Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Working together to grow libraries in developing countries
www.elsevier.com • www.bookaid.org

To Katheryn, my wife of 50 years in December 2014, to our children and their spouses (Chad and Chrissy, Whitney and Jeff, Stacie and Nick, Ryan and Danna, Scott and Cindy) and to our grandchildren (Olivia and Adam; Rebecca, Andrew, Katie, and Matthew; Sam, Anna, Michael, and Ellie; Grant, Ian, and Amelia; Landon, Parker, Rhys, and Brooke) for their love and support.

To my colleagues in Radiation Oncology, Surgery, Medical Oncology, Internal Medicine, Radiology, and Pathology for the opportunity to work together as a multidisciplinary team in the diagnosis and care of our patients.

Leonard L. Gunderson

To my wife Laurie, for her support and for teaching me what is important in life, and who has made me a better person; and my family, including, Miriam, Adam, Abigail, Agustin, Zekariah, Zohar, Sammy, Marcelo, Jonah, and Aurelio for the love and support they have given me for many years.

To my parents, who taught me the importance of education, learning, and doing that which should be done.

To my many mentors who taught me in the past, and those who continue to teach me.

To my professional colleagues, both at the University of North Carolina and around the country, who have made me a better physician.

Joel E. Tepper

CONTRIBUTORS

Ross A. Abrams, MD
Chairman and Professor
Dept. of Radiation Oncology
Rush University Medical Center
Chicago, Illinois

David J. Adelstein, MD, FACP
Professor of Medicine
Internal Medicine
Cleveland Clinic Lerner College of Medicine of Case Western Reserve University;
Staff Physician
Department of Solid Tumor Oncology, Taussig Cancer Institute
Cleveland Clinic
Cleveland, Ohio

Kaled M. Alektiar, MD
Attending Physician
Radiation Oncology
Memorial Sloan Kettering Cancer Center
New York, New York

Brian Alexander, MD, MPH
Assistant Professor
Radiation Oncology
Dana-Farber/Brigham and Women's Cancer Center, Harvard Medical School
Boston, Massachusetts

Jan Alsner, MD
Department of Experimental Clinical Oncology
Aarhus University Hospital
Aarhus, Denmark

Ersan Altun, MD
Associate Professor
Attending Radiologist
Department of Radiology
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Bethany Anderson, MD
Assistant Professor
Human Oncology
University of Wisconsin
Madison, Wisconsin

K. Kian Ang, MD, PhD[†]
Professor and Gilbert H. Fletcher Endowed Chair
Department of Radiation Oncology
University of Texas M.D. Anderson Cancer Center
Houston, Texas

[†]Deceased.

Douglas W. Arthur, MD
Professor
Department of Radiation Oncology
Virginia Commonwealth University
Richmond, Virginia

Jonathan B. Ashman, MD, PhD
Assistant Professor
Radiation Oncology
Mayo Clinic
Phoenix, Arizona

Matthew T. Ballo, MD
Chairman and Professor
Radiation Oncology
University of Tennessee Health Science Center
Memphis, Tennessee

Christopher Andrew Barker, MD
Assistant Attending Radiation Oncologist
Department of Radiation Oncology
Memorial Sloan Kettering Cancer Center
New York, New York

Beth M. Beadle, MD, PhD
Assistant Professor
Radiation Oncology
University of Texas M.D. Anderson Cancer Center
Houston, Texas

Phillipe Bedard, MD, FRCPC
Assistant Professor of Medicine
Department of Medical Oncology
University of Toronto,
Medical Oncologist
Department of Medical Oncology & Hematology
Princess Margaret Cancer Center
Toronto, Ontario, Canada

Jonathan J. Beitler, MD, MBA
Professor
Department of Radiation Oncology
Department of Otolaryngology
Dept of Hematology & Medical Oncology
Winship Cancer Institute of Emory University;
Georgia Research Alliance Cancer Scientist
Atlanta, Georgia

Michael W. Bishop, MD, MS
Research Assistant
Department of Oncology
St. Jude Children's Research Hospital
Memphis, Tennessee

A. William Blackstock, Jr., MD
Program Director, Comprehensive Cancer Center; Professor and Chair
Radiation Oncology
Wake Forest University
Winston Salem, North Carolina

Jeffrey A. Bogart, MD
Professor and Chair
Department of Radiation Oncology
Upstate Medical University
Syracuse, New York

James A. Bonner, MD
Professor and Chairman
Radiation Oncology
University of Alabama at Birmingham
Birmingham, Alabama

J. Daniel Bourland, BS, MSPH, PhD
Professor
Radiation Oncology
Wake Forest School of Medicine
Winston-Salem, North Carolina

Joseph Bovi, MD
Associate Professor
Radiation Oncology
Medical College of Wisconsin
Milwaukee, Wisconsin

John Breneman, MD
Professor
Radiation Oncology
University of Cincinnati;
Cincinnati Children's Hospital
Cincinnati, Ohio

Juan P. Brito, MD
Assistant Professor of Medicine
Division of Endocrinology
Mayo Clinic College of Medicine
Rochester, Minnesota

Paul D. Brown, MD
Professor
Department of Radiation Oncology
University of Texas M.D. Anderson Cancer Center
Houston, Texas

Michael D. Brundage, MD, MSc
Professor
Oncology, and Public Health Sciences
Queen's University;
Radiation Oncologist
Oncology
Cancer Centre of Southeastern Ontario
Kingston, Ontario, Canada

Thomas A. Buchholz, MD, FACR
Professor and Physician-in-Chief
Office of the Executive Vice President
Department of Radiation Oncology
University of Texas M.D. Anderson Cancer Center
Houston, Texas

Bryan Henry Burmeister, MB ChB, FFRad(T) SA, FRANZCR, MD
Professor
Faculty of Health Sciences
University of Queensland;
Director
Radiation Oncology
Princess Alexandra Hospital
Brisbane, Queensland, Australia

Stuart K. Calderwood, PhD
Associate Professor
Radiation Oncology
Harvard Medical School at Beth Israel Deaconess Cancer Center
Boston, Massachusetts

Matthew D. Callister, MD
Division Chief
Radiation Oncology
Banner M.D. Anderson Cancer Center
Gilbert, Arizona

Felipe A. Calvo
Professor and Chairman
Department of Oncology
University Hospital Gregorio Marañon
Madrid, Spain

George M. Cannon, MD
Radiation Oncologist
Intermountain Healthcare and LDS Hospital
Salt Lake City Utah;
Adjunct Assistant Professor
Radiation Oncology
University of Utah
Salt Lake City, Utah

Bruce A. Chabner, MD
Director of Clinical Research
Cancer Center
Massachusetts General Hospital;
Professor of Medicine
Harvard Medical School
Boston, Massachusetts

Michael D. Chan, MD
Assistant Professor
Co-Director of Gamma Knife Program
Department of Radiation Oncology
Wake Forest School of Medicine
Winston-Salem, North Carolina

Sam T. Chao, MD
Professor of Medicine
Rose Ella Burkhardt Brain Tumor and Neuro-oncology Center
Department of Radiation Oncology
Cleveland, Ohio

Anne-Marie Charpentier, MD, FRCPC
Radiation Oncologist
Department of Radiation Oncology
Centre hospitalier de l'Université de Montréal
Montreal, Quebec, Canada

Christine H. Chung, MD
Associate Professor
Oncology
Johns Hopkins University
Baltimore, Maryland

Peter W.M. Chung, MBChB, MRCP, FRCR, FRCPC
Associate Professor
Radiation Oncology
University of Toronto;
Staff Radiation Oncologist
Radiation Medicine Program
Princess Margaret Hospital Cancer Centre
Toronto, Ontario, Canada

Louis S. Constine, MD, FASTRO
The Philip Rubin Professor of Radiation Oncology and Pediatrics
Vice Chair
Department of Radiation Oncology
James P. Wilmot Cancer Center, University of Rochester Medical Center;
Rochester, New York

Benjamin W. Corn, MD
Chairman
Radiation Oncology
Tel Aviv Medical Center;
Professor
Oncology
Tel Aviv University School of Medicine
Tel Aviv, Israel

Allan Covens, MD, FRCSC
Head, Gynecologic Oncology
Sunnybrook Health Sciences Centre;
Professor
Obstetrics and Gynecology
University of Toronto
Toronto, Ontario, Canada

Oana I. Craciunescu, PhD
Associate Professor
Radiation Oncology
Duke University Medical Center
Durham, North Carolina

Christopher H. Crane, MD
Professor and Program Director, Gastrointestinal Section
Radiation Oncology
University of Texas M.D. Anderson Cancer Center
Houston, Texas

Carien L. Creutzberg, MD, PhD
Professor of Radiation Oncology
Department of Radiation Oncology
Leiden University Medical Center
Leiden, The Netherlands

Juanita M. Crook, MD, FRCPC
Professor
Radiation Oncology
University of British Columbia;
Radiation Oncologist
Center for the Southern Interior
British Columbia Cancer Agency
Kelowna, British Columbia, Canada

Walter J. Curran, Jr., MD
Executive Director
Winship Cancer Center;
Associate Vice President, Cancer
Woodruff Health Sciences Center;
Lawrence W. Davis Professor and Chairman of Radiation Oncology
Emory University
Atlanta, Georgia;
NRG Oncology Group Chairman
NRG Oncology Group
Philadelphia, Pennsylvania

Brian G. Czito, MD
Gary Hock and Lynn Proctor Associate Professor
Department of Radiation Oncology
Duke University Medical Center
Durham, North Carolina

Bouthaina S. Dabaja, MD
Associate Professor and Section Chief
Section of Hematology Radiation Oncology
Department of Radiation Oncology
University of Texas M.D. Anderson Cancer Center
Houston, Texas

Shiva Das, PhD
Professor and Director of Medical Physics
Department of Radiation Oncology
University of North Carolina School of Medicine
Chapel Hill, North Carolina

Marc David, MD, BSc
Assistant Professor
Montreal General Hospital
Radiation Oncology Department
Montreal, Quebec, Canada

Laura A. Dawson, MD
Professor
Department of Radiation Oncology
Princess Margaret Cancer Centre
University of Toronto
Toronto, Ontario, Canada

Thomas F. DeLaney, MD
Professor of Radiation Oncology
Harvard Medical School;
Co-Director
Connective Tissue Oncology Center
Massachusetts General Hospital
Boston, Massachusetts

Phillip M. Devlin, B. Phil, MTS, EdM, MD, FACR, FASTRO, FFRRSCI (Hon)
Chief
Division of Brachytherapy
Dana Farber Brigham and Women's Cancer Center;
Associate Professor
Radiation Oncology
Harvard Medical School;
Institute Physician
Radiation Oncology
Dana Farber Cancer Institute
Boston, Massachusetts

Mark Dewhirst, DVM, PhD
Gustavo Montana Professor
Radiation Oncology
Duke University
Durham, North Carolina

Don S. Dizon, MD, FACP
Director, Oncology Sexual Health and Attending Physician,
Gynecologic Oncology
Internal Medicine
Massachusetts General Hospital
Boston, Massachusetts

Jeffrey S. Dome, MD, PhD
Chief
Hematology and Oncology
Children's National Medical Center
Washington, D.C.

John H. Donohue, MD
Professor of Surgery
Mayo Clinic College of Medicine
Rochester, Minnesota

Thierry P. Duprez, MD
Professor
Medical Imaging and Radiology
Universite Catholique de Louvain;
Head of Neuro/H&N Section
Radiology
Cliniques Universitaires Saint-Luc (UCL)
Brussels, Belgium

Jason A. Efstathiou, MD, DPhil
Associate Professor
Radiation Oncology
Harvard Medical School;
Associate Radiation Oncologist
Radiation Oncology
Massachusetts General Hospital
Boston, Massachusetts

Avraham Eisbruch, MD
Professor
Radiation Oncology
University of Michigan;
Attending Physician
Radiation Oncology
Hospital of the University of Michigan
Ann Arbor, Michigan

David W. Eisele, MD, FACS
Andelot Professor and Director
Department of Otolaryngology—Head and Neck Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

Mary Feng, MD
Associate Professor
Radiation Oncology
University of Michigan
Ann Arbor, Michigan

Rui P. Fernandes, MD, DMD
Associate Professor
Surgery
University of Florida College of Medicine Jacksonville
Jacksonville, Florida

Julia R. Fielding, MD
Professor of Radiology
Department of Radiology
Associate Chair
Chief of Abdominal Imaging Section
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Gini F. Fleming, MD
Professor
Department of Medicine
University of Chicago
Chicago, Illinois

Robert L. Foote, MD, FASTRO
Professor and Chair
Radiation Oncology
Mayo Clinic College of Medicine and Mayo Clinic
Rochester, Minnesota

Benedick A. Fraass, PhD
Vice Chair for Research, Professor and Director of Medical Physics
Department of Radiation Oncology
Cedars-Sinai Medical Center;
Clinical Health Sciences Professor
Department of Radiation Oncology
UCLA
Los Angeles, California;
Professor Emeritus
Department of Radiation Oncology
University of Michigan
Ann Arbor, Michigan

Carolyn R. Freeman, MBBS, FRCPC, FASTRO
Professor of Oncology and Pediatrics
Radiation Oncology
McGill University Health Centre
Montreal, Quebec, Canada

Adam S. Garden, MD
Professor
Radiation Oncology
University of Texas M.D. Anderson Cancer Center
Houston, Texas

Lindell R. Gentry, MD, FACR
Professor
Department of Radiology
University of Wisconsin School of Medicine and Public Health
Madison, Wisconsin

Lilian T. Gien, MD, MSc, FRCSC
Gynecologic Oncologist
Division of Gynecologic Oncology
Odette Cancer Centre, Sunnybrook Health Sciences Centre;
Assistant Professor
Department of Obstetrics & Gynecology
University of Toronto
Toronto, Ontario, Canada

Mary K. Gospodarowicz, MD, FRCPC
Medical Director
Princess Margaret Cancer Centre;
Professor
Radiation Oncology
University of Toronto;
Staff Physician
Radiation Oncology
Princess Margaret Cancer Centre
Toronto, Ontario, Canada

Cai Grau, MD
Department of Oncology
Aarhus University Hospital
Aarhus, Denmark

Vincent Grégoire, MD, PhD, FRCR
Professor
Radiation Oncology
Université Catholique de Louvain, St-Luc University Hospital
Brussels, Belgium

Craig M. Greven, MD
Richard G. Weaver Professor and Chairman
Department of Ophthalmology
Wake Forest University School of Medicine
Winston-Salem, North Carolina

Kathryn McConnell Greven, MD
Professor and Vice Chair
Department of Radiation Oncology
Wake Forest University School of Medicine
Winston-Salem, North Carolina

Leonard L. Gunderson, MD, MS, FASTRO
Emeritus Professor and Consultant
Department of Radiation Oncology
Mayo Clinic College of Medicine and Mayo Clinic
Scottsdale, Arizona

Michael G. Haddock, MD
Professor and Vice Chair, Clinical Practice
Department of Radiation Oncology
Mayo Clinic College of Medicine and Mayo Clinic
Rochester, Minnesota

Michele Halyard, MD
Associate Professor
Radiation Oncology
Mayo Clinic College of Medicine and Mayo Clinic
Scottsdale, Arizona

Marc Hamoir, MD
Head
Head & Neck Surgery
Chairman of the Executive Board
Cancer Center
St Luc University Hospital Cancer Center,
Brussels, Belgium;
Full Professor
Medical School
Université Catholique de Louvain,
Louvain La Neuve, Belgium

Timothy Paul Hanna, MD, MSc, FRCPC
Clinician Scientist
Cancer Care and Epidemiology, Cancer Research Institute at Queen's University
Radiation Oncologist
Cancer Centre of Southeastern Ontario
Kingston General Hospital
Kingston, Ontario, Canada

Paul M. Harari, MD
Jack Fowler Professor and Chair
Human Oncology
University of Wisconsin School of Medicine and Public Health
Madison, Wisconsin

Ian D. Hay, MD, PhD
Professor of Medicine
Division of Endocrinology
Department of Internal Medicine,
The Dr RF Emslander Professor of Endocrine Research
Division of Endocrinology
Mayo Clinic College of Medicine;
Consultant in Endocrinology
Mayo Clinic
Rochester, Minnesota

Joseph M. Herman, MD, MSc
Associate Professor
Department of Radiation Oncology & Molecular Radiation Sciences
Johns Hopkins University School of Medicine
Baltimore, Maryland

Caroline L. Holloway, MD, FRCPC
Clinical Assistant Professor
Radiation Oncology
BC Cancer Agency, Vancouver Island Centre
Victoria, British Columbia, Canada

Theodore Sunki Hong, MD
Director of Gastrointestinal Radiation Oncology
Radiation Oncology
Massachusetts General Hospital
Boston, Massachusetts

Neil S. Horowitz, MD
Assistant Professor of Obstetrics and Gynecology
Harvard Medical School
Division of Gynecologic Oncology
Brigham and Women's Hospital and Dana Farber Cancer Institute
Boston, Massachusetts

Michael R. Horseman, MD
Department of Experimental Clinical Oncology
Aarhus University Hospital
Aarhus, Denmark

Julie Howle, BSc, MBBS, MS, FRACS
Doctor of Surgery
Westmead Hospital
Westmead, New South Wales, Australia;
Clinical Senior Lecturer
Surgery
University of Sydney
Sydney, New South Wales, Australia

Brian A. Hrycushko, PhD
Assistant Professor
Radiation Oncology
University of Texas Southwestern Medical Center at Dallas
Dallas, Texas

David Hsu, MD, PhD
William Dalton Family Assistant Professor of Medicine
Medical Oncology/Internal Medicine
Duke University
Durham, North Carolina

Patricia A. Hudgins, MD
Professor
Radiology and Imaging Sciences
Emory University School of Medicine
Atlanta, Georgia

Ryan C. Hutchinson, MD
Resident
Department of Urology
Mayo Clinic
Jacksonville, Florida

Christine Iacobuzio-Donahue, MD, PhD
Attending Pathologist
Pathology
Affiliate Member
Human Oncology and Pathogenesis Program
Associate Director for Translational Research
David M. Rubenstein Center for Pancreatic Cancer Research
Memorial Sloan Kettering Cancer Center
New York, New York

Benjamin Izar, MD, PhD
Internal Medicine Resident
Massachusetts General Hospital
Boston, Massachusetts

Valerie L. Jewells, DO
Associate Professor
Department of Radiology
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Joseph Gerard Jurcic, MD
Professor of Medicine at Columbia University Medical Center; Director, Hematologic Malignancies Section
Department of Medicine
Columbia University Medical Center;
Attending Physician
Department of Medicine
New York-Presbyterian Hospital/Columbia University Medical Center;
Member
Herbert Irving Comprehensive Cancer Center
New York, New York

John A. Kalapurakal, MD, FACR
Professor
Radiation Oncology
Northwestern University
Chicago, Illinois

Brian D. Kavanagh, MD, MPH, FASTRO
Professor
Radiation Oncology
University of Colorado Cancer Center;
University of Colorado Hospital
Aurora, Colorado

Kara M. Kelly, MD
Professor of Clinical Pediatrics
Division of Pediatric Oncology
Columbia University Medical Center
New York, New York

Amir H. Khandani, MD
Associate Professor of Radiology
Division of Nuclear Medicine, Department of Radiology
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Deepak Khuntia, MD
Vice President, Medical Affairs
Oncology Systems
Varian Medical Systems, Inc
Palo Alto, California;
Radiation Oncologist
Valley Medical Oncology Consultants
Pleasanton, California

Ana Ponce Kiess, MD, PhD
Instructor
Radiation Oncology and Molecular Radiation Sciences
Johns Hopkins Medical Institute
Baltimore, Maryland

Susan J. Knox, MD, PhD
Associate Professor
Radiation Oncology
Stanford University
Stanford, California

Wui-Jin Koh, MD
Professor
Radiation Oncology
University of Washington School of Medicine/Seattle Cancer Care Alliance
Seattle, Washington

Matthew J. Krasin, MD
Associate Member
Department of Radiation Oncology
St. Jude Children's Research Hospital
Memphis, Tennessee

Larry E. Kun, MD, FASTRO
Professor
Departments of Radiology and Pediatrics
University of Tennessee College of Medicine;
Clinical Director and Chair
Department of Radiological Sciences
St. Jude Children's Research Hospital
Memphis, Tennessee

Nadia Issa Laack, MD, MS
Assistant Professor
Radiation Oncology
Mayo Clinic
Rochester, Minnesota

Ann S. LaCasce, MD, MMsc
Assistant Professor of Medicine
Medical Oncology
Dana-Farber Cancer Institute
Boston, Massachusetts

Corey Jay Langer, MD
Professor of Medicine
Hematology-Oncology
University of Pennsylvania
Philadelphia, Pennsylvania

George E. Laramore, MD, PhD
Peter Wootton Professor
Radiation Oncology
University of Washington School of Medicine
Seattle, Washington

John Harris Associate Professor and Chief, Neuro-Oncology Division
Department of Neurology
Columbia University Medical Center;
Medical Director
Clinical Protocol & Data Management Office
Herbert Irving Comprehensive Cancer Center
New York, New York

Colleen A.F. Lawton, MD, FACR, FASTRO
Vice Chair and Professor
Radiation Oncology
Medical College of Wisconsin
Milwaukee, Wisconsin

Nancy Lee, MD
Radiation Oncologist
Radiation Oncology
Memorial Sloan Kettering Cancer Center
New York, New York

Benoît Lengelé, MD, PhD, FRCS, KB
Head of Department
Plastic & Reconstructive Surgery
Cliniques Universitaires St. Luc
Brussels, Belgium

William P. Levin, MD
Assistant Professor
Radiation Oncology
Abramson Cancer Center of the University of Pennsylvania
Philadelphia, Pennsylvania

Jacob C. Lindegaard, MD
Department of Oncology
Aarhus University Hospital
Aarhus, Denmark

John T. Lucas, Jr., MS, MD
Resident
Radiation Oncology
Wake Forest Baptist Medical Center
Winston Salem, North Carolina

Shannon M. MacDonald, MD
Associate Professor of Radiation Oncology
Massachusetts General Hospital/ Harvard Medical School
Francis H. Burr Proton Center
Boston, Massachusetts

William J. Mackillop, MB, ChB, FRCR, FRCPC
Professor
Oncology and Public Health Sciences
Queen's University
Kingston, Ontario, Canada

Anuj Mahindra, MD
Assistant Professor
Division of Hematology/Oncology
University of California San Francisco
San Francisco, California

Anthony A. Mancuso, MD
Professor and Chair
Department of Radiology
Professor of Otolaryngology
University of Florida College of Medicine
Gainesville, Florida

Karen Jean Marcus, MD
Division Chief
Pediatric Radiation Oncology
Boston Children's Hospital/Dana Farber Cancer Institute;
Associate Professor
Radiation Oncology
Harvard Medical School
Boston, Massachusetts

Lawrence B. Marks, MD, FASTRO
Dr. Sidney K. Simon Distinguished Professor of Oncology Research,
Chair, Radiation Oncology
University of North Carolina School of Medicine
Chapel Hill, North Carolina

Diana Matceyevsky, MD
Senior Physician in Radiotherapy Oncology
Tel Aviv Medical Center
Tel Aviv, Israel

Jean-Jacques Mazeron, MD, PhD
Professor and Chair
Oncology
Paris VI University;
Head of Department
Radiation Oncology
Pitié-Salpêtrière Hospital
Paris, France

Mark W. McDonald, MD
Associate Professor of Radiation Oncology
Department of Radiation Oncology
Winship Cancer Institute of Emory University
Atlanta, Georgia

Paul M. Medin, PhD
Associate Professor
Radiation Oncology
University of Texas Southwestern Medical Center
Dallas, Texas

Minesh P. Mehta, MD, FASTRO
Professor
Department of Radiation Oncology
University of Maryland
Baltimore, Maryland

William M. Mendenhall, MD
Professor
Radiation Oncology
University of Florida
Gainesville, Florida

Ruby F. Meredith, MD, PhD
Professor
Radiation Oncology
University of Alabama at Birmingham;
Senior Scientist
UAB Comprehensive Cancer Center
University of Alabama at Birmingham
Birmingham, Alabama

Jeff M. Michalski, MD, MBA, FACR, FASTRO
The Carlos A Perez Distinguished Professor of Radiation Oncology
Radiation Oncology
Washington University
St. Louis, Missouri

Michael T. Milano, MD, PhD
Associate Professor
Department of Radiation Oncology
University of Rochester
Rochester, New York

Bruce D. Minsky, MD
Professor
Radiation Oncology
University of Texas M.D. Anderson Cancer Center
Houston, Texas

William H. Morrison, MD
Professor
Radiation Oncology
University of Texas M.D. Anderson Cancer Center
Houston, Texas

Erin S. Murphy, MD
Assistant Professor
Radiation Oncology
Cleveland Clinic
Cleveland, Ohio

Rashmi K. Murthy, MD, MBE
Assistant Professor
Breast Medical Oncology
University of Texas M.D. Anderson Cancer Center
Houston, Texas

Andrea K. Ng, MD, MPH
Associate Professor
Department of Radiation Oncology
Dana-Farber Cancer Institute, Brigham and Women's Hospital; Harvard Medical School
Boston, Massachusetts

Marianne Nordsmark
Department of Oncology
Aarhus University Hospital
Aarhus, Denmark

Desmond A. O'Farrell, MSc, DABR, CMD
Teaching Associate in Radiation Oncology
Harvard Medical School;
Clinical Physicist
Department of Radiation Oncology
Dana-Farber/Brigham and Women's Cancer Center
Boston, Massachusetts

Paul Okunieff, MD
Director
University of Florida Shands Cancer Center;
Chair
Department of Radiation Oncology
University of Florida
Gainesville, Florida

Roger Ove, MD, PhD
Clinical Associate Professor
Department of Radiation Oncology
University Hospitals Case Medical Center
Seidman Cancer Center
Cleveland, Ohio

Jens Overgaard, MD
Department of Experimental Clinical Oncology
Aarhus University Hospital
Aarhus, Denmark

Manisha Palta, MD
Assistant Professor
Department of Radiation Oncology
Duke University
Durham, North Carolina

Alexander S. Parker, PhD
Professor of Epidemiology and Urology
Health Sciences Research
Mayo Clinic Florida
Jacksonville, Florida

Luke E. Pater, MD
Assistant Professor of Radiation Oncology
Radiation Oncology
University of Cincinnati; Cincinnati Children's Hospital
Cincinnati, Ohio

Jennifer L. Peterson, MD
Assistant Professor
Radiation Oncology
Mayo Clinic
Jacksonville, Florida

Thomas M. Pisansky, MD
Professor
Radiation Oncology
Mayo Clinic College of Medicine and Mayo Clinic
Rochester, Minnesota

Louis Potters, MD, FACR, FASTRO
Professor and Chairman
Department of Radiation Medicine
North Shore-LIJ Health System
New Hyde Park, New York

Harry Quon, MD, MS
Associate Professor
Department of Radiation Oncology
Johns Hopkins University;
Sidney Kimmel Comprehensive Cancer Center
Baltimore, Maryland

David Raben, MD
Professor
Radiation Oncology
University of Colorado, Anschutz Medical Campus
Aurora, Colorado

Abram Recht, MD
Professor
Radiation Oncology
Harvard Medical School;
Deputy Chief
Radiation Oncology
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Ramesh Rengan, MD, PhD
Associate Professor
Department of Radiation Oncology
University of Washington School of Medicine
Seattle, Washington

Marsha, Laufer Reyngold, MD, PhD
Department of Radiation Oncology
Memorial Sloan Kettering Cancer Center
New York, New York

Nadeem Riaz, MD, MSc
Instructor
Radiation Oncology
Memorial Sloan Kettering Cancer Center
New York, New York

Stephen S. Roberts, MD
Assistant Attending Physician
Pediatrics
Memorial Sloan Kettering Cancer Center
New York, New York

Kenneth B. Roberts, MD
Professor of Therapeutic Radiology
Department of Therapeutic Radiology
Yale University School of Medicine
New Haven, CT, USA

Jason K. Rockhill, MD, PhD
Associate Professor
Radiation Oncology
University of Washington School of Medicine;
Co-Director
Gamma Knife Center
Harborview Medical Center;
Director
Alvord Brain Tumor Center
UW Medicine;
Associate Residency Director
Radiation Oncology
University of Washington School of Medicine
Seattle, Washington

Claus M. Rödel, MD
Radiotherapy and Oncology
University Hospital Frankfurt, Goethe University
Frankfurt, Germany

Carlos Rodriguez-Galindo, MD
Director, Solid Tumor Program
Pediatric Hematology-Oncology
Dana-Farber/Boston Children's Cancer and Blood Disorders Center;
Associate Professor
Pediatrics
Harvard Medical School
Boston, Massachusetts

C. Leland Rogers, MD
Professor
Radiation Oncology
Virginia Commonwealth University
Richmond, Virginia

Todd L. Rosenblat, MD, MS
Assistant Professor
Department of Medicine
Columbia University Medical Center
New York, New York

William G. Rule, MD
Instructor
Radiation Oncology
Mayo Clinic—Arizona
Scottsdale, Arizona

Anthony Henryk Russell, MD
Associate Professor
Radiation Oncology
Harvard Medical School;
Chief, Gynecologic Cancers Section
Radiation Oncology
Massachusetts General Hospital
Boston, Massachusetts

PREFACE

The radiation oncology community has received the three previous editions of *Clinical Radiation Oncology* very well, and it has become the standard radiation oncology textbook for many physicians. For the fourth edition of *Clinical Radiation Oncology*, the intent is to maintain the many excellent features of the previous editions while adding some new features, new chapters and chapter authors, and one new Associate Editor. The most exciting new feature is that the chapters in the online version of the fourth edition of *Clinical Radiation Oncology* (www.expertconsult.com) will be periodically updated.

The fourth edition again has separate sections on Scientific Foundations of Radiation Oncology, Techniques and Modalities, and Disease Sites. Within the section on Scientific Foundations of Radiation Oncology, a new chapter has been added, "Radiation Physics: Stereotactic." In the section on Techniques and Modalities, the chapter on stereotactic irradiation has been divided into separate chapters, "Stereotactic Irradiation: CNS Tumors" and "Stereotactic Body Irradiation: Extracranial Tumors," in view of the expanded interest in and outcomes data for stereotactic body irradiation.

The associate editors for Disease Sites chapters were an important component of the success of the three previous editions and have been maintained. One new associate editor has been selected for the fourth edition—Dr. Andrea Ng for Lymphoma and Hematologic Malignancies. Associate editors are involved in the selection of chapter authors and in editing the chapters for scientific content and accuracy. For most Disease Sites, the associate editors also wrote an Overview that allowed them to discuss issues common to various Disease Sites within the section and to give their unique perspective on important issues.

Features that are retained within Disease Sites chapters include an opening page format summarizing the most important issues, a full-color format throughout each chapter, liberal use of tables and figures, and a closing section with a discussion of controversies and problems and a treatment algorithm that reflects the treatment approach of the authors. Chapters have been edited not only for scientific accuracy, but also for organization, format, and adequacy of outcome data (disease control, survival, and treatment tolerance).

We are again indebted to the many national and international experts who contributed to the fourth edition of *Clinical Radiation Oncology* as associate editors, senior authors, or coauthors. Their outstanding efforts combined with ours will hopefully allow this new edition to be a valuable contribution and resource in the coming years.

Leonard L. Gunderson
Joel E. Tepper

ACKNOWLEDGMENTS

We wish to thank our wives, Katheryn and Laurie, and Dr. Tepper's secretary, Betty Bush, for their patience and assistance during the many months we were involved in the preparation of the fourth edition of *Clinical Radiation Oncology*.

We also thank the associate editors and the many chapter senior authors and co-authors for their time, efforts, and outstanding contributions to this edition.

We acknowledge the editors and production staff at Elsevier, especially Kate Dimock, Deidre Simpson, and Rachel McMullen, who have done an outstanding job in collating and producing the fourth edition of *Clinical Radiation Oncology*.

Video 3: Ocular Melanoma

Video 4: Penile Brachytherapy

CHAPTER 1

The Biological Basis of Radiation Oncology

Elaine M. Zeman

WHAT IS RADIATION BIOLOGY?

In the most general sense, *radiation biology is the study of the effects of electromagnetic radiation on biological systems*. Three aspects of this definition deserve special mention. First, effects may include everything from DNA damage to genetic mutations, chromosome aberrations, cell killing, disturbances in cell cycle transit and cell proliferation, neoplastic transformation, early and late effects in normal tissues, teratogenesis, cataractogenesis, and carcinogenesis, to name but a few. Electromagnetic radiation refers to any type of radiant energy in motion with wave or particulate characteristics that has the capacity to impart some or all of its energy to the medium through which it passes. The amount of energy deposited can vary over some 25 orders of magnitude, depending on the type of electromagnetic radiation. For example, 1 kHz radio waves have energies in the range of 10^{-11} eV to 10^{-12} eV, whereas x- or γ-rays may have energies upwards of 10 MeV or more. The more energetic forms of electromagnetic radiation, the ionizing radiations, deposit energy as they traverse the medium by setting secondary particles in motion that can go on to produce further ionizations. Finally, biological systems may be, for example, simple cell-free extracts of biomolecules, or increasingly complex, from prokaryotes to single-celled eukaryotes, to mammalian cells in culture, to tissues and tumors in laboratory animals or humans, to entire ecosystems.

Radiotherapy-oriented radiobiology focuses on that portion of the electromagnetic spectrum energetic enough to cause ionization of atoms. This ultimately results in the breaking of chemical bonds that can lead to damaging important biomolecules. The most significant effect of ionizing radiation in this context is cell killing, which directly or indirectly is at the root of nearly *all* of the normal tissue and tumor responses noted in patients.

Cytotoxicity is not the only significant biological effect caused by radiation exposure, although it will be the main focus of this chapter. Other important radiation effects, carcinogenesis, for example, will also be discussed, although the reader should be aware that radiation carcinogenesis is a large discipline in and of itself, involving investigators from fields as diverse as biochemistry, toxicology, epidemiology, environmental sciences, molecular biology, tumor biology, health and medical physics, as well as radiobiology. Most radiation protection standards are based on minimizing the risks associated with mutagenic and carcinogenic events. Radiologic health professionals therefore are de facto educators of and advocates for the general public when it comes to ionizing radiation and need to be fully conversant in the potential risks and benefits of medical procedures involving radiation.

Finally, the majority of this chapter will be devoted to so-called classical radiobiology, that is, studies that largely predate the revolution in molecular biology and biotechnology during the 1980s and 1990s. Although the reader might be tempted to view this body of knowledge as rather primitive by today's standards, relying too heavily on phenomenology, empiricism, and descriptive models and theories, the real challenge is to integrate the new biology into the already existing framework of classical radiobiology; this will be discussed in detail in Chapter 2.

RADIOTHERAPY-ORIENTED RADIOBIOLOGY: A CONCEPTUAL FRAMEWORK

Before examining any one aspect of radiobiology in depth, it is important to introduce several general concepts to put the information in its proper perspective.

The Therapeutic Ratio

The most fundamental of these concepts is what is termed the *therapeutic ratio*, which is in essence a risk-versus-benefit approach to planning a radiotherapy treatment regimen. Many of the radiobiological phenomena to be discussed in this chapter are thought to play important roles in optimizing, or at least fine-tuning the therapeutic ratio. In theory, it should be possible to eradicate any malignant tumor simply by delivering a sufficiently high dose of radiation. Of course in practice, the biological consequences for normal tissues that are necessarily irradiated along with the tumor limit the total dose that can be safely administered. As such, a balance must be struck between what is deemed an acceptable probability of a radiation-induced complication in a normal tissue and the probability of tumor control. Ideally, one would hope to achieve the maximum likelihood of tumor control that does not produce unacceptable normal tissue damage.

The concept of therapeutic ratio is best illustrated graphically by comparing dose-response curves for both tumor control and normal tissue complication rates plotted as a function of dose. Examples of this approach are shown in Figure 1-1, for cases in which the therapeutic ratio is either "unfavorable," "favorable," or "optimal," bearing in mind that these are theoretical curves. Actual dose-response curves derived from experimental or clinical data are much more variable, particularly for tumors, which tend to show much shallower dose responses.[1] This serves to underscore how difficult it can be in practice to assign a single numerical value to the therapeutic ratio in any given situation.

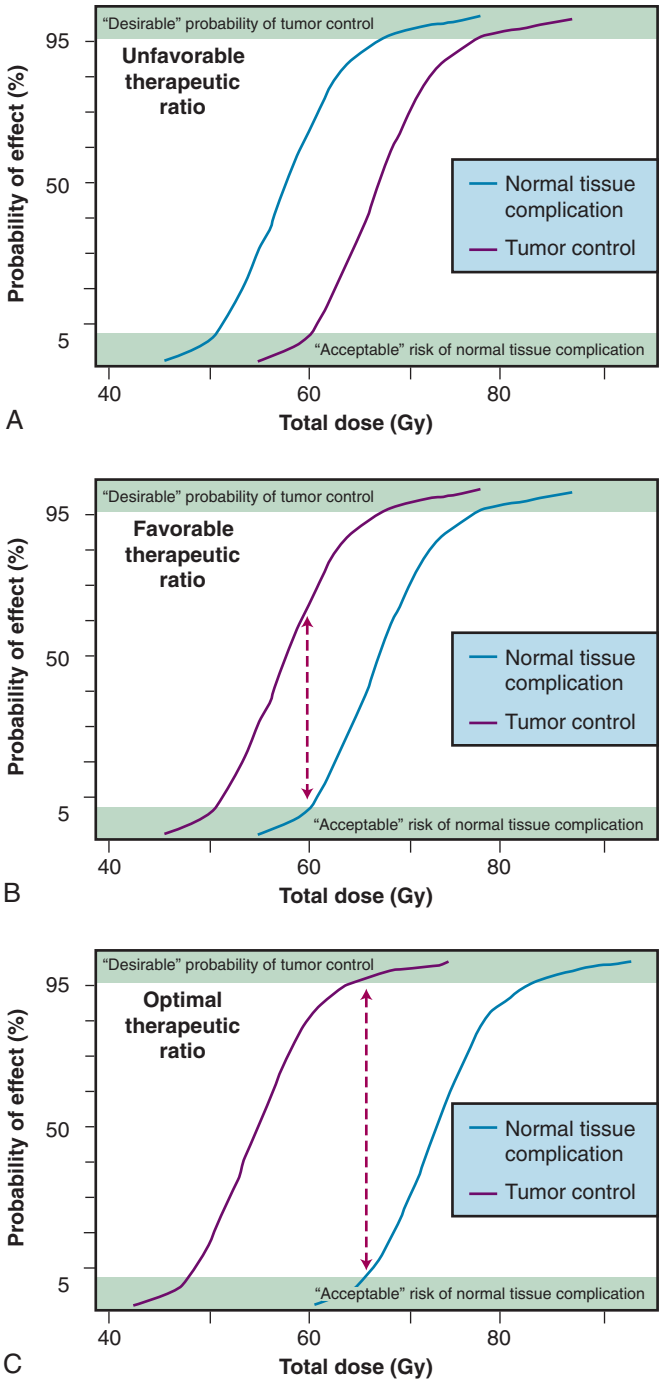

Figure 1-1 Illustrating the concept of therapeutic ratio under conditions in which the relationship between the normal tissue tolerance and tumor control dose-response curves is unfavorable *(upper panel)*, favorable *(middle panel)*, and optimal *(lower panel)*.

Many of the radiobiological properties of cells and tissues can have a favorable or adverse effect on the therapeutic ratio. Therefore, in planning a course of radiation therapy, the goal should be to optimize the therapeutic ratio as much as possible; in other words, using our graphical approach, increase the separation between the tumor control and normal tissue complication curves. This can be accomplished either by shifting the tumor control curve to the left with respect to the dose axis (toward lower doses, that is, radiosensitization), the normal tissue complication curve to the right (toward higher doses, that is, radioprotection), or perhaps, some combination of both. The key however is to shift these curves *differentially*, which is not necessarily an easy task given that there are not that many exploitable differences in the radiobiology of cells derived from tumors and those derived from normal tissues.

The Radiation Biology "Continuum"

There is a surprising continuity between the physical events that occur in the first few femtoseconds after ionizing radiation interacts with the atoms of a biomolecule and the ultimate consequences of that interaction on tissues. The consequences themselves may not become apparent until days, weeks, months, or even years after the radiation exposure. Some of the important steps in this radiobiology continuum are listed in Table 1-1. The orderly progression from one stage of the continuum to the next—from physical to physico-chemical to biochemical to biological—is particularly noteworthy not only because of the vastly different time scales over which the critical events occur, but also because of the increasing biological complexity associated with each of the endpoints or outcomes. Each stage of the continuum also offers a unique radiobiological window of opportunity: the potential to intervene in the process and thereby modify all the events and outcomes that follow.

Levels of Complexity in Radiobiological Systems

Another important consideration in all radiobiological studies is the nature of the experimental system used to study a particular phenomenon, the assay(s) used, and the endpoint(s) assessed. For example, one investigator may be interested in studying DNA damage caused by ionizing radiation, and in particular, the frequency of DNA double-stranded breaks (DSBs) produced per-unit dose. As an experimental system, he or she might choose DNA extracted from mammalian cells. Then, using a DNA elution assay, the rate at which the irradiated DNA passes through a semipermeable membrane is measured as an endpoint and compared with the rate of elution of DNA extracted from cells that had not been previously irradiated. DNA containing more DSBs elutes faster than DNA containing fewer breaks, allowing a calibration curve to be generated that relates the dose received to the elution rate. A second investigator, on the other hand, may be interested in improving the control rate of head and neck cancers with radiation therapy by employing a nonstandard fractionation schedule. In this case, the type of experiment would be a clinical trial. The experimental system would be a cohort of patients, some of whom are randomized to receive nonstandard fractionation, and the rest, standard fractionation. The endpoints assessed could be one or more of the following: loco-regional control, long-term survival, disease-free survival, normal tissue complication frequency, and so on and evaluated at specific times after completion of the radiation therapy.

In considering both the strengths and weaknesses of these two investigators' studies, any number of pertinent questions may be asked. Which is the more complex or heterogeneous system? Which is the more easily manipulated and controlled system? Which is more relevant for the day-to-day practice of radiation therapy? What kinds of results are gleaned from each, and can these results be obtained in a timely manner? In this example, it is clear that human patients with spontaneously arising tumors represent a far more heterogeneous and complex experimental system than an extract of mammalian DNA. On the other hand, the DNA system is much more easily manipulated, possible confounding factors can be more easily

TABLE 1-1 Stages in the Radiobiology Continuum

Time Scale of Events (Stage)	Initial Event	Final Event	Response Modifiers/ Possible Interventions
10^{-16} to 10^{-12} second (Physical)	Ionization of atoms	Free radicals formed in biomolecules	Type of ionizing radiation; shielding
10^{-12} to 10^{-2} second (Physico-chemical)	Free radicals formed in biomolecules	DNA damage	Presence or absence of free radical scavengers, molecular oxygen, or oxygen-mimetic radiosensitizers
1.0 second to several hours (Biochemical)	DNA damage	Unrepaired or mis-rejoined DNA damage	Presence or absence of functioning DNA damage recognition and repair systems; repair-inhibiting drugs; altering the time required to complete repair processes
Hours to years (Biological)	Unrepaired or mis-rejoined DNA damage	Clonogenic cell death; apoptosis; mutagenesis; transformation; carcinogenesis; early and late effects normal tissues; whole-body radiation syndromes; tumor control, etc.	Cell-cell interactions; biological response modifiers; adaptive mechanisms; structural and functional organization of tissues; cell kinetics; etc.

controlled, and the measurement of the desired endpoint (elution rate) plus the data analysis can be completed within a day or two. Obviously, this is not the case with the human studies, in which numerous confounding factors can and do influence results, manipulation of the system can be difficult if not impossible, and the experimental results typically take years to obtain.

The issue of relevance is an even thornier one. Arguably, both studies are relevant to the practice of radiation therapy insofar as the killing of cells is at the root of normal tissue and tumor toxicity caused by radiation, and that cell killing usually is, either directly or indirectly, a consequence of irreparable damage to DNA. As such, any laboratory findings that contribute to the knowledge base of radiation-induced DNA damage are relevant. Clearly however, clinical trials with human patients not only are a more familiar experimental system to radiation oncologists, but also efficacy in cancer patients is, ultimately, what leads to new standards of care in clinical practice, and becomes the gold standard against which all newer therapeutic strategies are judged.

All things considered then, there is a time and place both for relatively simple systems and more complex ones. The relatively simple, homogeneous, and easily manipulated systems are best suited for the study of the mechanisms of radiation action, such as measuring DNA or chromosomal damage, changes in gene expression, perturbations of the cell cycle, or the survival of irradiated cells maintained in culture. The more complicated and heterogeneous systems, with their unique endpoints, are more clinically relevant, such as assays of tumor control or normal tissue complication rates. Both types of assay systems have inherent strengths and weaknesses, yet both are critically important if we hope to improve the practice of radiation therapy based on sound biological principles.

Tissue Heterogeneity

Why is radiation therapy successful at controlling one patient's tumor but not another's, even when the two tumors seem identical? Why are we generally more successful at controlling certain types of cancers than others? The short answer to such questions is that, although the tumors may appear identical macroscopically, their component cells may be quite different phenotypically or genotypically. Also there may be important differences between the two patients' normal tissues.

Normal tissues, being composed of more than one type of cell, are somewhat heterogeneous, and tumors, owing both to the genetic instability of individual tumor cells and to microenvironmental differences, are heterogeneous. Different subpopulations of cells have been isolated from many types of human and experimental cancers, and these may differ in antigenicity, metastatic potential, and sensitivity to radiation and chemotherapy (for reviews, see Heppner et al[2], Suit et al[3]). This heterogeneity is manifest both within a particular patient, and to a much greater extent, between patients with otherwise similar tumors. Both intrinsic and extrinsic factors contribute to this heterogeneity. Intrinsic factors may include the following: inherent radiosensitivity, gene expression, biochemical repair processes, modes of cell death (e.g., mitotic catastrophe versus apoptosis), genomic instability, cell cycle kinetics, and how the tissue is structurally and functionally arranged. Extrinsic factors, on the other hand, tend to be related to physiological differences between tissues, such as the degree of vascularity, availability of oxygen and nutrients, pH, energy charge, and the proximity of, and degree of contact between, normal host tissue and the tumor.

What are the practical implications of normal tissue and tumor heterogeneity? First, if one assumes that normal tissues are the more uniform and predictable in behavior of the two, then tumor heterogeneity is responsible, either directly or indirectly, for most radiotherapy failures. If so, this suggests that a valid clinical strategy might be to identify the radioresistant subpopulation(s) of tumor cells, and then, tailor therapy specifically to cope with them. This approach is much easier said than done. Some clinical studies—both prospective and retrospective—now include one or more determinations of, for example, extent of tumor hypoxia,[4,5] or potential doubling time of tumor clonogens.[6] And although such measurements are not done routinely (because of their labor and intensiveness and longer turn-around times for results), the hope is that someday subsets of patients bearing tumors with different biological characteristics will be able to be assigned prospectively to different treatment groups.

Another consequence of tissue heterogeneity is that any radiobiological endpoint measured in an intact tissue is necessarily related to the radiosensitivities of all the subsets of cells, plus all the other intrinsic and extrinsic factors contributing to the overall response of the tissue. And because data on normal tissue tolerances and tumor control probabilities are also averaged across large numbers of patients, heterogeneity is even more pronounced.

Powers of Ten

Tumor control is achieved only when all clonogenic cells are killed or otherwise rendered unable to sustain tumor growth

indefinitely. To estimate the likelihood of cure, it is necessary to know, or at least have an appreciation for, approximately how many clonogenic cells the tumor contains, how radiosensitive these cells are (i.e., some measure of killing efficiency per unit radiation dose), and what the relationship is between the number of clonogenic cells remaining after treatment and the probability of recurrence. The latter is perhaps the easiest to ascertain, given our knowledge of both the random and discrete nature of radiation damage and the general shape of dose-response curves for mammalian cells and tissues. For a given number of surviving cells per tumor, the probability of local control can be derived from Poisson statistics using the equation $P = e^{-n}$, where P is the tumor control probability and n is the average number of surviving clonogenic tumor cells. For example, when, for a large number of tumors, an average of one clonogenic cell per tumor, remains at the end of radiation therapy, the tumor control rate will be about 37%, meaning that about 6 out of 10 tumors of the same size and relative radiosensitivity will recur. Should the treatment reduce clonogenic cell numbers to an average of 0.1 per tumor, the tumor control probability would increase to 90%, 0.05 per tumor, 95%, and 0.01 per tumor, 99%, respectively.

The tumor control probability for a given fraction of surviving cells is not particularly helpful if the total number of cells at risk is unknown, however, and this is where an understanding of logarithmic relationships and exponential cell killing is useful. Based on the resolution of existing tools and technology for cancer detection, let us assume that a 1-cm^3 (1-g) tumor mass can be identified reliably. A tumor of this size has been estimated to contain approximately 10^9 cells,[7] admittedly a theoretical value that assumes all cells are perfectly "packed" and uniformly sized and that the tumor contains no stroma. A further assumption, that all such cells are clonogenic (which is rarely, if ever, the case), suggests that at least 9 logs of cell killing would be necessary before any appreciable tumor control (about 37%) would be achieved, and 10 logs of cell killing would be required for a high degree of tumor control (i.e., 90%).

After the first log or two of cell killing however, some tumors respond by shrinking, which is a partial response. After two to three logs of cell killing, the tumor may shrink to a size below the current limits of clinical detection, that is, a complete response. Although partial and complete responses are valid clinical endpoints, a complete response does not necessarily mean tumor cure. At least six more logs of cell killing would still be required before any significant probability of cure would be expected. This explains why radiation therapy is not halted if the tumor disappears during the course of treatment; this concept is illustrated graphically in Figure 1-2.

Finally, it should be noted that although the goal of curative radiation therapy is to reduce tumor cell survival by at least nine logs, even for the smallest tumor likely to be encountered, it is much less clear how many logs of cell killing a particular normal tissue can tolerate before it loses its structural or functional integrity. This would depend on how the tissue is organized structurally, functionally, and proliferatively; which constituent cells are the most and least radiosensitive; and which cells are the most important to the integrity of the tissue. It is unlikely however that many normal tissues could tolerate a depletion of two logs (99%) of their cells, let alone nine or more logs.

