2 with PET-CT imaging. Patients with SER received augmented chemotherapy of ifosfamide and vinorelbine for an additional two cycles. Radiation prescription rules were novel in which the goal was an incremental reduction in the volume of RT over past trials while the dose used was 21 Gy in 14 fractions. Regions of disease targeted were confined to initial sites of bulky disease that included any gross splenic involvement, slow responding sites, and residual masses at least 2.5 cm in diameter. Whole lung RT was discouraged.

Nodular Lymphocyte Predominant Hodgkin Lymphoma

In contrast to classical HL, nLPHL is considered a different disease that is more akin to a low-grade B-cell non-HL, having an indolent pattern of spread and growth with relapses that may occur after many years of follow-up.[197] Patients with nLPHL are characterized by early-stage disease, limited peripheral lymph node (cervical, axillary, or inguinal) presentations with rare involvement of the mediastinum, a male predominance, and an overall good prognosis.[198] Late complications of treatment such as secondary malignancies or cardiopulmonary toxicity,[199] or transformation to aggressive B-cell lymphoma[200] account for the majority of adverse fatal events. Historically, patients with nLPHL were treated like classical HL but more recent experience suggests that minimal therapy is often sufficient in both adults and children. In adults, IFRT alone is now favored with reports of good outcomes using 30 Gy to 36 Gy.[201,202] Because of concerns of growth abnormalities and secondary cancers from these radiation doses, this approach is not appropriate in most children. Because this is still an uncommon disease in children, much data derive from small retrospective series with a variety of treatment approaches that generally have acceptable short-term outcomes.[199,203,204] However, unique for lymphoma management is the excellent outcomes for excisional surgery alone with nLPHL.[205,206] Roughly half of such patients undergoing surgery only had good long-term disease control in one European trial of 58 children.[206] Relapses tend to be localized and limited, quite amenable to additional therapy with curative potential.