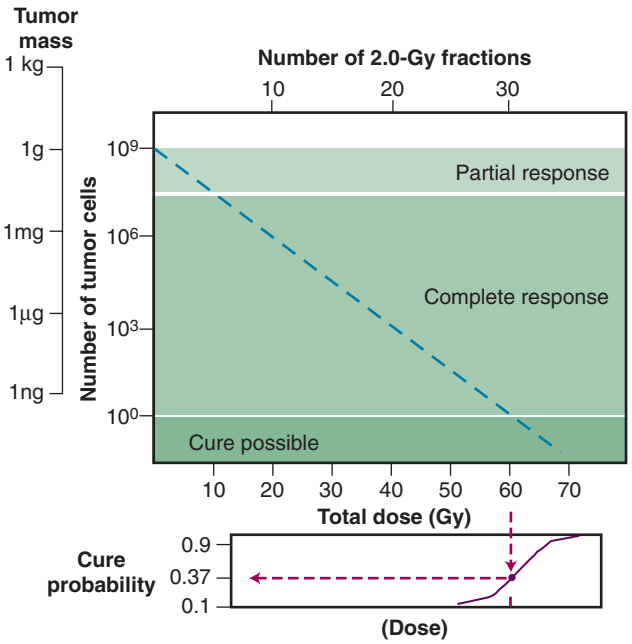

Figure 1-2 The relationship between radiation dose and tumor cell survival during fractionated radiotherapy of a hypothetical, 1-g tumor containing 10^9 clonogenic cells. Although a modest decrease in cell surviving fraction can cause the tumor to shrink (partial response) or disappear below the limits of clinical detection (complete response), few if any cures would be expected until at least 9 logs of clonogenic cells have been killed. In this example, a total dose of at least 60 Gy delivered daily, 2 Gy fractions would be required to produce a tumor control probability of 0.37, assuming each dose reduced the surviving fraction to 0.5.
Adapted from Steel G, Adams G, Peckham M, editors: The biological basis of radiotherapy, New York, 1983, Elsevier.

RADIATION BIOLOGY AND THERAPY: THE FIRST 50 YEARS

In less than four years after the discovery of x-rays by Roentgen,[8] radioactivity by Becquerel,[9] and radium by the Curies,[10] the new modality of cancer treatment known as radiation therapy claimed its first apparent cure of skin cancer.[11] Today, nearly 120 years later, radiotherapy is most commonly given as a series of small daily dose fractions of approximately 1.8 to 2.0 Gy each, 5 days per week, over a period of 5 to 7 weeks to total doses of 50 to 70 Gy. Although it is true that the historical development of this conventional radiotherapy schedule was empirically based, there were a number of early radiobiological experiments that suggested this approach.

In the earliest days of radiotherapy, both x-rays and radium were used for cancer treatment. Because of the greater availability and convenience of using x-ray tubes and the higher intensities of radiation output achievable, it was fairly easy to deliver large single doses in short overall treatment times. Thus, from about 1900 to the 1920s, this "massive-dose technique"[12] was a common way of administering radiation therapy. Unfortunately, normal tissue complications were often quite severe, and to make matters worse, the rate of local tumor recurrence was still unacceptably high.

Radium therapy was used more extensively in France. Because of the low activities available, radium applications necessarily involved longer overall treatment times to reach comparable total doses. Although extended treatments were less convenient, clinical results were often superior. Perceiving that the change in overall time was the critical factor, physicians began to experiment with the use of multiple, smaller x-ray doses delivered over extended periods. By that time, there was already a radiobiological precedent for expecting improvement in tumor control when radiation treatments were protracted.

As early as 1906, Bergonié and Tribondeau observed histologically that the immature, dividing cells of the rat testis showed evidence of damage at lower radiation doses than the mature, nondividing cells of the stroma.[13] Based on these observations, they put forth some basic laws, stating that x-rays were more effective on cells that were actively dividing, likely to continue to divide indefinitely, and poorly differentiated.[13] Because tumors were already known to contain cells that not only were less differentiated, but also exhibited greater mitotic activity, they reasoned that several radiation exposures might preferentially kill these tumor cells, but not their slowly proliferating, differentiated counterparts in the surrounding normal tissues.

The end of common usage of the single-dose technique in favor of fractionated treatment came during the 1920s as a consequence of the pioneering experiments of Claude Regaud et al.[14] Using the testes of the rabbit as a model tumor system (because the rapid and unlimited proliferation of spermatogenic cells simulated to some extent the pattern of cell proliferation in malignant tumors), Regaud showed that only through the use of multiple, smaller radiation doses could animals be completely sterilized without producing severe injury to the scrotum.[15] Regaud suggested that the superior results afforded the multifraction irradiation scheme were related to alternating periods of relative radioresistance and sensitivity in the rapidly proliferating germ cells.[16] These principles were soon tested in the clinic by Henri Coutard, who first used fractionated radiotherapy for the treatment of head and neck cancers, with, comparatively speaking, spectacularly improved results.[17,18] Largely as a result of these and related experiments, fractionated treatment subsequently became the standard form of radiation therapy.

Time-dose equivalents for skin erythema published by Reisner,[19] Quimby and MacComb,[20] and others[21,22] formed the basis for the calculation of equivalents for other tissue and tumor responses. By plotting the total doses required for each of these "equivalents" for a given level of effect in a particular tissue (as a function of a treatment parameter such as overall treatment time, number of fractions, dose per fraction, etc.) an isoeffect curve could be derived. All time-dose combinations that fell along such a curve would, theoretically, produce tissue responses of equal magnitude. Isoeffect curves, relating the total dose to the overall treatment time, which were derived in later years from some of these data,[23] are shown in Figure 1-3.

The first published isoeffect curves were produced by Strandqvist in 1944[24] and are also shown in Figure 1-3. When transformed on log-log coordinates, isoeffect curves for a variety of skin reactions and the cure of skin cancer were drawn as parallel lines, with common slopes of 0.33. These results implied that there would be no therapeutic advantage to using prolonged treatment times (i.e., multiple small fractions versus one, or a few, large doses) for the preferential eradication of tumors while simultaneously sparing normal tissues.[25] It was somewhat ironic that the Strandqvist curves were so popular in the years that followed because it was already known that the therapeutic ratio *did* increase (at least to a point) with prolonged, as opposed to very short, overall treatment times. However, the overarching advantage was that these isoeffect curves were quite reliable at predicting skin reactions, which were the dose-limiting factors at that time.

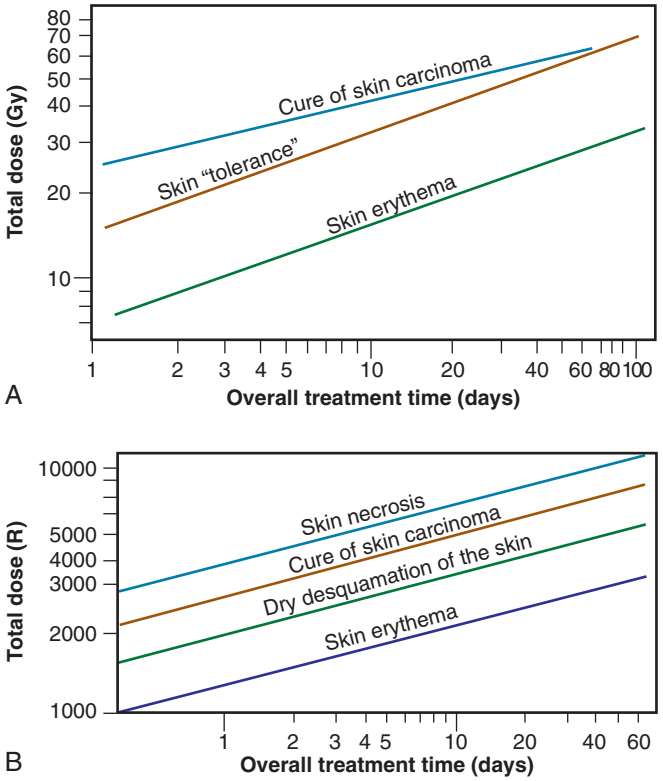

Figure 1-3 Isoeffect curves relating the log of the total dose to the log of the overall treatment time for various levels of skin reaction, and the cure of skin cancer. **A,** Isoeffect curves constructed by Cohen, based on a survey of previously published data on radiotherapy equivalents.[19-22,189] See text for details. The slope of the curves for skin complications was 0.33, and that for tumor control, 0.22. **B,** Strandqvist's[24] isoeffect curves, first published in 1944. All lines were drawn parallel, and had a common slope of 0.33.

THE GOLDEN AGE OF RADIATION BIOLOGY AND THERAPY: THE SECOND 50 YEARS

Perhaps the defining event that ushered in the golden age of radiation biology was the publication of the first survival curve for mammalian cells exposed to graded doses of ionizing radiation.[26] This first report of a quantitative measure of intrinsic radiosensitivity of a human cell line (HeLa, derived from a cervical carcinoma[27]), was published by Puck and Marcus in 1956.[26] To put this seminal work in the proper perspective, however, it is first necessary to review the physicochemical basis for why ionizing radiation is toxic to biological materials.

The Interaction of Ionizing Radiation with Biological Materials

As mentioned in the introductory section of this chapter, ionizing radiation deposits energy as it traverses the absorbing medium through which it passes. The most important feature of the interaction of ionizing radiation with biological materials is the random and discrete nature of the energy deposition. Energy is deposited in increasingly energetic packets referred to as "spurs" (100 eV or less deposited), "blobs"(100 to 500 eV), or "short tracks" (500 to 5000 eV), each of which can leave from approximately three to several dozen ionized atoms in its wake. This is illustrated in Figure 1-4, along with a segment of (interphase) chromatin shown to scale. The

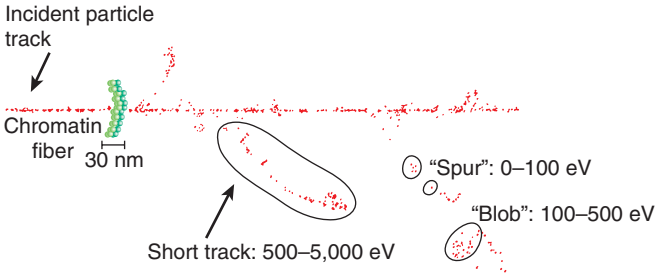

Figure 1-4 Hypothetical α-particle track through an absorbing medium, illustrating the random and discrete energy deposition events along the track. Each event can be classified according to the amount of energy deposited locally, which in turn determines how many ionized atoms will be produced. A segment of chromatin is also shown, approximately to scale.
Adapted from Goodhead DT: Physics of radiation action: microscopic features that determine biological consequences. In Hagen U, Harder D, Jung H, et al, editors: Radiation research 1895-1995, Proceedings of the 10th International Congress of Radiation Research. Volume 2: Congress Lectures, Wurzburg, 1995, Universitatsdruckerei H. Sturtz AG, pp 43-48.

frequency distribution and density of the different types of energy deposition events along the track of the incident photon or particle are measures of the radiation's linear energy transfer or LET (see also the "Relative Biological Effectiveness" section later in this chapter). Because these energy deposition events are discrete, it follows that although the average energy deposited in a macroscopic volume of biological material is rather modest, the distribution of this energy on a microscopic scale may be quite large. This explains why ionizing radiation is so efficient at producing biological damage; the total amount of energy deposited in a 70-kg human that will result in a 50% probability of death is only about 70 calories, which is about as much energy as is absorbed by drinking one sip of hot coffee.[28] The key difference is that the energy contained in the sip of coffee is uniformly distributed, not random and discrete.

Those biomolecules receiving a direct hit from a spur or blob receive, relatively speaking, a huge radiation dose, that is, a large energy deposition in a small volume. For photons and charged particles, this energy deposition results in the ejection of orbital electrons from atoms, causing the target molecule to be converted first into an ion pair and then into a free radical. Further, the ejected electrons—themselves energetic charged particles—can go on to produce additional ionizations. For uncharged particles such as neutrons, the interaction is between the incident particles and the nuclei of the atoms in the absorbing medium, causing the ejection of recoil protons (charged) and lower energy neutrons. The cycle of ionization, free radical production, and release of secondary charged particles continues until all the energy of the incident photon or particle is expended. These interactions are complete within a picosecond after the initial energy transfer. After that time, the chemical reactions of the resulting free radicals predominate the radiation response (see below).

Any and all cellular molecules are potential targets for the localized energy deposition events that occur in spurs, blobs, or short tracks. Whether the ionization of a particular biomolecule results in a measurable biological effect depends on a number of factors including how probable a target the molecule represents from the point of view of the ionizing particle, how important the molecule is to the continued health of the cell, how many copies of the molecule are normally present in the cell and to what extent the cell can react to the loss of working copies, how important the cell is to the structure or function of its corresponding tissue or organ, and so on. DNA for example is obviously an important cellular macromolecule and one that is present only as a single, double-stranded copy. On the other hand, other molecules in the cell may be less crucial to survival, yet are much more abundant than DNA, and therefore have a much higher probability of being hit and ionized. By far, the most abundant molecule in the cell is water, comprising some 70% to 80% of the cell on a per-weight basis. The highly reactive free radicals formed by the radiolysis of water are capable of augmenting the DNA damage resulting from direct energy absorption by migrating to the DNA and damaging it indirectly. This mechanism is referred to as indirect radiation action to distinguish it from the aforementioned direct radiation action.[29] The direct and indirect action pathways for ionizing radiation are illustrated next.

Direct Effect

$$\mathrm{DNA} \underset{\text{(irradiate)}}{\rightarrow} [\mathrm{DNA}^{+} + \mathrm{e}^{-}] \underset{\text{(ion pair)}}{\rightarrow} \underset{\text{(DNA free radical)}}{\mathrm{DNA}^{\bullet}}$$

Indirect Effect

$$\mathrm{H_2O} \underset{\text{(irradiate)}}{\rightarrow} [\mathrm{H_2O}^{+} + \mathrm{e}^{-}] \underset{\text{(ion pair)}}{\rightarrow} \underset{\substack{\text{(other radical reactions)}}}{\bullet\mathrm{OH} + \mathrm{DNA} \rightarrow \underset{\text{(DNA free radical and water)}}{\mathrm{DNA}^{\bullet} + \mathrm{H_2O}}}$$

The most highly reactive and damaging species produced by the radiolysis of water is the hydroxyl radical (•OH), although other free radical species are also produced in varying yields.[30,31] Cell killing by indirect action constitutes some 70% of the total damage produced in DNA for low LET radiation.

How do the free radicals produced by the direct and indirect action of ionizing radiation go on to cause the myriad lesions that have been identified in irradiated DNA? Because they contain unpaired electrons, free radicals are highly reactive chemically and will undergo multiple reactions in an attempt to either acquire new electrons, or rid themselves of remaining unpaired ones. These reactions are considered quite slow compared to the time scale of the initial ionization events but are still fast relative to normal enzymatic processes in a typical mammalian cell. For all intents and purposes, free radical reactions are complete in milliseconds after irradiation. The •OH radical is capable of both abstraction of hydrogen atoms from other molecules and addition across carbon-carbon or other double bonds. More complex macromolecules that have been converted to free radicals can undergo a series of transmutations in an attempt to rid themselves of unpaired electrons, many of which result in the breakage of nearby chemical bonds. In the case of DNA, these broken bonds may result in the loss of a base or an entire nucleotide, or a frank scission of the sugar phosphate backbone, involving either one or both DNA strands. In some cases, chemical bonds are broken initially but then are rearranged, exchanged, or rejoined in inappropriate ways. Bases in DNA may be modified by the addition of one or more hydroxyl groups (e.g., the base thymine converted to thymine glycol), pyrimidines may become dimerized, or the DNA may become cross-linked to itself or to associated protein components. And again, because the initial energy deposition events are discrete, the free radicals produced also are clustered, and therefore, undergo their multiple chemical reactions and produce multiple damages in a highly localized area. This has been termed the "multiply-damaged site"[32] or "cluster"[33] hypothesis. Examples of the types of damage found in irradiated DNA are shown in Figure 1-5.

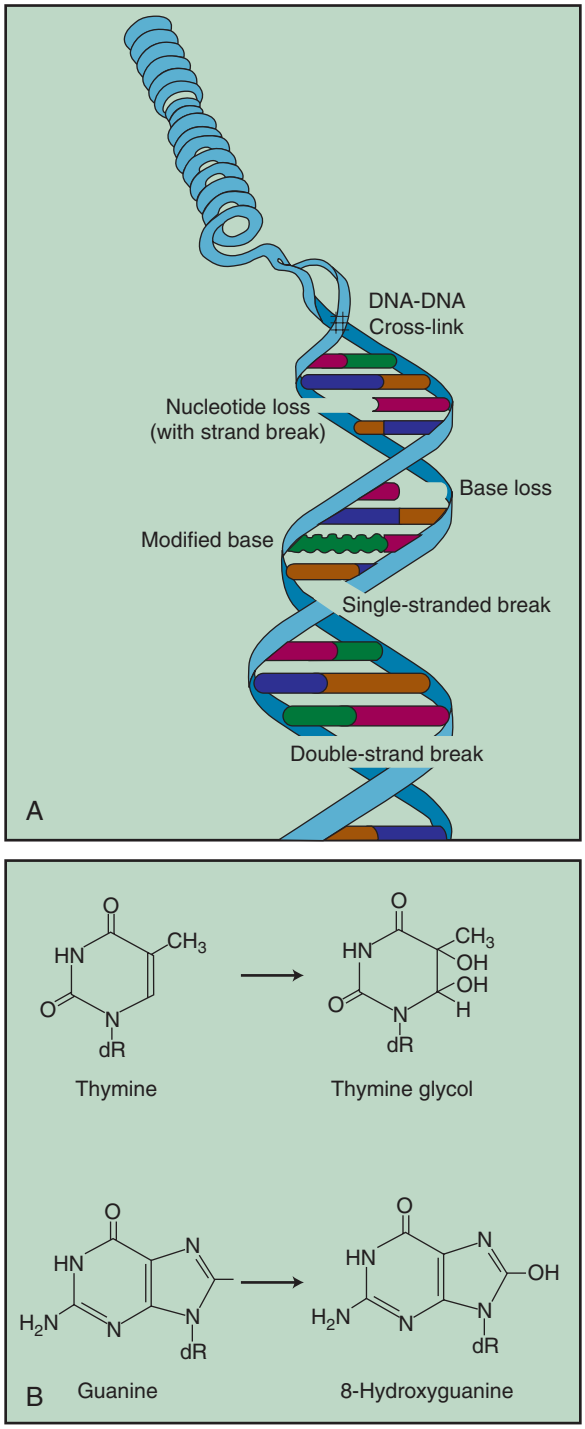

Figure 1-5 Types of DNA damage produced by ionizing radiation. **A,** Segment of irradiated DNA containing single- and double-stranded breaks, cross-links, and base damage. **B,** Two types of modified bases observed in irradiated DNA include thymine glycol, which results from the addition of two hydroxyl (OH) groups across the carbon-carbon double bond of thymine, and 8-hydroxyguanine, produced by •OH radical addition to guanine.

Biochemical Repair of DNA Damage

DNA is unique insofar as it is the only cellular macromolecule with its own repair system. Until as recently as 30 years ago, little was known about DNA repair processes in mammalian cells, particularly because of the complexities involved and the relative lack of spontaneously occurring mutants defective in genes involved with DNA repair. As a result, most studies of DNA repair were carried out either in bacteria or yeasts and usually employed ultraviolet (UV) radiation as the tool for producing DNA damage. Although these were rather simple and relatively clean systems in which to study DNA repair, their relevance to mammalian repair systems, and to the broader spectrum of DNA damage produced by ionizing radiation, ultimately limited their usefulness.

The study of DNA repair in mammalian cells received a significant boost during the late 1960s with publications by Cleaver[34,35] that identified the molecular defect responsible for the human disease xeroderma pigmentosum (XP). Patients with XP are exquisitely sensitive to sunlight and highly prone to (skin) cancer. Cleaver showed that cells derived from such patients were likewise sensitive to UV radiation and defective in the nucleotide excision repair pathway (see discussion in this chapter). These cells were not especially sensitive to ionizing radiation however. Several years later, Taylor et al[36] reported that cells derived from patients with a second cancer-prone disorder, ataxia telangiectasia (AT), were extremely sensitive to ionizing radiation and radiation-mimetic drugs, however not UV radiation. In the years that followed, cell cultures derived from patients with these two conditions were used to help elucidate the complicated processes of DNA repair in mammalian cells. Today, dozens of other clinical syndromes associated with either radiosensitivity, cancer proneness, or both have been identified.[37,38]

Today, many rodent and human genes involved in DNA repair have been cloned and extensively characterized.[39] Some 30 to 40 proteins participate in excision repair of base damage and about half that many are involved in the repair of strand breaks.[37] Many of these proteins function as component parts of larger repair complexes; some of these parts are interchangeable and participate in other DNA repair and replication pathways as well. It is also noteworthy that some are not involved with the repair process per se, but rather link DNA repair to other cellular functions, including transcription, cell cycle arrest, chromatin remodeling, and apoptosis.[40] This attests to the fact that the maintenance of genomic integrity results from a complex interplay between not only the repair proteins themselves, but also with others that serve as damage sensors, signaling mediators and transducers, and effectors. Collectively, this complex network of proteins that sense, initiate, and coordinate DNA damage signaling and repair with other cellular activities is termed the *DNA damage response* (DDR).[37,41] For example, the defect responsible for the disease AT is not in a gene that codes for a repair protein, but rather in a gene that acts as a damage sensor and also participates in the related pathway that normally prevents cells from entering S phase and beginning DNA synthesis while residual DNA damage is present. This is the *G_1 cell cycle checkpoint response*.[42] Because of this genetic defect, AT cells do not experience the normal G_1 arrest after irradiation, and they enter S phase with residual DNA damage. This accounts both for the exquisite radiosensitivity of AT cells and the resulting genomic instability that can lead to carcinogenesis.

The molecular and biochemical intricacies of DNA repair in mammalian cells are described in detail in Chapter 2, however a brief overview is also presented here.

Base Excision Repair

The repair of base damage is initiated by DNA repair enzymes, *glycosylases*, which recognize specific types of damaged bases and excise them without otherwise disturbing the DNA strand.[43] The action of the glycosylase results in the formation of another type of damage observed in irradiated DNA—an apurinic or apyrimidinic (AP) site. The AP site is then

recognized by another repair enzyme, an endonuclease that nicks the DNA adjacent to the lesion, in effect creating a DNA single-stranded break. This break then becomes the substrate for an exonuclease, which removes the abasic site along with a few additional bases. The small gap that results is patched by DNA polymerase using the opposite, and hopefully undamaged, DNA strand as a template. Finally, DNA ligase seals the patch in place.

Nucleotide Excision Repair

The DNA glycosylases that begin the process of base excision repair do not recognize all known forms of base damage however, particularly bulky or complex lesions.[43] In such cases, another group of enzymes, *structure-specific endonucleases*, initiate the excision repair process. These repair proteins do not recognize the specific lesion, but they are thought instead to recognize more generalized structural distortions in DNA, which necessarily accompany a complex base lesion. The structure-specific endonucleases incise the affected DNA strand on both sides of the lesion, releasing an oligonucleotide fragment made up of the damage site and several bases on either side of it. After this step, the remainder of the nucleotide excision repair process is similar to that of base excision repair; the gap is then filled by DNA polymerase and sealed by DNA ligase.

For both types of excision repair, active genes in the process of transcription are repaired preferentially and more quickly. This has been termed *transcription-coupled repair*.[44]

Single-Stranded Break Repair

Single-stranded breaks in the DNA backbone are common lesions, produced in the tens of thousands per day as part of normal cellular metabolism,[45] as well as any additional breaks introduced by radiation exposure. These are repaired using the machinery of excision repair, that is, gap filling (if any) by DNA polymerase and sealing by DNA ligase.

Double-Stranded Break Repair

Despite the fact that unrepaired or mis-rejoined DSBs often have the most catastrophic consequences for the cell in terms of loss of reproductive integrity,[46] how mammalian cells repair these lesions has been more difficult to elucidate than how they repair base damage. Much of what was originally discovered about these repair processes is derived from studies of rodent cells that were sensitive to x-rays and that were later discovered to harbor specific defects in strand break repair.[47] Since then, dozens of other rodent and human cells characterized by DDR defects have been identified and are also used to help probe these fundamental processes.

With respect to the repair of DSBs, the situation is more complicated in that the damage on each strand of DNA may be different, and therefore, no intact template would be available to guide the repair process. Under these circumstances, cells must rely on an error-prone process that rejoins the break(s) regardless of the loss of intervening base pairs for which there is no template (nonhomologous end joining [NHEJ]) or else depend on genetic recombination in which a template for presumably error-free repair is obtained from recently replicated DNA of a sister chromatid (homologous recombination [HR])[48] to cope with the damage. NHEJ occurs throughout the cell cycle but predominates in cells that have not yet replicated their DNA in anticipation of a subsequent cell division, that is, cells in the G_1 or G_0 phases of the cell cycle. NHEJ involves a heterodimeric enzyme complex consisting of the proteins Ku-70 and Ku-80, the catalytic subunit of DNA protein kinase ($DNA\text{-}PK_{CS}$), and DNA ligase IV. Cells that have already replicated most or all of their DNA—in the late S or G_2 phases of the cell cycle—depend on HR to repair DSBs. HR involves the assembly of a nucleoprotein filament that contains, among others, the proteins Rad51 and Rad52. This filament then invades the homologous DNA sequence of a sister chromatid, which becomes the template for repair. The BRCA2 protein is also implicated in HR as it interacts with the Rad51 protein.[38] Defects in either the *BRCA1* (which helps determine which DSB repair pathway will be used in a particular situation) or *BRCA2* genes are associated with hereditary breast and ovarian cancer.[49]

Mismatch Repair

The primary role of mismatch repair (MMR) is to eliminate from newly synthesized DNA errors such as base/base mismatches and insertion/deletion loops caused by DNA polymerase.[50] Descriptively, this process consists of three steps: mismatch recognition and assembly of the repair complex, degradation of the error-containing strand, and repair synthesis. In humans, MMR involves at least five proteins, including hMSH2, hMSH3, hMSH6, hMLH1, and hPMS2, as well as other members of the DNA repair and replication machinery.

Radiation-induced DNA lesions are not targets for MMR per se; however, one manifestation of a defect in MMR is germane to any study of oncogenesis: genomic instability,[51] which renders affected cells hypermutable. This mutator phenotype is associated with several cancer predisposition syndromes, in particular, hereditary nonpolyposis colon cancer ([HNPCC], sometimes called Lynch syndrome).[52,53] Genomic instability is considered one of the main enablers of nonmalignant cells to accumulate cancer-causing mutations and also drives tumor progression to more aggressive and potentially treatment-resistant phenotypes.

The DDR as a Clinical Target

Historically, attempts to inhibit the repair of radiation-induced DNA damage were of interest to researchers probing these fundamental processes; however, clinical translation was typically lacking, mostly out of concern that normal tissues would also be affected in an adverse way. More recently however, it has become clear that the cells of many tumors harbor one or more defects in the DDR, as a consequence of genomic instability, that are not present in normal cells and that this difference might be exploitable clinically.

One approach along these lines currently in clinical trials is the use of inhibitors of the protein poly(ADP-ribose) polymerase (PARP).[54,55] As of 2012, nearly a dozen trials, most in Phase I or II, were under way using PARP inhibitors.[37,55] PARP is an enzyme involved in the repair of DNA damage by base excision repair and SSB repair; its inhibition leads to the persistence of existing SSBs as well as the creation of new ones. If left unrejoined, these breaks can cause the collapse of replication forks in DNA that then impede both DNA replication and HR repair,[55] leading to radiosensitization and ultimately, cell death.[56]

In normal cells, little or no toxicity caused by PARP inhibition would be expected because all DDR pathways are intact and salvage repair pathways to bypass PARP inhibition are active. In tumor cells harboring defects in HR however, salvage pathways are typically dysregulated or absent, suggesting that PARP inhibition would be preferentially toxic to such repair-defective cells. One clinical example is the targeting of breast cancers harboring cellular defects in the BRCA1 and BRCA2 proteins—which either orchestrate or are directly involved in HR—for PARP inhibition. This overall approach of using the combined lethal effect of two genetic defects (one inherent HR defect, plus an additional synthetic one induced by PARP inhibition) that are otherwise nonlethal singly is termed *synthetic lethality*.[54-56] Approaches using synthetic lethality

targeting DDR proteins (including those other than PARP) likely will play increasingly important roles in the future.

Cytogenetic Effects of Ionizing Radiation

When cells divide following radiation exposure, chromosomes frequently contain visible structural aberrations, most of which are lethal to the cell. In some cases, these aberrations physically interfere with the processes of mitosis and cytokinesis and result in prompt cell death. In other cases, cell division can occur, but the loss or uneven distribution of genetic material between the cell's progeny is ultimately lethal as well, although the affected cells may linger for several days before they die (some may even be able to go through a few more cell divisions in the interim). It is clear that these aberrations are the result of any unrepaired or mis-rejoined DNA damage that persists from the time of irradiation until the time of the next cell division.

Most chromosome aberrations result from an interaction between two damage sites, and therefore, can be grouped into three different types of "exchange" categories. A fourth category is reserved for those chromosome aberrations that are thought to result from a single damage site.[57] These categories are described here, and representative types of aberrations from each category are also shown in Figure 1-6:

1. *Intraarm Exchanges*: an interaction between lesions on the same arm of a single chromosome (e.g., interstitial deletion).
2. *Interarm Exchanges*: an interaction between lesions on opposite arms of the same chromosome (e.g., centric ring).
3. *Interchanges*: an interaction between lesions on different chromosomes, either homologous or nonhomologous (e.g., dicentric).
4. *"Single-Hit" Breaks*: the complete severance of part of one arm of a single chromosome not obviously associated with any more than a single lesion (e.g., terminal deletion).

These four categories can be further subdivided according to whether the initial radiation damage occurred before or after the DNA is replicated during S phase of the cell cycle (a chromosome- vs. chromatid-type aberration, respectively), and, for the three exchange categories, whether the lesion interaction was symmetrical or asymmetrical. Asymmetrical exchanges always lead to the formation of acentric fragments, which are usually lost in subsequent cell divisions and therefore are nearly always fatal to the cell. These fragments may be retained transiently in the cell's progeny as extranuclear chromatin bodies, micronuclei. Symmetrical exchanges are more insidious in that they do not lead to the formation of acentric fragments and the accompanying loss of genetic material at the next cell division, they are sometimes difficult to detect cytologically, and they are not invariably lethal to the cell. As such, they will be transmitted to all the progeny of the original cell. Some types of symmetrical exchanges (e.g., a reciprocal translocation) have been implicated in radiation carcinogenesis, insofar as they have the net effect of either bringing new combinations of genes together or separating preexisting groups of genes.[28] Depending on where in the genome the translocation takes place, genes normally on could be turned off or vice versa, possibly with adverse consequences.

Quantitation of the types and frequencies of chromosome aberrations in irradiated cells can be used to probe dose-response relationships for ionizing radiation, and to a first approximation, they also can serve as a radiation dosimeter. For example, the dose-response curve for the induction of exchange-type aberrations after exposure to low LET radiation

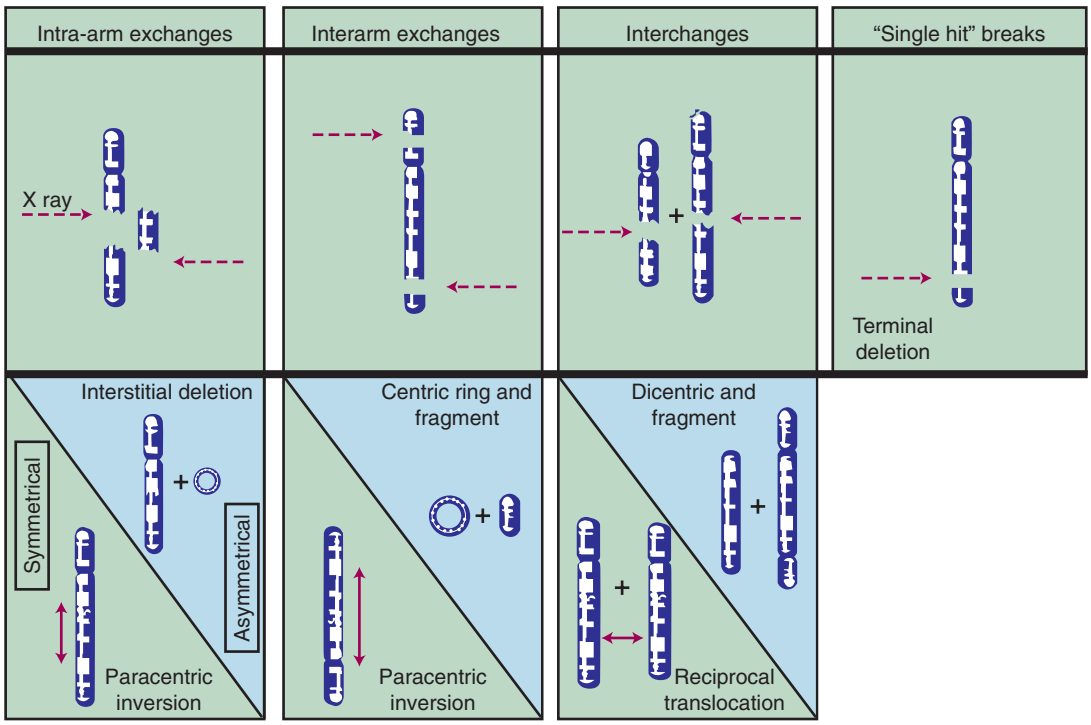

Figure 1-6 Types of radiation-induced chromosome aberrations that are the result of unrepaired or mis-rejoined DNA damage. Aberrations are classified according to whether they involve a single or multiple chromosomes, whether the damage is thought to be caused by the passage of a single charged particle track (one-hit aberration), or by the interaction of damages produced by two different tracks (two-hit aberration), and whether the irradiation occurred before or after the chromosomes had replicated (chromosome- vs. chromatid-type aberrations, respectively; only chromosome-type aberrations are shown). The aberrations can be further subdivided according to whether broken pieces of the chromosome rearrange themselves symmetrically (with no net loss of genetic material) or asymmetrically (acentric fragments produced).

tends to be linear-quadratic in shape, whereas that for single hit aberrations tends to be linear. In mathematical terms, the incidence, *I*, of a particular aberration as a function of radiation dose, *D*, can be expressed as:

$$I = \alpha D + \beta D^2 + c \quad \text{for exchange-type aberrations}$$
$$I = \alpha D + c \quad \text{for single hit aberrations}$$

where α and β are proportionality constants related to the yields of the particular type of aberration, and *c* is the spontaneous frequency of that aberration in unirradiated cells. For fractionated doses or continuous low dose rates of low LET radiation, the yield of exchange type aberrations decreases relative to that for acute doses, and the dose-response curve tends to become more linear. For high LET radiations, dose-response curves for aberration induction become steeper (higher aberration yields) and more linear compared to those for low LET radiations.

Cell Survival Curves and Survival Curve Theory

What Is Cell Death?

The traditional definition of death as a permanent, irreversible cessation of vital functions is not the same as what constitutes death to the radiation biologist or oncologist. For proliferating cells, including those maintained in vitro, the stem cells of normal tissues and tumor clonogens, cell death in the radiobiological sense refers to a loss of reproductive integrity, that is, an inability to sustain proliferation indefinitely. This type of reproductive or clonogenic death does not preclude the possibility that a cell may remain physically intact, metabolically active, and continue its tissue-specific functions for some time after irradiation. In fact, some reproductively dead cells can even complete a few additional mitoses before death in the more traditional sense.[58]

Compared to nearly 60 years ago, when the term *clonogenic death* was first coined and used as an endpoint in assays of cellular radiosensitivity,[26,59] it is now clearly an operationally defined term that encompasses several distinct mechanisms by which cells die, all of which result in a cell losing its ability to divide indefinitely. These modes of cell death include mitotic catastrophe, apoptosis, autophagy, necrosis, senescence, and strictly speaking, differentiation as well because differentiated cells lose their ability to divide.[60,61]

Mitotic catastrophe is the major cause of radiation-induced death for most mammalian cells, and occurs secondary to chromosome aberrations or spindle defects that interfere with the cell-division process.[62,63] Accordingly, this type of cell death occurs during or soon after an attempted cell division after irradiation (although not necessarily at the first division attempt) and leaves in its wake large, flattened, and multinucleated cells that are typically aneuploid. Apoptosis, or programmed cell death, is a type of nonmitotic or interphase death commonly associated with embryonic development and normal tissue remodeling and homeostasis.[64] However, certain normal tissue and tumor cells also undergo apoptosis following irradiation, including normal cells of hematopoeitic or lymphoid origin, crypt cells of the small intestine, salivary gland cells, plus some experimental tumor cell lines of gynecological and hematological origin.[65] Cells undergoing apoptosis exhibit a number of characteristic morphological (nuclear condensation and fragmentation, membrane blebbing, etc.) and biochemical (DNA degradation) changes that culminate in the fragmentation and lysis of the cell, often within 12 hours of irradiation and before the first postirradiation mitosis. Ultimately, the remains of apoptotic cells are phagocytized by neighboring cells, and therefore do not cause the type of inflammatory response, tissue destruction, and disorganization characteristic of necrosis. Apoptosis is an active and carefully regulated pathway that involves several genes and gene products and an appropriate stimulus that activates the pathway. The molecular biology of apoptosis, the apoptosis-resistant phenotype noted for many types of tumor cells, and the role that radiation may play in the process are discussed in detail in Chapter 2. Senescence refers to a type of genetically controlled cellular growth arrest that, although not eliminating damaged cells, does halt permanently their continued movement through the cell cycle, even in the presence of growth factors.[66] Radiation can also induce senescence, presumably as a result of the permanent triggering of cell cycle checkpoints; however it might better be termed *radiation-induced permanent growth arrest*, to distinguish it from the normal process of cell-age–related senescence.[67] The roles played by autophagy and necrosis, which are two additional modes of cell death that usually occur in response to diverse types of cellular stress, remain unclear with respect to radiation-induced cell death. Autophagy is defined as the controlled lysosomal degradation of cytoplasmic organelles or other cytoplasmic components[68,69] in response to cellular stressors, including nutrient deprivation, hypoxia, DNA damage, or an excess of reactive oxygen species. Likewise, necrosis—characterized by cell swelling followed by membrane rupture and the release of cellular contents into the extracellular space—can occur as a somewhat passive response to nutrient deprivation, but it also can follow a molecular program initiated by immune cells or various toxins.[70,71]

Most assays of radiosensitivity of cells and tissues, including those described in this chapter, use reproductive integrity, either directly or indirectly, as an endpoint. Although such assays have served the radiation oncology community well in terms of elucidating dose-response relationships for normal tissues and tumors, it is now clear that reproductive death is not necessarily the whole story. What remains unclear is whether and to what extent other modes of cell death, particularly apoptosis, contribute to our traditional measures of radiosensitivity based on clonogenic survival, and whether, for example, pretreatment assessment of apoptotic propensity in tumors or dose-limiting normal tissues is of prognostic significance. The interrelationships between these different pathways of cell death can be quite complex. Meyn[65] has suggested that a tumor with a high spontaneous apoptotic index may be inherently more radiosensitive because cell death might be triggered by lower doses than are usually required to cause reproductive death. Also, tumors that readily undergo apoptosis may have higher rates of cell loss, the net effect of which would be to partially offset cell production, thereby reducing the number of tumor clonogens. On the other hand,, recent studies suggest that the caspases that orchestrate the removal of radiation-damaged cells via apoptosis also may stimulate tumor cell repopulation during and after radiotherapy,[72] which is a decidedly undesirable outcome.

Cell Survival and Dose-Response Curve Models

Survival curve theory originated in a consideration of the physics of energy deposition in matter by ionizing radiation. Early experiments with macromolecules and prokaryotes established that dose-response relationships could be explained, in principle, by the random and discrete nature of energy absorption, if it was assumed that the response resulted from critical "targets" receiving random "hits."[73] With an increasing number of shouldered survival and dose response curves being described for cells irradiated both in vitro and in vivo, various equations were developed to fit these data. Target theory pioneers studied a number of different endpoints in the context of target theory, including enzyme

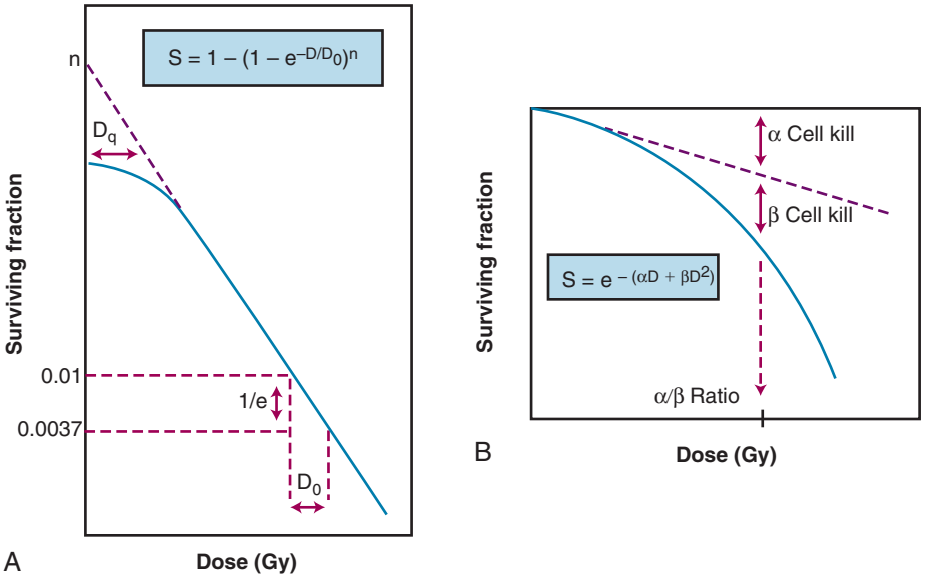

Figure 1-7 A comparison of two mathematical models commonly used to fit cell survival curve data. Left panel: The single-hit, multitarget model and its associated parameters, D_0, n, and D_q. Although this model has since been invalidated, values for its parameters are still used for comparative purposes. Right panel: The linear-quadratic model and its associated parameters, α and β. This model forms the basis for current isoeffect formulae used in radiation therapy treatment planning.

inactivation in cell-free systems,[29] cellular lethality, chromosomal damage, and radiation-induced cell cycle perturbations in microorganisms.[29,74] Survival curves, in which the log of the survival of a certain biological activity was plotted as a function of the radiation dose, were found to be either exponential or sigmoid in shape with the latter usually noted for the survival of more complex organisms.[29]

Exponential survival curves were thought to result from the single-hit, "all-or-nothing," inactivation of a single target, resulting in the loss of activity. A mathematical expression used to fit this type of dose-response relationship was $S = e^{-D/D_0}$. In this equation, S is the fraction of cells that survive a given dose; D and D_0 are the dose increment that reduces the cell survival to 37% (1/e) of some initial value on the exponential portion of the curve (i.e., a measure of the reciprocal of the slope). The sigmoid curves, characterized by a shoulder at low doses, were consistent with target theory if one assumed that either multiple targets or multiple hits in a single target (or a combination of both) were necessary for radiation inactivation. A mathematical expression based on target theory that provided a fairly good fit to survival data was $S = 1 - (1 - e^{-D/D_0})^n$, with n being the back extrapolation of the exponential portion of the survival curve to zero dose. Implicit in this multitarget model was that damage had to accumulate before the overall effect was registered.

It soon became apparent that some features of this model were inadequate.[75] The most obvious problem was that the single-hit, multitarget equation predicted that survival curves should have initial slopes of zero, that is, that for vanishingly small doses (e.g., repeated, small doses per fraction or continuous low-dose rate exposure), the probability of cell killing would approach zero. This was *not* what was observed in practice for either mammalian cell survival curves or as inferred from clinical studies in which highly fractionated or low-dose rate treatment schedules were compared to more conventional fractionation. There was no fractionation schedule that produced essentially no cell killing, that is, all other radiobiological factors being equal.

A somewhat different interpretation of cell survival was proposed by Kellerer and Rossi[76] in the late 1960s and early 1970s. The linear-quadratic or alpha-beta equation, $S = e^{-(\alpha D + \beta D^2)}$, was shown to fit many survival data quite well, particularly in the low-dose region of the curve, and also provided for the negative initial slope investigators had described.[75] In this expression, S is again the fractional cell survival following a dose D, α is the rate of cell kill by a single-hit process, and β is the rate of cell kill by a two-hit mechanism. The theoretical derivation of the linear-quadratic equation is based on two different sets of observations. Based on microdosimetric considerations, Kellerer and Rossi[76] proposed that a radiation-induced lethal lesion resulted from the interaction of two sublesions. According to this interpretation, the αD term is the probability of these two sublesions being produced by a single event (the "intratrack" component), whereas βD^2 is the probability of the two sublesions being produced by two separate events (the "intertrack" component). Chadwick and Leenhouts[77] derived the same equation based on a different set of assumptions, namely that a DSB in DNA was a lethal lesion and that such a lesion could be produced by either a single energy deposition involving both strands of DNA or by two separate events, each involving a single strand.

A comparison of the features and parameters of the target theory and linear-quadratic survival-curve expressions is shown in Figure 1-7.

Clonogenic Assays In Vitro

As mentioned previously, it was not until the mid-1950s that mammalian cell culture techniques were sufficiently refined to allow quantitation of the radiation responses of single cells.[59,78] Puck and Marcus'[26] acute-dose, x-ray survival curve for the human tumor cell line HeLa, is shown in Figure 1-8. Following graded x-ray doses, the reproductive integrity of single HeLa cells was measured by their ability to form macroscopic colonies of at least 50 cells (corresponding to approximately 6 successful postirradiation cell divisions) on petri dishes. A number of features of this survival curve were of particular interest. First, qualitatively at least, the curve was similar in shape to those previously determined for many microorganisms and was characterized by a shoulder at low doses and a

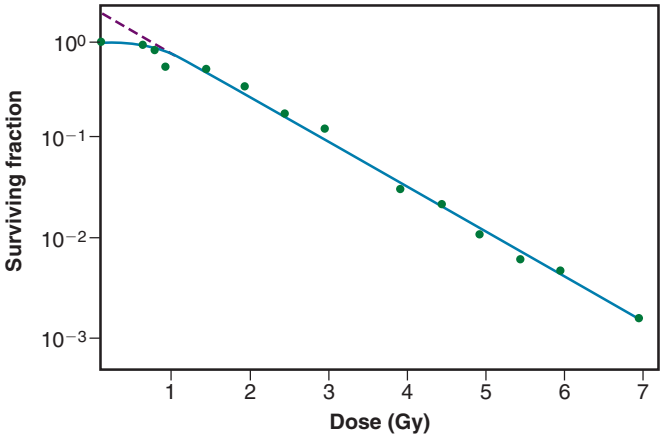

Figure 1-8 Clonogenic survival of HeLa cells in vitro as a function of x-ray dose. Like many mammalian cells of tumorigenic and nontumorigenic origin, the HeLa cell survival curve is characterized by a modest initial shoulder region (n = 2.0) followed by an approximately exponential final slope ($D_0 \approx 1.0$ Gy).
Adapted from Puck TT, Marcus PI: Action of x rays on mammalian cells. J Exp Med 103:653, 1956; copyright permission of The Rockefeller University Press.

roughly exponential region at high doses. Of note, however, was the finding that the D_0 for HeLa cells was only 96 R, which was some 10- to 100-fold less than D_0 determined for microorganisms, and 1,000- to 10,000-fold less than D_0 for the inactivation of isolated macromolecules.[58] Thus, cellular reproductive integrity was found to be a much more radiosensitive endpoint for HeLa cells than for prokaryotes or primitive eukaryotes. The value of the extrapolation number, n, was approximately 2.0, indicating that the survival curve did have a small shoulder, but again, much smaller than typically observed for microorganisms. Puck and Marcus suggested that the n value was a reflection of the number of critical targets in the cell, each requiring a single hit before the cell would be killed, and they further postulated that the targets were, in fact, the chromosomes themselves.[26] However, the potential pitfalls of deducing mechanisms of radiation action from parameters of a descriptive survival curve model were soon realized.[79,80]

Survival curves for other types of mammalian cells, regardless of whether they were derived from humans or laboratory animals or from tumors or normal tissues, have been shown to be qualitatively similar to the original HeLa cell survival curve.

Clonogenic Assays In Vivo

To bridge the gap between the radiation responses of cells grown in culture and in an animal, Hewitt and Wilson developed an ingenious method to assay single cell survival in vivo.[81] Lymphocytic leukemia cells obtained from the livers of donor CBA mice were harvested, diluted, and inoculated into disease-free recipient mice. By injecting different numbers of donor cells, a standard curve was constructed that allowed a determination of the average number of injected cells necessary to cause leukemia in 50% of the recipient mice. It was determined that the endpoint of this titration, the "50% take dose" or TD_{50}, corresponded to an innoculum of a mere two leukemia cells. Using this value as a reference, Hewitt and Wilson then injected leukemia cells harvested from γ-irradiated donor mice into recipients and again determined the TD_{50} following different radiation exposures. In this way, the surviving fraction after a given radiation dose could be calculated from the ratio of the TD_{50} for unirradiated cells to that for the irradiated cells. Using this technique, a complete survival curve was constructed that had a D_0 of 162 R, and an n value close to 2.0, which were values quite similar to those generated for cell lines irradiated in vitro. For the most part, in vivo survival curves for a variety of cell types were also similar to corresponding in vitro curves.

A similar trend was apparent when in vivo survival curves for nontumorigenic cells were first produced. The first experiments by Till and McCulloch,[82,83] using normal bone marrow stem cells, were inspired by the knowledge that failure of the hematopoietic system was a major cause of death following total body irradiation and that lethally irradiated animals could be "rescued" by a bone marrow transplant. The transplanted, viable bone marrow cells were observed to form discrete nodules or colonies in the otherwise sterilized spleens of irradiated animals. Subsequently, these authors transplanted known quantities of irradiated donor bone marrow into lethally irradiated recipient mice, were able to count the resulting splenic nodules, and then calculate the surviving fraction of the injected cells in much the same way as was done for in vitro experiments. The D_0 for mouse bone marrow was 0.95 Gy.[83] Other in vivo assay systems based on the counting of colonies or nodules included the skin epithelium assay of Withers,[84] the intestinal crypt assays of Withers and Elkind,[85,86] and the lung colony assay of Hill and Bush.[87] During the late 1960s and early 1970s, it also became possible to do excision assays, in which tumors irradiated in vivo were removed, enzymatically dissociated, and single cells plated for clonogenic survival in vitro, thereby allowing more quantitative measurement of survival and avoiding some of the pitfalls of in vivo assays (e.g., Rockwell et al[88]).

Nonclonogenic Assays In Vivo

Unfortunately some normal tissues and tumors are not amenable to clonogenic assays. Thus, new assays were needed that had clinical relevance, yet did not rely on reproductive integrity as an endpoint. Use of such assays required one leap of faith however, namely that the endpoints assessed would have to be a consequence of the killing of clonogenic cells, although not necessarily in a direct, one-to-one manner. Because nonclonogenic assays do not directly measure cell survival as an endpoint, data derived from them and plotted as a function of radiation dose are properly called dose-response curves rather than cell survival curves, although such data are often analyzed and interpreted similarly.

Historically, among the first nonclonogenic assays was the mean lethal dose or LD_{50} assay, in which the (whole body) radiation dose to produce lethality in approximately 50% of the test subjects is determined, usually at a fixed time after irradiation, such as 30 ($LD_{50/30}$) or 60 days ($LD_{50/60}$). Clearly, the LD_{50} assay is not specific in that the cause of death can result from damage to a number of different tissues.

Another widely used nonclonogenic method to assess normal tissue radioresponse is the skin reaction assay, which was originally developed by Fowler et al.[89] Pigs were often used because their skin is similar to that of humans in several key respects. An ordinate scoring system was used to compare and contrast different radiation schedules and was derived from the average severity of the skin reaction noted during a certain time period (specific to the species and whether the endpoint occurs early or late) following irradiation. For example, for early skin reactions, a skin score of "1" might correspond to mild erythema, whereas a score of "4" might correspond to confluent moist desquamation over more than half of the irradiated area.

Finally, two common nonclonogenic assays for tumor response are the growth delay/regrowth delay assay[90] and the tumor control dose assay.[91] Both assays are simple and direct,

are applicable to most solid tumors, and are clinically relevant. The growth delay assay involves the periodic measurement of a tumor's dimensions as a function of time after irradiation and a calculation of the tumor's approximate volume. For tumors that regress rapidly during and after radiotherapy, the endpoint scored is typically the time in days it takes for the tumor to regrow to its original volume at the start of irradiation. For tumors that regress more slowly, a more appropriate endpoint might be the time it takes for the tumor to grow or regrow to a specified size, such as three times its original volume. Dose-response curves are generated by plotting the amount of growth delay as a function of radiation dose.

The tumor control assay is a logical extension of the growth delay assay. The endpoint of this assay is the total radiation dose required to achieve a specified probability of local tumor control—usually 50% (TCD_{50})—in a specified period of time after irradiation. The TCD_{50} value is obtained from a plot of the percentage of tumors locally controlled as a function of total dose. The slope of the resulting dose-response curve may be used for comparative purposes as a measure of the tumor's inherent "radiosensitivity" or its degree of heterogeneity. More heterogeneous tumors tend to have shallower dose-response curves than more homogeneous ones, as do spontaneous tumors relative to experimental ones maintained in inbred strains of mice.

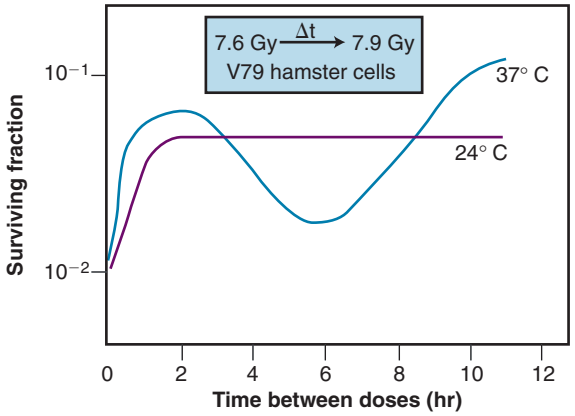

Figure 1-9 Split-dose or sublethal damage recovery demonstrated in cultured V79 hamster cells that received a first x-ray dose at time = 0, followed by a second dose after a variable radiation-free interval. Cells were maintained at room temperature (24° C) or at 37° C during the split time.
Adapted from Elkind M, Sutton-Gilbert H, Moses W, et al: Radiation response of mammalian cells grown in culture. V. Temperature dependence of the repair of x-ray damage in surviving cells (aerobic and hypoxic). Radiat Res 25:359, 1965.

Cellular Repair: Sublethal and Potentially Lethal Damage Recovery

Taking the cue from target theory that the shoulder region of the radiation survival curve indicated that hits had to accumulate before cell killing, Elkind and Sutton[92,93] sought to better characterize the nature of the damage caused by these hits and how the cell processed this damage. Even in the absence of any detailed information about DNA damage and repair at that time, a few things seemed obvious. First, those hits or damages that were registered as part of the accumulation process, yet did not in and of themselves produce cell killing, were, by definition, sublethal. Second, sublethal damage (SLD) only became lethal when it interacted with additional SLD, that is, when the total amount of damage had accumulated to a sufficient level to cause cell lethality. But what would be the result of deliberately interfering with the damage accumulation process, by, for example, delivering part of the intended radiation dose, inserting a radiation-free interval, and then delivering the remainder of the dose? The results of such split-dose experiments turned out to be crucial to the understanding of why and how fractionated radiation therapy works as it does. The discovery and characterization of SLD, as low tech and operational the concept may be by today's standards, still stands as arguably the single-most important contribution radiation biology has made to the practice of radiation oncology.

By varying the time interval between two doses of approximately 5.0 Gy and plotting the log of the surviving fraction of cells after both doses (i.e., 10 Gy total dose) as a function of the time between the doses, the resulting split-dose recovery curve was observed to rise to a maximum after about 2 hours and then level off. In other words, the overall surviving fraction of cells following 10 Gy was higher if the dose was split into two fractions with a time interval in between than delivered as a single dose. Elkind interpreted these results as indicating that the cells that survived the initial dose fraction had "repaired" some of the damage during the radiation-free interval, and as such, this damage was no longer available to interact with the damage inflicted by the second dose. At the time, Elkind referred to this phenomenon as *sublethal damage repair* (SLDR); however, in retrospect, it is perhaps preferable to call it *sublethal damage recovery*, because biochemical DNA repair processes were not actually measured, only changes in cell survival were.

Of additional interest was the observation that the shape of the split-dose recovery curve varied with the temperature during the radiation-free interval (Figure 1-9). When the cells were maintained at room temperature between the split doses, the SLDR curve rose to a maximum after about 2 hours and then leveled off. When the cells were returned to an incubator at 37°C for the radiation-free interval, a different pattern emerged. Initially, the split-dose recovery curve rose to a maximum after 2 hours, but then, the curve exhibited a series of oscillations, dropping to a second minimum for a split of about 4 to 5 hours and then rising again to a higher maximum for split dose intervals of 10 hours or more. The interpretation of this pattern of SLDR was that other radiobiological phenomena operated simultaneously with cellular recovery. In this case, the fine structure of the split-dose recovery curve was not caused by an oscillating repair process, but rather, by a superimposed cell cycle effect: the so-called radiation age response through the cell cycle. This is discussed in detail in the "Ionizing Radiation and the Cell Cycle" section (see also Figure 1-14).

Since Elkind and Sutton's original work, SLDR kinetics have been described for many different types of mammalian cells in culture[58] and for most normal and tumor tissues in vivo (e.g., Belli et al,[94] Emery et al[95]). Pertinent findings include:

1. The amount of SLD capable of being repaired for a given cell type varies both with the radiation quality (less for radiations of increasing LET) and the oxygenation status of the cells (recovery reduced or absent at extremely low-oxygen tensions).[28]
2. The half-time for SLDR in mammalian cells in culture is, on average, about 1 hour, although there is evidence that it may be somewhat longer for late responding normal tissues in vivo.[28]
3. The survival increase between split doses is a manifestation of the "regeneration" of the shoulder of the radiation survival curve. After an initial radiation dose and an adequate time interval for SLDR, the response of surviving cells to graded additional doses is nearly identical to that obtained

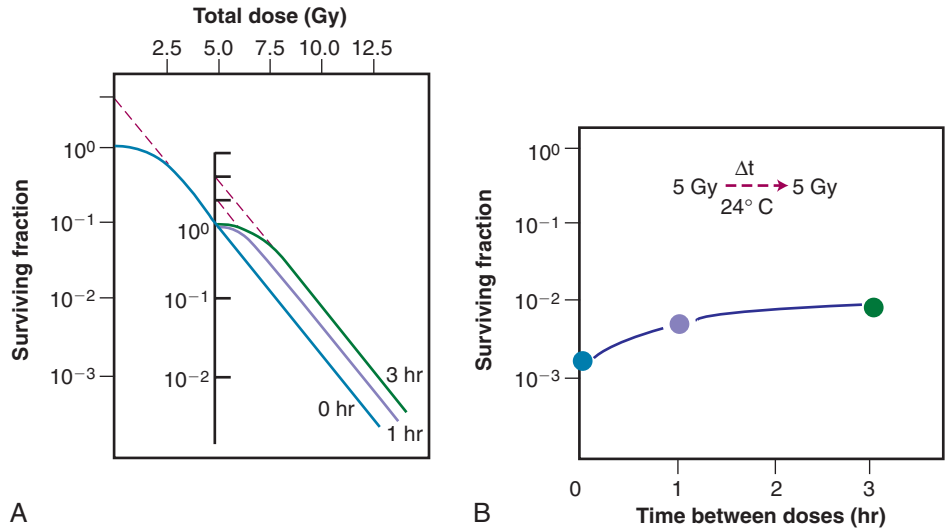

Figure 1-10 Sublethal damage recovery manifests as a return of the shoulder on the radiation survival curve when a total dose is delivered as two fractions separated by a time interval **(A)**. If the interfraction interval is shorter than the time it takes for this recovery to occur, the shoulder will only be partially regenerated (compare the shoulder regions of the survival curves for intervals of 1 vs. 3 hours). Regeneration of the shoulder **(B)** accounts for the observed survival increase in the corresponding split-dose assay (see Figure 1-9).

from cells without previous radiation exposure. Thus, the width of the shoulder of the survival curve came to be associated with the capacity of the cells for recovery from sublethal damage. This concept is illustrated in Figure 1-10.

4. Cells are able to undergo repeated cycles of damage and recovery without an apparent change in recovery capacity. As such, one would predict an equal effect per-dose fraction during the course of fractionated radiotherapy. In a more practical sense, this means that a multifraction survival curve can be generated using the formula $SF_n = (SF_1)^n$, where SF_1 is the surviving fraction of cells after a single-dose fraction (determined from a single-dose survival curve), and SF_n is the surviving fraction of cells after n dose fractions. Accordingly, multifraction survival curves are shoulderless and exponential (Figure 1-11).
5. Sublethal damage recovery is largely responsible for the dose rate effect for low LET radiation, which will be discussed in detail later in this chapter. As the dose per fraction (intermittent radiation) or dose rate (continuous irradiation) is decreased and the overall treatment time increased, the biological effectiveness of a given total dose is reduced. (Note that SLDR also occurs during continuous irradiation, that is, that a radiation-free interval is not required per se.)

A second type of cellular recovery following irradiation is termed po*tentially lethal damage repair or recovery* (PLDR) and was first described for mammalian cells by Phillips and Tolmach[96] in 1966. PLD is, by definition, a spectrum of radiation damage that may or may not result in cell lethality depending on the cells' postirradiation conditions. Conditions that favor PLDR include maintenance of cells in overcrowded conditions (plateau phase or contact-inhibited[97,98]) and incubation following irradiation at either reduced temperature,[99] in the presence of certain metabolic inhibitors,[96] or in balanced salt solutions rather than complete culture medium.[99] What these treatment conditions have in common is that they are suboptimal for continued growth of cells. Presumably, resting cells (regardless of why they are resting) have more opportunity to repair DNA damage before cell division than cells that continue traversing the cell cycle immediately after irradiation. Phillips and Tolmach[96] were the first to propose this repair-fixation or competition model to explain PLDR.

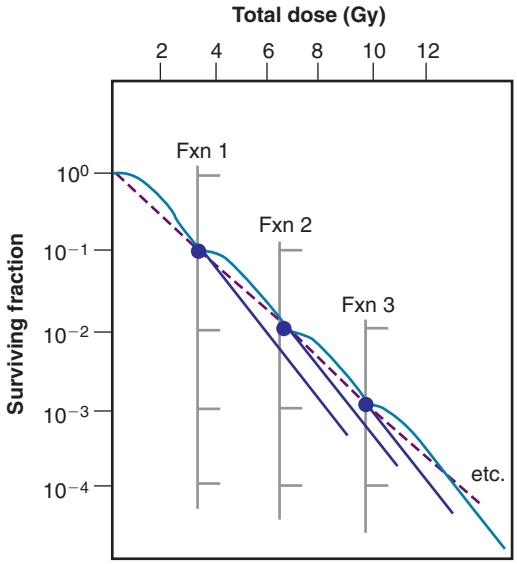

Figure 1-11 Hypothetical multifraction survival curve *(dashed line)* for repeated 3.0-Gy fractions under conditions in which sufficient time between fractions is allowed for full sublethal damage recovery and cell cycle and proliferative effects are negligible. The multifraction survival curve is shallower than its corresponding single-dose curve *(solid lines)* and has no shoulder (i.e., the surviving fraction is an exponential function of total dose).

Although admittedly, some of these postirradiation conditions are not likely to be encountered in vivo, slow growth of cells in general, with or without a large fraction of resting cells, is a common characteristic of many tissues. As might be expected, tumors (and subsequently, select normal tissues amenable to clonogenic assay) were shown to repair PLD.[98] Experiments using rodent tumors were modeled after comparable studies using plateau phase cells in culture, that is, a "delayed plating" assay was used. For such an experiment, irradiated cell cultures or animal tumors are left in a confluent state (either in the overcrowded cell culture or in the intact

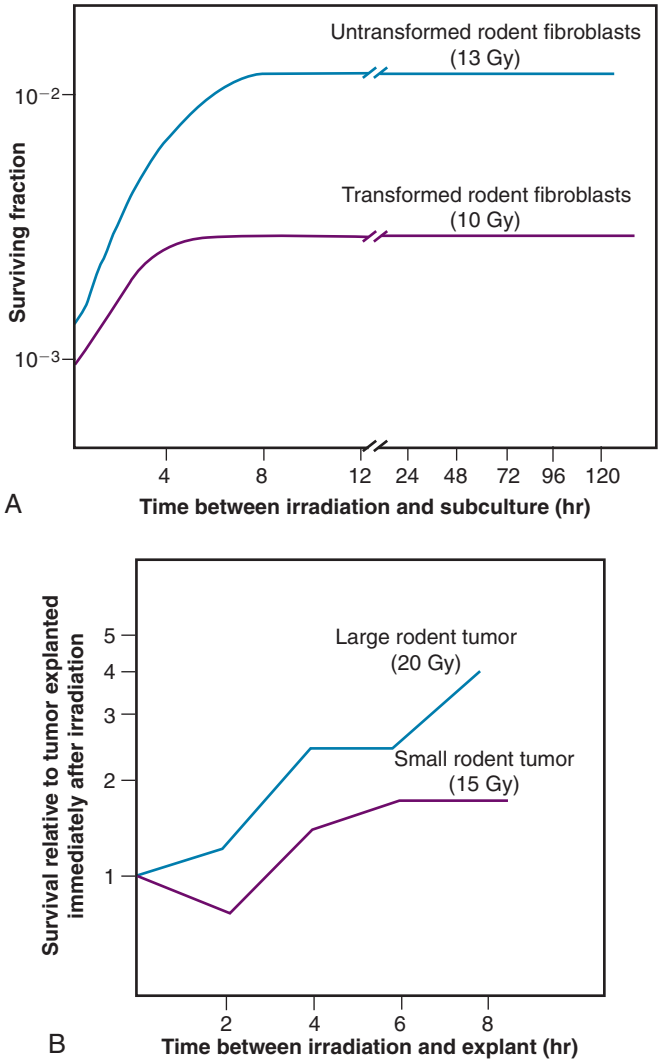

Figure 1-12 Potentially lethal damage recovery can be demonstrated using a delayed-plating assay in which a variable delay time is inserted between exposure to a large, single dose of radiation and the harvesting of the cells for a clonogenic assay. If cells are maintained in overcrowded or nutrient-deprived conditions during the delay period, the surviving fraction increases relative to that obtained when there is no delay. **A,** Potentially lethal damage recovery occurs in vitro in a nontumorigenic rodent fibroblast cell line and its transformed, tumorigenic counterpart. **B,** Potentially lethal damage recovery occurs in vivo in small and large mouse fibrosarcomas.
***A,** Adapted from Zeman E, Bedford J: Dose-rate effects in mammalian cells. V. Dose fractionation effects in noncycling C3H 10T1/2 cells. Int J Radiat Oncol Biol Phys 10:2089, 1984; **B,** adapted from Little J, Hahn G, Frindel E, et al: Repair of potentially lethal radiation damage in vitro and in vivo. Radiology 106:689, 1973.*

tumor in the animal) for varying lengths of time before removing them, dissociating them into single-cell suspensions and plating the cells for clonogenic survival at a low density. The longer the delay between irradiation and the clonogenic assay, the higher the resulting surviving fraction of individual cells, even though the radiation dose is the same. In general, survival rises to a maximum within 4-6 hours and levels off thereafter (Figure 1-12).

The kinetics and extent of recovery from both SLD and PLD are correlated with the molecular repair of DNA and the rejoining of chromosome breaks.[100,101] For the purposes of radiation therapy, however, the most important consideration is that both processes have the potential to increase the surviving fraction of cells between subsequent dose fractions. Such a survival increase could be manifest clinically as either increased normal tissue tolerance or decreased tumor control. It is also important to appreciate that small differences in recovery capacity between normal and tumor cells after a single-dose fraction are magnified into large differences after 30 or more dose fractions.

Repair in Tissues

When considering repair phenomenon in intact tissues, it is important to remember that both the magnitude of the repair (related both to the shape of the shoulder region of the corresponding dose-response curve and the dose delivered) and the rate of the repair can influence how the tissue behaves during a course of radiation therapy. For example, a particular tissue—normal or tumor—may be quite capable of repairing most damage produced by each dose fraction, but if the interfraction interval is so short as to not allow all the damage to be repaired before the next dose, the tolerance of that tissue will be less than otherwise anticipated. Second, although the sparing effect of dose fractionation for both normal and tumor tissues can be explained largely by SLD recovery between fractions, at sufficiently small doses per fraction, the degree of sparing will reach a maximum below which no further sparing occurs, that is, all other radiobiological factors being equal. This is a reflection of the fact that some radiation damage is necessarily lethal and not modifiable by either further fractionation or changing postirradiation conditions.

Ionizing Radiation and the Cell Cycle

Another basic feature of the cellular response to ionizing radiation is perturbation of the cell cycle. Such effects can modify the radioresponsiveness of tissues either directly or indirectly, depending on the fraction of cycling cells present in the tissue, their proliferation rates, and the kinetic organization of the tissue or tumor as a whole.

Advances in techniques for the study of cell cycle kinetics during the 1950s and 1960s paved the way for the generation of survival curves as a function of cell age. Using a technique known as autoradiography, Howard and Pelc[102] were able to identify the S, or DNA synthesis, phase of the cell cycle. When combined with the other cytologically obvious cell cycle marker, mitosis, they were able to discern the four phases of the cell cycle for actively growing cells: G1, S, G2, and M.

Methodology

Several techniques were subsequently developed for the collection of synchronized cells in vitro. One of the most widely used was the mitotic harvest or shake-off technique first described by Terasima and Tolmach.[103,104] By agitating cultures, mitotic cells, which tend to round up and become loosely attached to the culture vessel's surface, can be dislodged, collected along with the overlying growth medium, and inoculated into new culture flasks. By incubating these flasks at 37° C, cells begin to proceed synchronously into G1 phase (and semisynchronously thereafter). Thus, by knowing the length of the various phase durations for the cell type being studied and then delivering a radiation dose at a time of interest after the initial synchronization, the survival response of cells in different phases of the cell cycle can be determined.

A second synchronization method involved the use of DNA synthesis inhibitors such as fluorodeoxyuridine,[105] and later, hydroxyurea,[106] to selectively kill S phase cells, yet allow cells in other phases to continue cell cycle progression until they become blocked at the border of G1 and S phase. By incubating

cells in the presence of these inhibitors for times sufficient to collect nearly all cells at the block point, large numbers of cells can be synchronized. In addition, the inhibitor technique has two other advantages, namely that some degree of synchronization is possible in vivo[107] as well as in vitro, and that by inducing synchrony at the end of G1 phase, a higher degree of synchrony can be maintained for longer periods than if synchronization had been at the beginning of G1. On the other hand, the mitotic selection method does not rely on the use of drugs that themselves could perturb the normal cell cycle kinetics of the population.

Developments in the early 1970s, however, provided what is now considered among the most valuable tools for the study of cytokinetic effects: the flow cytometer and its offshoot, the fluorescence-activated cell sorter.[108] These have largely replaced the aforementioned longer and more labor-intensive cell cycle synchronization methods. Using this powerful technique, single cells are stained with a fluorescent probe that binds stoichiometrically to a specific cellular component, for example, DNA in the case of cell cycle distribution analysis. The stained cells are then introduced into a pressurized flow cell and forced to flow single file and at a high rate of speed through a focused laser beam that excites the fluorescent dye. The resulting light emission from each cell is collected by photomultiplier tubes, recorded, and output as a frequency histogram of cell number as a function of relative fluorescence, with the amount of fluorescence directly proportional to DNA content. Accordingly, cells with a "1X" DNA content would correspond to cells in G1 phase, cells with a "2X" DNA content in G2 or M phase, and cells with DNA contents between "1X" and "2X" in the S phase of the cell cycle. By performing a mathematical fit to the DNA histogram, the proportion of cells in each phase of the cell cycle can be determined, the phase durations can be derived, and differences in DNA ploidy can be identified. DNA flow cytometry is quite powerful in that not only can a static measure of cell cycle distribution be obtained for a cell population of interest, but also, dynamic studies of, for example, transit through the various cell cycle phases or treatment-induced kinetic perturbations, can be monitored over time (Figure 1-13). A flow cytometer can be outfitted to include a cell sorting feature; in this case, cells analyzed for a property of interest can be collected in separate "bins" after they pass through the laser beam, and if possible, used for other experiments.

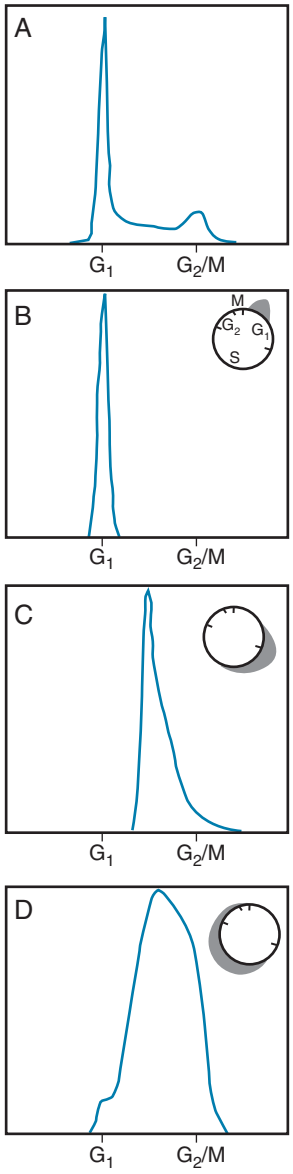

Figure 1-13 The analytic technique of flow cytometry has revolutionized the study of cell cycle kinetics by allowing rapid determination of DNA content in cells stained with a fluorescent dye that binds stoichiometrically to cellular DNA. **A,** Frequency distribution for a population of exponentially growing cells. The large and small peaks correspond to cells with G_1 (1×) and G_2/M (2×) phase DNA content, respectively; the cells in S phase have an intermediate DNA content. *B* to *D*, DNA histograms for a cell population synchronized initially in mitosis and then allowed to progress into G_1 **(B)**, S, and G_2/M (**C** and **D**).

Age Response Through the Cell Cycle

Results of an age response experiment of Terasima and Tolmach,[104] using synchronized HeLa cells, are shown in the lower panel of Figure 1-14. Following a single dose of 5 Gy of x-rays, cells were found to be most radioresistant in late S phase. Cells in G1 were resistant at the beginning of the phase but became sensitive toward the end of the phase, and G2 cells were increasingly sensitive as they moved toward the most sensitive M phase. In subsequent experiments by Sinclair,[109,110] age response curves for synchronized Chinese hamster V79 cells showed that the peak in resistance observed in G1 HeLa cells was largely absent for V79 cells. This is also illustrated in Figure 1-14 *(upper panel)*. Otherwise, the shapes of the age response curves for the two cell lines were similar. The overall length of the G1 phase determines whether the resistant peak in early G1 will be present; in general, this peak of relative radioresistance is only observed for cells with long G1 phases. For cells with short G1 phases, the entire phase is often of intermediate radiosensitivity. An analysis of the complete survival curves for synchronized cells[110,111] confirms that the most sensitive cells are those in M and late G2 phase, in which survival curves are steep and largely shoulderless, and the most resistant cells are those in late S phase. The resistance of these cells is conferred by the presence of a broad survival curve shoulder, rather than by a significant change in survival curve slope (Figure 1-15). When high LET radiations are used, the age response variation through the cell cycle is significantly reduced or eliminated because survival curve shoulders are either decreased or removed altogether by such exposures (see also "Relative Biological Effectiveness"). Similar age response patterns have been identified for cells synchronized in vivo.[107]

The existence of a cell cycle age response for ionizing radiation provided an explanation for the unusual pattern of SLDR observed for cells maintained at 37°C during the recovery interval (see Figure 1-9). In Elkind and Sutton's experiments,

exponentially growing cells were used, that is, cells that were asynchronously distributed across the different phases of the cell cycle. The cells that survived irradiation tended to be those most radioresistant. Thus, the remaining population became enriched with the more resistant cells. For low LET radiation, those cells that were most resistant were in S phase at the time of the first radiation dose. However, at 37°C, cells continued to progress through the cell cycle, so those surviving cells in S phase at the time of the first dose may have moved into G2 phase by the time the second dose was delivered. Thus, the observed survival nadir in the SLDR curve was not the result of a loss or reversal of repair, but rather, because the population of cells was now enriched in G2 phase cells, which are inherently more radiosensitive. For even longer radiation-free intervals, it is possible that the cells surviving the first dose would transit from G2 to M, and back into G1 phase, dividing and doubling their numbers. In this case, the SLDR curve again shows a surviving fraction increase because the number of cells has increased. None of these cell cycle-related phenomena occur when the cells are maintained at room temperature during the radiation-free interval because continued movement through the cell cycle is inhibited under such conditions; in that case, all that is noted is the initial survival increase resulting from SLDR.

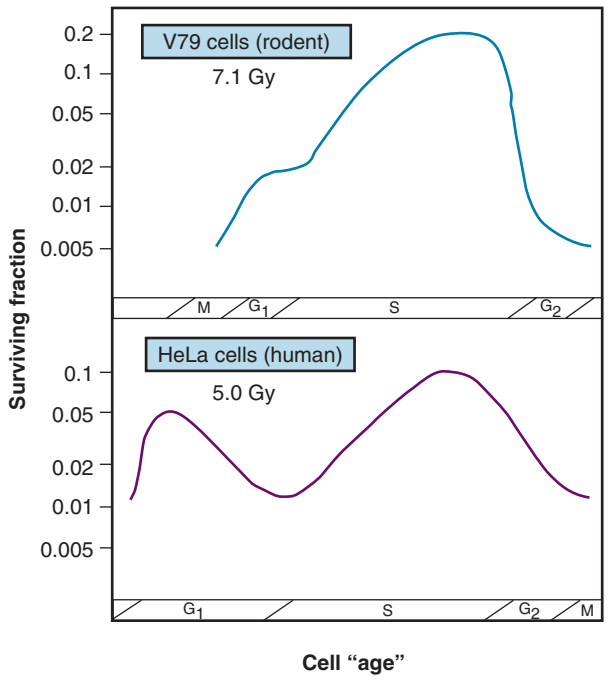

Figure 1-14 Cell cycle age response for sensitivity to radiation-induced cell killing in a representative rodent cell line (V79, *upper panel*) having a short G_1 phase duration and in a representative human cell line (HeLa, *lower panel*) having a long G_1 phase duration. Both cell lines exhibit a peak of radioresistance in late S phase and maximum radiosensitivity in late G_2/M phase. A second trough of radiosensitivity can be discerned near the G_1/S border for cells with long G_1-phase durations. *Adapted from Sinclair W: Dependence of radiosensitivity upon cell age. In Proceedings of the carmel conference on time and dose relationships in radiation biology as applied to radiotherapy. BNL Report 50203, Upton, NY, 1969, Brookhaven National Laboratory.*

Radiation-Induced Cell Cycle Blocks and Delays

Radiation is also capable of disrupting the normal proliferation kinetics of cell populations. This was recognized by Canti and Spear[112] in 1927 and studied in conjunction with radiation's ability to induce cellular lethality. With the advent of mammalian cell culture and synchronization techniques and time-lapse cinemicrography, it became possible for investigators to study mitotic and division delay phenomena in greater detail.

Mitotic delay, defined as a delay in the entry of cells into mitosis, is a consequence of upstream blocks or delays in the movement of cells from one cell cycle phase to the next. Division delay, which is a delay in the time of appearance of new cells at the completion of mitosis, is caused by the combined effects of mitotic delay, and any further lengthening of the mitosis process itself. Division delay increases with dose and is, on average, about 1 to 2 hours per Gray[104] depending on the cell line.

The cell cycle blocks and delays primarily responsible for mitotic and division delay are, respectively, a block in the G2-to-M phase transition and a block in the G1-to-S phase transition. The duration of the G2 delay, like the overall division delay, varies with cell type, but for a given cell type is dependent on both dose and cell cycle age. In general, the length of the G2 delay increases linearly with dose. For a given dose, the G2 delay is longest for cells irradiated in S or early G2 phase and shortest for cells irradiated in G1 phase.[113] Another factor contributing to mitotic and division delay is a block in the flow of cells from G1 into S phase. For x-ray doses of at least 6 Gy, there is a 50% decrease in the rate of tritiated thymidine uptake (indicative of entry into S phase) in

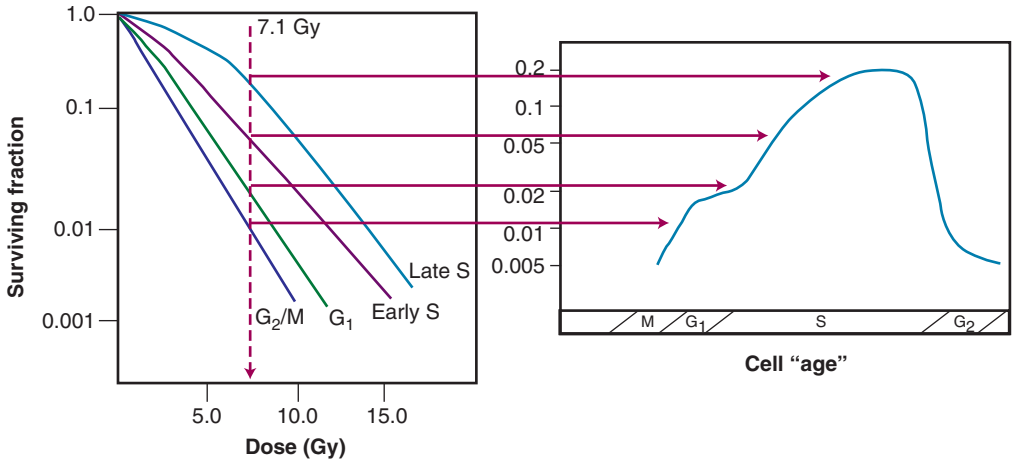

Figure 1-15 Cell survival curves for irradiated populations of Chinese hamster cells synchronized in different phases of the cell cycle *(left panel)*, illustrating how these radiosensitivity differences translate into the age-response patterns shown in the *right panel* (see Figure 1-14).

exponentially growing cultures of mouse L cells. Little[114] reached a similar conclusion from G1 delay studies using human liver LICH cells maintained as confluent cultures.

A possible role for DNA damage and its repair in the etiology of division delay was bolstered by the finding that certain cells types that either did not exhibit the normal cell cycle delays associated with radiation exposure (such as AT cells[42]), or conversely, were treated with chemicals (such as caffeine) that ameliorated the radiation-induced delays,[115] tended to contain higher amounts of residual DNA damage, and to show increased radiosensitivity.

It is now known that the radiation-induced perturbations in cell cycle transit are under the control of cell cycle checkpoint genes, whose products normally govern the orderly (and unidirectional) flow of cells from one phase to the next. The checkpoint genes are responsive to feedback from the cell as to its general condition and readiness to transit to the next cell cycle phase. DNA integrity is one of the criteria used by these genes to help make the decision whether to continue traversing the cell cycle, or to pause, either temporarily, or in some cases, permanently. Cell cycle checkpoint genes are discussed in Chapter 2.

Redistribution in Tissues

Because of the age response through the cell cycle, an initially asynchronous population of cells surviving a dose of radiation becomes enriched with S phase cells. As a result of variations in the rate of further cell cycle progression, however, this partial synchrony decays rapidly. Such cells are said to have redistributed[116] with the net effect of sensitizing the population as a whole to a subsequent dose fraction (relative to what would have been expected had the cells remained in their resistant phases). A second type of redistribution, in which cells accumulate in G2 phase (in the absence of cell division) during the course of multifraction or continuous irradiation because of a buildup of radiation-induced cell cycle blocks and delays, also has a net sensitizing effect. This has been observed during continuous irradiation by several investigators,[117] and in some of these cases, a net *increase* in radiosensitivity is seen at certain dose rates. This so-called inverse dose rate effect, in which certain dose rates are more effective at cell killing than other, higher dose rates, was extensively studied by Bedford et al (for a review, see Bedford et al[118]). The magnitude of the sensitizing effect of redistribution varies with cell type depending on what dose rate is required to stop cell division. For dose rates below the critical range that causes redistribution, some cells can escape the G2 block and proceed on to cell division.

Densely Ionizing Radiation

Linear Energy Transfer (LET)

The total amount of energy deposited in biological materials by ionizing radiation (usually expressed in units of keV, ergs or joules per g or kg) is in and of itself insufficient to describe the net biological consequences of those energy deposition events. For example, 1 Gy of x-rays, although physically equivalent in terms of total energy imparted per unit mass to 1 Gy of neutrons or α-particles, does not produce equivalent biological effects. It is the microdosimetric pattern of that energy deposition, that is, the spacing or density of the ionization events, that determines biological effectiveness. This quantity—the average energy deposited locally per unit length of the ionizing particle's track—is termed its LET.

LET is a function both of the charge and mass of the ionizing particle. Photons set in motion fast electrons that have a net negative charge but a negligible mass. Neutrons on the other hand give rise to recoil protons or α-particles, that possess one or two positive charges, respectively, and are orders of magnitude more massive than electrons. Neutrons therefore have a higher LET than photons and are said to be densely ionizing, whereas the x- or γ-rays are considered sparsely ionizing. The LET concept is illustrated in Figure 1-16 for both densely and sparsely ionizing radiations. For a given ionizing particle, the rate of energy deposition in the absorbing medium increases as the particle slows down. Therefore, a beam of radiation can only be described as having an average value for LET.

Representative LET values for types of radiations that have been used for radiation therapy include 0.2 keV/μm for ^{60}Co γ-rays; 2.0 keV/μm for 250 kVp x-rays; approximately 0.5 to 5.0 keV/μm for protons of different energies; approximately 50 to 150 keV/μm for neutrons of varying energy; 100 to 150 keV/μm for α-particles and anywhere from 100 to 2500 keV/μm for "heavy ions."

Relative Biological Effectiveness (RBE)

Insofar as the "quality" (LET) of the type of radiation influences its biological effectiveness, two questions immediately come to mind. First, why do seemingly subtle differences in microdosimetric energy deposition patterns lead to vastly different biological consequences? Second, how is this differing biological effectiveness manifest in terms of the commonly used assays and model systems of classical radiobiology, and how can this difference be expressed in a quantitative way?

Because high LET radiations are more densely ionizing than their low LET counterparts, it follows that energy deposition in a particular "micro" target volume will be greater, and therefore, more severe damage to biomolecules would be expected. In this case, the fraction of cell killing attributable to irreparable and unmodifiable DNA damage increases in relation to that caused by the accumulation of sublethal damage. Because of this, a number of radiobiological phenomena commonly associated with low LET radiation are decreased or eliminated when high LET radiation is used. For example, there is little, if any, sublethal[58] or potentially lethal damage recovery.[113] This is manifest as a reduction or loss of the shoulder of the acute-dose survival curve, little or no sparing effect of dose fractionation or dose rate, and a corresponding

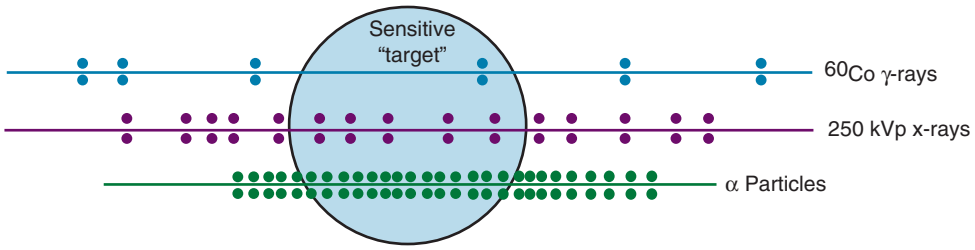

Figure 1-16 Variation in the density of ionizing events along an incident particle's track for radiations of different values of linear energy transfer (LET). The more closely the ionizing events are spaced, the more energy will be deposited in the target volume, and to a point, the more biologically effective per unit dose the type of radiation will be.

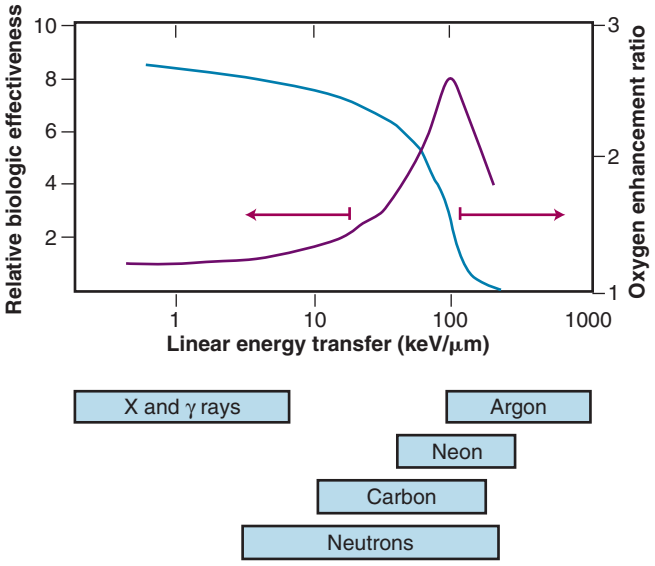

Figure 1-17 Relative biological effectiveness (RBE) is demonstrated on the left *y*-axis as a function of linear energy transfer (LET) for a number of biological endpoints, including production of chromosomal aberrations, cell kill, and tissue reactions. The RBE rises to a maximum corresponding to an LET of approximately 100 KeV/μm and then decreases as the LET continues to rise. Shown below the *x*-axis are the ranges of LET for photons plus several different types of particulate radiations that have been used clinically. Dependence of the oxygen enhancement ratio (OER) on LET is shown on the *y*-axis.

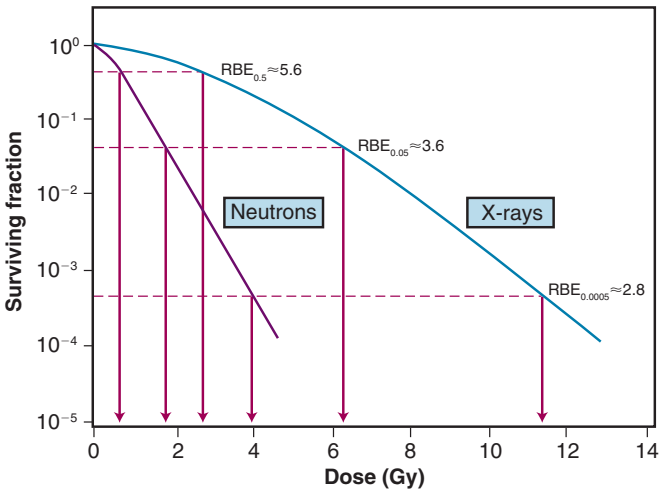

Figure 1-18 Theoretical cell survival curves for x-rays and neutrons, illustrating the increase in relative biological effectiveness (RBE) with decreasing dose. This occurs because higher linear energy transfer (LET) radiations preferentially decrease or eliminate the shoulder on cell survival curves.
Adapted from Nias A: Clinical radiobiology, ed 2, New York, 1988, Churchill Livingstone.

reduction in the tolerance doses for normal tissue complications, particularly for late-responding tissues.[119] Variations in the age response through the cell cycle also are reduced or eliminated for high LET radiation,[107] and the oxygen enhancement ratio (OER), which is a measure of the differential radiosensitivity of poorly- versus well-oxygenated cells (see discussion in this chapter), decreases with increasing LET.[120] The dependence of OER on LET is illustrated in Figure 1-17; at an LET of approximately 100 keV/μm, the relative radioresistance of hypoxic cells is eliminated.

In light of these differences between high and low LET radiations, the term *relative biological effectiveness* (RBE) has been coined to compare and contrast two radiation beams of different LET. RBE is defined as the ratio of doses of a known type of low LET radiation (historically, 250 kVp x-rays were the standard, but ^{60}Co γ-rays also can be used) to that of a higher LET radiation, to yield the same biological endpoint. RBE does not increase indefinitely with increasing LET however, but it reaches a maximum at approximately 100 keV/μm, and then decreases again, yielding an approximately bell-shaped curve.

One interpretation as to why the RBE reaches a maximum at an LET of approximately 100 keV/μm is that at this ionization density, the average separation between ionizing events corresponds roughly to the diameter of the DNA double helix (approximately 2 nm). As such, radiations of this LET have the highest probability of producing DSBs in DNA, the putative lethal lesion, by the passage of a single charged particle. Lower LET radiations have a smaller likelihood of producing such "two-hit" lesions from a single particle track, and therefore are less biologically effective. Radiation beams of higher LET than the optimum are also less biologically effective because some of the energy is wasted because more ionization events than minimally necessary to kill a cell are deposited in the same local area. This phenomenon has been termed the *overkill effect*.

Factors That Influence RBE

RBE is highly variable and depends on several parameters including the type of radiation, total dose, dose rate, dose fractionation pattern, and the biological effect being assayed. Therefore, when quoting an RBE value the exact experimental conditions used to measure it must be stated. Because increasing LET differentially reduces the shoulder region of the radiation survival curve compared to its exponential or near-exponential high-dose region, the single-dose RBE increases with decreasing dose (Figure 1-18). Second, the RBE determined by comparing two isoeffective acute doses is less than the RBE calculated from two isoeffective (total) doses given either as multiple fractions or at a low dose rate. This occurs because the sparing effect of fractionation magnifies differences in the initial slope or shoulder region of cell survival or tissue dose-response curves (Figure 1-19).

The Oxygen Effect

Perhaps the best known chemical modifier of radiation action is molecular oxygen. As early as 1909, Schwarz recognized that applying pressure to skin and thereby decreasing blood flow (and oxygen supply) caused a reduction in radiation-induced skin reactions.[121] For many decades thereafter, radiation oncologists and biologists continued to suspect that the presence or absence of oxygen was capable of modifying radiosensitivity. In 1955, however, Thomlinson and Gray[122] brought this idea to the forefront of radiation biology and therapy by proposing that tumors contain a fraction of still-clonogenic, hypoxic cells that, if persistent throughout treatment, would adversely affect clinical outcome. Although commonly considered a negative prognostic indicator for radiation therapy, hypoxia nevertheless has one particularly attractive feature: built-in specificity for tumors, to the extent that most normal tissues contain few, if any, hypoxic cells.

By studying histological sections of a human bronchial carcinoma, Thomlinson and Gray[122] noted that necrosis was always seen in the centers of cylindrical tumor cords having a radius in excess of approximately 200 μm. Further, regardless of how large the central necrotic region was, the sheath of

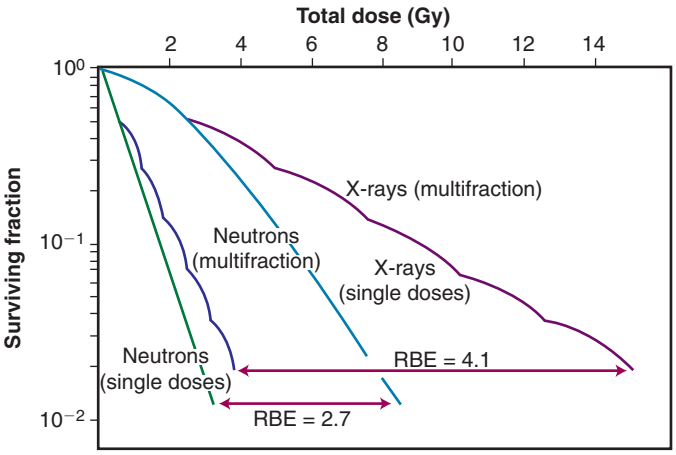

Figure 1-19 Increase in the relative biological effectiveness (RBE) of neutrons relative to x-rays when comparing single radiation doses with fractionated treatment. For a given level of cell kill (or other approximately isoeffective endpoint), the more highly fractionated the treatment, the higher the RBE.

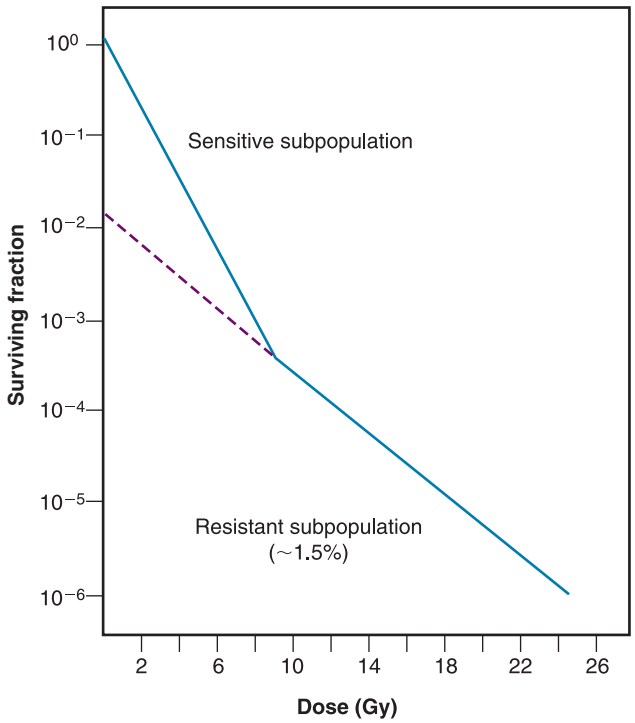

Figure 1-20 Cell survival curve for a murine lymphosarcoma growing subcutaneously and irradiated in vivo. The biphasic curve suggests the presence of a small but relatively radioresistant subpopulation of cells, determined in accompanying experiments to represent the tumor's clonogenic hypoxic fraction.
Adapted from Powers WE, Tolmach LJ: A multicomponent x-ray survival curve for mouse lymphosarcoma cells irradiated. Nature 197:710, 1963.

apparently viable cells around the periphery of this central region never had a radius greater than about 180 µm. The authors went on to calculate the expected maximum diffusion distance of oxygen from blood vessels and found that the value of 150 to 200 µm agreed quite well with the radius of the sheath of viable tumor cells observed histologically. With the advent of more sophisticated and quantitative methods for measuring oxygen utilization in tissues, the average diffusion distance of oxygen has since been revised downward to approximately 70 µm.[28] Thus, the inference was that the oxygenation status of tumor cells varied from fully oxic to completely anoxic depending on where the cells were located in relation to the nearest blood vessels. Accordingly, tumor cells at intermediate distances from the blood supply would be hypoxic and radioresistant, yet remain clonogenic.

The first unambiguous demonstration that a solid rodent tumor did contain clonogenic, radioresistant hypoxic cells was by Powers and Tolmach[123] in 1963. These authors used the dilution assay to generate an in vivo survival curve for mouse lymphosarcoma cells. The survival curve for this solid tumor was biphasic, having an initial D_0 of about 1.1 Gy, and a final D_0 of 2.6 Gy (Figure 1-20). Because the survival curve for lymphoid cells is shoulderless, it was simple to back-extrapolate the shallower component of the curve to the surviving fraction axis and determine that the resistant fraction of cells constituted about 1.5% of the total population. This was considered compelling evidence (yet did not unambiguously prove) that this subpopulation of cells was both hypoxic and clonogenic.

The question then became how to prove that this small fraction of tumor cells was radioresistant because of hypoxia, as opposed to being radioresistant for other reasons. An elegant if somewhat macabre method was developed to address this dilemma, called the *paired survival curve technique*.[123,124] In this assay, laboratory animals bearing tumors were divided into three treatment groups, one group irradiated while breathing air, a second group irradiated while breathing 100% oxygen, and a third group killed first by cervical dislocation and then promptly irradiated. Within each group, animals received graded radiation doses so that complete survival curves were generated for each treatment condition. When completed, the paired survival curve method yielded three different tumor cell survival curves: a fully oxic curve (most radiosensitive), a fully hypoxic curve (most radioresistant), and the survival curve for air-breathing animals, which, if the tumor contained viable hypoxic cells, was biphasic and positioned between the other two curves. It was then possible to mathematically strip the fully aerobic and hypoxic curves from the curve for air-breathing animals and determine the radiobiologically hypoxic fraction.

Across a variety of rodent tumors evaluated to date using the paired survival curve method, the percentage of hypoxic cells was found to vary between 0% and 50%, with an average of about 15%.[124]

Mechanistic Aspects of the Oxygen Effect

A more rigorous analysis of the nature of the oxygen effect is possible with cells or bacteria grown in vitro. Historically, oxygen had been termed a dose-modifying agent, that is, that the ratio of doses to achieve a given survival level under hypoxic and aerobic conditions was constant, regardless of the survival level chosen. This dose ratio to produce the same biological endpoint is termed the *OER* and is used for comparative purposes (Figure 1-21). The OER typically has a value of between 2.5 and 3.0 for large single doses of x- or γ-rays, 1.5 to 2.0 for radiations of intermediate LET, and 1.0 (i.e., no oxygen effect) for high LET radiations.

Increasingly, there is evidence that oxygen is not strictly dose modifying. Several studies have shown that the OER for sparsely ionizing radiation is lower at lower doses than at higher doses. Lower OERs for doses per fraction in the range commonly used in radiotherapy have been inferred indirectly from clinical and experimental tumor data and more directly in experiments with cells in culture.[125,126] It has been suggested that the lower OERs result from an age response for the oxygen

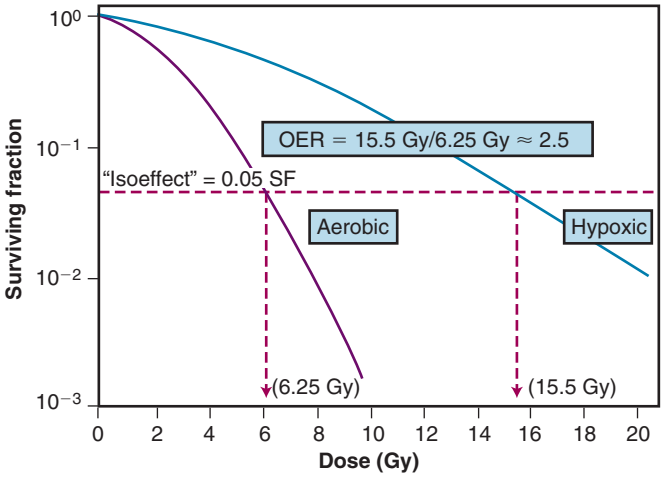

Figure 1-21 Representative survival curves for cells irradiated with x-rays in the presence (aerobic) or virtual absence (hypoxic) of oxygen. The oxygen enhancement ratio (OER) is defined as the ratio of doses under hypoxic-to-aerobic conditions to yield the same biological effect, which in this case is a cell surviving fraction (SF) of 0.05.

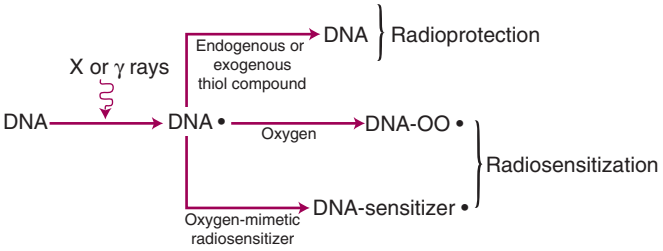

Figure 1-22 Schematic representation of the proposed mechanism of action for the oxygen effect. The radical competition model holds that oxygen acts as a radiosensitizer by forming peroxides in DNA already damaged by radiation, thereby fixing the damage. In the absence of oxygen, DNA can be restored to its preirradiated state by hydrogen donation from endogenous reducing species in the cell, such as the free radical scavenger glutathione. An oxygen-mimetic, hypoxic cell radiosensitizer may be used to substitute for oxygen in these fast, free radical reactions, or an exogenously supplied thiol compound may be used to act as a radioprotector.

effect, not unlike the age responses for inherent radiosensitivity and cell cycle delay.[28] Assuming cells in G1 phase of the cell cycle have a lower OER than those in S phase, and because G1 cells are also more radiosensitive, they would tend to dominate the low dose region of the cell survival curve.

Although the exact mechanism(s) of the oxygen effect are obviously complex, a fairly simplistic model can be used to illustrate our current understanding of this phenomenon (Figure 1-22). The radical competition model holds that oxygen acts as a radiosensitizer by forming peroxides in important biomolecules (including but not necessarily limited to, DNA) already damaged by radiation exposure, thereby "fixing" the radiation damage. In the absence of oxygen, DNA can be restored to its preirradiated condition by hydrogen donation from endogenous reducing species in the cell, such as the free radical scavenger glutathione, a thiol compound. In essence, this can be considered a type of fast chemical restitution or repair. These two processes, fixation and restitution, are considered to be in a dynamic equilibrium, such that changes in the relative amounts of either the radiosensitizer, oxygen, or the radioprotector, glutathione, tip the scales in favor of either fixation (more damage, more cell killing, greater

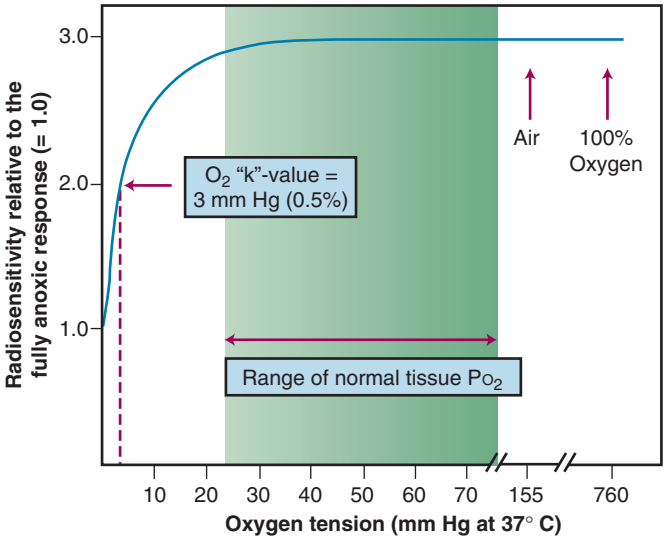

Figure 1-23 An oxygen *k-curve* illustrates the dependence of radiosensitivity on oxygen concentration. If a fully anoxic cell culture is assigned a relative radiosensitivity of 1.0, introducing even 0.5% (3 mm Hg) oxygen into the system increases the radiosensitivity of cells to 2.0. By the time the oxygen concentration reaches about 2%, cells respond as if they are fully aerated (i.e., radiosensitivity ≈ 3.0). The *green-shaded area* represents the approximate range of oxygen concentrations encountered in human normal tissues.

radiosensitivity) or restitution (less damage, less cell killing, greater radioresistance).

Consistent with this free radical-based interpretation of the oxygen effect is the finding that, for all intents and purposes, oxygen need only be present *during* the irradiation (or no more than a few milliseconds after irradiation) to produce an aerobic radioresponse.[127,128] The concentration of oxygen necessary to achieve maximum sensitization is quite small, evidence for the high efficiency of oxygen as a radiosensitizer. A sensitivity midway between a fully hypoxic and fully aerobic radioresponse is achieved at an oxygen tension of about 3 mm of mercury, corresponding to about 0.5% oxygen, which is much lower than partial pressures of oxygen usually encountered in normal tissues. This value of 0.5% has been termed *oxygen's k-value* and is obtained from an oxygen k-curve of relative radiosensitivity plotted as a function of oxygen tension[129] (Figure 1-23).

Reoxygenation in Tumors

After the convincing demonstration of hypoxic cells in a mouse tumor,[123] it was assumed that human tumors contained a viable hypoxic fraction as well. However, if human tumors contained even a tiny fraction of clonogenic hypoxic cells, simple calculations suggested that tumor control would be nearly impossible with radiation therapy.[130] Because therapeutic successes obviously do occur, some form of reoxygenation must take place during the course of multifraction irradiation. This was not an unreasonable idea because the demand for oxygen by sterilized cells would gradually decrease as they were removed from the tumor, and a decrease in tumor size, a restructuring of tumor vasculature, or intermittent changes in blood flow could make oxygen available to these previously hypoxic cells.

The reoxygenation process was extensively studied by van Putten and Kallman,[131] who serially determined the fraction of hypoxic cells in a mouse sarcoma during the course of a clinically relevant multifraction irradiation protocol. The fact that the hypoxic fraction was about the same at the end of

treatment as at the beginning of treatment was strong evidence for a reoxygenation process, because otherwise, the hypoxic fraction would be expected to increase over time as a result of repeated enrichment with resistant cells after each dose fraction. Reoxygenation of hypoxic, clonogenic tumor cells during an extended multifraction treatment would increase the therapeutic ratio, assuming that normal tissues remained well oxygenated. This is thought to be another major factor in the sparing of normal tissues relative to tumors during fractionated radiation therapy.

What physiological characteristics would lead to tumor reoxygenation during a course of radiotherapy, and at what rate would this be expected to occur? One possible cause of tumor hypoxia, and by extension, a possible mechanism for reoxygenation, was suggested by Thomlinson and Gray's pioneering work.[122] The type of hypoxia that they described is what is now called *chronic*, or *diffusion-limited hypoxia*. This results from the tendency of tumors both to outgrow their blood supply and have high oxygen consumption rates. It follows therefore that natural gradients of oxygen tension should develop as a function of distance from blood vessels. Cells situated beyond the diffusion distance of oxygen would be expected to be dead or dying of anoxia, yet in regions of chronically low-oxygen tension, clonogenic and radioresistant hypoxic cells could persist. Should the tumor shrink as a result of radiation therapy, or if the cells killed by radiation cause a decreased demand for oxygen, it is likely that this would allow some of the chronically hypoxic cells to reoxygenate. However, such a reoxygenation process could be quite slow—on the order of days or more—depending on how quickly tumors regress during treatment. The patterns of reoxygenation in some experimental rodent tumors are consistent with this mechanism of reoxygenation, but others are not.

Other rodent tumors reoxygenate quickly, on a time scale of minutes to hours.[132] This occurs in the absence of any measurable tumor shrinkage or change in oxygen utilization by tumor cells. In such cases, the model of chronic, diffusion-limited hypoxia and slow reoxygenation does not fit the experimental data. During the late 1970s, Brown[133] proposed that a second type of hypoxia may exist in tumors, an acute, *perfusion-limited hypoxia*. Based on the growing understanding of the vascular physiology of tumors, it was clear that tumor vasculature was often abnormal in both structure and function secondary to abnormal angiogenesis. If tumor vessels were to close transiently from temporary blockage, vascular spasm or high interstitial fluid pressure in the surrounding tissue, the tumor cells in the vicinity of those vessels would become acutely hypoxic almost immediately. Then, assuming blood flow resumed in minutes to hours, these cells would reoxygenate. However, this type of hypoxia can also occur in the absence of frank closure or blockage of tumor vessels (which is now considered a less common cause of acute hypoxia), from, for example, vascular shunting, longitudinal oxygen gradients, decreased red cell flux or overall blood flow rate, abnormal vascular geometry, and so on.[134] Because of this, perfusion-*limited* hypoxia is perhaps misleading; a better moniker might be *fluctuant* or *intermittent* hypoxia. Although intermittent hypoxia would explain the rapid reoxygenation observed for some tumors, it does not preclude the simultaneous existence of chronic, diffusion-limited hypoxia.

Intermittent hypoxia has since been demonstrated unambiguously for rodent tumors by Chaplin et al.[135] and human tumors by Lin et al.[134,136] It is still not clear how many human tumors contain regions of hypoxia (although many do—see discussion in this chapter), what type(s) of hypoxia is present, whether this varies with tumor type or site, and whether and how rapidly reoxygenation occurs. However, the knowledge that tumor hypoxia is a diverse and dynamic process opens up a number of possibilities for the development of novel interventions designed to cope with, or even exploit, hypoxia.

Measurement of Hypoxia in Human Tumors

Despite prodigious effort directed at understanding tumor hypoxia and developing strategies to combat the problem, it was not until the late 1980s that these issues could be addressed for human tumors because there was no way to measure hypoxia directly. Before that time, the only way to infer that a human tumor contained treatment-limiting hypoxic cells was by using indirect, nonquantitative methods. Some indirect evidence supporting the notion that human tumors contained clonogenic, radioresistant, hypoxic cells includes the following:

1. An association between anemia and poor local control rates, which, in some cases, could be mitigated by preir-radiation blood transfusions.[137]
2. Success of some clinical trials in which hyperbaric oxygen breathing was used to better oxygenate tumors.[138,139]
3. Success of a few clinical trials of oxygen-mimetic hypoxic cell sensitizers combined with radiation therapy.[140,141]

In 1988, one of the first studies showing a strong association between directly measured oxygenation status in tumors and clinical outcome was published by Gatenby.[142] An oxygen-sensing electrode was inserted into the patient's tumor, and multiple readings were taken at different depths along the probe's track. The electrode was also repositioned in different regions of the tumor to assess intertrack variability in oxygen tension. Both the arithmetic mean pO2 value for a particular tumor, as well as the tumor volume-weighted pO2 value, directly correlated with local control rate. A high tumor oxygen tension was associated with a high complete response rate, and vice versa. In a similar, prospective study, Höckel et al[4,143] concluded that pretreatment tumor oxygenation was a strong predictor of outcome among patients with intermediate and advanced stage cervical carcinoma (Figure 1-24).

Unfortunately, the use of oxygen electrodes has its limitations. One weakness is that relative to the size of individual tumor cells, the electrode is large, averaging an outer diameter of 300 µm, a tip recess of 120 µm, and a sampling volume of about 12 µm in diameter.[144] Thus, not only is the oxygen tension measurement regional, but the insertions and removals of the probe also no doubt perturb the oxygenation status. Another problem is that there is no way to determine whether

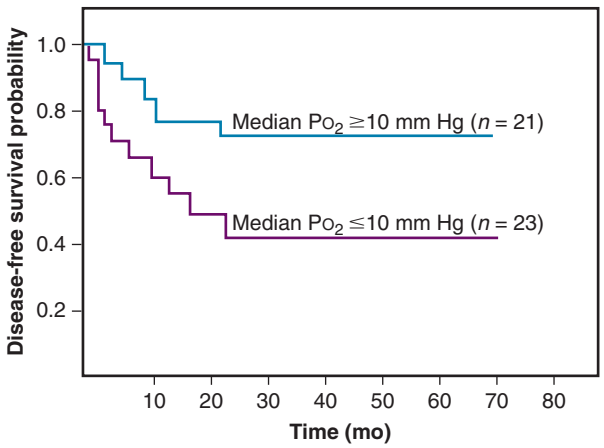

Figure 1-24 The disease-free survival probability of a small cohort of patients with cervical cancer stratified according to pretreatment tumor oxygenation measured using an oxygen electrode.
Adapted from Höckel M, Knoop C, Schlenger K, et al: Intratumoral Po_2 predicts survival in advanced cancer of the uterine cervix. Radiother Oncol 26:45, 1993.

the tumor cells are clonogenic or not. If such cells were hypoxic yet not clonogenic, they would not be expected to impact on radiotherapy outcome.

A second direct technique for measuring oxygenation status takes advantage of a serendipitous finding concerning how hypoxic cell radiosensitizers are metabolized. Certain classes of radiosensitizers, including the nitroimidazoles, undergo a bioreductive metabolism in the absence of oxygen that leads to their becoming covalently bound to cellular macromolecules.[145,146] Assuming that the bioreductively bound drug could be quantified by radioactive labeling,[147] or tagged with an isotope amenable to detection using positron emission tomography[148] or magnetic resonance spectroscopy,[149] a direct measure of hypoxic fraction can be obtained. Another approach to detecting those cells containing bound drug was developed by Raleigh et al.[150,151] This immunohistochemical method involved the development of antibodies specific for the already-metabolized, bound nitroimidazoles. After injecting the parent drug, allowing time for the reductive metabolism to occur, taking biopsies of the tumor and preparing histopathology slides, the specific antibody is then applied to the slides and regions containing the bound drug are visualized directly. This immunostaining method has the distinct advantages that hypoxia can be studied at the level of individual tumor cells,[152] spatial relationships between regions of hypoxia and other tumor physiological parameters can be assessed,[153] and the drug does not perturb the tumor microenvironment. However, the method remains an invasive procedure, is labor intensive, does not address the issue of the clonogenicity of stained cells (although such cells do have to be metabolically active), and requires that multiple samples be taken because of tumor heterogeneity.

One hypoxia marker based on the immunohistological method is commercially available and called HypoxyProbe-1; it detects reductively bound pimonidazole and has been used in experimental and clinical studies around the world (e.g., Bussink et al,[154] Nordsmark et al[155]). Applying HypoxyProbe-1 to human tumor specimens yields a range of hypoxic fractions similar to that noted for experimental rodent tumors and a mean value of approximately 15%.[151,156] This marker can also be used to probe disease states other than cancer that may have the induction of tissue hypoxia as part of their etiology, such as cirrhosis of the liver[157,158] and ischemia-reperfusion injury in the kidney.[159]

There is also considerable interest in *endogenous* markers of tissue hypoxia[160,161] that could reduce to some extent the procedural steps involved in, and the invasive aspects of, detecting hypoxia using exogenous agents. Among the endogenous cellular proteins being investigated in this regard are the hypoxia-inducible factor 1-alpha (HIF-1α, that acts as a transcription factor for hypoxia-regulated genes[162]), the enzyme carbonic anhydrase IX (CA-9 or CAIX, involved in respiration and maintenance of the proper acid-base balance in tissues[163,164]), glucose transporter-1 (GLUT-1, which facilitates glucose transport into cells[165-167]), lysyl oxidase (LOX, which oxidizes lysine residues in extracellular matrix proteins that can enhance the processes of tumor invasion and metastasis[168,169]) and osteopontin (OPN, a glycoprotein recently identified as a promoter of tumor angiogenesis, invasion, and metastasis[170-172]).

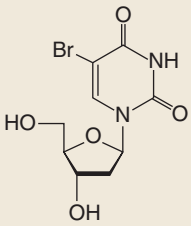
Clearly, although aberrant expression of some individual hypoxia markers has been associated with poor clinical outcome, no one marker is likely to be sufficiently robust or reproducible to either be diagnostic for the presence of a malignancy (or at least, the presence of hypoxia in an already-diagnosed tumor) or be prognostic of treatment outcome. Thus, there has been increasing interest in the study of patterns of hypoxia-associated gene or protein expression for multiple markers simultaneously (e.g., Le,[5] Erpolate et al,[172] Toustrup et al[173]).

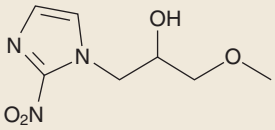
Radiosensitizers, Radioprotectors, and Bioreductive Drugs

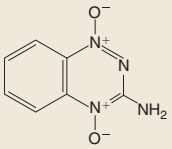
The perceived threat that tumor hypoxia posed spawned much research into ways of overcoming the hypoxia problem. One of the earliest proposed solutions was the use of high LET radiations,[174] which were less dependent on oxygen for their biological effectiveness. Other agents enlisted to deal with the hypoxia problem included hyperbaric oxygen breathing,[138] artificial blood substitutes with increased oxygen carrying capacity,[175] oxygen-mimetic hypoxic cell radiosensitizers such as misonidazole or etanidazole,[140] hyperthermia,[176] normal tissue radioprotectors such as amifostine,[177] vasoactive agents thought to modify tumor blood flow such as nicotinamide,[178] agents that modify the oxygen-hemoglobin dissociation curve such as pentoxifylline,[179] and bioreductive drugs designed to be selectively toxic to hypoxic cells such as tirapazamine.[180,181]

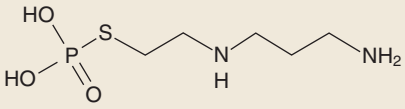
Radiosensitizers

Radiosensitizers are loosely defined as chemical or pharmacological agents that increase the cytotoxicity of ionizing radiation. True radiosensitizers meet the stricter criterion of being relatively nontoxic in and of themselves, acting only as potentiators of radiation toxicity. Apparent radiosensitizers still produce the net effect of making the tumor more radioresponsive, yet the mechanism is not necessarily synergistic, nor is the agent necessarily nontoxic when given alone. Ideally, a radiosensitizer is only as good as it is selective for tumors. Agents that show little or no differential effect between tumors and normal tissues do not improve the therapeutic ratio, and therefore may not be of much clinical utility. Table 1-2 summarizes some of the classes of radiosensitizers (and radioprotectors, see discussion) that have been used in the clinic.









Hypoxic Cell Radiosensitizers

The increased radiosensitivity of cells in the presence of oxygen is believed to be as a result of oxygen's affinity for the electrons produced by the ionization of biomolecules. Molecules other than oxygen also have this chemical property known as electron affinity,[182] including some agents that are not otherwise consumed by the cell. Assuming such an electron-affinic compound is not used by the cell, it should diffuse further from capillaries and reach hypoxic regions of a tumor, and acting in an oxygen-mimetic fashion, sensitize hypoxic cells to radiation.

One class of compounds that represented a realistic tradeoff between sensitizer efficiency and diffusion effectiveness was the nitroimidazoles, which include such drugs as metronidazole, misonidazole, etanidazole, pimonidazole, and nimorazole. The nitroimidazoles consist of a nitroaromatic imidazole ring, a hydrocarbon side chain that determines the drug's lipophilicity, and a nitro group that determines the drug's electron affinity. Misonidazole was extensively characterized in cellular and animal model systems, culminating in its use in clinical trials. Clinical experiences with misonidazole and some of its successor compounds are discussed in Chapter 7.

The relative efficacy of a particular hypoxic cell radiosensitizer is most often described in terms of its sensitizer enhancement ratio (SER), which is a parameter similar in concept to the OER. Whereas the OER is the ratio of doses to produce the same biological endpoint under hypoxic versus aerobic conditions, the SER is the dose ratio for an isoeffect under hypoxic conditions alone versus under hypoxic conditions in the presence of the hypoxic cell sensitizer. Accordingly, if a dose of a sensitizer produces an SER of 2.5 to 3.0 for large single doses

TABLE 1-2 Selected Chemical Modifiers of Radiation Therapy

Chemical Structure	Name (Type of Compound)	Mechanism of Action	Clinic Status
	5-Bromodeoxyuridine (Halogenated Pyrimidine)	Radiosensitizer of rapidly proliferating cells through incorporation into DNA during S phase. Uptake results in decrease or removal of the shoulder of the radiation survival curve.	No clear evidence of clinical efficacy has been established to date. The drug continues to be used in a research setting.
	Misonidazole (2-Nitroimidazole)	Radiosensitizer of hypoxic cells. Principal mechanism of action is mimicry of oxygen's ability to "fix" free radical damage caused by exposure to radiation and some toxic chemicals.	Clinical trial results were disappointing overall, except in selected sites, most notably, head and neck cancer. The drug's failure largely has been ascribed to a dose-limiting toxicity, peripheral neuropathy.
	Tirapazamine (Organic Nitroxide)	Bioreductive drug selectively toxic to hypoxic cells. The drug is reduced to a toxic intermediate capable of producing DNA strand breaks only in the relative absence of oxygen.	Phase II and II clinical trials to date have been disappointing overall, except in select subsets of patients with head and neck or lung cancer. Some trials are still ongoing for the drug combined with radiotherapy and cis-platinum.
	Amifostine (Thiol Free Radical Scavenger)	Radioprotector capable of restituting free radical damage caused by exposure to radiation and some toxic chemicals.	FDA-approved indications for amifostine include protection against the nephro- and ototoxicity of platinum drugs, and to reduce the incidence and severity of xerostomia in patients receiving radiotherapy for head and neck cancer.

of low LET radiation, it can be considered, to a first approximation, as effective as oxygen. This statement can be misleading however, in that the dose of the sensitizer required to produce the SER of 3.0 would be higher than the comparable dose of oxygen and high enough in some cases to preclude its use clinically. Finally, because the primary mechanism of action of the nitroimidazoles is substitution for oxygen in radiation-induced free radical reactions, these drugs need only be present in hypoxic regions of the tumor at the time of irradiation.

Unfortunately, the nitroimidazoles also have characteristics that decrease their clinical usefulness. The hydrocarbon side chain of the molecule determines its lipophilicity, and this chemical property affects the drug's pharmacokinetics, which is a primary determinant of drug-induced side effects.[183] The dose-limiting toxicity of the fairly lipophilic agent misonidazole is peripheral neuropathy, an unanticipated and serious side effect.[140,184] Etanidazole was specifically designed to be less lipophilic[185] in the hopes of decreasing the neurological toxicity. Although this goal was accomplished as a proof of concept, clinical results with etanidazole were otherwise disappointing[186] (see also Chapter 7).

Finally, in considering the prodigious amount of research and clinical effort that has gone into the investigation of hypoxic cell radiosensitizers over the past 50 years, it is difficult not to be discouraged by the predominantly negative results of the clinical trials. However, these negative results have prompted a rethinking of the hypoxia problem and novel approaches to dealing with it, as well as consideration of other factors that may have contributed to the lack of success of the nitroimidazole radiosensitizers.[184] Among the more obvious questions raised include:

1. Did the patients entered on the various clinical trials actually have tumors that contained clonogenic hypoxic cells? At the time of most of these studies, hypoxia markers were not yet available, so it was not possible to triage patients into subgroups in advance of treatment.
2. Do hypoxic cells really matter to the outcome of radiotherapy? If reoxygenation is fairly rapid and complete during radiotherapy, the presence of hypoxic cells before the start of treatment may be of little consequence.
3. Given that the OER is lower for small than for large doses, it follows that the SER would be reduced as well. If so, a benefit in a subgroup of patients might not be readily observed, at least not at a level of statistical significance.

Bioreductive Drugs

In the wake of the failure of most hypoxic cell radiosensitizers to live up to their clinical potential, a new approach to

combating hypoxia emerged: the use of bioreductive drugs that are selectively toxic to hypoxic cells. Although these agents kill rather than sensitize hypoxic cells, the net effect of combining them with radiation therapy is an apparent sensitization of the tumor, resulting from the elimination of an otherwise radioresistant subpopulation. Such drugs have been shown to outperform the nitroimidazole radiosensitizers in experimental studies with clinically relevant fractionated radiotherapy.[187] To the extent that hypoxic cells are also resistant to chemotherapy because of tumor microenvironmental differences in drug delivery, pH or the cell's proliferative status, complementary tumor cell killing might be anticipated for combinations of bioreductive agents and anticancer drugs as well.[188]

Most hypoxia-specific cytotoxic drugs fall into three categories: the nitroheterocyclics, the quinone antibiotics, and the organic nitroxides.[189] All require bioreductive activation by nitroreductase enzymes, such as cytochrome P450, DT-diaphorase, and nitric oxide synthase, to reduce the parent compound to its cytotoxic intermediate, which is typically an oxidizing free radical capable of damaging DNA and other cellular macromolecules. The active species is either not formed or else immediately back-oxidized to the parent compound in the presence of oxygen, which accounts for its preferential toxicity under hypoxic conditions. Examples of nitroheterocyclic drugs with bioreductive activity include misonidazole and etanidazole[190,191] and dual function agents such as RSU 1069.[192] The latter drug is *dual function* because its bioreduction also activates a bifunctional alkylating moiety capable of introducing cross-links into DNA. Mitomycin C and several of its analogs (including porfiromycin and EO9) are quinones with bioreductive activity that have been tested in randomized clinical trials in head and neck tumors (e.g., Haffty et al[193]).

The lead compound for the third class of bioreductive drugs, the organic nitroxides, is tirapazamine (SR 4233, see Table 1-2).[180,181,187] The dose-limiting toxicity for single doses of tirapazamine is a reversible hearing loss; other effects observed include nausea and vomiting and muscle cramps.[194]

Tirapazamine is particularly attractive because it both retains its hypoxia-selective toxicity over a broader range of (low) oxygen concentrations than the quinones and nitroheterocyclic compounds,[195] and its hypoxic cytotoxicity ratio, which is the ratio of drug doses under hypoxic versus aerobic conditions to yield the same amount of cell killing, averages an order of magnitude higher than for the other classes of bioreductive drugs.[188] Laboratory and clinical data also support a tumor sensitizing role for tirapazamine in combination with the chemotherapy agent cisplatinum.[194]

To date, randomized Phase II and III clinical trials with tirapazamine combined with radiotherapy and/or chemotherapy (particularly, cisplatinum) have yielded mixed results[194,196,197]; however, it has improved outcomes for some standard treatments. Although it is disappointing that tirapazamine hasn't made a more significant impact on clinical practice, the search for more effective agents from the same or similar chemical class continues.

Proliferating Cell Radiosensitizers

Another source of apparent radioresistance is the presence of rapidly proliferating cells. Such cells may not be inherently radioresistant, but rather, have the effect of making the tumor seem refractory to treatment because the production of new cells outpaces the cytotoxic action of the therapy.

Analogs of the DNA precursor thymidine, such as bromodeoxyuridine (BrdUdR) or iododeoxyuridine (IdUdR), can be incorporated into the DNA of actively proliferating cells in place of thymidine because of close structural similarities between the compounds. Cells containing DNA substituted with these halogenated pyrimidines are more radiosensitive than normal cells, with the amount of sensitization directly proportional to the fraction of thymidine replaced.[198] In general, the radiosensitization takes the form of a decrease in or elimination of the shoulder region of the radiation survival curve. To be maximally effective, the drug must be present for at least several rounds of DNA replication before irradiation. Although the mechanism by which BrdUdR and IdUdR exert their radiosensitizing effect remains somewhat unclear, it is likely that both the formation of more complex radiation-induced lesions in the vicinity of the halogenated pyrimidine molecules and interference with DNA damage sensing or repair are involved.[199]

The clinical use of halogenated pyrimidines began in the late 1960s, with a major clinical trial in head and neck cancer.[200] In retrospect, the choice of head and neck tumors for this study was far from ideal because the oral mucosa is also a rapidly proliferating tissue and was similarly radiosensitized, causing severe mucositis and a poor therapeutic ratio overall. In later years, tumors selected for therapy with halogenated pyrimidines were chosen in the hopes of better exploiting the differential radiosensitization between tumors and normal tissues.[201] Aggressively growing tumors surrounded by slowly proliferating or nonproliferating normal tissues, such as high-grade brain tumors or some sarcomas, have been targeted for example.[202,203] Later strategies for further improving radiosensitization by BrdUdR and IdUdR involved changing the schedule of drug delivery: giving the drug as a long, continuous infusion both before and during radiotherapy[204] and administering the drug as a series of short, repeated exposures.[205] Overall however, the use of halogenated pyrimidines in the clinic has remained experimental and has not become mainstream.

Chemotherapy Drugs as Radiosensitizers

Several chemotherapy agents have long been known to increase the effectiveness of radiotherapy, despite not being true radiosensitizers like the nitroimidazoles. This has driven the clinical practice of treating many more patients today than in the past with chemotherapy and radiation therapy given concurrently. Two drugs in particular used for chemoradiotherapy are 5-fluorouracil (5-FU, effective against GI malignancies[206]) and cisplatinum (effective against head and neck[207] and cervical cancers[208]).

Based on these clinical successes in combining radiation with concurrent chemotherapy and with ever-increasing numbers of molecularly targeted drugs and biologics available today, it is naturally of interest whether any of these novel compounds could also act as radiosensitizers. Two classes of such drugs already have entered the clinical mainstream as sensitizers: the anti-epidermal growth factor receptor (EGFR) inhibitors and the anti-vascular endothelial growth factor (VEGF) inhibitors. Cetuximab is a monoclonal antibody raised against the EGFR that has been shown to improve outcomes in advanced head and neck cancers when combined with radiation therapy,[209] and bevacizumab, a humanized monoclonal antibody raised against VEGF, prolongs overall and progression-free survival in patients with advanced colorectal cancer when combined with standard chemotherapy.[210] It is hoped that these and other targeted agents will play greater roles in cancer therapy in the future.

Normal Tissue Radioprotectors

Amifostine (WR 2721, see Table 1-2) is a phosphorothioate compound developed by the U.S. Army for use as a radiation protector. Modeled after naturally occurring radioprotective sulfhydryl compounds such as cysteine, cysteamine, and glutathione,[211] amifostine's mechanism of action involves the scavenging of free radicals produced by ionizing radiation, which are radicals that otherwise could react with oxygen and "fix" the chemical damage. Amifostine can also detoxify other

reactive species through the formation of thioether conjugates, and in part because of this, the drug can also be used as a chemoprotective agent.[212] Amifostine is a pro-drug that is dephosphorylated by plasma membrane alkaline phosphatase to the free thiol WR 1065, the active metabolite. As is the case with the hypoxic cell radiosensitizers, amifostine need only be present at the time of irradiation to exert its radioprotective effect.

In theory, if normal tissues could be made to tolerate higher total doses of radiation through the use of radioprotectors, then the relative radioresistance of hypoxic tumor cells would be less likely to limit radiation therapy. However, encouraging preclinical studies demonstrating radioprotection of a variety of cells and tissues notwithstanding,[213,214] radioprotectors like amifostine would *not* be expected to increase the therapeutic ratio unless they could be introduced selectively into normal tissues but not tumors. The pioneering studies of Yuhas et al[177,215,216] addressed this issue by showing that the drug's active metabolite reached a higher concentration in most normal tissues than in tumors and that this mirrored the extent of radio- or chemoprotection. The selective protection of normal tissues results from slower tumor uptake of the drug, and tumor cells being both less able to convert amifostine to WR 1065 (resulting from lower concentrations of the required phosphatases) and to transport this active metabolite throughout the cell.

Dose reduction factors (DRFs, the ratio of radiation doses to produce an isoeffect in the presence versus the absence of the radioprotector) in the range of 1.5 to 3.5 are achieved for normal tissues, whereas the corresponding DRFs for tumors seldom exceed 1.2. Those normal tissues exhibiting the highest DRFs include bone marrow, gastrointestinal tract, liver, testes, and salivary glands.[177] Brain and spinal cord are not protected by amifostine, and oral mucosa is only marginally protected.[177] Comparable protection factors are obtained for some chemotherapy agents, including cyclophosphamide and cisplatin.[217,218] The dose-limiting toxicities associated with the use of amifostine include hypotension, emesis, and generalized weakness or fatigue.[219]

Amifostine is currently indicated for the reduction of renal toxicity associated with repeated cycles of cisplatin chemotherapy in patients with advanced ovarian and non–small cell lung cancer. It is also approved for use in patients receiving radiotherapy for head and neck cancer, in the hopes of reducing xerostomia secondary to exposure of the parotid glands.

Finally, just as there are apparent radiosensitizers, there are also apparent radioprotectors that have the net effect of allowing normal tissues to better tolerate higher doses of radiation and chemotherapy but through mechanisms of action not directly related to the scavenging of free radicals. Various biological response modifiers, including cytokines, prostaglandins (such as misoprostol[220,221]), anticoagulants (such as pentoxifylline[222,223]), and protease inhibitors are apparent radioprotectors because they can interfere with the chain of events that normally follows the killing of cells in tissues by, for example, stimulating compensatory repopulation or preventing the development of fibrosis. Finally, there is also growing interest in the use of biologics that inhibit apoptosis as normal tissue radioprotectors.[224,225] Such agents should have little or no effect on tumor cells, most of which are already resistant to apoptosis.

CLINICAL RADIOBIOLOGY

Growth Kinetics of Normal Tissues and Tumors

In the simplest sense, normal tissues are normal because the net production of new cells, if it occurs at all, exactly balances the loss of old cells from the tissue. In tumors, the production of new cells exceeds cell loss, even if only by a small amount. Although the underlying radiobiology of cells in vitro applies equally to the radiobiology of tissues, the imposition by growth kinetics of this higher level of organizational behavior makes the latter far more complex systems.

Descriptive Classification Systems

Two qualitative classification systems based loosely on the proliferation kinetics of normal tissues are in use. Borrowing heavily from the pioneering work of Bergonié and Tribondeau,[13] Rubin and Casarett's[226] classification system for tissue radiosensitivity consists of four main categories:

Type I or vegetative intermitotic (VM) cells are considered the most radiosensitive and consist of regularly dividing, undifferentiated stem cells, such as are found in the bone marrow, intestinal crypts, and the basal layer of the epidermis of the skin.

Type II or differentiating intermitotic (DIM) cells are somewhat less radiosensitive and consist of transitional cells that are in the process of developing differentiated characteristics, yet are still capable of a limited number of cell divisions. Myelocytes of the bone marrow and spermatocytes of the testis are examples of Type II cells.

Type III or reverting postmitotic (RPM) cells are relatively radioresistant and consist of those few types of cells that are fully differentiated and do not divide regularly, yet under certain conditions can revert to a stem cell-like state and divide as needed. Examples of Type III cells include hepatocytes and lymphocytes, although the latter are unique in that they are a notable exception to the Rubin and Casarett classification system—an RPM cell type that is exquisitely radiosensitive.

Type IV or fixed postmitotic (FPM) cells are the most radioresistant and consist of the terminally differentiated, irreversibly postmitotic cells characteristic of most normal tissue parenchyma, such as neurons and muscle cells. Should such cells be killed by radiation, they typically cannot be replaced.

A second, simpler classification system, based on anatomical and histological considerations, has been proposed by Michalowski.[227] Using this system, tissues are categorized on the basis of whether the tissue stem cells, if any, and the functional cells are compartmentalized (so-called Type H or hierarchical tissues, such as skin, gut epithelium, testis, etc.), or intermixed (Type F or flexible tissues, such as lung, liver, kidney, and spinal cord).

Growth Kinetic Parameters and Methodologies

To predict the response of an intact tissue to radiation therapy in a more quantitative way, a number of kinetic parameters have been described that provide a better picture of the proliferative organization of tumors and normal tissues (Table 1-3).

Growth Fraction

Among the first kinetic characteristics described was the growth fraction (GF). The presence of a fraction of slowly or noncycling cells in experimental animal tumors was first noted by Mendelsohn et al[228,229] and subsequently, in human tumors by others. Although normal tissues don not grow and therefore do not have a growth fraction per se, many are composed of noncycling cells that have differentiated to carry out tissue-specific functions. Some normal tissues do contain a small fraction of actively proliferating stem cells, and others contain apparently dormant or resting cells that are temporarily out of the traditional four-phase cell cycle but are capable of renewed proliferation in response to appropriate stimuli.

TABLE 1-3 Estimated Cell Cycle Kinetic Parameters for Human Tumors

Parameter	Definition	How Measured	Representative Values for Human Solid Tumors	Notes
T_c	(Average) cell cycle time	Percent labeled mitosis technique; flow cytometry	0.5-6.5 days (median ≈ 2.5 days)	T_c in vivo usually longer than for comparable cells cultured in vitro
GF	Growth fraction	Estimated from continuous labeling technique	0.05-0.90 (median ≈ 0.40?)	Difficult to measure directly; not much data available
T_{pot}	Potential doubling time	Flow cytometry (relative movement method: $T_{pot} = \lambda T_s/LI$)	2-19 days (median ≈ 5 days)	$T_{pot} \approx T_c$ as GF approaches 1.0
ϕ	Cell loss factor	$1 - T_{pot}/T_d$	0.30-0.95 (median ≈ 0.90?)	Thought to be the major cause of long T_d for human tumors; particularly high in carcinomas
T_d	Volume doubling time	Direct measurement of tumor dimensions over time	5-650 days (median ≈ 90 days)	Increases with increasing tumor size, often because of increases in Tc and f, and a decrease in GF
T_{eff}/T_p	Effective clonogen doubling time	Estimated from clinical data on the loss of local control with increasing overall treatment time	4-8 days	T_p approaches T_{pot} toward the end of a course of fractionated radiotherapy

Data from Steel GG: Growth kinetics of tumours, Oxford, 1977, Clarendon Press; and Joiner M, van der Kogel A, editors: Basic clinical radiobiology, ed 4. London, 2009, Hodder Arnold.

Lajtha gave these resting but recruitable cells of normal tissues the designation G_0.[230] Although a tumor counterpart of the G_0 cell may or may not exist, the majority of slowly or noncycling tumor cells are thought to be in such a state because of nutrient deprivation, not because of a normal cell cycle regulatory mechanism. Thus, Dethlefsen[231] has suggested that the term *Q cell* be reserved for quiescent cells in tumors to distinguish them from the G_0 cell of normal tissues.

Measurement of a tumor's growth fraction is problematic,[232,233] but an estimate can be obtained with a technique known as continuous thymidine labeling. Using this method, the tumor receives a continuous infusion of radio-labeled thymidine for a period of time long enough for all proliferating cells to have gone through at least one round of DNA synthesis and incorporated the radioactive label. Then, a biopsy of the tumor is obtained and tissue sections prepared for autoradiography. Once the slides are processed and scored, the continuous labeling index, which is that fraction of the total population of tumor cells containing tritiated thymidine, is calculated. This value is a rough estimate of the tumor's growth fraction.

Cell Cycle and Volume Doubling Times

The percent labeled mitosis (PLM) technique of Quastler and Sherman[234] was a key development in the study of the cell cycle in vivo because it provided a unique window into the behavior of that small fraction of cells within a tissue that was actively proliferating. By focusing on cells in mitosis, the assay allowed both the overall cell cycle time (T_c) and the durations of the individual cell cycle phases to be determined without the uncertainties introduced by the presence of noncycling cells in the population. Today, flow cytometric methods have largely replaced the arduous and time-consuming PLM assay.

Briefly, the PLM technique involves tracking a cohort of proliferating cells over time that initially was in S phase (and exposed briefly to tritiated thymidine) and then proceeded through subsequent mitotic divisions. Serial biopsy samples from the tissue of interest are obtained at regular intervals following labeling, and the fraction of cells both in mitosis (identified cytologically) *and* carrying the radioactive label is determined. A first peak of labeled mitoses is observed within 24 hours after labeling, and as cells pass through their second division, a second wave of labeled mitoses is noted. The average T_c for the population of proliferating cells corresponds to the peak-to-peak interval of the resulting PLM curve, a plot of the fraction of labeled mitoses as a function of time following the radioactive pulse. With sufficiently robust data, the durations of the individual cell cycle phases can be obtained as well. The PLM technique is illustrated schematically in Figure 1-25.

Historically, the interpretation of PLM curves was sometimes hampered by technical artifacts and by the fact that proliferating cell populations have distributed cell cycle times.[232,233,235] Despite these limitations, it is clear that most cells in vivo proliferate more slowly than their in vitro counterparts. Although the variation in intermitotic times is quite large, a median value for T_c of 2-3 days is a reasonable estimate.[232]

Although the cycle times of proliferating cells in vivo are long by cell culture standards, they are quite short when compared to the corresponding population or volume doubling times (T_d) for human tumors. Although highly variable from tumor type to tumor type and somewhat difficult to measure, the T_d for human solid tumors averages about 3-4 months.[232] In many cases, sample calculations further suggest that the discrepancy between T_c for proliferating tumor cells and T_d for the tumor as a whole cannot be accounted for solely by the tumor having a low growth fraction.

Cell Loss Factor

Cell kineticists initially adhered to the notion that the continued growth of tumors over time reflected abnormalities in cell production. Pathologists and tumor biologists meanwhile had ample evidence that tumors routinely lost large numbers of cells, which was the result of cell death, maturation, or emigration.[232,236,237] It is now clear that the overall rate of tumor growth, as reflected by its T_d, is governed by the competing processes of cell production and cell loss. In fact, the cell loss factor, ϕ, which is the rate of cell loss expressed as a fraction of the cell production rate, is surprisingly high for both experimental and human tumors, as high as 0.9 or more for carcinomas, and lower, on average, for sarcomas.[232] Cell loss is usually

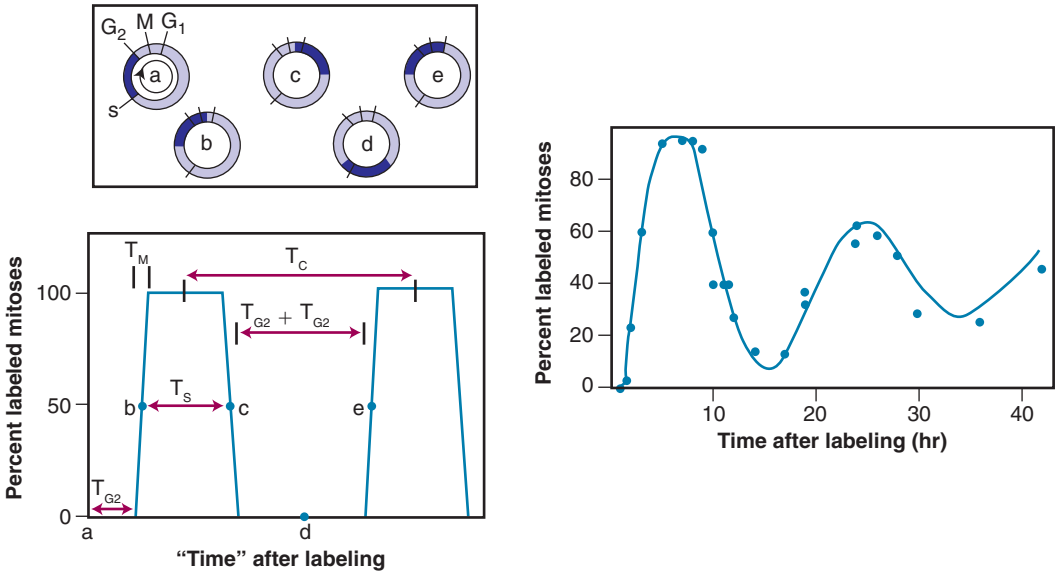


Figure 1-25 The technique of percent labeled mitoses (PLM) for an idealized cell population with identical cell cycle times *(left panels)* and for a representative normal tissue or tumor with a dispersion in cell cycle times *(right panel)*. *Upper left panel*, After a brief exposure to tritiated thymidine or equivalent at time a, the labeled cohort of S-phase cells continues *(dark shading)* around the cell cycle and is sampled at times b, c, d, and e. *Lower left panel*, For each sample, the percentage of cells both in mitosis and containing the thymidine label is determined, and it is plotted as a function of time. From such a graph, individual cell cycle phase durations can be derived. *Right panel*, In this more practical example, a mathematical fit to the PLM data would be needed to calculate the (average) cell cycle phase durations.

the most important factor governing the overall volume doubling time of solid tumors.

The clinical implications of tumors having high rates of cell loss are obvious. First, any attempts at making long-term predictions of treatment outcome based on short-term regression rates of tumors during treatment are misleading. Second, although regression rate may not correlate well with eventual outcome, it may be a reasonable indicator of when best to schedule subsequent therapy, on the assumption that a smaller tumor will be more radio- and chemo-sensitive, as well as easier to remove surgically.

Potential Doubling Time and Effective Doubling Time

With the recognition that cell loss plays a major role in the overall growth rate of tumors and that it can mask a high cell production rate, a better measure of the potential repopulation rate of normal tissues and tumors was needed.[238] One indicator of regenerative capacity is the potential doubling time, or T_{pot}.[232,239] By definition, T_{pot} is an estimate of the time that would be required to double the number of clonogenic cells in a tumor in the absence of cell loss. It follows therefore that T_d will usually be much longer than T_{pot} because of cell loss, and T_c will usually be shorter than T_{pot} because of the presence of non-proliferating cells.[235]

T_{pot} can be estimated from a comparison of the S phase pulse labeling index (LI) and the duration of S phase (T_S) by using the following equation,

$$T_{pot} = \lambda\, T_S / LI$$

where λ is a correction factor related to the nonuniform distribution of cell ages in a growing population (usually, $\lambda \approx 0.8$). T_S and LI can determined by the relative movement method.[239,240] This technique involves an injection of a thymidine analog, usually BrdUrd, which is promptly incorporated into newly synthesized DNA and whose presence can be detected using flow cytometry. The labeled cohort of cells is then allowed to continue movement through the cell cycle, and a biopsy of the tumor is taken several hours later, at which point the majority of the cells containing BrdUrd have progressed into G_2 phase or beyond. A value for LI is determined from the fraction of the total cell population that contains BrdUrd, and T_S is calculated from the rate of movement of the labeled cohort during the interim between injection of the tracer and biopsy.

Values for T_{pot} for human tumors have been measured, and although quite variable, typically range between 2 and 20 days.[232,238,241] These findings lend support to the important idea that slowly growing tumors can contain subpopulations of rapidly proliferating cells. To the extent that these cells retain unlimited reproductive potential, they may be considered the tumor's stem cells (in a generic sense at least) capable of causing recurrences after treatment. These cells represent a serious threat to local control of the tumor by conventional therapies, especially protracted treatments (that provide them additional time to proliferate).

The use of a cell kinetic parameter such as T_{pot} as either a predictor of a tumor's response to therapy or as a means of identifying subsets of patients particularly at risk for recurrence has been attempted, with some positive, but mostly negative, results.[6,139,242] Lest these negative findings suggest that proliferation in tumors is *un*important, bear in mind that it is unlikely that a pretreatment estimate of T_{pot}—or any other single cell kinetic parameter (e.g., LI) for that matter—would be relevant once treatment commences and the growth kinetics of the tumor are perturbed.

One approach to dealing with this problem is to measure proliferative activity *during* treatment. Although not without other limitations, the use of an effective clonogen doubling time (T_{eff} or T_p) has been advocated.[243-245] Estimates of T_p can be obtained from two types of experiments. In an experimental setting, T_p can be inferred from the additional dose necessary to keep a certain level of tissue reaction constant as the overall treatment time is increased. (When expressed in terms of dose rather than time, the proper term would be D_{eff}, although the underlying concept is the same.) For example,

acute skin reactions usually both develop and begin to resolve during the course of radiation therapy, suggesting that the production of new cells in response to injury gradually surpasses the killing of existing cells by each subsequent dose fraction. By intensifying treatment once this repopulation begins, it should be theoretically possible to reach a steady state wherein the tissue reaction remains constant. In a clinical setting, T_p can be estimated from a comparison of tumor control rates for treatment schedules in which the dose per fraction and total dose used were held approximately constant, but the overall treatment time varied. In some cases, the rate of loss of local control with increasing overall treatment time provides an estimate not only of T_p but also of the delay time before the repopulation begins, sometimes referred to as T_k, which is the repopulation kickoff time.[246-248]

Repopulation in Tumors and Normal Tissues

As discussed previously, both normal tissues and tumors are capable of increasing their cell production rate in response to depopulation caused by radiation exposure, a process known as regeneration or repopulation. The time of onset of the regenerative response varies with the turnover rate of the tissue or tumor because cell death (and depopulation) following irradiation is usually linked to cell division. Generally, tissues that naturally turn over fairly rapidly repopulate earlier and more vigorously than tissues that turn over slowly. However, it has been shown that the repopulation patterns of normal tissues and tumors following the start of irradiation tend to be characterized by a delay (of at least several weeks in many cases; see T_k discussion) before the rapid proliferative response.[246-248] Once this proliferative response begins, however, it can be quite vigorous. Although this is clearly desirable for early-responding normal tissues attempting to recover from radiation injury, rapid proliferation in tumors is certainly counterproductive.[249] For example, clinical studies of local control of head and neck tumors indicate that an average of about 0.6 Gy per day is lost to repopulation.[243] Unfortunately, attempts to counteract this accelerated proliferation by dose intensification during the latter part of a treatment course can be problematic because late-responding normal tissues do not benefit from accelerated repopulation during treatment and risk incurring complications.

Increased cell production in response to injury is thought to occur by one or more of three basic mechanisms: a decrease in the cell loss rate, a shortening of the cell cycle time, or an increase in the growth fraction.[57,232] Normal tissues are capable of using at least the latter two strategies to accelerate repopulation. It is still not clear how, when, and to what extent tumors accelerate their proliferation in response to cell killing. Laboratory and clinical findings suggest that a decrease in cell loss may be a major mechanism, possibly as a consequence of resistance to apoptosis, which is a hallmark of most types of cancer.[244,250,251] This is a provocative finding in that it suggests that there may be a fundamental—and potentially exploitable—difference in the way normal and tumor tissues respond to ionizing radiation.

Early and Late Effects in Normal Tissues

Early versus Late

Normal tissue complications observed following radiation therapy are the result, either directly or indirectly, of the killing of critical target cells within the tissue that are crucial to the tissue's continued functional or structural integrity. The loss of these target cells can occur either as a direct consequence of the cytotoxic action of the radiation or indirectly as a result of the radiation injury or killing of other cells. In some cases, the tissue's response to the depletion of its component cells can exacerbate the injury, for example, when a hyperproliferation of fibroblasts and the resulting collagen deposition replace a tissue's parenchymal cells, resulting in fibrosis.

It is important to realize that a particular tissue or organ may contain more than one type of target cell, each with its own radiosensitivity. One tissue may manifest more than one complication following radiation therapy, with the severity of each determined by the radiosensitivity of the particular target cell and the time-dose fractionation schedule employed. It follows from this that the severity of one complication does not necessarily predict for the severity of another complication, even within the same tissue (although consequential late effects secondary to severe early reactions are possible in some cases[252]). For example, dry or moist desquamation of the skin results from the depletion of the basal cells of the epidermis, fibrosis results from damage to dermal fibroblasts, and telangiectasia results from damage to small blood vessels in the dermis. For many tissues however, the target cell(s) whose death is (are) responsible for a particular normal tissue injury remain unclear.

Although the radiosensitivity of the putative target cells determines the severity of an early or late effect in a normal tissue, the earliness or lateness of the clinical manifestation of that injury is related to the tissue's proliferative organization (discussed previously). The distinction between the radiosensitivity of a tissue's cells and the radioresponsiveness of the tissue as a whole can be a source of confusion. Bergonié and Tribondeau's laws,[13] for example, confused the concepts of radiosensitivity and radioresponsiveness to some extent, referring to tissues that responded to damage early as radiosensitive, when this was not necessarily the case.

Whole-Body Radiation Syndromes

Many human beings have been exposed to total body irradiation, including the survivors of Hiroshima and Nagasaki, Polynesian Islanders and military personnel present during aboveground nuclear tests during the 1950s, and victims of accidental exposures in the workplace (including Chernobyl, and possibly, Fukushima). Of the latter, about 100 fatalities resulting from radiation accidents have been documented since the mid-1940s.[253-255]

The whole-body radiation syndromes are considered early effects of radiation exposure because, for sufficiently high doses, death occurs within weeks after irradiation. The clinical syndromes described herein only occur when most or all of the body is irradiated. Also, although total body irradiation (TBI) is a prerequisite for the manifestation of these syndromes, neither the dose received nor its biological consequences are necessarily uniform. The radiosensitivities of the respective target cells determine the effective threshold dose below which the syndrome does not occur, whereas the onset time of individual symptoms is governed more by the proliferative organization of the tissue.

The mean lethal dose or LD_{50} is defined as the (whole body) dose that results in mortality for 50% of an irradiated population. The LD_{50} value is often expressed in terms of the time scale over which the deaths occur, such as at either 30 or 60 days after irradiation. For humans, the single-dose $LD_{50/60}$ for x- or γ-rays is approximately 3.5 Gy in the absence of medical intervention and about twice that with careful medical management.[28,255] The LD_{50} increases with decreasing dose rate of low LET radiation and decreases for radiations of higher LET.

The Prodromal Syndrome

The prodromal syndrome consists of one or more transient, neuromuscular and gastrointestinal symptoms that begin soon after irradiation and persist for up to several hours. The symptoms, which can include anorexia, nausea, vomiting,

diarrhea, fatigue, disorientation, and hypotension, and their severity and duration, increase with increasing dose. Because in most radiation accident situations the dose victims received is unknown initially, careful attention to the prodromal syndrome can be used as a crude dosimeter.

The Cerebrovascular Syndrome

The cerebrovascular syndrome occurs for total body doses in excess of 50 Gy. The onset of signs and symptoms is almost immediate following exposure, consisting of severe gastrointestinal and neuromuscular disturbances including nausea and vomiting, disorientation, ataxia, and convulsions.[28,255] The cerebrovascular syndrome is invariably fatal, and survival time is seldom longer than about 48 hours. Only a few instances of accidental exposure to such high doses have occurred, two of which (a nuclear criticality accident at Los Alamos National Laboratory in 1958, and a ^{235}U reprocessing plant accident in Rhode Island in 1964) have been extensively documented in the medical literature.[256,257]

The immediate cause of death for the cerebrovascular syndrome is likely vascular damage leading to progressive brain edema, hemorrhage, or cardiovascular shock.[255] Following such high doses delivered acutely, even cells traditionally considered radioresistant, such as neurons and the parenchymal cells of other tissues and organs, will be killed, as well as the more radiosensitive vascular endothelial cells and the various glial cells of the central nervous system.

The Gastrointestinal Syndrome

For doses upward of about 8 Gy, the gastrointestinal syndrome predominates, characterized by lethargy, vomiting and diarrhea, dehydration, electrolyte imbalance, malabsorption, weight loss, and ultimately, sepsis. These symptoms begin to appear within a few days of irradiation and are progressive in nature, culminating in death after 5 to 10 days. The target cells for the gastrointestinal syndrome are principally the crypt stem cells of the gut epithelium. As mature cells of the villi are lost over a several-day period, no new cells are available to replace them, so the villi begin to shorten and eventually become completely denuded. This greatly increases the risk of bleeding and sepsis, both of which are aggravated by declining blood counts.

Before the Chernobyl accident, in which approximately a dozen firefighters received total doses sufficient to succumb to the gastrointestinal syndrome, there was only one other documented case of a human dying of gastrointestinal injury.[28,255] To date, no human has survived a documented whole-body dose of 10 Gy of low LET radiation.

The Hematopoietic Syndrome

Acute doses of approximately 2.5 Gy or more are sufficient to instigate the hematopoietic syndrome, which is a consequence of the killing of bone marrow stem cells and lymphocytes. This syndrome is characterized by a precipitous (within a day or two) reduction in the peripheral blood lymphocyte count, followed by a more gradual reduction (over a period of 2 to 3 weeks) in the numbers of circulating leukocytes, platelets, and erythrocytes. The granulocytopenia and thrombocytopenia reach a maximum within 30 days after exposure, and death, if it is to occur, is usually a result of infection or hemorrhage.[28,255] Theoretically, the use of antibiotics, blood transfusions, and bone marrow transplantation can save the lives of individuals who receive doses at or near the LD_{50}. In practice however, the exact dose is seldom known and should it be high enough to reach the threshold for the gastrointestinal syndrome, such heroic measures would be in vain. Unfortunately, this was the case for all but 2 of the 13 Chernobyl accident victims who received bone marrow transplants.[28] Of the two survivors, only one can rightfully be claimed as having had his life saved by the transplant; the other survivor showed autologous bone marrow repopulation.

Teratogenesis

One of the most anxiety-provoking risks of irradiation in the eyes of the general public is prenatal exposure of the developing embryo or fetus.[254,255] In part, such concern is warranted because teratogenic effects are quite sensitive to induction by ionizing radiation, with readily measurable neurological abnormalities noted in individuals exposed prenatally to doses as low as approximately 0.06 Gy.[28] The radiation-induced excess relative risk of teratogenesis during the most sensitive phase of gestation is approximately 40% per Gy.[28] (By comparison, the spontaneous incidence of a congenital abnormality occurring during an otherwise normal pregnancy is about 5% to 10%.[255])

Information on the teratogenic effects of radiation in humans come from two major sources, the Japanese atomic bomb survivors and patients who received diagnostic or therapeutic irradiation either before the establishment of modern radiation protection standards or in clinical emergency situations. Although a range of abnormalities have been identified in individuals irradiated in utero (including anecdotal reports of miscarriages and stillbirths, cataracts and other ocular defects, gross malformations, sterility, etc.), the most commonly reported are microcephaly, mental retardation, other, more subtle neurological defects, and growth retardation.[28,254,255] Each of these teratogenic effects has a temporal relationship to the stage of gestation at the time of irradiation, as well as a radiation dose and dose rate dependency. Lethality is the most common consequence of irradiation during the preimplantation stage (within 10 days of conception), growth retardation has been noted for irradiation during the implantation stage (10 to 14 days after conception), and during the organogenesis period (about 15 to 50 days after conception), the embryo is sensitive to both lethal, teratogenic, and growth retarding effects.[255] Radiation-induced gross abnormalities of the major organ systems do not occur during the fetal period (more than 50 days after conception), although generalized growth retardation and some neurological defects have been noted for radiation doses in excess of 1 Gy.

Radiation-Induced Cataracts

Late effects resulting from irradiation of the eye were noted within a few years of the discovery of x-rays,[226,255] with cataracts being the most frequent pathological finding. From a clinical perspective, the induction of a cataract following radiotherapy is a normal tissue complication that can be corrected surgically, and as such, is not considered quite as dire as other late effects. In addition, some radiation-induced lens opacities are subtle and do not interfere with vision. From a radiobiologic perspective, however, cataracts are unique among the somatic effects of radiation in several respects. First, although the lens of the eye is a self-renewing tissue complete with a stem cell compartment of epithelial cells that divide and gradually differentiate into mature lens fibers, there appears to be no clear mechanism of cell loss.[28] As such, the primitive cells damaged by radiation (which manifest themselves as abnormal, opaque lens fibers) persist, eventually leading to a cataract. Second, radiation-induced cataracts are among the few lesions that *can* be distinguished pathologically from their spontaneously occurring counterparts; radiation-induced cataracts first appear in the posterior pole of the lens, whereas spontaneous cataracts usually begin in the anterior pole.[258] Third, radiogenic cataracts exhibit a variable latency period (anywhere from about one year to several decades) that decreases with increasing radiation dose. Finally,

cataract formation is a nonstochastic (deterministic) process; that is, there is a threshold dose below which no cataracts occur, but above the threshold, the severity of the cataract increases with increasing dose.[258] For low LET radiation, the single-dose threshold for cataractogenesis in humans is approximately 2 Gy, and this increases to about 4 Gy for fractionated exposures. Neutrons are also known to be quite effective at inducing cataracts, with RBEs of about 5 to 10 commonly observed in laboratory rodents.[255]

Radiation Carcinogenesis

Unrepaired or mis-rejoined DNA damage caused by radiation exposure is usually lethal to the cell, although this is not invariably the case, particularly when the genetic material is simply rearranged rather than deleted. Whether such changes have further implications for the cell bearing them depends on the location of the damage in the genome, the nature and extent of the mutational event, whether working copies of proteins can still be produced from the gene or genes involved, what function these proteins normally have, and the type of cell. There is compelling evidence that some of these radiation-induced genetic rearrangements—particularly ones that activate oncogenes or inactivate tumor suppressor genes—either alone or in combination with other such changes, predispose a cell to neoplastic transformation, a necessary early step in the process of tumor induction.[254,259]

Laboratory Studies

Although ionizing radiation is one of the most studied and best understood carcinogens, it is not a particularly potent one. This fact hampers studies of radiation carcinogenesis in humans because the investigator must identify a modest radiogenic increment of excess risk with a long latency period against a high background spontaneous cancer rate and multiple confounding factors. Nevertheless, from a public health perspective, carcinogenesis is the most important somatic effect of radiation for doses of 1.5 Gy or less.[28]

The use of cell cultures and laboratory rodents to study carcinogenesis avoid some of the pitfalls of human epidemiological studies but have their own inherent limitations. Cell culture systems employ neoplastic transformation as the endpoint, which is a prerequisite for, but by no means equal to, carcinogenesis in vivo. Neoplastic transformation is defined as the acquisition of one or more phenotypic traits in nontumorigenic cells that are usually associated with malignancy, such as immortalization, reduced contact inhibition of growth, increased anchorage-independent growth, reduced need for exogenously supplied nutrients and growth factors, various morphological and biochemical changes, and in nearly all cases, the ability to form tumors in histocompatible animals.[235] Such systems can be used to study relatively early events in the carcinogenesis process, have much greater sensitivity and statistical resolution than in vivo assays, and can be used to measure dose-response relationships. Laboratory animal studies however are considered more relevant in that tumor formation is the endpoint, latency periods are shorter, statistical variability is reduced, and the carcinogen exposure conditions can be carefully controlled.

Pertinent results from laboratory studies of radiation carcinogenesis include:

1. Carcinogenesis is a stochastic effect, that is, a probabilistic function of the dose received, with no evidence of a dose threshold. Increasing the radiation dose increases the probability of the effect but not its severity.[254,259]
2. The neoplastic transformation frequency increases with dose, at least over the low-dose range (about 1.5 Gy or less).
3. There is a dose rate effect for transformation and carcinogenesis (for low LET radiations); protracted exposures carry a reduced risk relative to acute exposures.
4. The processes of neoplastic transformation and carcinogenesis are necessarily in competition with the cell killing effects of ionizing radiation.[28] As such, dose-response curves for tumor formation in vivo tend to be bell-shaped as a function of dose (e.g., Upton[260]). In vitro, where cytotoxicity can be assessed separately from transformation and appropriate corrections made, dose-response curves tend to be linear.

Epidemiological Studies in Humans

In humans, most of the information useful for risk estimation is derived from epidemiological studies, with the dose almost always exceeding 0.1 Gy, and often, exceeding 1.0 Gy. However, most of the controversy concerns doses less than 0.1 Gy, delivered over protracted, rather than acute, time periods. Therefore, to infer low-dose effects from high-dose data, epidemiologists make extrapolations and assumptions about dose-response relationships that may or may not be valid in all cases.

Many sources of error can also plague epidemiological data, including selection bias, small sample size, heterogeneous population characteristics, and dose uncertainties.[255] The human populations that have been, and continue to be, evaluated for radiation-induced excess cancers are Japanese atomic bomb survivors, persons exposed to fallout from nuclear tests or accidents, radiation workers receiving occupational exposure, populations living in areas characterized by above-average natural background radiation, or in proximity to artificial sources of radiation, and patients exposed to repeated diagnostic or therapeutic radiation. Pertinent findings from these studies include:

1. Within the limits of statistical resolution, the shape of the dose response curve is *not inconsistent* with a linear, no threshold model.[254,259]
2. Different tissues have different sensitivities to radiation-induced carcinogenesis, with bone marrow (leukemias other than chronic lymphocytic), breast (female), salivary glands, and thyroid the most susceptible, followed by colon, stomach, lung, ovary, and skin.[255]
3. The latency period between irradiation and the clinical presentation of a solid tumor averages 20 years or more and about half that for hematological malignancies. However, the latency period varies with the age of the individual, generally increasing with decreasing age at exposure.
4. Two risk-projection models have been used to predict the risk of radiation carcinogenesis in the human population: the absolute risk model and the relative risk model. Using the absolute risk model, excess risk in an irradiated population begins after the latency period has passed and is *added* to the age-adjusted spontaneous cancer risk. After a period of time, the cancer risk returns to spontaneous levels. The relative risk model predicts that the excess cancer risk is a *multiple* of the spontaneous incidence. It remains debatable which model is the most appropriate for estimating the excess cancer risk.[255] At present, the epidemiological data tend to support the relative risk model for most solid tumors and the absolute risk model for leukemia.
5. The current recommendations of the International Commission on Radiological Protection (ICRP) state that the nominal probability of radiation-induced cancer death is approximately 4% per Sievert (Sv) for working adults and about 5% per Sv for the whole population, under conditions of chronic, low-dose exposure.[261] These risk estimates double for acute, high-dose exposures. The Sv is a unit of dose equivalent used for radiation protection purposes and

is equal to the radiation dose (in Gy) multiplied by a quality factor specific for the type of radiation (with the quality factor roughly equivalent to the radiation's RBE).

Carcinogenic Risk from Prenatal Irradiation

The risk of carcinogenesis as a result of prenatal radiation exposure is made even more controversial by conflicting results of epidemiological studies. One major study cohort consisted of several thousand children (plus a demographically similar population of unirradiated children) who received prenatal exposure from diagnostic procedures during the 1950s and 1960s. The Oxford Survey of Childhood Cancer[262] reported nearly twice the incidence of leukemia in children who had received prenatal irradiation. Although other epidemiological studies lend credence to the Oxford Survey's findings,[254,259] it is still unclear whether factors other than the x-ray exposure may have caused, or at least contributed to, the excess cancer risk. Other studies, particularly from the Japanese A-bomb survivors who were pregnant at the time of the bombing, did not support the Oxford Survey's findings of increased risk of childhood malignancy but did support an increased risk of malignancy later in life.[28]

On the assumption that it is preferable to overestimate risk than underestimate it, it is prudent to assume that the carcinogenic risk of radiation exposure to the embryo or fetus is about twice that for postnatal exposure.

Carcinogenic Risk from Medical Imaging Procedures

Recent data gleaned from the Japanese A-bomb survivors indicate a small but statistically significant excess cancer risk even for doses as low as 35 to 150 mSv.[263,264] That this is in the range of doses delivered during a CT scan—in particular, a pediatric CT scan[265,266]—has made the headlines and both sparked controversy[267] as well as increased awareness[268] of radiation's risks. Estimates are that an abdominal helical CT scan of a pediatric patient results in a risk of a fatal cancer later in life of approximately one in a thousand.[264]

A small risk of radiation carcinogenesis from a CT scan may seem trivial, especially to the radiation oncologist who typically delivers more than ten times that dose to a patient each day (albeit not to the whole body). Nevertheless, the finding of a radiation-induced excess cancer risk associated with a medical imaging procedure whose use has skyrocketed over the past 35 years,[264] certainly has the makings of a public health issue. Currently, more than 70 million CT scans are performed annually in the United States.[264] That disproportionately, this increase in CT scanning has been in a pediatric population both inherently more sensitive to ionizing radiation *and* with the longest life span in which to express those radiation-induced malignancies, is all that much more concerning.

Because of this, radiation oncologists, as de facto experts on the health and medical effects of ionizing radiation, should be willing to serve as educators of the public as to both the benefits and risks associated with the common procedures they employ.

Early and Late Effects Following Radiotherapy

It is not the intent of this section to provide either an exhaustive review of the various histopathological changes observed in the irradiated normal tissues of radiation therapy patients, but the reader is referred to several textbooks and pertinent review articles on the subject (e.g., Rubin et al,[226] Mettler et al,[255] Fajardo[269]). This section will focus instead on recent developments that promise to increase our understanding of the etiology of normal tissue injury, and hopefully, provide clues as to how to decrease or even prevent their occurrence.

Molecular Cascades and Cytokines

As mentioned previously, the early and late effects that occur in irradiated normal tissues result directly or indirectly from the killing of critical target cells. Although this statement is true in a general sense, it is clearly an oversimplification of what is now known to be a highly complex and dynamic process of cellular signaling, radiation-induced gene expression, multiple modes of cell death, and compensatory proliferative responses. Cytokines and growth factors, inducible proteins released by irradiated tissues that stimulate other cells to produce a biological response, participate in some of these processes. Although produced locally within the irradiated volume and intended to influence the behavior of cells in the same tissue, some cytokines also enter the circulation and can stimulate cells distant from the irradiated site.

For example, the radiation-inducible cytokines interleukin-1 (IL-1) and tumor necrosis factor (TNF), released by leukocytes and tumor cells, alter the growth of hematopoietic progenitor cells, stimulate the growth of vascular endothelial cells, and induce collagen deposition.[270,271] These same molecules are involved in the acute inflammatory response often noted in irradiated tissues, and along with ICAM-1, an intracellular adhesion molecule, in the changes in vascular permeability that lead to edema. Lung irradiation results in the expression of TNF, several interleukins, transforming growth factor-β (TGF-β) and basic fibroblast growth factor (bFGF), all of which are involved in acute radiation pneumonitis or late fibrosis.[272,273] Finally, TNF, bFGF, and platelet-derived growth factor (PDGF) are associated with aberrant growth of cells within blood vessels. These proteins are induced in the vascular endothelium to stimulate cell proliferation and minimize radiation-induced apoptosis.[274]

Functional Subunits and Volume Effects

Radiation oncologists traditionally reduce the total dose when the irradiation field involves a large volume of normal tissue. Although this practice evolved empirically, the biological basis for decreasing normal tissue tolerance with increasing irradiation volume remains unclear. Withers[238,275] proposed a descriptive model for the pathogenesis of radiation injury in normal tissues based on the structural and functional organization of the tissue at risk for a complication. Conceptually, tissues are considered to be organized into functional subunits (FSUs), which can be inactivated by radiation exposure secondary to the killing of their constituent target cell(s). These FSUs may be anatomically defined, such as the nephron of the kidney or the lobule of the liver, or anatomically undefined (skin, nervous system).[28] The main difference between the two is that surviving target cells from surrounding FSUs have the potential to migrate and help repopulate anatomically undefined FSUs, but not anatomically defined ones, presumably because of the lack of any structural demarcation. This could have the net effect of making anatomically undefined FSUs able to tolerate higher radiation doses.

Whether the inactivation of one or more FSUs impacts the overall tissue function (in the form of a radiation-induced complication) depends on how many of the tissue's FSUs are in the irradiation field and their spatial arrangement. The spinal cord responds to changing irradiation volume as if its corresponding FSUs are arranged in series. There is a steep reduction in the tolerance dose for white matter necrosis of the rat spinal cord with increasing treatment volume for small radiation fields (up to about 2 cm exposed cord length), but little or no volume dependence for larger treatment fields, presumably because inactivation of one FSU inactivates the entire cord.[139] The lung on the other hand, seems to have a large functional reserve, and it is only when much larger

volumes are irradiated, and correspondingly large numbers of FSUs inactivated, that a functional deficit develops. This is more in keeping with a tissue whose functional subunits operate relatively independently and are arranged in parallel. Some other organs are believed to behave as if they have both serial and parallel components.

One immediate clinical implication for tissues with parallel versus serially arranged FSUs is that a small dosimetric hotspot would be relatively innocuous for a parallel tissue but potentially catastrophic for a serial tissue.

Reirradiation Tolerance

A common problem that radiation oncologists face is whether or not to risk reirradiation of a previously treated site. If a decision is made to retreat, even in the most ideal case in which the previous treatment course is well-documented and the treatment fields still identifiable, the clinician is nevertheless left with the uncertainty of what time, dose, and fractionation pattern to use.

Radiobiological research in this area has been slow in coming (given the nature of studies involving late effects), but some progress has been made and some of the factors thought to be important in normal tissue tolerance to retreatment have been identified. These include whether the initial treatment course was to "full tolerance" or not, the likelihood that residual damage from the first treatment course has persisted, the amount of time that has elapsed between the first course and the second, the target volume to be reirradiated compared to the original target volume, and the structural and function makeup of the tissue at risk.

A few general concepts are beginning to emerge from studies with laboratory rodents (for reviews, see Joiner et al,[139] Travis et al,[276] Thames et al[277]):

1. For rapidly proliferating tissues such as skin, bone marrow, or testis, recovery following the first course of treatment is rapid, such that the tissue can be reirradiated to near the full tolerance dose within about 2-3 months.
2. Some slowly proliferating tissues such as spinal cord and lung are capable of more limited long-term recovery after the first course of treatment and can be retreated to a partial (50% to 75%) tolerance dose, with the dose generally increasing the longer the time between the two treatments (3 to 6 months minimum).
3. Other slowly dividing tissues like bladder seem to show permanent, residual injury from the first treatment, such that the total dose for a second course must be reduced by at least half, regardless of how much time has elapsed between treatments. In addition, there is evidence that complications arising from retreatment tend to occur much earlier (relative to the second treatment) than they would have from a single treatment.
4. One apparent exception to this type of classification system is the kidney, for which retreatment tolerance decreases with time between the first and second treatment courses.

A model that is consistent with these observations suggests that target cells that survive the initial treatment course have three possible fates. Some may regenerate their numbers over time, making the tissue as a whole better able to tolerate a second treatment, with the rate of regeneration determining how much time should elapse between the two treatments and what total dose can be delivered safely during the second course. Other target cells may maintain a steady state number of survivors after the first treatment, and therefore, the tissue would appear to harbor residual damage and never be able to tolerate a full second course of radiation therapy. Finally, some target cells may undergo continued depletion after the first treatment, such that tolerance to a second treatment course will actually decrease the longer the time between treatments. This may be related to a progressive expression of otherwise subclinical residual damage from the initial treatment.

Radiation-Induced Second Malignancies

With increasing numbers of long-term cancer survivors, the risk of second malignancies arising as a consequence of prior treatment becomes significant. Leukemia is thought to account for about 20% of second malignancies, with the remainder presenting as solid tumors in and around the previously irradiated site.[278,279] Certain subpopulations of patients previously treated are at an even higher risk than the majority and deserve special attention, including children and young adults, those with a known genetic predisposition to cancer, immunocompromised individuals, and those with known exposure to other carcinogens (such as chemotherapy). For example, large epidemiological studies have assessed the breast and lung cancer risk in Hodgkin's lymphoma survivors,[280,281] leukemia and sarcomas in cervical cancer survivors,[282] and sarcomas in long-term survivors of childhood retinoblastoma.[283]

A final concern with respect to radiation-induced second malignancies is the growing use of highly conformal, intensity-modulated radiation therapy, designed specifically to deliver lower doses to normal tissues immediately surrounding the tumor but at the expense of leaked or scattered dose to larger volumes of the body.[284] Such conditions—large volumes and low doses—tend to be those most associated with radiation carcinogenesis.

Dose Rate and Dose Fractionation Effects

Although the sparing effects of fractionated, external beam radiotherapy and brachytherapy are assumed to be a result of the repair of SLD, other factors may be involved as well, most notably, repopulation. In the isoeffect relationship derived by Strandqvist,[24] however, the time factor included both the effects of dose fractionation (presumably, the result of SLDR) and overall treatment time (presumably, repopulation). It was not until 1963 that Fowler et al[89,130,285] attempted to separate the contributions of these two factors by performing fractionation experiments with pig skin. In their experiments, five equal fractions were given in overall treatment times of either 4 or 28 days, and three different-sized doses per fraction were used to make sure that at least one of them would result in a measurable level of early skin reaction. In changing from an overall time of 4 days to 28 days, only an additional 6 Gy was required to reach the same level of skin response. This was thought to reflect the contribution of overall time (i.e., repopulation) to the isoeffect total dose because the size and number of fractions was kept constant. In a parallel series of experiments in which the overall time was kept constant (28 days), but the number of fractions was increased from 5 to 21, it was found that an additional 13 Gy was required to reach the skin isoeffect level. This increase was almost as great as the 16 Gy additional dose required when changing from a single-dose treatment to a treatment protocol of five fractions in 4 days, implying that the change in fraction number was more important than the change in the overall treatment time.

During the 1960s and 1970s, dose rate effects were studied extensively. The clinical community was also becoming more attuned to the biological underpinnings of radiation therapy, especially the "Four R's of Radiotherapy": repair, reoxygenation, redistribution, and repopulation.[286] These are considered key radiobiological phenomena that influence the outcome of multifraction radiotherapy.

Bedford and Hall[287,288] generated in vitro survival curves for HeLa cells irradiated at various dose rates between about 0.1 Gy per hour and 7.3 Gy per minute. The killing effectiveness per unit dose decreased as the dose rate was reduced,

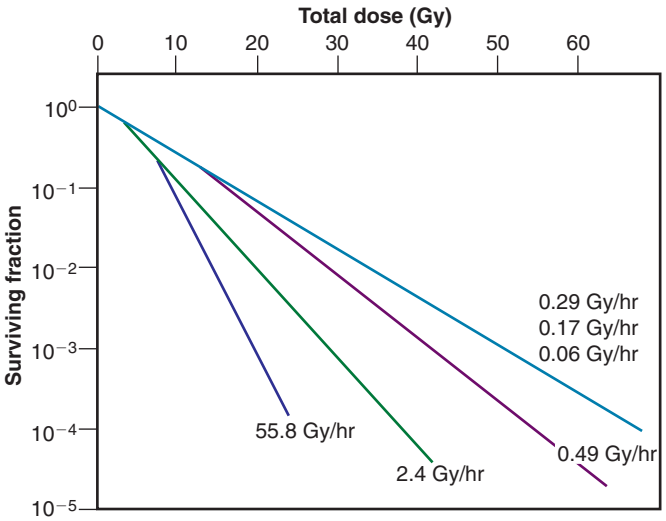

Figure 1-26 The dose rate effect for nonproliferating C3H 10T1/2 mouse cells maintained in vitro. As the dose rate decreases from about 56 to 0.3 Gy/hr, survival curves become progressively shallower, reflecting the repair of radiation damage during the continuous irradiation interval. For dose rates less than about 0.3 Gy/hr, no further sparing effect of dose protraction is observed, suggesting that there is an effective limit to the repair-dependent dose rate effect. This is considered compelling evidence that cell survival curves have nonzero initial slopes.

TABLE 1-4 Recovered Dose as a Function of Dose per Fraction for Skin Reactions in Human Radiotherapy Patients

Single Dose (D_s)	Split Dose (2 D_i)*	Recovered Dose ($D_r = 2D_i - D_s$)
15 Gy	2 × 8.5 Gy	2 Gy
13 Gy	2 × 7.5 Gy	2 Gy
8 Gy	2 × 5.5 Gy	3 Gy
6 Gy	2 × 4 Gy	2 Gy
3.5 Gy	2 × 2 Gy	≤0.5 Gy

Data from Dutreix J, Wambersie A, Bounik C: Cellular recovery in human skin reactions: application to dose fraction number overall time relationship in radiotherapy. Eur J Cancer 9:159-167, 1973.
**Interfraction interval (i) was 6 hours.*

however, a limit to this dose rate or dose fractionation effect was reached under conditions in which cell cycle and proliferative effects were eliminated by the use of lower temperatures[289] or by growing cells to plateau phase before irradiation[290-292] (Figure 1-26).

Similar conclusions about the nature of dose rate and dose fractionation effects were reached from clinical studies. Dutreix et al[293] studied dose fractionation effects in human skin under conditions where cell cycle and proliferative effects were minimized (i.e., short interfraction intervals and overall treatment times). Their data indicated that the incremental dose recovered as a result of SLDR when a single dose was replaced by two equal fractions became small when the size of the dose per fraction dropped below approximately 2 Gy (Table 1-4). This finding is consistent with the hypothesis that survival curves have negative (rather than zero) initial slopes, and therefore, that a limit to the repair-dependent dose fractionation effect should be reached for smaller and smaller-sized dose fractions or dose rates. Accordingly, these authors cautioned that isoeffect equations in common clinical use at the time (the NSD model—see discussion in this chapter) would be inaccurate for predicting tolerances when doses per fraction were quite small. Further, small differences in the initial slopes of survival curves for different cell types could be magnified into large differences in the limiting slopes for continuous or multifraction survival curves.

Time-Dose-Fractionation Relationships

The NSD Model

Based on Strandqvist's isoeffect curves,[24] Fowler and Stern's pig skin experiments,[89,285] and other laboratory and clinical findings,[23] Ellis[294,295] formulated the NSD concept in 1969. The NSD equation, $D = (NSD)\ N^{0.24}\ T^{0.11}$, where D is the total dose delivered, N the number of fractions used, T the overall treatment time, and NSD the nominal standard dose (a proportionality constant thought to be related to the tolerance of the tissue being irradiated), became widely used for the design of biologically equivalent treatment schedules, particularly when its more mathematically convenient derivatives, such as the TDF[296] or CRE[297] equations became available.

The introduction of the NSD equation theoretically allowed radiotherapy treatment practices worldwide to be compared and contrasted with respect to putative biological equivalence. It also permitted the calculation of dose equivalents for split-course treatments and brachytherapy and provided a means of revising treatment prescriptions in the event of unforeseen treatment interruptions. Because the NSD formula was based on observations of early-onset radiation effects, it was quite useful as a predictor of some tissue tolerances, as long as it was not used for treatments involving extremes of fraction number or overall time.

On the other hand, the NSD formula was ill-equipped to deal with some clinical problems, particularly the prediction of late effects in normal tissues (especially at nonstandard doses per fraction), and the patterns of repopulation in normal tissues and tumors.[241] The use of a fixed exponent for the overall time component, T, gave the false impression that extra dose to counteract proliferation would be needed from the outset of treatment, rather than after a delay of several weeks, which is what is observed in practice (e.g., Joiner et al,[139] Denekamp[298]).

In light of the growing frustration with the NSD model, and research at the time focusing on the shape of the shoulder region of cell survival curves and the nature of dose rate and dose fractionation effects, new, radiobiologically based approaches to isoeffect modeling were developed during the late 1970s and early 1980s.

The Linear-Quadratic Isoeffect Model

In ambitious multifraction experiments using laboratory rodents in which a broad range of fraction sizes and interfraction intervals was used, Douglas and Fowler[299] developed a novel method of data analysis in which they interpreted their resulting isoeffect curves in terms of the shape of the underlying dose-response curves for the putative target cells. Because overall treatment times were kept quite short, proliferative effects were assumed to be negligible, so repair was thought to be the only factor involved. The shapes of the underlying dose-response curves were deduced by plotting $1/D$, where D was the total dose delivered ($D = n \times d$), as a function of d, the dose per fraction. This was termed a reciprocal dose plot and is used to obtain values for the ratio α/β, parameters of the linear-quadratic survival curve formula,[76,77] which, as

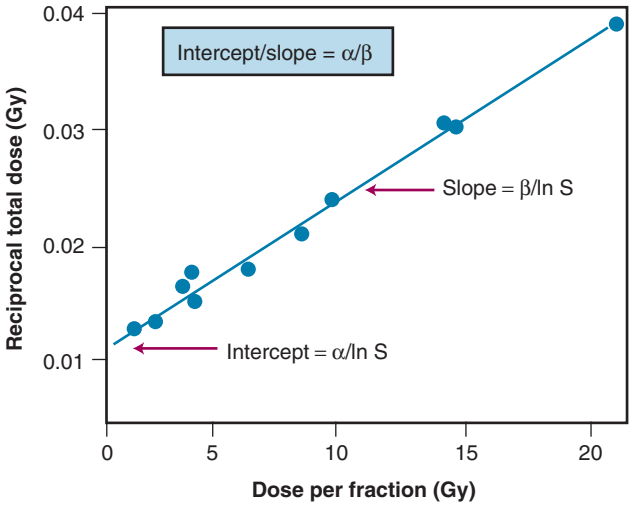

Figure 1-27 The reciprocal dose or Fe plot technique of Douglas and Fowler is used to determine a normal tissue or tumor's α/β ratio. Using this method, the reciprocal of the total dose necessary to reach a given isoeffect is plotted as a function of the dose per fraction. Assuming that the killing of target cells responsible for the tissue effect can be modeled using the linear-quadratic cell survival expression, $S = e^{-(\alpha D - \beta D^2)}$, the α/β ratio can be obtained from the ratio of the isoeffect curve's intercept to slope.
Adapted from Douglas B, Fowler J: The effect of multiple small doses of x rays on skin reactions in the mouse and a basic interpretation. Radiat Res 66:401, 1976.

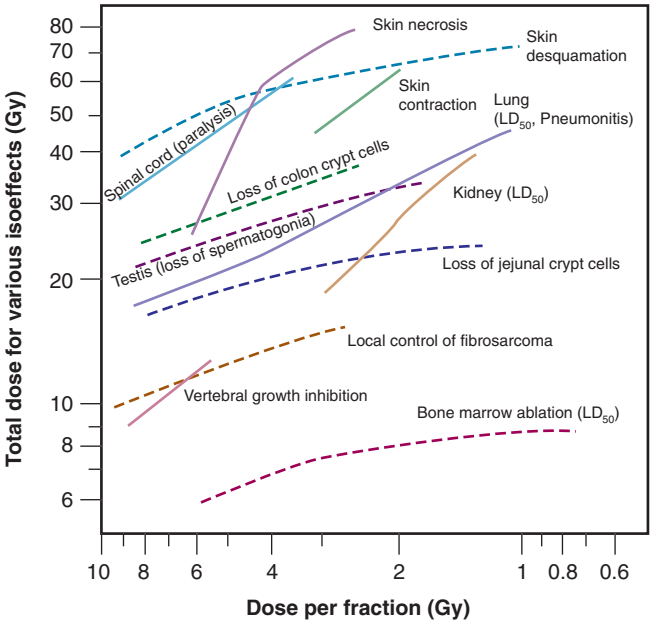

Figure 1-28 Isoeffect curves in which the total dose necessary to produce a certain normal tissue or tumor endpoint (indicated on the graph) is plotted as a function of the dose per fraction under conditions in which cell proliferation is negligible. Isoeffect curves for late-responding normal tissues *(solid lines)* tend to be steeper than those for early-responding normal tissues and tumors *(dashed lines)*. This suggests that for the same total dose, late reactions may be spared by decreasing the size of the dose per fraction used. It also follows that by using smaller dose fractions, a somewhat higher total dose could be given for the same probability of a late reaction but with the hope of higher tumor control probability.
Adapted from Withers H, Thames H, Peters L, et al: Normal tissue radioresistance in clinical radiotherapy. In Withers H, Thames H, Peters L, editors: Biological basis and clinical implications of tumor radioresistance, New York, 1983, Masson, p 139.

discussed previously, provided good fits to experimental survival data, at least over the first two decades of cell killing. A representative reciprocal dose plot is shown in Figure 1-27. However, it should be noted that the curves obtained using this technique are not true cell survival curves, but rather, effective dose-response curves derived from isoeffect data for different time, dose, and fractionation combinations.

This new approach to isoeffect analysis, in which attention was focused on repair parameters and dose-response curve shapes, emphasized that the critical parameter in radiotherapy is the size of the dose per fraction, more so than the overall treatment time. During the course of experimental and clinical fractionation studies, it became clear that there was a systematic difference between early- and late-responding tissues and tumors in their responses to different fractionation patterns. In other words, the capacity for repair of radiation damage was somehow related to the proliferative state of the tissues being irradiated (Figure 1-28).[300,301] Isoeffect curves for the slowly or nonproliferating normal tissues, such as kidney and spinal cord for example, are steeper in general than those for more rapidly proliferating, early-responding tissues, such as skin and gut epithelium, and significantly, most tumors.[300,301] A steep isoeffect curve implies that late effects tissues are more sensitive to changes in the size of the dose per fraction, experiencing greater sparing with decreasing fraction size than their early effects counterparts (Figure 1-29). This difference is also reflected in the α/β ratios derived for these tissues, which are usually low for late-responding tissues (on the order of 1 to 6 Gy, with an average of about 3 Gy), and high for early-responding tissues and tumors (usually 7 to 20 Gy, with an average of about 10 Gy) (Tables 1-5 and 1-6).

Clinical Applications of the Linear Quadratic Isoeffect Model

The most important assumptions of the linear-quadratic model are[300,301]: an isoeffect in a tissue is a reflection of the isosurvival of appropriate target cells; turnover kinetics of target cells determine the time of expression of radiation injury; radiation damage is either repairable or irreparable, with the repairable damage accounting for the sparing effect of dose fractionation; sufficient time is allowed between dose fractions for the repairable damage to be completely repaired; repopulation during the course of treatment is negligible; and the damage caused by each successive dose fraction is the same as that produced by the prior dose fraction, that is, there is an equal effect per fraction.

Within this conceptual framework then, the shapes of tissue and tumor isoeffect curves and their calculated α/β ratios have a number of clinical applications. One possible application is to design radiotherapy treatments for which the α/β ratios for the dose-limiting tissues are known reasonably well.[246] It is also possible using α/β ratios to equate treatment schedules employing different-sized doses per fraction to match the probability of causing a tissue injury, assuming the overall treatment times are similar in both schedules or the tissue at risk of a complication is relatively insensitive to treatment duration.[246] The equation, $D_2/D_1 = (\alpha/\beta + d_1) / (\alpha/\beta + d_2)$ can be used for this purpose, where D_1 and d_1 are, respectively, the total dose and dose per fraction (in Gy) of one radiotherapy treatment plan, D_2 and d_2 are the total dose and dose per fraction for an alternate treatment plan designed to be biologically equivalent for a particular tissue effect, and with the fractionation sensitivity of that tissue defined by its unique α/β ratio. Of course, avoiding a normal tissue complication is not the

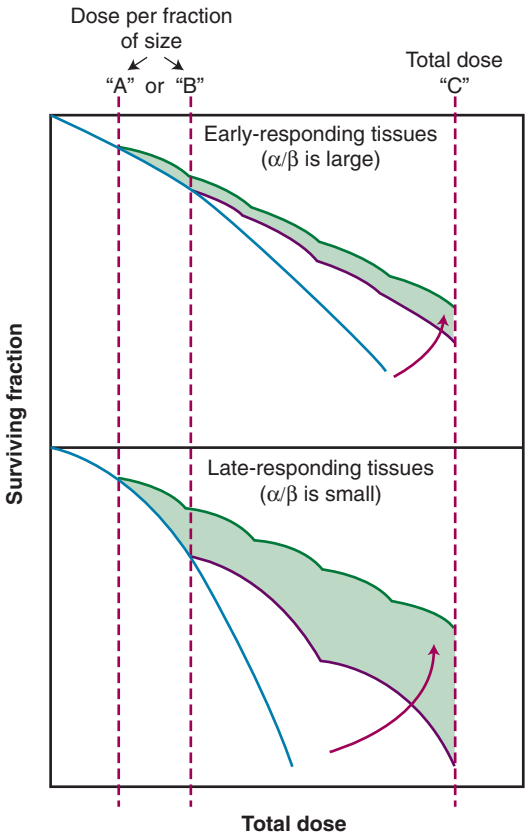

Figure 1-29 Hypothetical survival curves for target cells whose deaths are responsible for an acute *(upper panel)* or late *(lower panel)* effect in an irradiated normal tissue, depending on whether the total dose C is delivered using dose fractions of size A or B. Because of the difference in the initial slopes of the corresponding single-dose survival curves for these cell types, reducing the fraction size from B to A preferentially spares late-responding normal tissues *(green-shaded areas). Adapted from Withers H, Thames H, Peters L: Differences in the fractionation response of acutely responding and late-responding tissues. In Karcher K, Kogelnik H, Reinartz G, editors: Progress in radio-oncology II, New York, 1982, Raven Press, p 287.*

TABLE 1-5 Representative α/β Ratios for Human Normal Tissues and Tumors

Tissue Type (and Endpoint)	α/β Ratio (± 95% Confidence Interval)
Early-Responding Normal Tissues	
Skin: erythema	10.6 (1.8; 22.8) Gy
Desquamation	11.2 (8.5; 17.6) Gy
Lung: pneumonitis ≤90 days after radiotherapy	>8.8 Gy
Oral mucosa: mucositis	8-15 Gy
Late-Responding Normal Tissues	
Skin: telangiectasia	~2.7 (–0.1; 8.1) Gy
Fibrosis	1.7 (0.6; 3.0) Gy
Breast: cosmesis	3.4 (2.3; 4.5) Gy
Fibrosis	3.1 (1.8; 4.4) Gy
Lung: pneumonitis >90 days after radiotherapy	4.0 (2.2; 5.8) Gy
Fibrosis	3.1 (–0.2; 8.5) Gy
Bowel: perforation/stricture	3.9 (2.5; 5.3) Gy
Various other	4.3 (2.2; 9.6) Gy
Spinal cord: myelopathy	<3.3 Gy
Muscle, vasculature, or cartilage: impaired movement	3.5 (0.7; 6.2) Gy
Nerve: brachial plexopathy	2.0-3.5 Gy
Optic neuropathy	1.6 (–7; 10) Gy
Head and neck: various	3.5-4 Gy
Tumors	
Head and neck: nasopharynx	16 (–11; 43) Gy
Vocal cord	~13 Gy
Buccal mucoas	~6.6 (2.9; ∞) Gy
Tonsil	7.2 (3.6; ∞) Gy
Larynx	14.5 (4.9; 24) Gy
Lung: squamous cell carcinoma	~50-90 Gy
Cervix: squamous cell carcinoma	>13.9 Gy
Skin: squamous cell carcinoma	8.5 (4.5; 11.3) Gy
Melanoma	0.6 (–1.1; 2.5) Gy
Prostate	1.1 (–3.3; 5.6) Gy
Breast (early stage invasive ductal, lobular, and mixed)	4.6 (1.1; 8.1) Gy
Esophagus	4.9 (1.5; 17) Gy
Liposarcoma	0.4 (–1.4 ; 5.4) Gy

Data from Joiner M, van der Kogel A, editors: Basic clinical radiobiology, ed 4, London, 2009, Hodder Arnold.

sole criterion used in treatment planning; in considering a particular time, dose and fraction size combination, the responses of the tumor, and *all* incidentally irradiated normal tissues should be taken into account simultaneously.

An important implication of the steeper isoeffect curves for late-responding tissues compared to those for tumors is that it might be possible to increase the therapeutic ratio by using larger numbers of smaller fractions to a somewhat higher total dose than traditionally used.[246,247,302] Although such treatments might be expected to exacerbate acute effects in normal tissues and the tumor, late effects would be spared preferentially. The use of multiple fractions per day of smaller than conventional size (less than about 1.8 Gy) but to a somewhat higher total dose, with little or no change in overall treatment time, has been termed *hyperfractionation*. With particularly aggressive tumors that proliferate rapidly, it has been suggested that multiple treatments per day might also be useful to decrease the overall treatment time, thereby allowing less time for repopulation of clonogenic tumor cells.[303,304] Treatment with multiple daily fractions of approximately standard size and number (and to about the same total dose), but in shorter overall times, has been called *accelerated fractionation*. In practice, however, a combination of accelerated and hyperfractionated treatment is often used.[277] Finally, *hypofractionation*, the use of one or a few large dose fractions delivered over short periods of time (e.g., stereotactic radiosurgery or radiotherapy, intraoperative radiation therapy, or, to some extent, high dose rate brachytherapy) is also an option. Indications for such would include cases where the frank ablation of small tumors is the goal, or in the relatively unusual circumstance in which the tumor is suspected of having a low, rather than high, α/β ratio. Prostate cancer appears to be a tumor type that meets this criteria, although this remains a controversial and sometimes contentious subject, as does the use of hypofractionation in general.[305-307] Whatever the case, extra care must be taken to exclude late-responding normal tissues from the treatment field when hypofractionation is considered because the use of high doses per fraction for tissues with low α/β ratios is associated with higher complication frequencies.

TABLE 1-6 Summary of the Linear-Quadratic Isoeffect Model Parameters and Concepts

Tissue Type	α/β Ratio*	Dose-Response Curve Shape†	Isoeffect Curve Shape‡
Early-responding normal tissues and most tumors	High (6-30 Gy)	Steep initial slope (α is large)	Shallow
Late-responding normal tissues	Low (1-6 Gy)	Shallow initial slope (α is small)	Steep

**Determined from the reciprocal dose plot technique of Douglas BG, Fowler JF: The effect of multiple small doses of x-rays on skin reactions in the mouse and a basic interpretation, Radiat Res 66:401-426, 1976.*

†Based on the assumption that differences in the calculated α/β ratio are usually caused by differences in α rather than β.

‡Using the Thames and colleagues isoeffect curve plot. Thames HD, Withers HR, Peters LJ, et al: Changes in early and late radiation responses with altered dose fractionation: implications for dose-survival relationships, Int J Radiat Oncol Biol Phys 8:219-226, 1982. (See also Figure 1-28.)

The decision to opt for one of these fractionation protocols would depend not only on the α/β ratios for the tissues being irradiated but also on their relative repair rates and proliferative responses before, during, and after exposure. At present, although data related to the former parameters continue to accumulate and become more reliable, data on proliferation characteristics, especially for tumors, are still lacking.[241,303]

With nonstandard fractionation now the standard, radiation oncologists find themselves confronted with the same problem faced by their counterparts in the 1930s, that is, how to compare and contrast different treatment schedules for presumptive isoeffectiveness? The biologically effective dose (BED) method,[248] another derivative of the linear-quadratic model, attempts to address this issue. Although this method is a bit confusing to use in practice, conceptually, the ideas are fairly straightforward. Knowing that cell survival and dose-response curves have negative initial slopes, and that, for a sufficiently low dose per fraction or dose rate, a limit to the repair-dependent dose fractionation effect occurs that "traces" this initial slope, the question may be asked, "In the limit, for an infinite number of infinitely small dose fractions, what total radiation dose will correspond to normal tissue tolerance, tumor control, or any other endpoint of interest?" Clearly, this theoretical dose will be quite large for a tissue characterized by a dose-response or survival curve with a shallow initial slope (like many late-responding normal tissues) and appreciably smaller for a tissue characterized by a dose-response curve with a steep initial slope (like most tumors and early-responding normal tissues). *It is also important to bear in mind that BEDs are not real doses, but rather extrapolates based on the limiting slope of the multifraction dose response curves for the tissues at risk, which in turn depend on the α/β ratio.* For this reason, the units used to describe these extrapolated doses are, for example, Gy_3 and Gy_{10}, rather than Gy, where the subscripts 3 and 10 refer to the assumed α/β ratio of the tissue at risk. A second caveat is that, although two different radiotherapy treatment schedules can be compared qualitatively on the basis of their respective Gy_3 *or* Gy_{10} doses, Gy_3 *and* Gy_{10} cannot be intercompared.

A mathematical rearrangement of the linear-quadratic survival expression $S = e^{-(\alpha D + \beta D2)}$, yields:

$$\text{B.E.D.} = E/\alpha = nd\,(1 + d/\alpha/\beta)$$

where *E* is the (iso)effect being measured (*E* is divided by α to obtain the BED value in units of dose), *n* is the number of fractions, *d* is the dose per fraction, and the α/β ratio is specific for the tissue at risk. The factor "(1 + d/α/β)" has been called the *relative effectiveness term* because, in essence, it is a correction factor for the fact that treatment is not really given as an infinite number of infinitely small dose fractions but rather as a finite number of fractions of a finite size.

Perhaps the best way to illustrate the use of the BED equation is by example. Suppose that a radiation oncologist is developing a clinical protocol in head and neck cancer comparing standard fractionation (30 fractions of 2 Gy to a total dose of 60 Gy in an overall treatment time of about 6 weeks) to a schedule of 50 fractions of 1.4 Gy to a total dose of 70 Gy in approximately the same overall treatment time. The tissues of most concern for radiation injury are the tumor, the oral mucosa, and the spinal cord, that is, two early- and one late-responding tissues. Finally, assume an α/β ratio of 10 Gy is appropriate for the tumor and oral mucosa, and an α/β ratio of 3 Gy is appropriate for the spinal cord. *For calculation purposes, an α/β ratio of 10 Gy can be used for most early-responding normal tissues and tumors, and 3 Gy for most late-responding normal tissues, unless more robust, better-vetted values are available.* For example, an α/β ratio of 4 Gy may be more appropriate for breast cancer; 20 Gy for non–small cell lung cancer; approximately 2 Gy for central nervous system, kidney and prostate cancer; and approximately 0.6 Gy for melanoma.[245]

For the standard fractionation schedule therefore:

For tumor and mucosa:

$$E/\alpha = 60\text{ Gy}\,(1 + 2\text{ Gy}/10\text{ Gy}) = 72\text{ Gy}_{10}$$

For the spinal cord:

$$E/\alpha = 60\text{ Gy}\,(1 + 2\text{ Gy}/3\text{ Gy}) = 100\text{ Gy}_3$$

And, for the more highly fractionated schedule (rounded off to the nearest whole number):

For tumor and mucosa:

$$E/\alpha = 70\text{ Gy}\,(1 + 1.4\text{ Gy}/10\text{ Gy}) = 80\text{ Gy}_{10}$$

For the spinal cord:

$$E/\alpha = 70\text{ Gy}\,(1 + 1.4\text{ Gy}/3\text{ Gy}) = 103\text{ Gy}_3$$

Although little quantitative information can be gleaned from this exercise, a few qualitative statements can be made. First, a comparison of the Gy_{10} values for the two treatment schedules suggests that the more highly fractionated schedule should result in somewhat better tumor control, albeit at the expense of more vigorous mucosal reactions (i.e., 72 Gy_{10} compared to 80 Gy_{10}, an 11% increase in "biodose"). However, the comparison of the Gy_3 values for the two schedules suggests that the spinal cord tolerance would be essentially unchanged (i.e., 100 Gy_3 compared to 103 Gy_3, a 3% increase).

Even with the BED concept being only semiquantitative at best, its use for treatment planning purposes over the past two decades has provided a wealth of clinical data that has allowed a better definition of what is or is not tolerable for a particular normal tissue, in terms of Gy_3 or Gy_{10}. Using head and neck cancer as an example, Fowler et al[245,308,309] have suggested that the tolerance dose for acute mucosal reactions is in the range

TABLE 1-7 Current Status of Existing and Proposed Parameters of the Linear-Quadratic Isoeffect Model for Human Normal Tissues and Tumors

Parameter	Property Governed	Availability of Data with Respect to:		
		Early Effects	Late Effects	Tumors
α/β Ratio	Fractionation sensitivity	Can assume 10 Gy for most	Can assume 3 Gy for most	Can assume 10 Gy for most
$T_{1/2}$ (Repair half-time)	Repair kinetics	Poor/fair	Poor	None/poor
Tp (Effective clonogen doubling time) or T_k (Kickoff time—time proliferation begins relative to the start of treatment)	Dose lost to accelerated proliferation during radiotherapy	Fair	Poor; N/A	Poor/fair
Volume effect	Variation in tissue tolerance with increasing target volume	Poor	Poor	None/poor
γ (Normalized dose response gradient)	Steepness of dose-response curve for effect; can be used to estimate the normal tissue complication probability	Fair	Fair	Fair

Modified from Bentzen SM: Estimation of radiobiologic parameters from clinical data. In Hagen U, Jung H, Streffer C, editors: Radiation research 1895-1995: volume 2, congress lectures. Wurzburg, 1995, Universitatsdruckerei H. Sturtz AG, pp 833-838, with permission.

of 59 to 63 Gy_{10}, and for late reactions, in the range of 110 to 117 Gy_3.

Finally, another way of using the BED equation would be to design schedules to match an acceptable probability of a complication, radiation myelitis for example, and then calculate the expected benefit (or lack thereof) with respect to tumor control.

It would be remiss to conclude any discussion of the linear-quadratic isoeffect model, or any biologically based model with potential clinical application, without a few words of warning. First, this model, although certainly more robust than the NSD model and much better grounded in biological principles, is still a theoretical model. Some limitations of the basic model are obvious: an overly simplistic assumption that an isoeffect in a tissue directly corresponds to an isosurvival of a particular cell type; no provision for the influence of cell cycle, proliferative or microenvironmental effects in the overall dose-response relationship; no way to account for differences in repair rates between different tissues; no consideration of volume effects; uncertainty surrounding the model's applicability for extremes of fractionation; and a limited understanding of how to apply the model in patients receiving multimodality therapy.

Various add-ons to the linear-quadratic model have been proposed,[310-312] especially with respect to compensating for tumor cell repopulation and differing repair rates between different tissues. However, the lack of robust values at present for the parameters introduced in such calculations (e.g., potential doubling times, half-times for repair, repopulation kick-off times, etc.), ultimately limit their usefulness beyond rough approximations or proofs-of-concept. The current status of some of the existing and proposed parameters of the linear-quadratic model for human tumors and normal tissues is summarized in Table 1-7.

RADIATION BIOLOGY IN THE 21ST CENTURY

Since the mid-1980s, most graduate students pursuing careers in oncology necessarily trained as molecular, cellular, or tumor biologists, and not as radiation biologists per se, although a few may have worked with ionizing radiation as a tool for probing fundamental cellular processes or as part of translational research designed to develop new cancer therapies. Even fewer have ever taken a formal course in radiation biology, let alone in its more clinical aspects. This shift in focus and training is part of the natural evolution of the oncologic sciences over the years and surely not an unexpected or unwarranted one. However, the fact remains that the field of radiation biology as a distinct entity, with its rich, 120-year history that has contributed in major ways to fields as diverse as carcinogenesis, epidemiology, toxicology, DNA damage and repair, genetics and cytogenetics, cell cycle biology, and radiation oncology to name but a few, is threatened with extinction.

This too could be viewed as a necessary price of scientific progress, were it not for the fact that there remains a need for all radiologic science professionals (from radiologic technologists and radiation therapists, medical physicists and dosimetrists, to radiologists and radiation oncologists) to be at least reasonably well-versed in the basic principles of radiation biology. Physicians in particular need to be familiar both with the classical and modern aspects of the field, in keeping with the close relationship between the histories of ionizing radiation itself, radiation biology, and the medical specialties of radiology and radiation oncology. And unfortunately, since the events of September 11, 2001, a new mandate has emerged: the need to provide expertise in the basics of radiation biology and radiation protection to emergency responders, civic leaders, and the general public in the event of a radiological or nuclear terrorist attack.

Nevertheless, 21st-century radiation biology continues to flourish and remains cutting edge in many respects. Fundamental studies of genomic instability,[313,314] epigenetics,[315,316] and cell signaling as it applies to radiation response[317,318] continue to be active areas of research. Our growing understanding of the complex roles played by cytokines in the etiology of normal tissue complications following radiation exposure[319,320] promises to someday deliver novel, molecularly based radioprotectors that may benefit radiation accident victims, first responders during radiation emergencies, and astronauts on deep-space missions. Radiation cytogeneticists study the role telomeres and telomerase play in cellular aging

and neoplastic transformation.[321] Radiation scientists have also been important contributors to the fields of genomics and proteomics, functional and molecular imaging and molecularly targeted cancer therapy, and to the search for tumor-specific biomarkers that can aid in cancer diagnosis, staging, and the monitoring of treatment progress.

As long as the molecular underpinnings of some of these fundamental processes remain poorly understood, and a more comprehensive picture of the full range of radiation-induced gene expression and signaling remains elusive, there will always be a role for radiation biology research.

CHAPTER

2 Molecular and Cellular Biology

Mary Ann Stevenson and Stuart K. Calderwood

The past two decades have seen revolutions in two areas of cell and molecular biology that are closely related to radiation therapy. The pathways involved in response to genomic stress, including mechanisms for sensing DNA damage and responding by cell cycle changes and DNA repair, have been elucidated by studies of model organisms, particularly the yeast *Saccharomyces cerevisiae*.[1,2] In the second major area, understanding pathways of programmed cell death (PCD), which may play a major role in treatment response, studies of *Caenorhabditis elegans* were the most informative in demonstrating the significance of individual death genes.[3] The challenge is to combine these two areas of knowledge and provide a rational understanding of how tumor cells can be made to enter the death pathways and how the processing of DNA damage could be minimized. Considerable technological improvements also have enabled significant progress in the translation of experimental advances, including rational, *in silico* drug design and high-throughput screening of chemical libraries, which could permit the application of advances in molecular biological knowledge to the development of drugs for use in combination with radiation therapy.

ESSENTIAL STEPS IN TUMOR PROGRESSION

Much evidence suggests that tumors are formed by a stepwise progression of cells from a minimally altered state, where they are able to grow and form nodules or polyps (e.g., solid tumors) to a state of maximal transformation, characterized by multiply deviated cells that are capable of unlimited growth, manipulation of their local environment, invasion of surrounding tissues, and escape into the circulation to establish new colonies of secondary tumors, or metastases.[4] Tumor progression involves an array of molecular and morphologic changes. In their landmark review, Hanahan and Weinberg suggested organizing these traits into six essential alterations in cell physiology: self-sufficiency in growth signals, insensitivity to growth inhibition, evasion of PCD, limitless replicative potential, sustained angiogenesis, and tissue invasion and metastasis.[5] Although the initial steps are believed to occur earlier in tumor progression, the exact order of occurrence varies among different malignancies, and some phenotypic transformations appear to require more than one molecular change.[6,7] The occurrence in tumor cells of this series of radical, primarily genetic alterations in physiology is in part the result of an evolving instability of the tumor genome resulting from a breakdown in the DNA repair pathways that accompanies tumor progression.

In addition to progressing and acquiring enhanced malignant capabilities, most human tumors undergo further selections through exposure to various forms of cytotoxic therapy such as irradiation and chemotherapy, leading to the development of resistant phenotypes in the surviving cells.[8] However a new paradigm is emerging that may challenge our views of tumorigenesis. This is the concept that only a small proportion of the tumor cell population can give rise to tumor initiation and these cells have many of the properties of stem cells.[9] According to this theory, tumors contain a small population of cancer stem cells that renew by dividing slowly and that also give rise to more "differentiated" progeny forming the bulk of tumors. Tumor eradication would thus involve killing this small, slowly dividing, and often treatment-resistant population. Studies in this area could revolutionize the cell and molecular underpinnings of radiation biology.

All cancer treatments are aimed at reversing the hallmarks of neoplastic transformation and tipping the balance toward tumor cell death in both the bulk population and the stem cell fraction. Ionizing radiation kills cells almost exclusively through the generation of DNA double-stranded breaks (DSBs).[10] The evolving modification of the cellular phenotype during tumorigenesis leads to the development of resistance to therapy. Our major task is to explore the links among DSB response pathways, engagement of cell death mechanisms, and the outcome of radiation therapy.

RADIATION THERAPY AND RADIATION BIOLOGY

Ionizing radiation has long been known to be a potent modality in cancer therapy, killing cells and leading to tumor regression.[11] Killing by ionizing radiation involves the oxygen-dependent generation of free radicals and subsequent damage to multiple molecular structures within the cell.[10] The generation of DSBs is the dominant mechanism of direct lethality. Indeed, it has been estimated that the existence of even one unrepaired DSB can lead to cell death.[12] Within whole organisms, direct and indirect forms of lethality occur. Radiation can cause the death of hematopoietic stem cells in the bone marrow and stem cells in crypts of the small intestine, which leads to secondary damage caused by immunosuppression and infection, as the gastrointestinal lining is eroded.[13,14] The challenge facing radiation therapy is to enhance cell killing within tumors while avoiding dose-related complications in organs containing rapidly renewing stem cell populations.

Early studies using the clonogenic cell survival assay established the notion of optimizing radiobiological parameters such as dose, fractionation, and cell cycle inhibition as a means of inhibiting reproductive cell death in critical normal tissues.[15] The clonogenic cell survival assay is a useful measure of cell inactivation because the effects of ionizing radiation seen in vitro often mirror the responses of tumors in vivo.[10] However, a weakness in the informative power of the method is that it does not allow for discrimination or elucidation of the various mechanisms leading to cell death. That kind of detailed information is essential for the successful combination of radiation therapy with other modalities, which may result in sensitization, protection, or both. Irradiation activates a number of pathways that mediate reproductive death, including various forms of PCD (e.g., apoptosis, autophagy), replicative senescence, and necrosis, the default pathway that often dominates when other types of cell death are inhibited.[16,17] The susceptibility to each of these forms of cell death changes over the course of tumor progression, and the tumor cell response to ionizing radiation is likely to reflect the aggregate of genetic changes that accompany tumor progression. The task of

radiation biology is to examine mechanisms by which ionizing radiation gives rise to unrepaired DSBs and how such damage is coupled to the pathways of cell killing within the moving target of the evolving cancer cell.

DNA DOUBLE-STRANDED BREAK RESPONSE

All cells have become adapted to live in an environment that is more or less mutagenic and have thus evolved responses to permit survival when the genome is damaged.[18] DNA may be damaged during the normal processes of DNA replication and segregation. Within tumor cells, these initial changes become progressively altered because cells compete for survival in the tumor milieu and are subjected to selection by various forms of cytotoxic therapy.[19] The response to DSBs involves two principal components: (1) arrest of cell proliferation to prevent replication and segregation of the damaged DNA and, when possible, (2) repair of the lesion.[19] A third component in the DSB response in multicellular organisms may be altruistic entry of irreversibly damaged cells into the PCD pathways.[20,21] The latter effect is the desired response to cytotoxic therapy. Understanding how the DSB response is regulated at the molecular level may be one of the keys to understanding the differential response to irradiation in individual tumors and the rational design of radiosensitizing drugs. There are several basic questions regarding regulation of this response, including: (1) By which mechanism do tumor cells arrest in the cell cycle? (2) How is the presence of DNA DSBs detected in such cells? (3) What are the major pathways for repair of DSBs? (4) How does the deployment of these pathways affect tumor response to therapy?

Mechanisms of Cell Cycle Arrest: The Cell Cycle and Checkpoints

The cell cycle is a series of molecular programs that read out in a preferred order, leading to duplication of the genome and other cellular components, permitting division into two cells, each with a full set of chromosomes and the organelles required for life.[22] Orderly, high-fidelity, and complete duplication of the genome is required for cell cycle progression. This is achieved through a surveillance system that detects DNA damage or unreplicated DNA and imposes cell cycle arrest at designated checkpoints, blocking the forward progress of the cell cycle engine (Figure 2-1). Because ionizing radiation produces severe damage to DNA, checkpoints are essential for facilitating repair and subsequent cell survival after radiation exposure, and they provide an ultimate target for strategies aimed at sensitizing cells to radiation therapy.

The cell cycle is driven by sequential activation of a series of protein kinases that determine the order and rate of the metabolic events required in each stage. These cell division kinases, or cyclin-dependent kinases (CDKs), are activated by binding proteins originally designated as cell division cycle (CDC) molecules, now known as cyclins.[22] These complexes formed between cyclins and CDK molecules are the master regulators that determine the rates of the individual component reactions regulating each stage of the cell cycle.[23] Phosphorylation of individual cell cycle effector proteins by the cyclin-CDK complexes acts as a series of switches, turning on cell cycle stages in orderly fashion. In mammalian cells, the cyclins regulate individual stages of the cell cycle, and these include the G_1 cyclins (cyclins D and E), S phase-specific cyclins, and G_2-specific cyclins (cyclins A and B), which associate, respectively, with G_1-specific (CDK2, CDK4, and CDK6), S-specific, and G_2-specific (CDC2) cyclin-dependent kinases. The events of G_1 (i.e., synthesis of enzymes and other molecules involved in DNA replication), S phase (i.e., DNA replication), and G_2/M (i.e., chromosome condensation, disappearance of the nuclear envelope, and mitosis) are regulated by the transient accumulation and subsequent degradation of the cyclins.[22-24] Switching off the reactions that characterize individual stages involves targeted degradation of the cyclins by a protein destruction machine called the *proteasome*.[24] Targeted destruction of the cyclins after they have carried out their function ensures unidirectional, irreversible progression around the cell cycle.[23] The timing of the various cell cycle phases under normal conditions is related to the time required

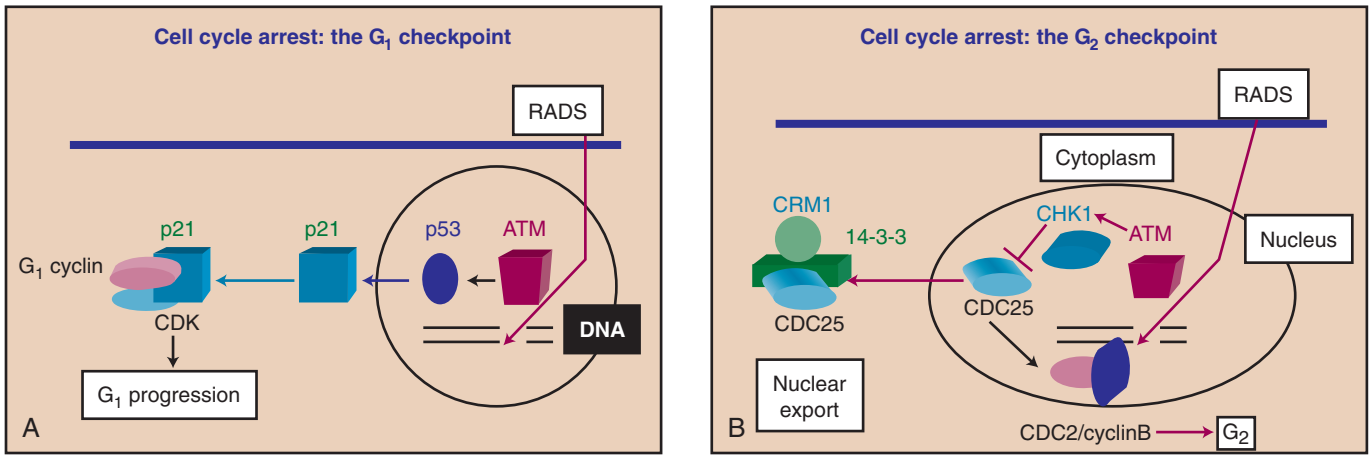

Figure 2-1 Cell cycle checkpoints. **A,** To progress through G_1 to the replication (S) phase, cells require the activity of G_1 cyclins (D, E) and cyclin-dependent kinases (CDK2, CDK4, and CDK6) to phosphorylate substrates such as the retinoblastoma protein (RB1). DNA damage is sensed by the protein kinase ATM, which activates TP53 (p53), leading to transcription of the CDKN1A (p21) protein, a powerful inhibitor of cyclin-CDK complex kinase activity, and to arrest in G_1. DNA damage may be repaired, leading to deactivation of the checkpoint block and progression into S phase. If it is unrepaired, TP53-dependent programmed cell death may occur. **B,** To progress through G_2 into M, the activity of the protein phosphatase CDC25 is required. DNA damage *(red arrows)* also leads to ATM activation, which causes a cascade response as ATM kinase activates the CHK kinases and CHK1 phosphorylates CDC25, leading to recruitment of the activation protein YWHA (formerly designated 14-3-3) and an adapter protein that couples CDC25 to the nuclear export machinery of the cell. Exported from the nucleus, CDC25 is no longer able to mediate dephosphorylation of CDC2 at the G_2/M transition and progression through G_2.

for cyclin-CDK complexes to reach appropriate, critical concentrations and for the phosphorylation of key substrates.[23]

Irradiation leads to prolongation of the cell cycle and arrests in G_1, G_2, and S phases because of checkpoint activation (see Figure 2-1).[25] Although this phenomenon was observed many years ago, it was only later understood at the biochemical and genetic levels. Arrest of cells at the G_1 checkpoint has been particularly well studied (see Figure 2-1, *A*). G_1 arrest is caused by the accumulation of a CDK inhibitory protein, CDKN1A (formerly designated p21 or Cip1), and this molecule prevents the key events that are required for transit through G1, including phosphorylation of the retinoblastoma (RB1) protein and activation of the E2F transcription factors (e.g., E2F1, E2F2, E2F4, E2F6) necessary for accumulation of enzymes required to traverse S phase.[26,27] CDKN1A can be induced at the transcriptional level by TP53 (also known as p53), which accumulates in irradiated cells and binds to the *CDKN1A* promoter, thereby activating transcription. TP53 accumulation depends on the activation by radiation exposure of a DSB sensor molecule, the protein kinase ATM (ataxia-telangiectasia, mutated).[26,27] The exact mechanism involved in detecting accumulation of DSBs and activation of ATM is unclear, although it involves ATM autophosphorylation.[28]

The common mechanism for regulating the G_1 and G_2 checkpoints is inhibition of the CDK components of the interphase cell cycle engine and a block to phosphorylation and activation of effector molecules (see Figure 2-1).[23,27] A variation on this theme is seen at the mitotic spindle checkpoint. Progression through mitosis requires switching off CDK activity through targeted degradation of cyclin B.[29] Arrest in M phase, when the mitotic spindle is compromised, involves the TP53-dependent stabilization of cyclin B. The mitotic spindle checkpoint guarantees that replication is followed by cell division, ensuring prevention of aneuploidy. Not surprisingly, the polyploidy nature of many tumor cells is related to TP53 inactivation.[29] Most evidence indicates that ATM (and its homologues in other organisms) functions as a sensor for DNA damage through a complex series of interactions with the damaged DNA. This ultimately leads to ATM activation and downstream signaling cascades involving the kinases CHK1 and CHK2 (also called CHEK1 and CHEK2), which couple to the cell cycle engine at the level of individual cyclin-CDK complex molecules (see Figure 2-1, *B*).[1,2,19,27,30] The molecular details of these processes are evolving rapidly, and referenced reviews can provide more detailed insight into the mechanisms of DNA damage, sensing, and checkpoint engagement.

TP53: Cellular Triage after Ionizing Radiation Exposure

TP53 is a nuclear phosphoprotein with sequence-specific DNA binding activity. It can function as both transcriptional activator and repressor and plays a triage role in deciding whether to undergo cell cycle arrest and repair or to enter the pathways of PCD or replicative senescence (Figure 2-2).[31,32] When cells are exposed to ionizing radiation or chemotherapeutic agents, the levels of wild-type TP53 protein are increased. TP53 then transcriptionally activates a number of genes, most notably *CDKN1A*, the CDK inhibitor that mediates many of the properties of TP53.[33] In addition to G_1 arrest, genotoxic stress and ionizing radiation can induce TP53-dependent PCD pathways, including caspase-dependent apoptosis.[33] TP53 can transcriptionally activate the proapoptotic *BAX* gene, induce synthesis of JUN kinase, and repress transcription of the anti-apoptotic gene *BCL2*, suggesting that TP53 is a central mediator of PCD processes.[31,34] DNA damage in the presence of wild-type TP53 causes G_1 arrest, followed by a period of DNA repair; if the damage is too great to be easily repaired, the cell is eliminated

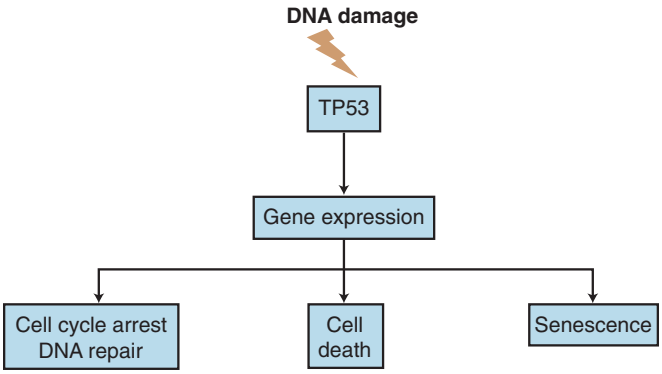

Figure 2-2 TP53 plays a triage role in deciding a cell's fate after exposure to ionizing radiation. TP53 is activated after irradiation, largely through protein stabilization that results from phosphorylation by the protein kinase ATM. Most effects of TP53 are mediated through its transcriptional activity, with some gene products (e.g., CDKN1A [p21]) leading to cell cycle arrest and others (e.g., BID, BBC3 [formerly designated PUMA], PMAIP1 [formerly NOXA]) to programmed cell death. A third fate appears to be senescence, which is mediated largely through CDKN1A. The triage decision appears to be related to radiation dose (i.e., degree of DNA damage), with greater damage favoring the death and senescence pathways.

through TP53-dependent PCD pathways. However, approximately 50% of human tumors possess inactivating mutations in the *TP53* gene.[35] TP53 becomes inactivated in many tumors as a result of selection against its pro-apoptotic properties. The resultant loss of its central function as "sentinel of the genome" may be a type of collateral damage incurred in cells because of the selection advantage for survival accruing from the loss of TP53 apoptotic function.[32,36] The loss of TP53 function is linked to poorer prognosis in malignancies such as lung, breast, colorectal, and hematopoietic tumors.[37] Many tumor cell lines containing mutant TP53, including breast, glioma, and lymphoma cell lines, are more resistant to therapy than their wild-type TP53 counterparts.[38,39]

The loss of wild-type TP53 function in human malignancies may be a key step in the progression of human cancer, and the TP53 status of cells may control the outcome of many tumor types in response to chemotherapy or radiation therapy.[36] Although most of the other DSB response genes have molecular equivalents in yeast, TP53 does not. The TP53 gene appears to be required to determine the fate of damaged cells, which in mammalian cells may be PCD, a sacrifice that contributes to the well-being of the whole organism. TP53 monitors the degree of DNA damage and acts as a master switch, moving the cells from a state of cycle arrest and DNA repair to death or senescence pathways. Loss of TP53 in tumors compromises this critical surveillance and triage function. With the loss of this critical decision-point molecule, damaged and mutated tumor cells may survive to generate new and more malignant phenotypes (see Figure 2-2).

ATM Gene: Master Regulator of the DNA Double-Stranded Break Response

One of the many defects in ataxia-telangiectasia (AT) cells is increased chromosomal instability. Exposure to ionizing radiation also produces an increased number of chromosomal aberrations in AT cells compared with normal cells.[40,41] This effect and the sequence similarity between *ATM* and the DNA repair protein DNA-PK suggested that AT cells might have deficient DNA repair. However, most studies have shown that AT cells do not have gross abnormalities in their ability to repair DNA damage. In general, it does not appear that the radiosensitivity

of AT cells is caused by faulty DNA repair; it more likely results from an inability to detect the presence of DNA damage. Exposure to ionizing radiation causes normal cells to delay at the G_1/S and G_2/M transition phases of the cell cycle, and these checkpoints are thought to allow the cells to repair DNA damage before DNA synthesis or mitosis occurs[27] Both checkpoints are absent in AT cells, suggesting clues to the function of ATM.[27]

Although ATM and TP53 cooperate in radiation-induced apoptosis, there are ATM-independent pathways for the induction of TP53-dependent apoptosis, and many of the downstream effects of ATM are independent of TP53.[27,28] Wild type and knockout mice have been evaluated for acute and late toxicity after whole-body exposure to ionizing radiation. The *ATM*- and *ATM/TP53*-knockout mice had similar severe toxicity profiles, suggesting that TP53 does not play a role in acute radiation toxicity. Both TP53- and *ATM*-knockout mice preferentially developed lymphoid tumors, whereas *ATM/TP53* double knockouts had an accelerated time to tumor formation and a broader spectrum of tumor types. Analysis of the acquired tumors in *ATM*-null/*TP*53-heterozygous mice revealed that three of seven had loss of the remaining *TP*53 allele. These studies showed that ATM and TP53 interact in a complex manner that is specific to cell type and outcome. This interaction most likely relies on a variety of other pathways and will require much additional work before a complete understanding of the ATM/TP53 relationship is obtained.

With isolation of the *ATM* gene it became possible to attempt correction of the cellular defects of the AT phenotype using gene transduction techniques. Several groups have reported that the introduction of ATM into AT cells resulted in reversal of AT defects.[27,41] The transfection of full-length ATM into AT cells reversed DSBs, restored normal sensitivity to ionizing radiation, and decreased the number of chromosomal abnormalities. Transfection of full-length ATM also reversed the defective activation of CDKN1A (p21) and JUN kinase in response to ionizing radiation.[42,43]

Histones and Chromatin Structure

Native DNA exists in the cell in the form of chromatin complexed with a family of proteins called *histones*. Histones are involved in packaging DNA in the nucleus into a compact form. For gene transcription or DNA repair to occur, the histones are altered by posttranslational modifications, most notably acetylation and methylation, that permit decondensation and access of factors to the DNA.[44] The histone acetylase TIP60 is important both in this process and in the modification of ATM itself.[26,45] For effective DNA repair, acetylation of histones by histone acetylases must occur to permit access of repair proteins to the sites of DSBs.[46] DNA is then remodeled by adenosine triphosphate (ATP)-dependent remodeling enzymes to permit repair molecules such as Mre11, RAD50, and NBS1 to access sites of DSBs.[47,48] A novel histone, H2AX, found in low concentrations on chromatin, has been shown to play a crucial signaling role in the response to genomic stresses such as ionizing radiation. H2AX phosphorylation is one of the earliest events occurring after exposure to ionizing radiation, and ATM-dependent phosphorylation of H2AX may be involved in signaling to cell cycle checkpoints and DNA repair enzymes involved in recombination repair.[49,50]

Mechanisms of DNA Repair after Ionizing Radiation

Maintaining undamaged DNA is essential to cell survival. Cells have therefore evolved a wide range of mechanisms to halt cell cycle progression, survey DNA, and repair damage. Radiation causes a number of types of damage either by direct interaction with DNA or indirectly through effects on nearby water molecules and free radical generation. Types of damage include DNA base damage, damage to the deoxyribose sugar backbone, and physical breaks in one or both strands of the DNA. DNA damage induced by ionizing radiation tends to be clustered so that multiple damaged sites are found in proximity along the double helix, known as *locally multiply damaged sites*.[51]

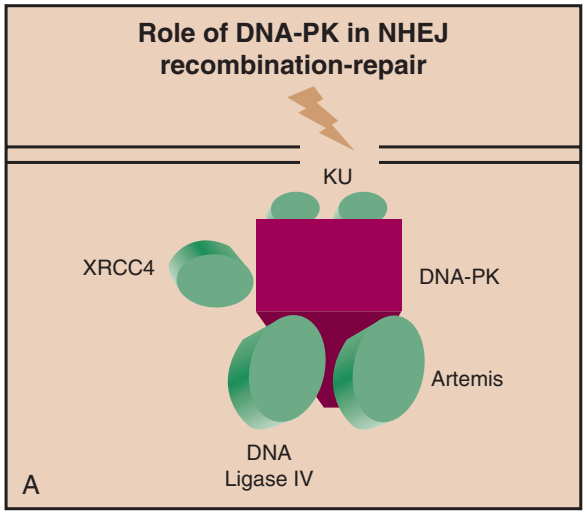
Among the less catastrophic forms of DNA damage induced by ionizing radiation are the singly damaged bases, which can be repaired by base excision repair. This is a process by which the damaged base is recognized and removed by an N-glycosylase, the apurinic or apyrimidinic (AP) site is cleaved by an AP endonuclease, a patch of DNA is excised, DNA is then resynthesized using the other strand as the template, and the repaired strand is ligated.[18,52] In settings in which the base damage is not recognized by the N-glycosylase, another mechanism for repair exists, called *nucleotide excision repair*. In a manner somewhat similar to base excision repair, a damaged section of DNA is removed by incision and excision, a patch is resynthesized using the remaining strand, and the repaired strand is then ligated. Although no naturally occurring mammalian mutants have been identified that are defective in base excision repair, there are a number of different excision repair mutants, which are exemplified by *xeroderma pigmentosum* and Cockayne's syndrome.[18] They are characterized by abnormalities in the repair of damage caused by ultraviolet light, although the clinical spectrum of these repair-deficiency syndromes varies. The abnormal genes are identified by finding the human gene that corrects rodent cell defects, called *excision repair cross-complementing* (ERCC) groups. For a comprehensive review on repair of single-stranded breaks we recommend Friedberg et al.[18]

DNA Strand Breaks

Cellular lethality after radiation involves generation of DSBs.[53-55] Misjoined or unrepaired DSBs lead to chromosome deletions, translocations, and acentric or dicentrics, with lethal consequences for the cell. As with the excision repair defects (e.g., ERCCs), there are several x-ray repair defects in the x-ray cross-complementation (XRCC) groups involved in the repair of DSBs. DNA single-stranded repair is carried out in a manner similar to base damage repair, with the undamaged DNA strand serving as a template. DSB repair is more complicated because there is no adjacent, undamaged template available to form a template for repair of the broken strands. The ends of the broken DNA must be protected, and the damaged site must be reconstituted by the processes of *homologous recombination* and *nonhomologous end joining* (NHEJ).

DNA DSB repair has much in common with the recombinatorial processes involved in immunoglobulin and T-cell receptor gene rearrangement in the immune response. The XRCC groups that have been identified and are involved in DNA DSB repair include genes that produce DNA end-binding proteins XRCC6 (formerly designated KU70 or Ku70) and XRCC5 (formerly designated KU80 or Ku80) and a DNA-dependent protein kinase (DNA-PK). Defects in DNA repair genes are seen in severe combined immunodeficiency (SCID) mice, indicating the importance of recombination in the restoration of DNA integrity after DSBs and in the immune response.[18,53]

Double-Stranded Break Damage and Repair



Experiments in yeast and human cells indicate that a single unrepaired DSB can lead to cell death.[53,55] However, cells have the capacity to detect such DSBs and repair them. DSB repair

would be predicted to require three functional components: (1) a mechanism for detecting and gauging DNA damage, (2) a signal transduction system, and (3) an effector system for DNA repair. These components are discussed in the following paragraphs, commencing with the repair component. DSBs can be repaired by a number of mechanisms, but the most prevalent are homologous recombination and NHEJ. Human cells appear to differ from yeast in that homologous recombination predominates in yeast, whereas the opposite is true in mammalian cells.[53,55]

Genetic analysis has revealed the existence of a large number of genes that regulate DSB repair. One essential gene, involved in resistance to cell killing by ionizing radiation and the repair of DSBs, is *XRCC5*, which encodes XRCC5, a protein that binds with high affinity to the ends of the double strands (Figure 2-3, *A*).[1,18] XRCC5 functions in normal cellular processes that require DSBs rejoining, most notably V(D)J rejoining in the immunoglobulin and T-cell receptor genes of immature B and T lymphocytes. XRCC5 exists in cells in a heterodimeric complex with XRCC6, the product of the *XRCC6* gene. The XRCC5/XRCC6 heterodimer is required for the end-binding and repair functions.[56] The XRCC (formerly designated KU) proteins recognize the ends of DSBs and protect them from further degradation before the onset of end-joining reactions required for DSB repair. An associated protein in the complex with important functions in DNA repair is the protein kinase DNA-PK, the product of the *XRCC7* gene.[56]

DNA-PK is a serine/threonine kinase involved in regulating the cellular response to DNA damage.[56,57] DNA-PK is a member of the phosphatidylinositol-3-kinase gene family (*PIK*) that produce a group of high-molecular-weight proteins that contain a conserved kinase domain at the carboxyl-terminal end. PIK family proteins have been identified in yeast, *Drosophila*, and in mammalian cells, and include the human *ataxia-telangiectasia* gene (*XRCC7*) for DNA-PK and the yeast genes *TEL1* and *MEC1*.[56,57] Homology with genes of other organisms can provide a clue to the function of the family of genes in mammalian systems. For example, the *S. cerevisiae TEL1* gene is a homolog of the human *ATM* gene. *TEL1* mutants have shortened telomeres and exhibit chromosome instability. In mice, the SCID mutation results in the loss of expression of functional DNA-PK.[58] SCID mice are deficient in the repair of DNA DSBs, have faulty V(D)J recombination, and are sensitive to radiation.[58] The binding of the XRCC complex (XRCC5 and XRCC6) to DNA-PK activates its kinase activity. The DNA-PK/XRCC complex is involved in recognizing DNA DSBs. Thus in SCID cells, the catalytic subunit for DNA-PK is absent, and its loss may account for increased sensitivity to ionizing radiation, reduced ability to repair DNA DSBs, and the known immune defects.

Genetic evidence indicates the existence of numerous other factors required for efficient DSB repair in human cells.[18,53,55] Among the genes are homologues of the yeast *RAD52* epistasis group, RAD50 and *MRE11*.[26,59-61] RAD50 and MRE11, together with the product of the *XRS2* gene, form a complex in *S. cerevisiae* that is involved in nonhomologous recombination (see Figure 2-3, *B*). RAD50 has been suggested to bind to DNA at the site of DSBs and mark them for repair or recombination. Such a signaling role for RAD50/MRE11 complexes is suggested by studies indicating the formation of nuclear foci containing these proteins in cells after irradiation.[61] The RAD50/MRE11 complexes also contain another important protein, NBN (nibrin; formerly NBS1 or p95), which is inactivated in the Nijmegen breakage syndrome.[26,61] The RAD50/MRE11 foci fail to form in ATM-deficient cells, suggesting a role for this complex downstream of the ATM protein. DSB repair can also be carried out in human cells by homologous recombination, an alternative pathway involving a different

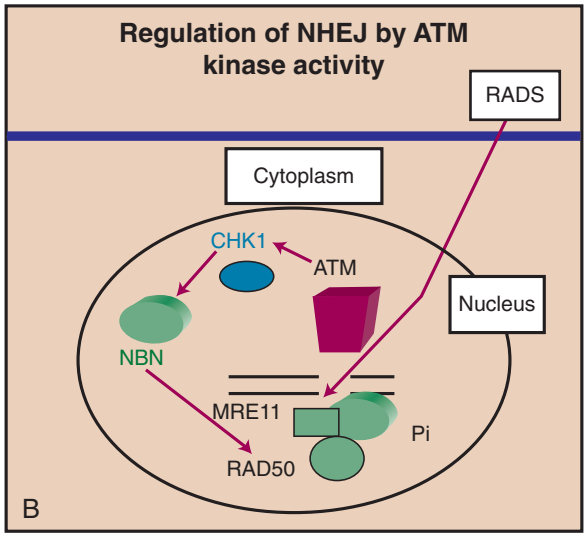


Figure 2-3 **A,** Formation of DNA repair complexes on damaged DNA. Radiation-induced DNA damage causes immediate changes in the vicinity of double-stranded breaks (DSBs). These include rapid phosphorylation of the atypical histone H2AFX and activation of ATM. Protein complexes then begin to assemble on DNA, including the DNA-dependent protein kinase (DNA-PK) complex shown here. This complex is a molecular machine for DNA repair that includes DNA end-binding proteins XRCC6 (formerly KU70) and XRCC5 (formerly KU80); DNA-PK itself, which appears to be a signaling and scaffold protein; and proteins involved in the effector stages of repair. **B,** Another important protein complex mediating DNA DSB repair by the nonhomologous end joining (NHEJ) pathway is the RAD50 complex. The diagram shows the signal transduction pathway leading from ATM, the sensor of DNA DSB, to the phosphorylation of NBN (nibrin, formerly designated NBS1), which induces recruitment of RAD50 and MRE11 into a DNA repair complex at the site of the DNA DSB.

group of genes, including *RAD51* through *RAD57*. RAD51 is the eukaryotic homolog of the bacterial protein RecA and forms structures in meiotic chromosomes containing ATM, suggesting functional coupling between these proteins. The complex also contains TP53 and may be involved in coupling of DNA DSB formation to cell cycle arrest, as well as in carrying out recombination and repair.[62]

The tumor suppressor genes *BRCA1* and *BRCA2* also have function in DNA repair. Although the these proteins have multiple functions, it has been shown that *BRCA1* interacts

with RAD51 and assists in cell cycle arrest through activation of *CDKN1A*, a gene that is normally activated by TP53.[63] RAD51 is thus targeted by three major gene products: ATM, TP53, and BRCA1. Loss of RAD51 leads to cancer development, suggesting that this pathway of DNA repair and replication is crucial in protection of cells from genotoxic stress. That this RAD51 pathway of DSB repair is separate from the RAD50 end-joining pathway is indicated by findings that ionizing radiation causes the formation of nuclear foci containing RAD50 or RAD51 but never both complexes.[64] However, further studies are required to understand the relative contributions of the two pathways to cell survival after exposure to ionizing radiation. As with the RAD50 pathway, understanding of mammalian recombination repair is still preliminary and is difficult to assemble into a fully coherent molecular pathway. *BRCA2* mutant cancer cells are also deficient in DSB repair and have increased radiosensitivity.[63] It is apparent that DNA damage recognition and repair is complex, involving interaction among molecules that can cause cell cycle arrest, apoptosis, and signal transduction. Defects in any of these pathways could lead to radiation sensitivity in normal tissues (and perhaps the corresponding tumor) or to the development of secondary mutations and the mutator phenotype, as with mismatch repair defects. For radiation therapy, the aim of course is to maximize accumulation of DSBs in tumor cells by targeting these pathways.

PATHWAYS OF IONIZING RADIATION-INDUCED PROGRAMMED CELL DEATH

The ability to inhibit the pathways of cell death appears to be a key step in the origin of cancer cells, with the small percentage of cells that are able to evade PCD being the ones most capable of forming tumors.[16] Multiple genetic alterations are involved in escape from PCD, most notably in the *TP53* and *BCL2* families.[16] Radiation oncologists are thus faced with the undesirable situation in which tumor cells are selected for resistance to PCD, whereas normal cells retain these altruistic pathways. Apoptosis and senescence are key PCD pathways with potential roles in cancer induction and resistance to therapy. Excellent reviews have been provided by Edinger and Thompson[32] and Danial and Korsmeyer.[65]

Apoptosis is a normal physiologic process that permits altruistic death of cells during tissue remodeling or the elimination of T-cell populations after the reversal of viral infection.[65] Apoptosis is characterized morphologically by cell shrinkage, membrane blebbing, chromatin condensation, and ultimate fragmentation of the cell into apoptotic bodies. Molecular characteristics include activation of class of proteases (protein degrading enzymes) the caspases. These are involved in intracellular death signaling. Additionally, activation of enzymes that degrade DNA (endonucleases) is seen. In the final stage of apoptosis, the cell corpses exhibit "eat me" signals a process that involves alteration of the cell surface (including expression of annexin V binding sites on the plasma membrane) permitting neighboring cells to remove the apoptotic bodies without the induction of an inflammatory reaction. Apoptosis is mediated by changes in the outer mitochondrial membrane that lead to the release of death signals such as cytochrome c. BCL2 and related family members function as anti-apoptotic factors by blocking pro-death changes in mitochondrial membrane potential or as anti-apoptotic factors by antagonizing the pro-apoptotic factor BAX. The terminal stages involve DNA degradation, which cleaves DNA into 50- to 300-kb fragments and later into smaller fragments by cleavage of the exposed regions of DNA between nucleosomes.[65]

REPLICATIVE SENESCENCE

In addition to vulnerability to overt killing, all somatic cells possess replicative checkpoints that place limits on the number of permitted cell divisions over the lifetime of the cell. For unlimited growth, cells must bypass crisis, the point at which the telomeres on chromosomes have shortened enough to prevent successful future cell divisions. TP53-sensitive (and CDKN1A-sensitive) expression of the enzyme telomerase in tumor cells is sufficient to bypass crisis and permit unlimited growth in some cells (see Figure 2-2). In addition to crisis, cells undergo telomerase-independent forms of senescence, regulated in many cases by the retinoblastoma protein RB1 and the CDK inhibitory protein CDKN2A (formerly designated p16).[66,67] However, TP53 appears to be the primary regulator of senescence and activated this process downstream of DNA damage detected by ATM activation or other pathways.[27] Few experiments have been carried out to examine the role of senescence in responses to ionizing radiation, although in one study, ionizing radiation induced premature senescence that occurred independently of ATM expression.[68]

ACTIVATION OF ANABOLIC SIGNALING PATHWAYS BY IONIZING RADIATION

One of the primary features of cancer is its autonomy in terms of growth signals. There are three operationally defined steps in growth signaling: (1) transmembrane receptor occupation by growth factors and transmembrane signaling, (2) stimulation of cytoplasmic cascades that amplify primary signals, and (3) activation of downstream effector proteins. Step 1 classically involves dimerization and autophosphorylation of receptor tyrosine kinases (RTKs) or recruitment of nonreceptor tyrosine kinases (NRTKs). Such events occur commonly after ionizing radiation, and a generalized activation of the HER1 through HER4 RTKs occurs in irradiated cells (Figure 2-4).[69] Ionizing radiation can induce the release of growth factors such as epidermal growth factor (EGF, TGF-α) and paracrine activation of growth in adjacent cells.[69] Increases in cellular phosphotyrosine levels were observed after exposure to x-rays in a number of cells, and activation of NRTKs has been observed.[69] Of particular importance in step 2 processes are members of the mitogen-activated protein kinase (MAPK) family, which play crucial roles in cell growth and survival. Ionizing radiation stimulates the activity of MAPK members that carry the mitogenic signal (e.g., MAPK1 [formerly ERK2], MAPK3 [formerly ERK1]).[70] The paradigm for step 3 is the activation of factors that bind the promoters of mammalian immediate early genes such as *FOS* and *EGR1* through receptor activation, tyrosine phosphorylation, and MAPK activation. Such transcription factors include serum response factor, ETS domain factors such as TCF62, ELK-1, activating protein-1 (AP1), and cyclic adenosine monophosphate-binding protein (i.e., cAMP response element binding [CREB]).[71] Each of these factors is activated by ionizing radiation, and the promoter of at least one immediate early gene (*EGR1*) is induced by radiation treatment. Therefore, exposure to ionizing radiation could amplify the growth signals already active in cancer cells, suggesting that the RTK-MAPK pathway may be a fruitful target in the selection of radiation sensitizers.[69,72]

Radiation-induced signaling may be secondary to the free radical generation. Radiation produces two main species that combine to kill cells in a clinical setting and that may also double as primary stress signals.[10] These signals are reactive oxygen species (ROS) and DSBs discussed previously. ROS play a role in signal transduction after stimulation by platelet-derived growth factor (PDGF) and phorbol esters.[70,73] ROS

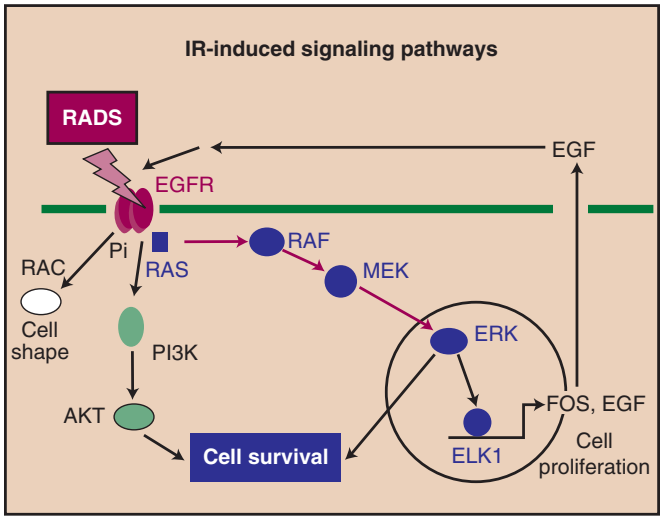

Figure 2-4 Induction of transmembrane signals by ionizing radiation (IR), which directly activates several transmembrane receptors. Free radicals induced in cells by ionizing radiation can activate transmembrane tyrosine kinase receptors such as the epidermal growth factor (EGFR) and HER2, HER3, and HER4 (not shown). Receptor activation gives rise to a network of signals that lead to activation of the powerful prosurvival PI3K/AKT pathway and the growth-mediating RAF/MEK/ERK cascade. Further amplification may take place as a result of transcriptional induction and the release from cells of cytokines with growth factors such as EGF and transforming growth factor-α, which give rise to secondary activation of receptors.

produced by cellular stress, such as peroxide, superoxide, hydroxyl radicals, and nitrous oxide, may feed into this ROS-transduced pathway at a number of places.[74] Cell kill by radiation is closely correlated with the accumulation of DSBs. The dictates of logic and much preliminary evidence strongly suggest a role for DSBs in the sensing and response to ionizing radiation.[27] Cells evidently possess at least one system to sense and respond to radiation, the ATM family of protein kinases, which appear to be situated close to the primary event in DSB-induced signaling as described previously.[27,53] ATM activation leads to phosphorylation of TP53, which couples DSB accumulation to cell cycle arrest in G_1.[30] Vectoral signaling is then coupled to the metronomic events of the cell division cycle. ATM belongs to the lipid kinase family that includes PIK and DNA-PK.[27,40] PIK is activated by ionizing radiation and is required for cell survival during irradiation. DNA-PK is intimately involved in cell responses to radiation, and its ability to sense DSBs in combination with DNA end-binding proteins XRCC6 and XRCC5 suggests that it may be able to function independently of ATM in cell signaling after exposure to ionizing radiation.[56]

Regulatory changes in cells after irradiation may therefore be caused by the aggregate and combinatorial interactions of three distinct types of signaling pathways: classic signal transduction, signaling pathways mediated by ROS, and those initiated in the nucleus by DSBs.

RADIATION AND THE RNA WORLD

Over recent years there has been a revolution in understanding the role of RNA in biology and cancer.[75] In addition to its housekeeping function as mRNA and rRNA, novel RNAs have been shown recently to play key regulatory roles. Small interfering RNA and microRNA play negative regulatory roles in diminishing specific RNA levels and targeting structures in the 3′ and 5′ regions of mRNA.[76,77] Large noncoding RNA plays a role in regulation of transcription, although its regulation of radiation responses is not known.[78] Study of the roles of these molecules in the radiation response has begun.[77,79]

TUMOR MICROENVIRONMENT AND RESPONSES TO IONIZING RADIATION IN VIVO

In addition to malignant cells, tumors contain normal cells and structural elements, including endothelial cells, fibroblasts, extracellular matrix molecules, inflammatory cells, and blood vessels. The tumor microenvironment is abnormal in being largely deficient in nutrients such as oxygen and glucose, and abundant in the waste products of metabolism such as lactic acid and carbon dioxide.[80,81] Thus, the concentrations of nutrients and cell-cell and cell-matrix contacts are abnormal and may be in a constant state of flux because of intermittent perfusion by the microvasculature. The tumor microenvironment is a key determinant of the response to ionizing radiation. Hypoxic cells are markedly radioresistant because of the requirement for oxygen in the formation of the free radicals that mediate radiation-induced DSBs.[10] Defining the tumor milieu and how it is regulated is thus important in understanding the radiosensitivity of tumors.

Hypoxia, Microenvironment, and Radiation Response

The role of hypoxia in radioresistance has been studied for many years.[10,82] Cell killing by radiation is decreased at intermediate- and low-oxygen conditions, and a number of studies have correlated low pretreatment tumor oxygenation with a worse disease outcome.[83,84] Whether there is a direct cause-and-effect relationship between low-oxygen concentration and outcome remains to be resolved, primarily through clinical trials that deliberately attempt to correct the poor oxygenation status of the tumors. In addition to directly inhibiting cell killing by ionizing radiation, hypoxia may amplify the mutator phenotype in the severely hypoxic cells in the central cores of tumors, increasing the rate of evolution of resistant clones and amplifying the malignant phenotype.[85]

Many genes are induced or repressed within the tumor microenvironment.[86,87] The largely unregulated environment found in poorly vascularized tumors could be thought of as resembling the conditions under which many unicellular organisms grow. Survival for these organisms depends on their ability to withstand environmental stresses such as nutritional deprivation, temperature and pH changes, radiation exposure (e.g., ultraviolet light, x-rays), and xenobiotics. Among the molecules induced by hypoxia are members of the unfolded protein response family stress proteins (e.g., glucose-regulated proteins [GRPs], redox enzymes such as heme oxygenase, metallothionein IIA, DT-diaphorase; transcription factors such as JUN, FOS, AP1, TP53, nuclear factor-KB [NF-κB], HIF1) and growth factors or cytokines (e.g., erythropoietin, vascular endothelial cell growth factor [VEGF], EGF receptor, interleukin-1α [IL-1α]).[86,87] HIF1 appears to be of key significance in the response of cells to the microenvironment at the molecular level because this transcription factor regulates expression of many of the factors that mediate angiogenesis.[88]

Tumor Angiogenesis

Another of the hallmarks of cancer is the ability of cancer cells to induce de novo angiogenesis to sustain growth.[36,89,90] Tumors contain multiple angiogenic factors including angiopoietin, acidic fibroblast growth factor (FGF), basic FGF, angiogenin,

PDGF, prostaglandins E_1 and E_2, transforming growth factor-β, tumor necrosis factor-α, and VEGF (also known as vascular permeability factor). The VEGF family has received much attention as potential therapeutic targets. In addition antiangiogenic factors are also expressed and include angiostatin, endostatin, interferon-α and interferon-β, thrombospondin, and tissue inhibitor of metalloproteinase.[90,91] The outcome for vascularization and tumor growth depends on a balance between the factors.

The use of antiangiogenic therapy with local radiation has been investigated in several laboratories.[92,93] One important aspect for combining vascular targeting and radiation therapy and probably also for systemic agents is whether the antiangiogenic therapy increases or decreases tumor oxygenation. The relationship between angiogenesis, antiangiogenic therapy, and the more conventional cancer therapies remains to be elucidated but offers some exciting areas of investigation. The ability to suppress metastases and hold local tumor growth[92,93] offered by vascular targeting may greatly increase the potential role for radiation therapy. However, if antiangiogenic therapy leads to decreased perfusion or hypoxia, the effects are likely to be confounding. Given the role of blood vessels in late radiation injury, the use of antiangiogenic therapy with radiation in clinical treatment will require careful study and assessment of long-term toxicities and late effects.

RADIATION AND THE CELL BIOLOGY OF CANCER

Study of the cell biology of cancer has lagged behind molecular biology studies. However, it is apparent that, rather like normal tissues, tumors contain only a small proportion of cells that can proliferate in the long term. These are known as cancer stem cells by analogy with their normal counterparts. As such cells are resistant to most treatments, targeting them may be important in improving cancer therapy; this is an area of intensive study. In addition to heterogeneity conferred by cell differentiation hierarchies, tumors contain populations of normal cells that confer a growth-promoting niche in the tissue and protect tumor cells by suppressing immunity. Such cells include tumor-associated macrophages and fibroblasts, myeloid suppressor cells, and regulatory T cells. Heterogeneity in terms of cell hierarchy and normal cell infiltration may determine many key features of tumor progression including invasion and metastasis of cancer cells and susceptibility to immune killing. The role of radiation in these processes is under investigation and may be a key area for future development.

TARGETING MOLECULAR PATHWAYS IN THE RADIATION RESPONSE: DISCOVERY OF NEW DRUGS

The accumulated data regarding the signaling circuitry underlying the response of cells to DSBs suggests an opportunity for the development of novel adjuvant therapies. Approaches based on small-molecule inhibitors of specific reactions, RNA interference (small interfering RNAs), and antisense and gene therapy are attractive and follow directly from the basic research available. There is much excitement regarding the potential use of kinase inhibitors in cancer treatment, based on the idea that they work catalytically, are present in small amounts, and often regulate key processes in the cell. The most popular paradigm is a kinase inhibitor, known as imatinib (Gleevec), which has greatly influenced the treatment of hematologic malignancies. Given that the cell cycle checkpoint component of the DNA DSB response is regulated largely at the posttranscriptional level by batteries of protein kinases and phosphatases, many inviting targets are available. Proof of principle that such an approach may work is suggested by studies using agents that inhibit the RAS signal transduction pathway, protein kinase C, or the PIK pathway, which were shown to enhance radiation-induced cell killing.[94,95,96,97,98,99,100] Members of the PIK family may be feasible targets for pharmacologic intervention in the clinic. Loss of function of PIK proteins is usually associated with increased radiosensitivity. Compounds that block the function of these proteins would greatly enhance the efficacy of agents that cause DNA damage, such as radiation therapy, and allow for the treatment of tumors that are particularly radioresistant.

The fungal metabolite wortmannin is a specific inhibitor of the p110 PIK, now designated PIK3CD. Wortmannin forms a covalent adduct with Lys802 of PIK3CD, inactivating the kinase activity.[101,102] This Lys802 is conserved in DNA-PK and AT proteins, suggesting that both would be sensitive to wortmannin. In vitro studies with a wide range of tumor-derived cells, including those of the breast, colon, and prostate, indicate that wortmannin is an effective radiosensitizer of human cells. Wortmannin can inhibit the kinase activity of DNA-PK in vitro and in vivo. DNA-PK also is involved in the activation of TP53 after irradiation of cells, and wortmannin suppresses the activation of TP53 after irradiation. Other studies have shown that wortmannin may exert its primary effect by inhibiting the repair of DNA strand breaks in cells.

In addition to drugs, the development of small interfering RNA approaches offers the promising possibility of "knocking down" selective genes that may mediate resistance.[76] There has been much excitement regarding the use of targeted gene therapy to introduce genes of interest or their antisense partners within viral vectors. Some of the enthusiasm about these approaches has waned because of the potential toxicity of the viral vectors (particularly adenovirus) and a number of other operational problems, such as accurately reaching the target site, achieving sufficient gene production in situ (i.e., drug, enzyme, or toxic molecule) to alter the radiation response, altering the radiation response sufficiently to show an impact on local tumor control, having a positive therapeutic ratio, and ideally, having an impact on survival in addition to enhanced local control. Despite these problems, the approach remains popular, particularly for local expression of products that diffuse from cells, such as cytokines. With the advent of newer, safer vectors for delivery of agents, the approach holds promise.[103]

Previous radiation modifiers in clinical use have been developed based on conventional radiation biology models, such as hypoxia (e.g., radiation sensitizers and enhancers, altered oxygen delivery), the competition model (e.g., thiol depletion and radioprotectors), and increasing susceptibility of DNA to radiation damage (e.g., halopyrimidines).[101,102,104] Although such therapies were not based on the new molecular targets that have more recently been elucidated, much can be learned by studying the relationships between these therapies and the molecular processes. For example, it may be possible to understand how better to use the halopyrimidines in relation to cell cycle checkpoints, hypoxic sensitizers in relation to hypoxia-induced processes, and protectors in terms of specific DNA lesions or activity of repair enzymes.

As mentioned, tumor cells exist in a unique microenvironment that is depleted of oxygen and glucose and rich in carbon dioxide and lactate. Drugs may be designed to prosper in this altered microenvironment and enhance treatment efficacy. Among these more conventional approaches, the bioreductive agents, such as mitomycin C and tirapazamine, require enzymatic activation that occurs preferentially in hypoxic environments.[105]

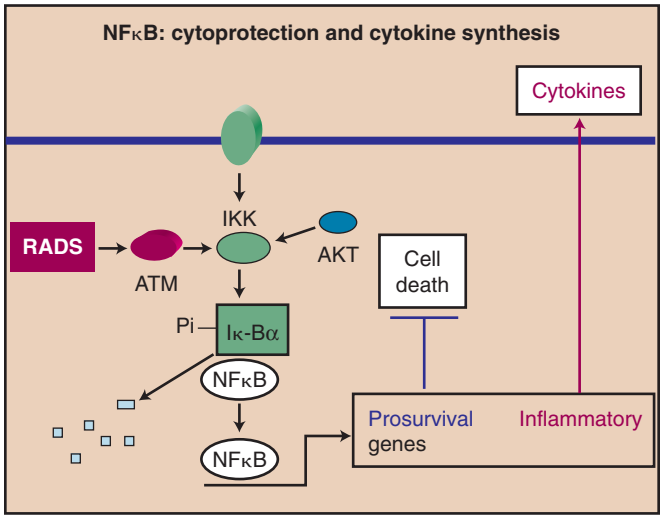

Figure 2-5 Ionizing radiation activates the NF-κB pathway. NF-κB is induced by inflammatory ligands such as bacterial products that stimulate the IKK kinase complex and activate NF-κB through destruction of the inhibitor IK-Bα. This pathway also can be activated by ionizing radiation through a number of mechanisms, particularly IKK activation by the DNA DSB sensor molecule ATM. NF-κB activation has at least two known consequences: increased cell survival through synthesis of death-antagonizing NF-κB products and proinflammatory effects caused by increased expression of cytokines and adhesion factors.

NORMAL TISSUES

Radiation therapy depends for its selective treatment of cancer on tight control of delivery to tumors and avoidance of normal tissues. Most normal tissues that express wild-type TP53 are sensitive to TP53-induced PCD.[106] Renewable tissues such as hematopoietic stem cells and crypt cells in the gastrointestinal tract may be particularly vulnerable.[33] Indirect forms of lethality may occur in whole-body irradiation, leading to the death of hematopoietic stem cells in the bone marrow, or depletion of mature tissues can lead to secondary damage caused by red blood cell depletion, immunosuppression, and gross infection as the gastrointestinal lining is lost.[10,13,14]

Additional changes occur that are thought to be the result of a persistent oxidative state in tissues such as lung, which may lead to chronic inflammatory changes and induction of cytokines and adhesion molecules.[107,108] Changes may result from induction of the transcription factor NF-κB by ionizing radiation in an ATM-dependent manner (Figure 2-5).[109,110] NF-κB, in addition to its role in cytoprotection, plays a broader part in the acute inflammatory response through transcription of a wide range of proinflammatory cytokines and adhesion molecules.[111] Induction of an inflammatory environment in normal tissues may be a side effect of activation of NF-κB in a cytoprotective reaction (see Figure 2-5).

BASIC CONCEPTS AND TECHNIQUES OF RADIATION SCIENCES

Techniques and approaches to molecular and cellular biology in humans and other model organisms, largely developed in the 1960s and 1970s, continue to revolutionize knowledge of basic cancer biology and radiation sciences. The ability to inactivate genes by homologous recombination, which came into frequent use in the 1980s, has permitted the movement of this approach into animal models, allowing study of molecular genetics in vivo. This has permitted us to test the significance of the key genes in the cell cycle, DNA repair, and PCD, which mediate the sensitivity of cells to ionizing radiation and define their role in radiation response. Novel "big biology" approaches, including such genomic techniques as microarray screening, deep sequencing and mass spectrometry permit discovery-based research with the potential for fundamental advances.[112-114] Because of the progress in deciphering human and other genomes in the 1990s, a total readout of expression of all human genes can be undertaken. This has opened the way for identification of signature genes in human cancers that correspond to poor prognosis, treatment resistance, and metastasis. The impact of gene expression profiling on radiation biology is perhaps less than in general cancer biology because most responses to genomic stress occur at the post-transcriptional level. The development of proteomics is being developed, based on advances in mass spectrometry, and this approach allied with deep sequencing may permit the rapid study of critical changes in posttranslational modification, such as phosphorylation, acetylation, and ubiquitination, which mediate many regulatory responses to genomic stress. The increased speed and accuracy of drug development, based on robotic approaches to assaying chemical libraries and in silico design, should also increase the rate of drug discovery and hasten the translation of molecular findings into the clinic.

SUMMARY

The past 20 years have seen an impressive transformation in understanding of the genes that determine the development of the cancer cell, its subsequent response to radiation and chemotherapy, and the signaling circuitry that links the products of such genes to DNA damage response pathways. The rate of accumulation of new knowledge, particularly in the field of DNA sensing and repair, has been so rapid that its future impact on the practice of radiation oncology is difficult to predict. One area of incomplete knowledge is the exact molecular mechanisms of radiation cell death, their link to the DNA damage response pathways, and how they might be altered by the evolving patterns of gene expression in tumor progression. This dilemma is well illustrated by TP53, the factor that in normal cells links the accumulation of genomic damage to cell death by apoptosis, autophagy, and senescence but that is inactivated in most cancers. In contrast, identification of ATM as the master regulator of the response to genomic stress suggests this pathway as one that can be targeted for radiation sensitization. Another interesting possibility for targeting new treatment approaches is that of necrosis, particularly in tumor cells, in which the pathways of PCD have been closed off through alterations in the TP53 and BCL2 pathways. The success of future approaches to cancer treatment and cure will be determined by their ability to inhibit or facilitate normal and adaptive changes in cell physiology to maximize the deleterious effects on the tumor while preserving viability of the surrounding normal tissues.

CHAPTER

3 Dose-Response Modifiers in Radiation Therapy

Michael R. Horsman, Jacob C. Lindegaard, Cai Grau, Marianne Nordsmark, Jan Alsner, and Jens Overgaard

When cancer patients undergo radiation therapy there is a clear dose-response relationship between the dose delivered and the response of the tumor to the radiation. This is illustrated in Figure 3-1. Unfortunately, there is also an increase in normal tissue damage with increasing radiation dose, and it is this complication that limits the total radiation dose that can be given. Substantial effort has been made to try and modify these dose-response relationships and to thus increase the separation between the tumor and normal tissue dose-response curves. The approach has been either to selectively increase the radiation damage in tumors without affecting the normal tissues or by protecting the normal tissues without having a similar protective effect in tumors.

Agents capable of enhancing radiation response include certain conventional chemotherapeutic agents, the halogenated pyrimidines, and treatments that specifically overcome radioresistance resulting from the presence of hypoxic cells that occur as a result of the environmental conditions within most solid tumors. The most widely investigated method applied to the hypoxia problem is radiosensitization of the hypoxic cells with either electron-affinic sensitizing drugs or hyperthermia. Another approach often used to reduce hypoxia—especially in experimental systems—involves increasing oxygen availability (1) by having patients breathe high-oxygen-content gas, (2) introducing perfluorochemical emulsions into the vascular system to increase the oxygen carrying capacity of the blood, (3) modifying oxygen transport or delivery by using agents that affect hemoglobin, (4) using drugs that increase tumor blood perfusion, or (5) a more recent approach of decreasing the oxygen consumption rate of the "nonhypoxic" cell population, thereby increasing the oxygen diffusion distance. Many experimental studies have also demonstrated that hypoxic cells can be preferentially destroyed by bioreductive drugs that are active under reduced oxygen conditions, or again using hyperthermia; each of these hypoxic-cell cytotoxins improve the radiation response of tumors. Another group of agents, which preliminary data suggests have the potential to enhance radiation damage, are the so-called vascular targeting agents. These include drugs that inhibit angiogenesis, the process by which tumors develop their own vascular supply, or agents that preferentially damage the already established tumor vessels.

Radiation protectors fall into several categories based on the timing of their administration in relation to radiotherapy. There are the true "radiation protectors," in particular sulfhydryl compounds, which are used as a prophylactic strategy and administered before radiotherapy and primarily appear to interact with radicals that are formed as a result of radiation exposure. Another group consists of "radiomitigators" that reduce the effects on normal tissues before the emergence of symptoms if given during or shortly after radiotherapy. Finally, there are "therapeutic agents," which are administered after radiotherapy to treat symptoms that have already developed, especially fibrosis.

Radiosensitization by conventional chemotherapeutic agents (e.g., cisplatin, 5-fluorouracil, and mitomycin C), halogenated pyrimidines (e.g., 5-bromodeoxyuridine and 5-iododeoxyuridine), and hyperthermia are discussed in detail elsewhere in this book. In this chapter, the focus will be on hypoxic cell modifiers, vascular targeting drugs, and radioprotectors.

THE HYPOXIA PROBLEM

Importance of Oxygen

In 1909 Gottwald Schwarz,[1] in a simple but elegant experiment, demonstrated that the radiation response of skin was markedly decreased if the blood flow in the irradiated area was reduced by compression. Although he did not acknowledge that the phenomenon was the result of a lack of oxygen, his study was probably the first radiobiologically oriented clinical study implicating the importance of environmental parameters in the outcome of radiotherapy. This finding was used to introduce the concept of "kompressionsanämie" by which the skin was made anemic, thereby allowing a higher dose to be given to deeply situated tumors. Following the work of Schwarz, in 1910 Müller[2] reported that tissues in which the blood flow was stimulated by diathermia showed a more prominent response to radiation. This early study not only demonstrated the importance of oxygen supply in radiotherapy, but it was also the first clinical approach showing how resistance could be overcome by using hyperthermia. Subsequently, sporadic clinical and experimental observations indicated the importance of sufficient blood supply to secure an adequate radiation response. These observations led Gray et al[3] in the early 1950s to postulate that oxygen deficiency or hypoxia was a major source of radiation resistance.

The first clinical indication that hypoxia existed in tumors was made around the same time by Thomlinson and Gray[4] when, from histological observations in carcinoma of the bronchus, they reported seeing viable tumor regions surrounded by vascular stroma from which the tumor cells obtained their nutrient and oxygen. As the tumors grew, the viable regions expanded and areas of necrosis appeared at the center. The thickness of the resulting shell of viable tissue was found to be between 100 and 180 μm, which was within the same range as the calculated diffusion distance for oxygen in respiring tissues. It was thus suggestive that as oxygen diffused from the stroma, it was consumed by the cells and, although those beyond the diffusion distance were unable to survive, the cells immediately bordering the necrotic area might be viable yet hypoxic. In 1968, Tannock[5] described an inverted version of the Thomlinson and Gray picture, with functional blood vessels surrounded by cords of viable tumor cells outside of which were areas of necrosis. This "corded" structure, illustrated in Figure 3-2, is the more typical picture found in most solid tumors.[6] It arises because the tumor blood vessels, which are derived from the normal tissue vessels by a process of angiogenesis, are inadequate to meet the needs of the rapidly growing tumor cells. This hypoxia is more commonly called *chronic hypoxia*.

It was also suggested that hypoxia in tumors could be acute in nature.[7] However, it was not until later that Chaplin et al[8] were able to confirm the existence of acutely hypoxic cells in tumors and demonstrate that these cells were the result of

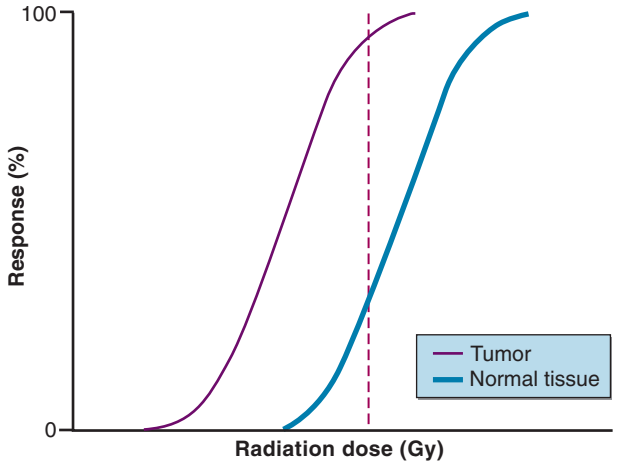

Figure 3-1 Schematic illustration of the proportion of patients cured and patients with normal tissue complications as a function of the total radiation dose received.

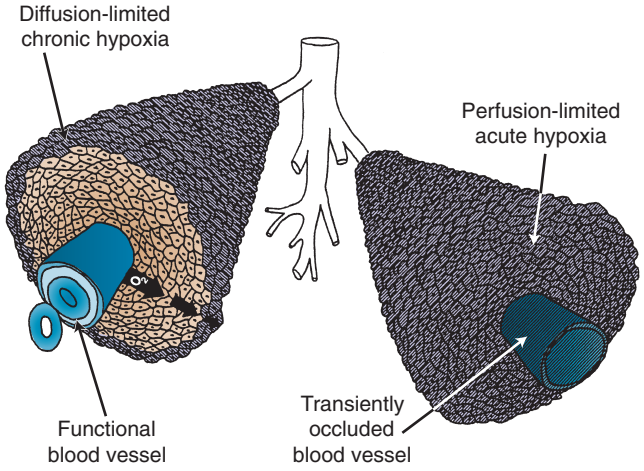

Figure 3-2 Schematic representation of the interrelationship between tumor cells and the vascular supply. On the left, cells are seen growing as a "corded" structure around a functional vessel from which the cells receive their oxygen supply. As oxygen diffuses out from the vessel it is used up, thus the outermost viable cells (shown by the shading) are oxygen deprived or chronically hypoxic. A similar arrangement is seen on the right, but here flow through the vessel is transiently stopped, thus making all the cells oxygen deprived.

transient stoppages in tumor blood flow (see Figure 3-2). To date, these temporary cessations in blood flow have been observed in mouse and rat tumors, as well as human tumor xenografts, with anywhere from around 4% to 8% of the total functional vessels involved,[9] although the exact causes of these stoppages are not known. The current use of chronic or acute to explain hypoxia in tumors is probably an oversimplification of the real situation. Chronic hypoxia generally refers to prolonged and reduced oxygen concentrations that influence radiation response, but there is evidence that oxygen concentrations that are higher, yet below normal physiological levels, are often found.[10] Furthermore, reduced perfusion can be both partial as well as total,[11] and while cells under the former condition would be oxygen deprived, with the latter they would be starved of oxygen and nutrients, and as such, their survival and response to therapy would be expected to be different.

Evidence for Hypoxia in Tumors

In experimental tumors it is not only relatively easy to identify hypoxia, but one can also quantitatively estimate the percentage of cells that are hypoxic. Three major techniques are routinely used.[12] These are the paired survival curve, the clamped tumor growth delay, and the clamped tumor control assays. All involve a comparison of the response of tumors when irradiated under either normal air-breathing conditions or when tumors are artificially made hypoxic by clamping. Using these procedures hypoxia has been directly identified in most animal solid tumors, with the values ranging from less than 1% to well more than 50% of the total viable cell population.[12] Unfortunately, none of these procedures can be applied to the clinical situation. One therefore must rely on indirect techniques.

Estimating hypoxia in human tumors has generally involved the use of indirect methods.[13] Some of the earliest attempts focused on the vascular supply because it was only via the tumor vasculature that oxygen could be delivered. The endpoints included immunohistochemical estimates of intercapillary distance, vascular density, and distance from tumor cells to the nearest blood vessel[14-16]; oxyhemoglobin saturation determined using cryophotometry, or noninvasively with near-infrared spectroscopy or magnetic resonance imaging (MRI)[17-19]; or measurements of tumor perfusion using MRI, computed tomography (CT), or positron emission tomography (PET).[20-22] With the finding that hypoxia could up-regulate gene/protein expression, it was suggested that endogenous markers could be used to identify hypoxia.[23] The principal markers have included hypoxia inducible factor 1 (HIF-1), carbonic anhydrase IX (CAIX), the glucose transporters GLUT-1 and GLUT-3, and osteopontin (OPN).[24-27] These have been applied either individually or combined with other endogenous markers in gene signatures.[13] More popular techniques involve measurements of the binding of exogenous markers. This can be achieved following immunohistological analysis of biopsied sections, using, for example, pimonidazole or EF5.[28,29] It can also be done noninvasively with PET, single-photon emission computed tomography (SPECT), or MRI analysis of radioactively labeled nitroimidazoles (i.e., [^{18}F] labeled misonidazole or FAZA; [^{123}I] labeled azomycin arabinoside), or PET imaging of [$^{60\text{-}64}$Cu]-ATSM.[30-33]

The most direct method involves determining oxygen partial pressure (PO_2) distributions with polarographic electrodes.[34-39] How this approach can be used to detect hypoxia and relate the measurements to radiotherapy outcome is illustrated in Figure 3-3. In this international multicenter study in head and neck cancer patients, their tumor's pO_2 was measured before radiation therapy and was found to correlate with overall survival, in that those patients with lower tumor oxygenation status, did significantly worse.[40]

Probably the best evidence for the existence of hypoxia in human tumors comes from the large number of clinical trials in which hypoxic modification has shown some benefit.[41] The latter situation constitutes a circular argument: if hypoxic modification shows an improvement then hypoxic clonogenic cells must have been present in tumors. It is, however, likely that even tumors with the same histological makeup and of the same type have substantial heterogeneity with respect to the extent of hypoxia. It must be admitted that today, a century after the first clinical description, the importance of hypoxia and its influence on the outcome of radiotherapy is still the subject of substantial debate. However, we will now discuss in detail how the different hypoxic modifiers have been used to modify the radiation dose response of tumors.

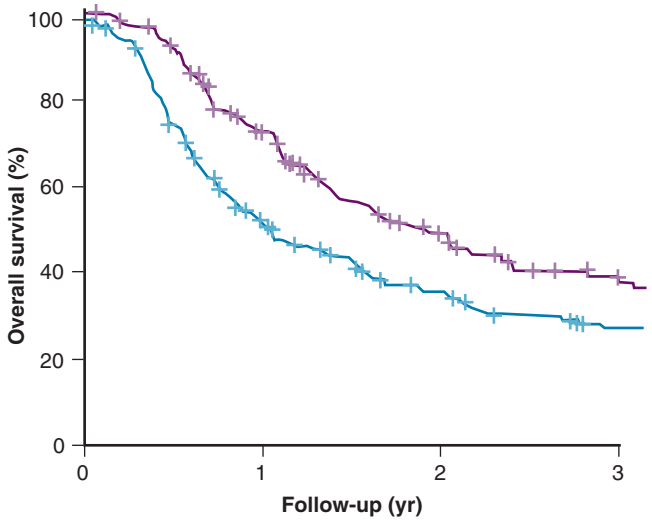

Figure 3-3 Oxygen levels were measured with Eppendorf electrodes before radiation therapy in 397 patients with squamous cell carcinomas of the head and neck. Tumors were stratified by whether the fraction of pO_2 values ≤ 2.5 mm Hg (HP2.5) were above or below the median value for the whole group (i.e., 19%). The lines show Kaplan Meier estimates of actuarial overall survival probability for patients with less hypoxic tumors (HP2.5 ≤ 19%; *red line*) compared with more hypoxic tumours (HP2.5 > 19%; *blue line*), $p = 0.006$.

OVERCOMING TUMOR HYPOXIA

High-Oxygen-Content Gas Breathing

Because the oxygen supply to tumors is insufficient to meet the needs of all the tumor cells, radiation-resistant hypoxia develops; therefore, an obvious solution to improving the tumor's radiation response would be to increase the oxygen supply. This has been tried, both experimentally and clinically, by simply allowing the tumor bearing host to breathe high-oxygen-content gas mixtures before and during irradiation.

Early experimental studies reported that breathing either oxygen and carbogen (95% O_2 + 5% CO_2) could substantially enhance the response of murine tumors to radiation and that the best effect was generally seen when the gasses were inspired under hyperbaric (typically 3 atmospheres [3 atm]) rather than normobaric conditions.[42,43] This is not surprising because hyperbaric conditions would be expected to saturate the blood with oxygen more than normobaric conditions. However, later studies indicated that the radiosensitizations produced by normabaric oxygen or carbogen were quite substantial;[44,45,46] because it is quicker and easier to breathe gas under normobaric conditions, the use of cumbersome, expensive, and complex hyperbaric chambers is probably not necessary.

Clinically, the use of high-oxygen-content gas breathing, specifically under hyperbaric conditions, was introduced relatively early by Churchill-Davidson et al.[47] Most trials were fairly small, and suffered from the applications of unconventional fractionation schemes, but it appeared that the effect of hyperbaric oxygen was superior to radiotherapy given in air, especially when few and large fractions were applied.[47-49] In the large, multicenter clinical trials conducted by the British Medical Research Council (Table 3-1), the results from both uterine cervix and advanced head and neck tumors showed a significant benefit in local tumor control and subsequent survival.[48,50-53] The same findings were not observed in bladder cancer nor were they seen in a number of smaller studies.[53] In retrospect, the use of hyperbaric oxygen was stopped somewhat prematurely. This was partly the result of the introduction of hypoxic radiosensitizers and partly because of problems with patients' compliance; it has been claimed that hyperbaric treatment caused significant suffering, but the discomfort associated with such a treatment must be considered minor compared to the often life-threatening complications associated with chemotherapy, which is used with less restrictive indications.

The use of high-oxygen-content gas breathing under normobaric conditions to radiosensitize human tumors has also been tried clinically, but it failed to show any dramatic improvement.[54-56] In the most recent study this may have been the result of size limitation,[56] but in previous studies it may have been caused by the failure to achieve the optimum preirradiation gas breathing time.[54,55] Experimental studies have shown that the amount of time is critical for the enhancement of radiation damage and that it can vary from tumor to tumor.[43-45,57]

Hypoxic Cell Radiosensitizers

An alternative approach to the hypoxia problem is the use of chemical agents that mimic oxygen and preferentially sensitize the resistant population to radiation. The advantage of these drugs over oxygen is that they are not rapidly metabolized by the tumor cells through which they diffuse and thus

the drugs can penetrate further than oxygen and so reach all the tumor cells. In the early 1960s, researchers found that the efficiency of radiosensitization was directly related to electron-affinity[58] and that ultimately led to in vitro studies demonstrating preferential radiosensitization of hypoxic cells by highly electron-affinic nitroaromatic compounds.[59,60] Several of these compounds were later shown to be effective at enhancing radiation damage in tumors in vivo,[61] and as a result, they underwent clinical testing.

The drugs reaching clinical evaluation include metronidazole, misonidazole, benznidazole, desmethylmisonidazole, etanidazole, pimonidazole, nimorazole, ornidazole, sanazole, and doranidazole. Initial clinical studies were with metronidazole in brain tumors and were followed, in the latter part of the 1970s, by a boom in clinical trials exploring the potential of misonidazole as a radiosensitizer.[53,61,62] The results from the multicenter randomized trials are summarized in Table 3-2. Most of the trials with misonidazole were unable to generate any significant improvement in radiation response, although a benefit was seen in some trials, especially the second Danish Head and Neck Cancer study (DAHANCA 2), which found a highly significant improvement in the stratification subgroup of pharynx tumors but not in the prognostically better glottic carcinomas.[63] The overall impression of the "misonidazole-era" was a prolongation of the inconclusive experience from the hyperbaric oxygen trials, namely, that the problems related to hypoxia had not been ruled out indefinately.[61] Therefore, the search for more efficient or less toxic hypoxic sensitizers continues. Furthermore, the experience from the misonidazole trials has been taken into account to select a more homogeneous tumor population in which hypoxia is more likely to be present.

Results from subsequent randomized trials with other nitroaromatic compounds have been conflicting. The European pimonidazole trial in uterine cervix was disappointing,[64] whereas the two other multicenter trials in head and neck cancer, using etanidazole, showed no benefit.[61,65] On the other hand, studies with the low toxic drug nimorazole given to patients with supraglottic and pharynx carcinomas (DAHANCA 5) showed a highly significant benefit in terms of improved locoregional tumor control and disease-free survival rates (Figure 3-4),[66] thereby confirming the result of the DAHANCA 2 study. More recent trials with the 3-nitrotriazole compound, sanazole (AK-2123), in uterine cervical cancer[67] and doranidazole in pancreatic cancer[68] demonstrated significant improvements in both local tumor control and overall survival.

The potential benefit of using hypoxic radiosensitizers to improve radiotherapy is probably best illustrated from a recent meta-analysis of randomized clinical studies in squamous cell carcinoma of the head and neck.[69] These results are summarized in Figure 3-5 and clearly showed that radiosensitizer modification of tumor hypoxia significantly improved locoregional tumor control and overall survival with odds ratios of 0.71 and 0.87, respectively. Although the overall observed gain were small (5% to 10% for local control and 0% to 6% for survival) they are actually relevant. We can conclude that the nonsignificant outcome of most clinical trials (see Table 3-2) is not the result of a biological lack of importance of hypoxia, but in most cases is considered a consequence of poor clinical trials methodology with an overly optimistic study design and an expected treatment gain that goes far beyond what is reasonable. Overall, the results with nitroimidazoles add to the general consensus that if a nontoxic hypoxic modification can be applied, then such treatments may certainly be relevant as a baseline therapy together with radiotherapy for cancers such as advanced head and neck cancer.

Figure 3-5 Meta-analysis of hypoxic modification of radiotherapy in squamous cell carcinomas of the head and neck. Results show summary data from 32 randomized trials (including 4805 patients). Patients received radiation alone or radiation with a hypoxic modifier that included high-oxygen-content gas breathing under normobaric or hyperbaric conditions, or a hypoxic radiosensitizer.
Adapted from Overgaard J: Hypoxic modification of radiotherapy in squamous cell carcinoma of the head and neck—a systemic review and meta-analysis. Radiother Oncol 100:22–32, 2011.

Such a strategy has been adopted in Denmark where nimorazole has become part of the standard radiotherapy treatment in cancer of the head and neck.

Dose Modification Based on Hemoglobin

One of the major factors influencing the delivery of oxygen to tumors is the concentration of hemoglobin. It is, therefore, not surprising that low hemoglobin concentration in general has a negative impact on tumor radiation response. In a review of 51 studies involving 17,272 patients the prognostic relationship between hemoglobin concentration and local tumor control were analyzed, and of these, 39 studies (14,482 patients) showed a correlation, whereas only 12 (2790 patients) did not.[70] However, the relationship between hemoglobin concentration and tumor oxygenation status is not clear because a large (397 patients) international multicenter study in head and neck cancer failed to show a correlation between these parameters.[40]

Although a well-documented causal relationship between hemoglobin concentration, tumor oxygenation, and response to radiotherapy has not been shown, it is likely that such a relationship does exist and there is thus a rationale for investigating the possibility of improving the outcome of radiotherapy in relevant tumor sites in patients with low hemoglobin concentration given curative radiotherapy. This was investigated in two randomized trials using transfusion to raise the hemoglobin levels.[66,71] Despite an initial positive report from the Canadian trial in uterine cervix carcinoma, both studies concluded that the use of such transfusions did not significantly improve treatment outcome. In the DAHANCA 5 study, transfusion was given several days before radiotherapy and

adaptation may have occurred. Based on preclinical data it was hypothesized that any increase in tumor hypoxic fraction induced by anemia will be only transient, with tumors adapting to the lowered oxygen delivery[72]; transfusing anemic animals decreased tumor hypoxia, but this effect also was only transient and the tumors were able to adapt to the increased oxygen level. This suggests that when correcting for anemia it may not necessarily be the final hemoglobin concentration by itself that is important. Rather, an increasing hemoglobin concentration occurring at the time when the tumors are regressing during radiotherapy may be more likely to result in an increased oxygen supply to tumors and a subsequent improvement in response to radiotherapy.

Increasing the hemoglobin concentration by stimulation with erythropoietin (EPO), a hormone normally secreted from the kidney in response to tissue hypoxia and low serum levels, has also been investigated. Several preclinical studies have shown that the induction of anemia in animals could be corrected by serial injection with EPO and that this EPO treatment also overcame the anemia-induced radiation resistance.[73,74] The concept of using EPO to correct for anemia has also been tested in several clinical trials. However, although low hemoglobin can be effectively and safely improved by EPO,[75,76] patients treated with radiation and EPO had a poorer outcome than the control arms not treated with EPO.[77] Although this clearly raises concerns about the use of such agents to improve radiation therapy through a manipulation of hemoglobin levels, it does not make the concept of having a high hemoglobin concentration during radiation therapy an irrelevant issue.

Other "hemoglobin-related" methods for improving tumor oxygenation have been investigated.[78] These include the use of artificial blood substances, such as perfluorocarbons,[79] which are small particles capable of carrying more oxygen than hemoglobin, or by manipulating the oxygen unloading capacity of blood by modifying the oxy-hemoglobin dissociation curve. This can be achieved either by increasing the red blood cell 2,3-DPG content,[80] 2,3-DPG being one of the most important allosteric factors controlling the hemoglobin-oxygen dissociation curve, or using antilipidemic drugs.[81] Although each of these approaches has been shown to improve the oxygenation status of experimental tumors or enhance radiation damage, none of them have yet reached controlled clinical testing; thus, their potential usefulness in the clinic is uncertain.

Changing Oxygen Consumption

A novel approach that is currently receiving attention focuses on reducing tumor hypoxia by decreasing the oxygen consumption of cells close to blood vessels and thereby increasing the oxygen diffusion distance, which makes more oxygen available to the hypoxic cells. This may be achieved using the drug metformin, which has undergone extensive clinical evaluation for the treatment of diabetes and has been linked to decreased rates of certain types of cancer.[82] One preclinical study has clearly shown that high doses of metformin can decrease cellular oxygen consumption in vitro.[83] Additional in vivo data from that study demonstrated that metformin could improve tumor radiation response, but whether or not this was the direct result of reduced oxygen consumption is not entirely known. Further studies in this area are clearly warranted.

Dealing with the Problem of Fluctuating (Acute) Hypoxia

Although several of the procedures used to combat radiation resistance caused by hypoxic cells have met with some success, the results are far from satisfactory. A possible explanation is that most of the procedures used clinically seem to operate primarily against diffusion-limited chronic hypoxia and have little or no influence on fluctuating hypoxia, which is caused by transient variations in tumor blood flow.[9]

Experimental studies have clearly demonstrated that the vitamin B3 analog, nicotinamide, can enhance radiation damage in a variety of murine tumor models using both single and fractionated treatments (Figure 3-6).[9] The enhancement of radiation damage appears to depend on the tumor type, drug dose, and time of irradiation after drug administration.[9] The drug can also enhance radiation damage in certain normal tissues, but generally the effects are less pronounced than those seen in tumors.[9] Nicotinamide seems to primarily prevent or reduce the transient fluctuations in tumor blood flow that normally lead to the development of acute hypoxia.[9] This finding led to the suggestion that the optimal approach would be to combine nicotinamide with treatments that specifically overcome chronic hypoxia. This was subsequently demonstrated with hyperthermia,[84] perfluorochemical emulsions,[85] and carbogen breathing.[57,86-88] Combining nicotinamide with carbogen has undergone testing in a number of European clinical studies, and the results in head and neck[89] and bladder cancer[90] demonstrated an improved response to radiation therapy.

Bioreductive Drugs

The early preclinical studies with electron-affinic radiosensitizers showed that these agents, which were relatively nontoxic to cells under normal oxygenated conditions, were reduced to a more toxic form under hypoxia.[91] This led to the development of various bioreductive drugs that preferentially killed the radiation-resistant hypoxic tumor cell population. Basically, these drugs can be divided into three major groups, as illustrated in Figure 3-7. They are the quinones, nitroaromatics, and N-oxides.[92]

The quinine derivative, Mitomycin-C (MMC), is probably the prototype bioreductive drug.[93] It has been used clinically for many years as a chemo-radiosensitizer, long before it was realized it had preferential effects against hypoxic cells. It is activated by bioreduction to form products that crosslink DNA and therefore produce cell killing. Several randomized clinical trials in patients with squamous cell carcinoma of the head and neck were undertaken, specifically using MMC to counteract the effects of hypoxia, but not all showed a benefit.[94-98] This may not be surprising when one considers that MMC actually has a small differential killing effect between aerobic and hypoxic cells (see Figure 3-7) and was only administered once or twice during the entire course of radiotherapy. Attempts to find more efficient quinones have been undertaken and to that end porfiromycin, RH1, and EO9 were developed.[92] Of these EO9 is currently being evaluated in a phase II trial in bladder cancer.

The finding that misonidazole was preferentially toxic toward hypoxic cells led to numerous efforts to find other nitroimidazoles that were better. The first drug developed was RSU-1069 (see Figure 3-7). This compound has the classic 2-nitroimidazole radiosensitizing properties, but also an aziridine ring at the terminal end of the chain, which gave the molecule substantial potency as a hypoxic cell cytotoxin, both in vitro and in vivo.[99] In large-animal studies it was found to cause gastrointestinal toxicity and a less toxic prodrug was therefore developed (RB-6145), which is reduced in vivo to RSU-1069. Although this drug was found to have potent antitumor activity in experimental systems, further animal studies revealed that this drug induced blindness; this is perhaps not surprising when one realizes that the retina is hypoxic, thus further development of this drug was halted. However, other

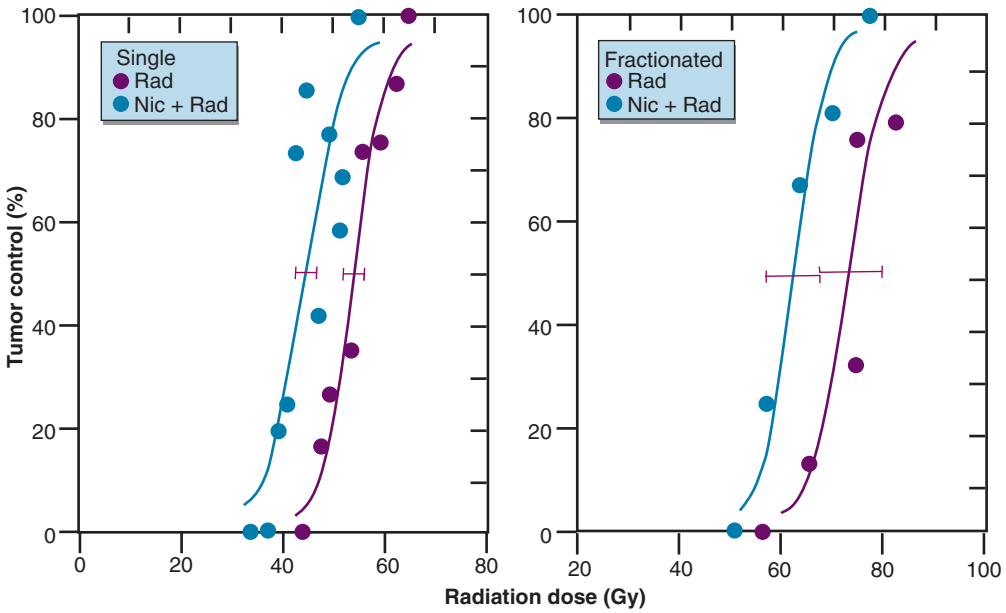

Figure 3-6 Effect of nicotinamide (500-1000 mg/kg) on local tumor control measured as a function of the total radiation dose given either as a single treatment to C3H mammary carcinomas or in fractionated schedule to the carcinoma NT. The drug was i.p. injected 30-60 minutes before irradiation. *Modified from Horsman MR, Chaplin DJ, Overgaard J: Combination of nicotinamide and hyperthermia to eliminate radioresistant chronically and acutely hypoxic tumor cells. Figure 3-7 Survival of mammalian cells exposed to mitomycin C, RSU 1069, or tirapazamine under aerobic *(red symbols)* of hypoxic *(blue symbols)* conditions.
Adapted from Stratford IJ, Stephens MA: The differential hypoxic cytotoxicity of bioreductive agents determined in vitro by the MTT assay. Int J Radiat Oncol Biol Phys 16:973–976, 1989, and Hall EJ: Radiobiology for the radiobiologist. ed 4. Philadelphia, 1994, JB Lippincott.

nitro-containing compounds have been developed, including NLCQ-1, CB 1954, SN 23862, PR-104, and TH-302,[92] of which the latter is currently under Phase II/III clinical evaluation albeit in combination with chemotherapy.

Perhaps the most promising group of bioreductives is the organic nitroxides, of which the benzotriazene di-N-oxide, tirapazamine, is the lead compound (see Figure 3-7). The parent moiety shows limited toxicity toward aerobic cells, but after reduction under hypoxic conditions, a product is formed that has been shown to be highly toxic and can substantially enhance radiation damage to tumors in vivo.[100] Most clinical studies have involved combining tirapazamine with chemotherapy, although there have been a few trials with radiation with or without chemotherapy.[92] The results from the phase II trials generally showed promise, but in the few randomized trials that have been completed the results were somewhat disappointing. However, it has now been suggested that the benefit of tirapazamine might be achieved if one could select patients who had hypoxic tumors before treatment. Other N-oxides currently under development include chlorambucil N-oxide, SN30000, and AQ4N (Banoxantrone), the latter being combined with radiation in a number of clinical trials.[92]

VASCULAR TARGETING AGENTS

Angiogenesis Inhibitors

The tumor's vascular supply plays a critical role in determining the tumor's microenvironmental factors that influence radiotherapy.[101] This vasculature develops from the normal tissue vessels via the process of angiogenesis,[102] which is a highly complex process triggered by the release of specific growth factors from the tumor cells.[103] These growth factors initiate a series of physical steps, including local degradation of the basement membrane surrounding capillaries, invasion of surrounding stroma by the endothelial cells in the direction of the angiogenic stimulus, proliferation of the endothelial cells, and, finally organization of the endothelial cells into three-dimensional structures that connect with other similar structures to form the new blood vessel network.[103] The importance of this process makes it an attractive target for therapy and numerous approaches for inhibiting the various steps in the angiogenic process have been tested in preclinical models.[104,105] Many of these therapies have now moved into clinical evaluation[106] and, of these, the antivascular endothelial growth factor (anti-VEGF) antibody bevacizumab (Avastin) has been shown to improve outcome in a number of chemotherapy-based trials.[107] Preclinical studies using rodent and human tumor xenografts show that certain angiogenesis inhibitors can be effectively combined with radiation to improve tumor response (Table 3-3),[105] and as a result, a limited number of clinical studies have been initiated combining certain angiogenesis inhibitors with radiation therapy.[106]

The consensus opinion is that the improvement in radiation response found in preclinical studies is the consequence of normalization of the tumor vasculature, resulting in a decrease in tumor hypoxia.[108] Although there are certainly preclinical studies showing an improved tumor oxygenation status with such treatment, there are just as many studies showing no change and even a decrease in tumor oxygenation.[105] These findings not only make it unclear as to the role of vessel normalization in influencing the combination of angiogenesis inhibitors with radiation, but they also indicate that timing and sequencing of the two modalities may be critical for an optimal benefit.

Vascular Disrupting Agents

An alternative approach for targeting tumor vasculature involves using agents that can damage the already established tumor vessels.[104,105] This is not a new concept; it was first demonstrated with the tubulin binding agent colchicine back in the 1940s.[109] Since then a number of vascular disrupting agents (VDAs) have been proved capable of preferentially damaging tumor vessels, leading to a reduction in tumor perfusion which results in an increase in tumor ischemia and necrosis, subsequently producing an inhibitory effect on tumor growth.[105] The VDAs include physical treatments (e.g., hyperthermia, photodynamic therapy, and even radiation), chemotherapeutic agents (e.g., tumor necrosis factor, vinca alkaloids, and arsenic trioxides), and small molecule agents (e.g., flavonoid derivatives such as 5,6-dimethylxanthenone-4-acetic acid; tubulin binding drugs such as Combretastatin A-4 phosphate).

As with the angiogenesis inhibitors, several of the VDAs have been combined with radiation (see Table 3-3), and significant improvements in response have been seen in preclinical models.[105] This is illustrated in Figure 3-8 using a C3H mammary carcinoma grown in CDF1 mice. The radiation dose needed to control 50% of treated animals (±95% confidence intervals) following single dose radiation treatment alone was found to be 53 Gy (51-56). This was significantly reduced (Chi-squared test; $p < 0.05$) to 46 Gy (42-49) when tumors were locally irradiated, but 30 minutes later mice were given a single intraperitoneal injection of a large but nontoxic dose of Combretastatin A-4 phosphate (CA4P), the lead VDA in clinical evaluation.[105,107] On its own, in this tumor model, such a drug dose will only slow the growth of the tumors by about 2 days. The enhancement of tumor radiation damage is known to be time and schedule dependent, with the greatest effect seen when the drug is given within a few hours after irradiating.[105] It is also tumor specific with no enhancement of radiation response seen in normal tissues. This has been shown for CA4P in acutely responding normal skin (see Figure 3-8) or late-responding bladder and lung.[105] These differences between the tumor and normal tissue results are entirely consistent with the drugs' ability to induce damage in tumor vessels but not vessels in normal tissue.[105]

RADIATION PROTECTORS

Sulfhydryl-Containing Compounds

More than 50 years ago it was realized that certain amino acids, glutathione, and ascorbic acid were able to modulate radiation induced inactivation of biological material. Based on those observations Patt et al investigated the effect of treating mice with the thiol-containing amino acid, cysteine.[110] They found that administering this compound to mice before whole-body irradiation resulted in a remarkable increase in animal survival (Figure 3-9). In contrast no effect was observed when cysteine was given after irradiation. During the Cold War, this finding led to a large research program at the Walter Reed Army Institute of Research aimed at developing a drug that could protect soldiers from nuclear weapons.[111] Numerous sulfhydryl-containing substances with substantial radioprotective properties were detected, but only WR-2771 (amifostine) was found to exhibit acceptable toxicity. The idea of using amifostine in oncology arose when preclinical studies, performed mainly in the 1970s and 1980s, suggested a selective protection of normal tissue from damage induced not only by irradiation but also from chemotherapy.[112,113] Despite these findings, the interest in amifostine over the years has waxed and waned, although this interest was boosted by commercialization of the drug, US Federal Drug Administration (FDA) approval, and the

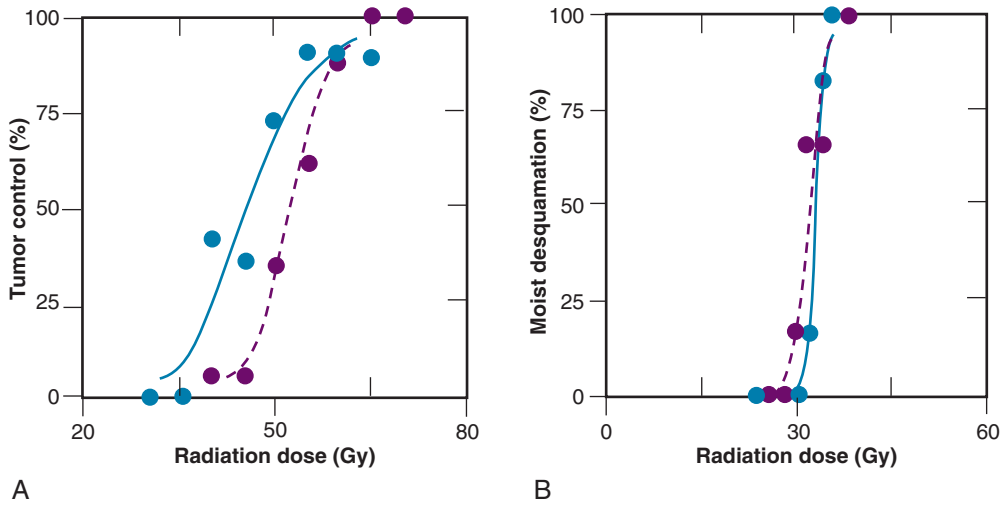

Figure 3-8 Effect of Combretastatin A-4 disodium phosphate (250 mg/kg) on either local control of a C3H mammary carcinoma **(A)** or the development of moist desquamation in the foot skin of CDF1 mice **(B)** following radiation treatment. Radiation was either given alone *(red symbols)* or 30 minutes before intraperitoneal injection of the drug *(blue symbols)*.

establishment of authoritative guidelines.[114] The lack of interest was probably related to the fact that there is no fail-safe modification of traditional radiotherapy.[115] Many normal tissues are dose limiting; therefore, evaluating the therapeutic benefit of a radioprotector requires either that the protector have absolute normal tissue selectivity (and thus fewer complications with an unchanged rate of tumor control for a given radiation dose) or, if selectivity is uncertain, that an increase in radiation dose may be needed to maintain the same rate of tumor control. However, this scenario requires that the protective effect on tumor tissues is predictable and exceeded by the protection offered to all relevant normal tissues. In addition, the "perfect" radioprotector must have an acceptable toxicity profile and must be easy to handle if generalized clinical use is to be expected with routine fractionated radiotherapy.[116-118]

It is not entirely clear how amifostine induces radioprotection. The drug must first undergo dephosphorylation to its active metabolite WR-1065, which is further metabolized to the disulfide WR-33278; the latter metabolite may also afford some protection, although to a lesser extent.[119] Several mechanisms are involved in radioprotection, depending on the quality of the radiation. Protection against sparsely ionizing radiation, such as x-rays, is mainly obtained by scavenging of free radicals[120,121]; such scavenging has also been observed with glutathione, superoxide dismutase and its mimetics, and isoflavones like genistein. Because WR-1065 and WR-33278 react with free radicals in competition with oxygen, the protection obtained by scavenging is highly influenced by oxygen tension (Figure 3-10). Here the protection is maximal at intermediate levels of oxygen (20% to 50% oxygen in the inspired air). At higher oxygen tensions, WR-1065 is counterbalanced by excess oxygen and the protection is gradually lost. The degree of protection is also diminished at low-oxygen tensions where scavenging of free radicals is no longer important because the lack of oxygen by itself provides radioprotection. Additional and complex mechanisms are undoubtedly involved. Some of these may involve hypoxia created locally by direct interaction of thiols with oxygen, chemical repair by thiol-donation of hydrogen, or decreased accessibility of radiolytic attack sites by induction of DNA packaging.[116]

Preclinical studies have shown that many tissues can be protected from radiation damage by amifostine (Table 3-4). However, the protection observed in different normal tissues is unfortunately heterogeneous. Some normal tissues—such as central nervous system, which often is dose limiting in radiotherapy—are not protected because amifostine probably does not cross the blood-brain barrier.[122] In other normal tissues such as salivary glands and hematopoietic system, amifostine affords significant radioprotection. These variations are probably explained by tissue variations in oxygen concentration, dephosphorylation activity, and distribution of amifostine and its metabolites.[119,121,123] To make things even more complicated, tumor protection has been impossible to rule out by preclinical experiments.[115] In addition, large single doses of irradiation have often been used, and relevant

comparison with tumor effects have been absent or difficult to translate into a clinical meaningful context.[116]

On the clinical side there have been far too many publications of phase I-II studies with limited number of patients and a few underpowered randomized studies. In addition, chemotherapy has often been applied together with radiotherapy, making it difficult to evaluate the results (Table 3-5). Despite the long list of preclinical normal tissues studies with a proven effect of amifostine, disappointingly few have been confirmed in the clinical setting. Amelioration of acute radiation toxicity has been observed in studies which often employed various types of treatment intensification like concomitant chemotherapy or accelerated radiotherapy. However, definite confirmation regarding late morbidity such as fibrosis has not been obtained. A pivotal trial by Brizel et al[128] showed that amifostine significantly protected against radiation-induced xerostomia with no apparent loss of tumor control in head and neck cancers. That was followed by amifostine being approved by the US Federal Drug Administration for use in patients undergoing postoperative fractionated radiotherapy in the head and neck region to decrease the incidence of acute and chronic xerostomia. In light of the paucity of relevant clinical data this recommendation seems premature. A later large meta-analysis of published data concluded that amifostine could significantly reduce acute and late side effects associated with radiation therapy.[129] However, that review has since been criticized

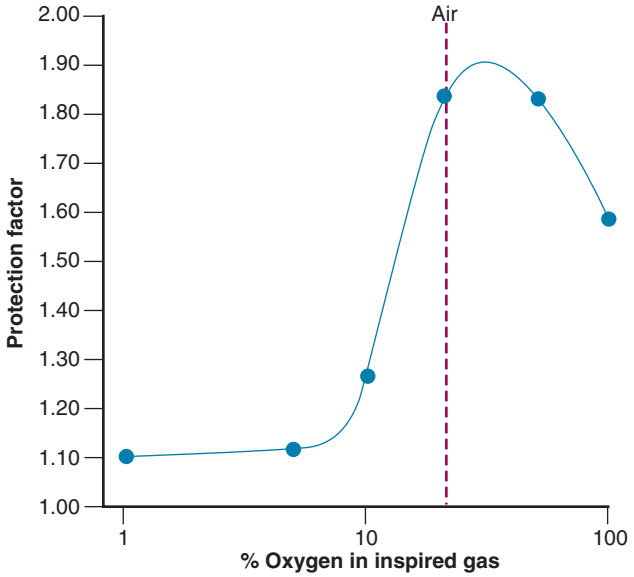

Figure 3-10 The variation in normal skin protection in mice given 400 mg/kg WR-2721 30 to 45 minutes before irradiation in mice that breathed various oxygen concentrations.

for publication and classification bias and the quality of the trials included.[130] A more comprehensive meta-analysis found that amifostine did not change radiation-induced overall or progression free survival,[130] thus further studies are needed to explore the potential benefits of amifostine.

Modifiers of the Oxygen Supply

Because hypoxia reduces radiation sensitivity, decreasing the availability of oxygen to tissues may be way to achieve radiation protection. One way to accomplish this might be to modify hemoglobin-oxygen affinity. The most widely studied agents in this context are the substituted benzaldehyde, BW12C, and derivatives.[149,150] These agents preferentially bind to oxy-hemoglobin and so increase the affinity of the hemoglobin for oxygen.[151,152] Consequently this decreases the amount of oxygen available to the tissues. Although this radioprotects some normal tissues,[149,153] there is evidence that in certain normal tissues BW12C can actually increase perfusion,[154] which should increase oxygen delivery. Additionally, experimental studies have also shown that BW12C will significantly radioprotect tumors.[149,150]

Carbon monoxide reduces oxygen transport to tissues by binding to hemoglobin, thereby decreasing the amount available for oxygen transport, as well as causing a left shift of the hemoglobin-oxygen dissociation curve. Therefore, any oxygen that binds to the hemoglobin does so more strongly.[155] This approach to increase hypoxia and reduce radiation response has been well documented in experimental systems.[156,157] Unfortunately, this effect was demonstrated in tumors and not normal tissues. The effect of carbon monoxide in patients has also been observed, as shown in Figure 3-11, which illustrates that patients with head and neck carcinomas who were smokers (and therefore had higher carboxyhemoglobin levels) had a poorer response to radiation therapy than nonsmokers.

Because most modifiers of the oxygen supply already discussed also provide radioprotection for tumors as well as normal tissues, their use in this context must be considered limited. However, this may not be true for pentoxifylline. This is a drug that alters red blood cell deformability and inhibits platelet aggregation and fibrinolytic activity.[158] As a result, red blood cells are better able to transverse narrowed arterioles and capillaries. When given before irradiation, pentoxifylline enhances radiation damage in tumors,[159] presumably because of an improvement in oxygen delivery,[160,161] but it has no effect on the response of normal tissues.[159] However, when administered on a daily basis after irradiation, pentoxifylline had no effect on early skin reactions in mice but did significantly reduce the incidence of late reactions.[162]

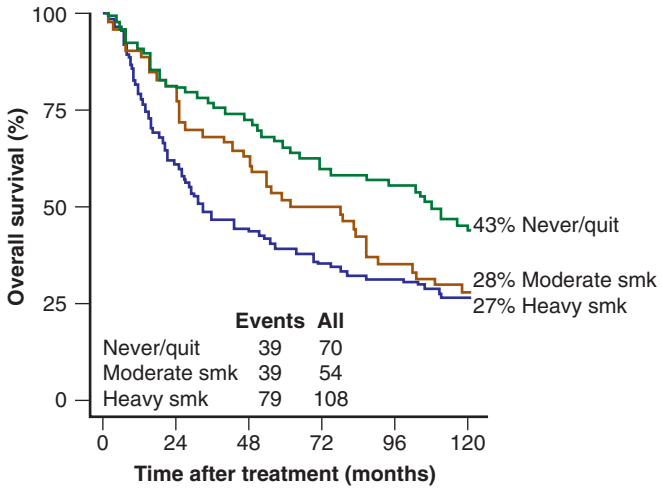

Figure 3-11 Influence of smoking (smk) during treatment on the outcome of radiotherapy in 232 patients with advanced head and neck carcinoma. Results show 10-year survival when comparing nonsmokers and quitters to moderate or heavy smokers (>20 cigarettes or one pack per day).

Other Radioprotectors

Various other agents have been reported to be capable of radioprotecting certain normal tissues.[163-165] These include cytokines, such as granulocyte-macrophage colony-stimulating factor, interleukin-1, tumor necrosis factor-α (TNF-α), transforming growth factor-β (TGF-β), and basic fibroblast growth factor.[166-170] Another interesting group of agents inhibit the process of apoptosis. Many tumors have acquired mutations that prevent them from undergoing radiation-induced apoptosis. Proliferating normal cells, however, are often killed by radiation-induced apoptosis, and several apoptosis inhibitors have shown radioprotective potentials in animal models. These include p53 inhibitors (pifithrin-α and pifithrin-μ), growth factors [KGF-1 (palifermin), KGF-2 (repifermin), FGF-20 (velafermin)], activators of NRF2 (triterpenoids), and inhibitors of NF-κB (CBLB502).[163-165] Another recent approach, designed to take advantage of a typically acquired defect in tumor cells, is to induce a G1 cell cycle arrest in normal cells, thereby temporarily arresting them in the relatively radioresistant G1 phase allowing for improved DNA repair (e.g., PD0332991 and 2BrIC).[163-165] Agents are also being developed that target molecular pathways involved in radiation-induced effects, including the TGF-β1/Smad, CTGF/RHO/ROCK, TNF-α, and PDGF/PDGFR pathways.[163-165] Finally, there is a group of miscellaneous inhibitors that include the angiotensin-converting enzyme inhibitor captopril, corticosteroids, prostaglandins, and essential fatty acids.[171-175] However, the mechanisms of action are not entirely clear, nor is there evidence that these agents do not also radioprotect tumors.

SUMMARY

The use of radiation to treat certain types of cancer with curative intent is a well-established and effective therapy, but there is still room for improvement. The additional use of treatments that can either increase radiation damage in tumors without affecting normal tissues, or protect normal tissues without having a similar protective effect in tumors, is clearly warranted. Because the vasculature and microenvironment of tumors differs from those of normal tissues, targeting these parameters should lead to tumor specificity. Many preclinical studies have demonstrated this to be a viable approach. But despite numerous clinical studies confirming the potential of such methods to significantly improve outcome to radiation therapy only one agent has become established in standard radiation therapy protocols. That agent is the radiosensitizer nimorazole, which is only used in Denmark and only in head and neck cancers. The use of radioprotectors is more controversial. Experimentally, several agents have been shown to radioprotect certain normal tissues, but data also demonstrate that some of these agents induce radiation protection in tumors. Results from clinical studies investigating the potential of radioprotectors have also been inconclusive, and until good human data demonstrating radioprotection of normal tissues, but not tumors, become available the use of radioprotectors must be considered experimental.

CHAPTER

4 Interaction of Chemotherapy and Radiation

Christopher Douglas Willey, Eddy Shih-Hsin Yang, and James A. Bonner

Oncology has increasingly become a multidisciplinary field of medicine: (1) Surgery remains the definitive local treatment modality; (2) Chemotherapy remains the definitive systemic treatment modality; and (3) Radiation therapy is the definitive loco-regional treatment modality. Although, historically, these approaches have predominantly been used exclusively of one another, the past 25 years have seen an explosion of both preclinical and clinical efforts that have sought to combine these therapies for improved outcomes, including improved local and regional control, overall survival, cosmesis, and organ preservation. We have learned a great deal about the interactions between chemotherapy and radiation from clinical trials that have combined these treatment modalities in sequential and concomitant regimens. In addition, laboratory investigations have demonstrated key molecular targets and pathways that can potentially be exploited for improved outcome. Indeed, the combination of chemotherapy and radiation has changed the management approach in several disease sites, which are broadly reviewed here.

HISTORICAL PERSPECTIVE

Radiosensitization and chemosensitization are complex concepts that have many different interpretations and have been used to describe many different interactions.[1,2] The use of radiation and chemotherapy for mutual or even simultaneous sensitization adds to the intricacies of these interactions. Indeed, more than 100 years ago, radiation treatment and benzene systemic therapy were combined for leukemia treatment.[3] However, probably the best historical model of chemotherapy and radiation therapy interaction is that of 5-fluorouracil.

5-Fluorouracil

In the 1950s, the halogenated pyrimidine, 5-fluorouracil (5-FU), was combined with external beam irradiation (EBRT) after this class of drug was determined to have anticancer properties.[4] In the last 50 years, 5-FU has been successfully combined with radiation to treat a variety of gastrointestinal cancers, as well as cervical cancer and head and neck cancers.[5] The route of administration and scheduling of 5-FU has been manipulated many times in an attempt to reduce toxicity and maximize tumor control. What began as bolus delivery at the beginning and end of a fractionated radiation treatment course ("Moertel" regimen) has progressed to protracted venous infusion (PVI) and now to twice daily oral 5-FU analog formulations. These approaches have allowed for an increase in cumulative dose of the drug, decreased chemotherapy toxicity, and improved radiosensitization. Indeed, 5-FU has proven to be a staple drug in the armamentarium of medical oncologists and a key radiosensitizer for the radiation oncologist.

RATIONALE

Limitations in Current Therapeutic Approach

Over the past several decades, we have seen the great technological advances in surgery and radiation while novel systemic agents are being developed at a never-before-seen pace. Nevertheless, cancer morbidity and mortality remain major problems. The advent of combined modality therapy has sought to improve on the limitations that surgery, chemotherapy, and radiation carry independently. For several decades, radiation has complemented surgery by improving loco-regional control. Unfortunately, tumor-specific and patient-specific factors limit both surgical and radiation success. In this chapter, we will focus on the multiple ways that systemic therapies are used in an attempt to overcome the shortcomings of radiation treatment. The presence of micrometastatic disease, disease outside of our treatment fields, and the inability to deliver adequate dose to the target region as a result of normal tissue toxicity risk are some of the most frequently cited reasons. In addition, tumors may contain regions of relative hypoxia or subpopulations of cells with intrinsic or acquired resistance to radiation damage. We will briefly review the current understanding of these topics.

Tumor Detection

If ionizing radiation were without normal tissue toxicity, tumor detection would be immaterial, and radiotherapy could be delivered to the entire body much like chemotherapy. Obviously this is not the case, and much like surgeons, we must be able to identify the tumor so that we can precisely and accurately target it with our radiation akin to "carving out" a tumor with a scalpel. Fortunately, advances in radiology have dramatically improved our ability to detect tumor location and extent. Whereas computed tomography (CT) and magnetic resonance imaging (MRI) provide excellent anatomic information, when combined with biological or functional imaging such as positron emission tomography (PET) and single photon emission computed tomography (SPECT), the radiation oncologist can more confidently define tumor vs. nontumor. Emerging MRI sequences including dynamic contrast enhanced and fast imaging employing steady-state acquisition (FIESTA) ultrafast pulse sequence approaches, and MR spectroscopy are providing improved anatomic (and biologic in the case of MR spectroscopy) imaging for surgeons and radiation oncologists. Nevertheless, the resolution of our current techniques (on the order of 5 mm for PET resolution[6]) and high false-negative rates with small tumors still limit our ability to identify microscopic tumor extent and micrometastatic disease. Future technologies such as PET/MRI as well as novel radiopharmaceuticals may provide improvements.

Inherent and Acquired Resistance

We know, empirically, that certain tumors have inherent radiation resistance pathways that manifest with high rates of local failure following radiation. In some cases, such as in pancreatic cancer, it is difficult to deliver adequate doses of radiation to the target because of the limitations in dose tolerance of surrounding bowel, kidney, and liver. However, there are other tumors with extremely high local failures despite dose escalation. A prime example is glioblastoma multiforme, which has local recurrence rates approaching 100%. Biological factors within the tumor or tumor microenvironment also generate resistance. Figure 4-1 summarizes some of the major

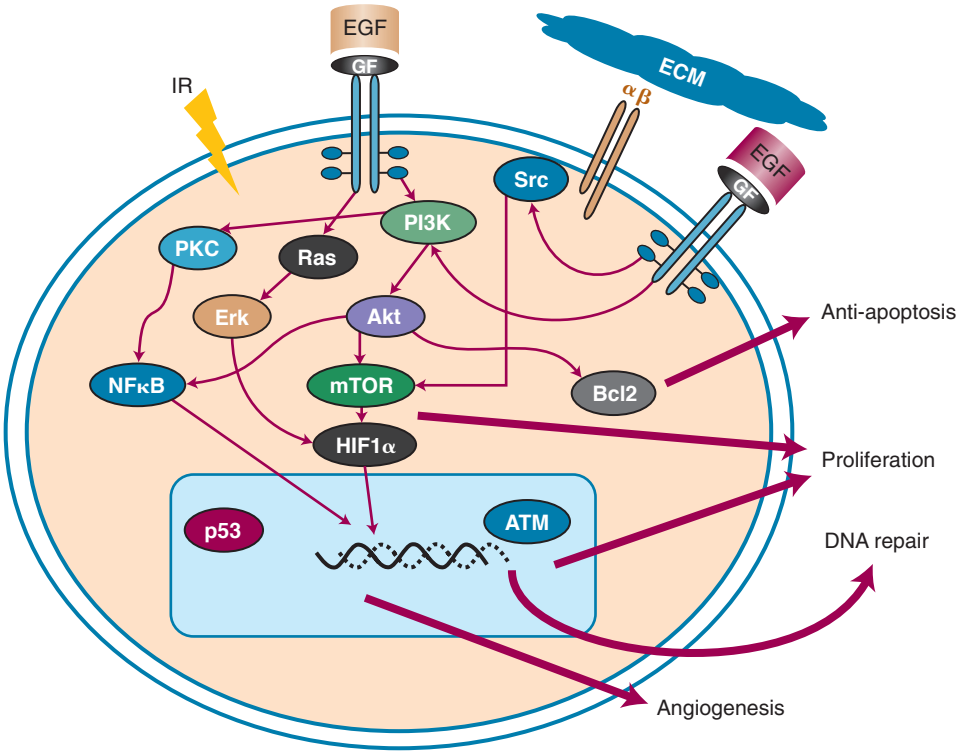

Figure 4-1 Schematic of radiation-induced signal transduction cascades indicating pathways leading to antiapoptosis, proliferation, DNA repair, and angiogenesis.

resistance pathways within tumors. Later in this chapter we will describe how chemotherapeutics can potentially mitigate these resistance pathways.

Increased Toxicity

In the original treatise by Steel and Peckham on combining chemotherapy and radiation,[7] it was assumed that each modality functioned independently in both beneficence and toxicity. However, it is abundantly clear that concurrent chemoradiation has increased toxicity suggesting some level of overlapping toxicity, chemosensitization by radiation, or radiosensitization by the chemotherapy. Because chemoradiation is often used when tumors have wide anatomic extension (thus, precluding surgery), the volume of normal tissue irradiated, and therefore, at risk of toxicity, is larger. In some cases, a patient has comorbid conditions that prevent aggressive therapy as well.

Therapeutic Index

The features described previously generate the need for a metric to determine efficacy relative to toxicity so that newer approaches can be compared. This metric, known as the *therapeutic index* (or therapeutic ratio) refers to the ratio of the probability of tumor control to the probability of normal tissue toxicity. Typically, the ratio is calculated based on the 50% control rate of tumor versus the 50% normal tissue toxicity. These sigmoidal-shaped curves determine the estimated efficacy versus toxicity of treatment. Figure 4-2 depicts an idealized form of these curves. Therapeutic index has been, and will continue to be, the "holy grail" of cancer therapy. For this reason, it is no surprise that it takes careful treatment planning to try to achieve maximal tumor cell kill while also sparing normal tissue in hopes of preserving function. There are a host of technological factors that impact this therapeutic ratio.

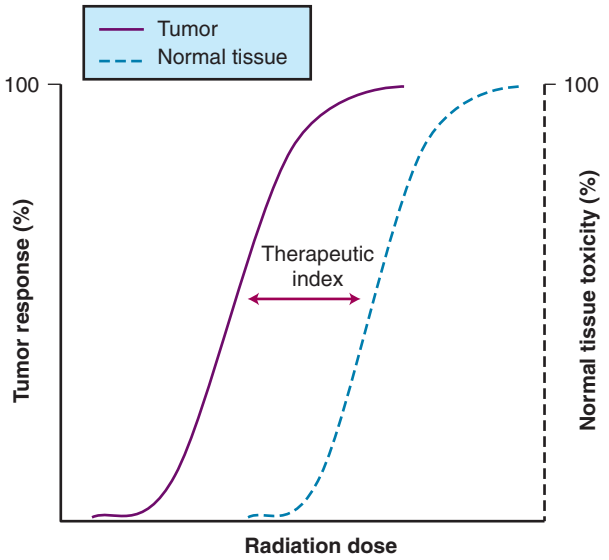

Figure 4-2 Graph of an idealized therapeutic index curve. The therapeutic index is indicated as the difference in probability of tumor response and probability of normal tissue toxicity. The greater the separation of these two curves, the greater the therapeutic index.

Certainly our ability to correctly identify tumor versus normal tissue will affect therapeutic ratio. The expanding use of PET, MRI, and SPECT imaging, as described previously, are allowing radiation oncologists to better differentiate target from nontarget. Obviously, the ability to precisely deliver radiation through techniques such as intensity modulated radiation therapy (IMRT), stereotactic procedures, and proton therapy allow us to avoid normal tissue while targeting tumor.

Moreover, our ability to accurately deliver radiation via image guidance (IGRT) has grown by leaps and bounds, which enables smaller margin expansions and will also limit dose to normal tissue. Nevertheless, based on the anatomical location of the tumor, there are technological limits to what can be accomplished with radiation in and of itself. Therefore, additional improvement will likely rely on the interaction of systemic agents with our technologically advanced radiation delivery methods.

Strategies to Improve Therapeutic Index

The fundamental approach to improving outcomes through combined modality therapy has its basis on the theoretical strategies set forth by Steel and Peckham in 1979.[7] Their seminal paper defined four potential means by which combined therapy could improve the therapeutic index and were described as (1) independent toxicity, (2) normal tissue protection, (3) spatial cooperation, and (4) enhanced tumor response. As will be discussed, the first theoretical concept may not actually function as in the original intent. However, the latter three concepts are relevant for modern strategies of combining drugs with radiation. Additional mechanistic considerations have been identified in recent years that expand on Steel and Peckham's "exploitable mechanisms in combined radiotherapy-chemotherapy" that was described more than three decades ago.[7] These newer concepts of biological cooperation and temporal modulation are impacting current investigative strategies for improving the therapeutic index.

Independent Toxicity

One of the main concepts suggested by Steel and Peckham as a means to improve the therapeutic index is to select a chemotherapeutic regimen with a distinct toxicity profile from that of radiation. This ideal selection of nonoverlapping toxicities could allow for increased tumor cell kill with minimal impact in terms of tissue toxicity. Although this has been pursued in therapy selection, the actual success in finding independent toxicity has been elusive. However, the inverse relationship has been implemented to a great extent. Indeed, the avoidance of drugs with overlapping toxicities is standard of care practice, for instance, avoiding methotrexate with cranial radiation, Adriamycin with breast irradiation, or bleomycin with lung irradiation.

Normal Tissue Protection

The identification of clinically relevant agents that promote normal tissue protection without protecting tumors has provided little in terms of therapeutics. Limited success has been achieved with the free radical scavenging agent, amifostine (WR-2721), which appears to be selectively taken up by normal tissue relative to tumor where it is converted into the active thiol metabolite, WR-1065.[8] Although amifostine has been shown to protect against xerostomia in head and neck cancers treatment (Table 4-1) and to limit renal toxicity from cisplatin, several clinical trials have failed to show an advantage to amifostine use. Undoubtedly, investigations into novel radioprotectors will continue with the potential to impact the therapeutic ratio.

Spatial Cooperation

The concept of spatial cooperation implies that chemotherapy and radiation therapy are independent players with systemic therapy acting systemically, that is, targeting micrometastatic disease, and radiation therapy acting loco-regionally. Because

TABLE 4-1 Possible Drug–Radiation Interactions

Mechanism	Example	Notes
Normal Tissue Protection	Amifostine in head and neck cancers	Reduces xerostomia rates from RT alone
Spatial Cooperation	Early stage breast cancer with adjuvant chemotherapy PCI in SCLC	RT provides locoregional control for breast cancer but no impact on DM SCLC chemotherapy does not effectively cross BBB → RT can effectively treat the brain
Biological Cooperation	Targeted therapies inhibit prosurvival/proliferation pathways within tumors	Kinase targeted agents including tyrosine kinase inhibitors such as dasatinib and sunitinib as well as monoclonal antibodies such as cetuximab and bevacizumab; mTOR inhibitors
Temporal Modulation	Drugs that impact tumor response in between fractions, namely targeting repair, repopulation, reoxygenation, and redistribution.	This is essentially a composite of several of the other mechanisms but requires concomitant delivery of the drug rather than sequential.
Increased DNA Damage	Drugs that incorporate into DNA	5-FU and platinum are classic examples
Inhibition of DNA Repair	DNA intercalators and nucleoside analogs can disrupt repair and enhance radiation cytotoxicity	Alkylators, antimetabolites, platinum, and topoisomerase inhibitors are a few examples
Cell Cycle Effects	Most chemotherapeutics are cell cycle specific (except alkylators) Cell cycle arrest in radiosensitive phases (microtubule targeting agents at M-phase) Elimination of radioresistant cells (S-phase)	Taxanes, epothilones, 5-FU, gemcitabine, and topoisomerase inhibitors are good examples
Targeting Repopulation	Conceivably any systemic agent that has at least cytostatic properties can prevent repopulation	Molecularly targeted agents as well as chemotherapeutics (particularly antimetabolites) can function this way
Hypoxia Targeting	Mitomycin C and tirapazamine selectively targeting hypoxic cells Tumor shrinkage by chemotherapy decreases interstitial pressure and improves oxygenation	Taxanes and other chemotherapies that can produce tumor shrinkage are indirect means (given as induction therapy) whereas mitomycin C and tirapazamine are directly affecting hypoxic cells.
Tumor Microenvironment Targeting	Antiangiogenesis promotes vascular renormalization	Bevacizumab in glioma

5-FU, *5-Fluorouracil;* BBB, *blood-brain barrier;* DM, *distant mets;* PCI, *prophylactic cranial irradiation;* RT, *radiation therapy;* SCLC, *small-cell lung carcinoma.*

these therapies function independently, it could be assumed that a full dose of each will be required to achieve the desired outcome. If the drug and radiation did function completely independently, then concurrent administration should be possible with nonoverlapping toxicities. It is unclear whether a completely independent action can actually be achieved with the chemotherapies that are currently used with radiation treatment, however, because in-field toxicities do occur suggesting some level of localized radiation sensitization. Therefore, sequential therapy is probably the best means to exploit spatial cooperation. Many clinical examples exist for this approach, such as breast cancer with adjuvant chemotherapy followed by radiation, consolidative radiation to bulky disease in lymphoma, or prophylactic cranial irradiation in small cell lung cancer (see Table 4-1).

Enhanced Tumor Response (Cytotoxic Enhancement)

Currently, a tremendous amount of investigative effort is focused on achieving cytotoxic enhancement with combined modality treatment. In other words, the combination of therapies leads to an interaction on some level that generates improved antitumor effect relative to each treatment alone. Interestingly, we have some clinical examples that subtherapeutic, or radiosensitizing, doses of chemotherapy can impact distant disease control suggesting either that increased locoregional control can diminish distant metastatic disease potential or that lower dose chemotherapy can treat micrometastatic disease (i.e., spatial cooperation).

Biological Cooperation

The term, *biological cooperation*, is a newer concept[9] that involves independent targeting of subpopulations of cells within the tumor itself (see Table 4-1). Although similar to the spatial cooperation concept, biological cooperation implies that some portion of the actual radiation target (i.e., in-field) is resistant to radiation, which is the target of the drug given concomitantly. The most prominent example for biological cooperation is hypoxic cell cytotoxins such as tirapazamine. Because hypoxia is a known radiation resistance condition, tirapazamine will target these subpopulations of cells since it is most potent in anoxic conditions. Tirapazamine is discussed in more detail later in this chapter.

Temporal Modulation

The four R's of classical radiobiology, which include reoxygenation, repair, redistribution, and repopulation,[10] refer to factors that are particularly important for fractionated radiation therapy. For example, antiproliferative therapies could prevent accelerated repopulation between fractions, which might not be detectable using single fraction assays, in vitro. Conversely, although DNA damage repair blockade may enhance radiation sensitivity in the tumor, if DNA repair is also inhibited in normal tissue, outcomes may be worse in fractionated therapy.[9] Depending on which factors are most prominent in normal and tumor cells, the therapeutic index can be shifted in either beneficial or detrimental directions. Therefore, temporal modulation implies therapeutics that optimize these four radiobiology factors in between fractionated radiation treatments (see Table 4-1).[9]

POTENTIAL BIOLOGICAL MECHANISMS OF DRUG RADIATION INTERACTION

There are a host of potential mechanisms by which a drug may impact radiation efficacy that are summarized in Table 4-1. Classical definitions of radiosensitizers indicated an enhancement of DNA damage as the critical factor. However, with increased understanding of cancer cell biology, it is apparent that targets other than DNA damage can enhance radiation efficacy. Therefore, a broader defined "radiation enhancer" can impact several potential mechanisms to increase radiation effect.

Increasing Radiation Damage

The classical radiobiology definition of a radiosensitizer implied that the drug would enhance DNA damage. This is accomplished when the drug incorporates itself into the DNA or causes damage to the DNA itself by forming adducts, thereby increasing susceptibility of the DNA to radiation damage. Examples of this type of interaction include 5-FU and cisplatin.

Inhibition of DNA Repair

Cancer cells that can effectively repair DNA damage will have resistance to radiation effect. Therefore, compounds that can interfere with the DNA damage repair signal transduction pathway can potentially enhance radiation damage. Several chemotherapeutics target this process, particularly those that disrupt nucleotide biosynthesis and utilization. Modified nucleotides such as 5-FU, bromodeoxyuridine, gemcitabine, fludarabine, methotrexate, etoposide, hydroxyurea as well as cisplatin fall into this category. Additionally, as will be described, compounds that alter the cell cycle may indirectly inhibit DNA repair.

Cell Cycle Effects

A multitude of preclinical work has identified the G2/M as the most radiation-sensitive and S as the most radiation-resistant phases of the cell cycle.[11,12] In addition, many cytotoxic chemotherapeutics are cell cycle specific. Therefore, agents that can maintain cells in radiation-sensitive phases or eliminate those cells in radiation-resistant phases will cooperate with radiation for enhanced efficacy. Although this is clearly seen in preclinical settings, there is much less direct evidence for this phenomenon in clinical data. Nevertheless, taxanes and nucleoside analogs and modified pyrimidines appear to work in this manner.[13-16]

Repopulation

In normal adult tissue, the rate of cell loss is balanced by that of cell proliferation. When increased cell loss occurs from injury, including radiation treatment, signaling for proliferation occurs resulting in a repopulation. Cancers, however, have an excess of cell proliferation relative to cell loss by their very nature. Therefore, when a subtotal cell loss occurs during fractionated radiation, cancers can also promote increased proliferation. This is known as *accelerated repopulation*. Chemotherapeutics with cytotoxic or even cytostatic effects when given concurrently with radiation, can counteract this repopulation and enhance efficacy.

Hypoxia/Tumor Microenvironment

Solid tumors, particularly those that have grown to any significant size, will contain regions of lower oxygen tension because of the limitations in vascular flow as well as oxygen diffusion within the tumor. Although many tumors trigger angiogenic factors within the tumor, these stimulants manifest as aberrant vasculature often with disorganized architecture. Moreover, larger tumors may have increased interstitial

pressure that leads to further collapse of blood vessels creating hypoxic regions and overt necrosis at times.

Hypoxia is one of the most potent factors of radiation protection known because radiation relies on the production of oxygen free radicals (hypoxia generates two- to threefold less radiation sensitivity).[17] Therefore, drug therapies that mitigate this hypoxia can enhance radiation efficacy. There are four general chemotherapeutic approaches for accomplishing this: (1) chemotherapy can shrink the tumor through cytotoxic action thereby decreasing interstitial pressure. Moreover, because chemotherapy typically targets the fastest proliferating cells, those cells located next to blood vessels are removed bringing the hypoxic regions into closer proximity with the oxygenated region. A good example of this process is demonstrated by taxanes such as paclitaxel.[18] (2) Antiangiogenic therapies such as bevacizumab, an antibody targeting the vascular endothelial growth factor (VEGF), can potentially normalize vascular flow by eliminating the aberrant neovasculature of the tumor. Work by Rakesh Jain[19,20] and others[21,22] provide evidence of this phenomenon. (3) Hypoxic cell targeting agents, such as tirapazamine, can provide biological cooperation by eliminating the most radiation-resistant cells. (4) Hypoxic cell radiation sensitizers can reverse the inherent radiation resistance of the hypoxic cells. Drugs such as misonidazole, a nitroimidazole compound, can mimic the effects of oxygen within the hypoxic regions.[23,24]

Cell Death Pathway Effects

All of the preceding potential mechanisms of drug-radiation interaction display their efficacy through the consequence of cytotoxicity. However, in recent years, it has become clear that there are several ways in which cytotoxicity manifests itself. In 2005, the Nomenclature Committee on Cell Death (NCCD) was created and a classification system based purely on morphological criteria defined four modes of cell death: apoptosis (Type 1), autophagy (Type 2), necrosis (oncosis) (Type 3), and mitotic catastrophe.[25] Although these are distinct forms of cell death, the stimuli and processes involved interrelated. Moreover, there is evidence that ionizing radiation can manifest its cytotoxicity by each type of cell death. Therefore, as our understanding of these cell death pathways improve, novel therapeutics targeting these forms of cell death could enhance radiation efficacy. These cell death mechanisms are briefly described here.

Apoptosis

Apoptosis is the most clearly defined and studied mechanism of cell death. This programmed cell death involves characteristic morphologic changes including chromatin condensation (nuclear pyknosis) and nuclear fragmentation (karyorrhexis). Apoptotic bodies ultimately form and the cell is removed through phagocytosis but without generating inflammatory response. Apoptosis can occur with or without caspase activation[26,27] and does not require DNA fragmentation,[25] although this is a classical hallmark. Apoptosis is considered the major mechanism for chemotherapy-induced cell death. As a mechanism for radiation-induced cytotoxicity, apoptosis occurs readily in "liquid tumors" as opposed to most solid tumors in which apoptosis is a minor component of cell death. As such, drugs targeting the apoptosis pathway may enhance radiation cytotoxicity in solid tumors.

Autophagy

Whereas apoptosis is a clear self-destruct mechanism for the cell, the role of autophagy in cell death is more controversial. Autophagy, literally meaning "self-eating," can provide a protective mechanism for a cell during times of stress (such as nutrient deprivation) because it allows recycling of cellular building blocks through a controlled break down of cytoplasmic components. However, autophagic cell death does occur, which principally differs from apoptosis because of the lack of chromatin condensation.[25]

Necrosis

Type 3 death, or necrosis, is a cell death mechanism in which the cell swells (oncosis), ruptures the plasma membrane, and releases its contents resulting in a local inflammatory response.[25] The best example of this type of cell death is ischemic injury. Large, single fraction radiation, or radio-ablative doses, can produce this type of cell death as seen in stereotactic radiosurgery of brain lesions.

Mitotic Catastrophe

Mitotic catastrophe is a unique form of cell death that involves failed mitotic events.[25] Typically, this is manifest as micronucleation and multinucleation suggesting a series of mitotic divisions occur without cytokinesis that ultimately leads to cell death.

ANALYZING DRUG–RADIATION INTERACTION

Several methodologies for determining the interaction between a drug and radiation have been detailed in the literature. Moreover, several definitions for the possible interactions have also been described. The concept of radiosensitization originated many years ago, and classic radiosensitization has been defined as an increased amount of radiation-induced cell death that results from exposure to a second agent, after correction for the cytotoxicity of this agent. Clonogenic survival assays, that measure all forms of cell death as well as prolonged or irreversible cell cycle arrest, is the most encompassing method of measuring radiation cytotoxicity in vitro (Figure 4-3). Survival curves are generated by plating known quantities of cells on plates and treating them with various doses of radiation or drug and plotting the surviving fraction of colonies formed in a semilogarithmic fashion. Normalization is

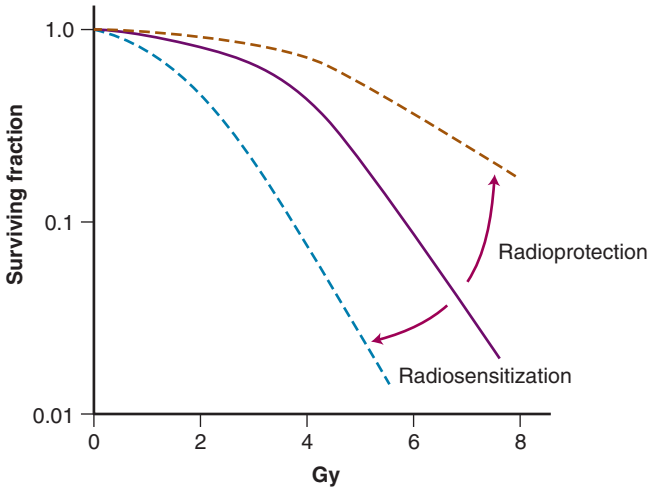

Figure 4-3 Graph of the concept of radiation modulation. The solid line indicates the control clonogenic survival assay plotted as surviving fraction relative to dose in Gy. A combined treatment that causes a rightward shift of the curve indicates a radioprotection effect, whereas a leftward shift of the curve indicates a radiosensitization effect.

performed by dividing the surviving fraction for treated groups by the plating efficiency, which is defined as the surviving fraction of the untreated cells. Modification in radiosensitization, therefore, is demonstrated in clonogenic survival curve data in which a downward or leftward shift of the normalized surviving fraction implies a radiosensitizing interaction, whereas an upward or rightward shift implies a radioprotective shift. Although survival curves can show interaction between chemotherapy and radiation, a better description of radiation modulation is necessary because both chemotherapy and radiation cytotoxicity do not typically follow a linear relationship.

One of the early attempts at providing a more descriptive system was provided by Tyrell,[28] which may be a better starting point for describing various interactions among therapies:

Antagonism: used in all cases in which the action of two treatments is less than would be expected from the addition of the two treatments given independently.
Zero interaction: used when two treatments lead to the effect expected from the addition of the two treatments given independently.
Positive interaction: used in all cases in which the action of two treatments is greater than would be expected from the addition of the two treatments given independently.
Synergism: a special case of a positive interaction; strictly, used when kinetic data are available.

These terms seem to have been supplanted by the "additivity" descriptors including supraadditive, additive, and infraadditive. Once again, the classic paper by Steel and Peckham[7] describes the construction of an "envelope of additivity" for evaluating the interaction of two treatments using isobologram analysis. This envelope of additivity is constructed from cytotoxicity data by calculating a mode 1 curve that assumes that both agents have completely independent mechanisms of action as well as a mode 2 curve that assumes that the two agents have exactly the same mechanism of action. When plotting combination therapy data points on the isobologram, they can either fall between mode 1 and 2 (additive interaction—within the envelope), above mode 1 (infraadditive), or below mode 2 (supraadditive, or synergistic). An idealized isobologram is shown in Figure 4-4 and a step-by-step method for constructing an isobologram is included in the Expert Consult Website.

Additional text available at https://expertconsult.inkling.com/ for a step-by-step method for constructing an isobologram.

Median Dose Effect Principle

A mathematical modeling system that has gained fairly widespread use for interactions of cytotoxic agents is the median effect principle of Chou and Talalay.[29-31] This system was derived from Michaelis-Menten equations and basic mass-action law considerations. This system has been useful for describing competitive enzyme interactions and interactions of cytotoxic agents. The primary relationship of the median effect principle is described by the following equation: $f_a/f_u = (D/D_m)^m$, in which D is dose, f_a is the fraction affected, f_u is the fraction unaffected, D_m is the dose required to produce the median effect (50%), and m is a Hill-type coefficient used to describe the sigmoid nature of the curve. For first-order Michaelis-Menten kinetics, m = 1.

The following manipulation of this equation can be performed, with surviving fraction (SF) substituted for fraction unaffected in the last step:

$$\log(f_a/f_u) = \log[(D/D_m)^m]$$

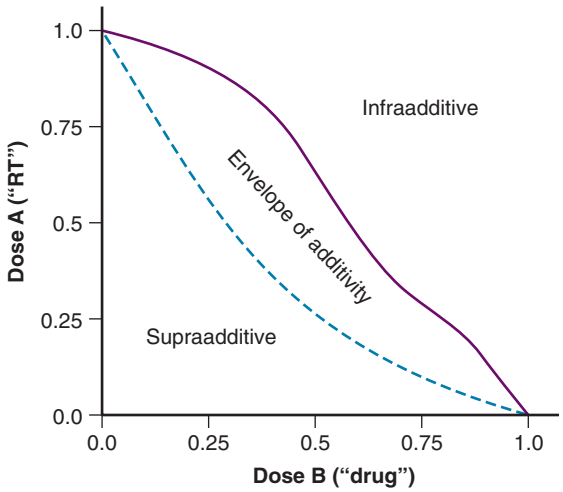
$$\log(f_a/f_u) = m\log(D) - m\log(D_m)$$

$$\log[(1/SF) - 1] = m\log(D) - m\log(D_m)$$

The general equation is $y = mx + b$.

A plot of log[(1/SF) – 1] on the *y*-axis and log(D) on the *x*-axis results in a line with a slope of *m* and a *y*-intercept of $m\log(D_m)$. The survival curves for the individual agents and for the combination treatment (the individual agents given together in some fashion) can be fitted to the equation for a line by linear regression. If the interaction of two agents is assessed, three lines (i.e., median effect plots) are produced: one for each agent and one for the combination treatment. A graph of the median effect plots for mock individual agents A and B and for the combination of A and B is shown in Figure 4-5. For the combination treatment, D is the sum of the doses of the two agents given concomitantly; it is helpful to perform the experiments with the two agents given together in a fixed ratio of doses (e.g., 1:2). By using various total doses (i.e., the sum), with the agents given in the same ratio, it is possible to determine the contribution of the individual agents to the combination treatment in a later calculation.

This concept can be visualized in Figure 4-5. For instance, in the case of $\log[(1/SF) - 1] = 0$, where SF is surviving fraction, the corresponding log(D), D indicating the sum of the doses of the two agents, can be calculated from the median effect plot for the combination treatment. An example of an actual combination treatment that has been assessed in this manner is radiation followed by a 24-hour exposure to etoposide.[29] In this example, a set of experiments was performed with the dose ratio fixed as 32 Gy to 1 μg/mL of etoposide. In this example, the dose D that resulted in log[(1/SF) – 1] equaling a given value was a combination of radiation and etoposide given in the ratio of 32:1. The radiation and etoposide components could be discerned, from the median effect plot of the combination treatment, by dividing the resulting dose into the appropriate components based on the ratio of delivery of the two agents.



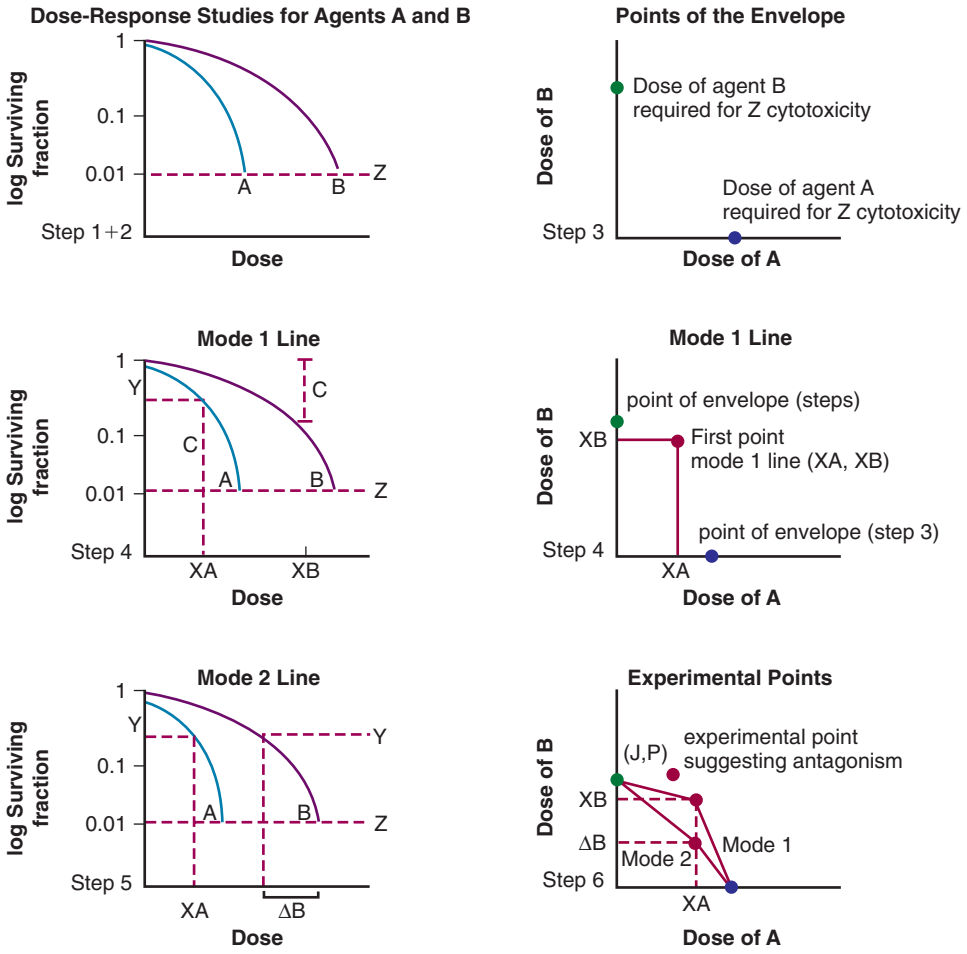


Figure 4-4 Graph of an isobologram for examining the interaction of radiation (RT) and a drug. Isoeffective doses of A (RT) and B (drug) are indicated on the axes. This diagram shows regions of infraadditivity, supraadditivity, as well as an envelope of additivity.

eFigure 4-1 Step-by-step construction of an isobologram to define an envelope of additivity for two cancer treatments. Isobologram analysis is used to evaluate the interaction of two treatments, and it requires the construction of an envelope of additivity that is bordered by mode 1 and mode 2 lines. The mode 1 line assumes that the two agents have completely independent mechanisms of action, whereas the mode 2 line assumes that the two agents have the same mechanism of action.

The following is a step-by-step procedure for calculating isobolograms using Steel and Peckham's method[7,29] (see eFigure 4-1).

Step 1. The investigator must choose to make the assessments at one level of cytotoxicity (e.g., construct an isobologram that represents the interaction of the agents for a cumulative cytotoxicity of 50%, 10%, or 1%). The example in Figure 4-3 depicts the chosen level of cytotoxicity as horizontal line Z: 1% cytotoxicity (0.01 surviving fraction) in this case.

Step 2. Plots are made of dose-response data for both agents. In eFigure 4-1, the dose-response data for the two agents are represented by curves A and B.

Step 3. The extreme points of the envelope of additivity are determined. Initially, a separate cartesian graph is created. The *y*-axis represents the dose of agent B, and the *x*-axis the dose of agent A. The first extreme point of the envelope is placed on the *y*-axis at the dose of agent B alone that causes a specific level of cytotoxicity, as determined by the dose-response curve of agent B, at the intersection of line Z (see eFigure 4-1). The second extreme point of the envelope is placed on the *x*-axis, at the dose of agent A alone that results in that level of cytotoxicity at the intersection of the dose-response curve with line Z (see eFigure 4-1).

Step 4. The mode 1 line is constructed assuming that the agents function independently. The individual dose-response curves are used for this construction. After exposure to dose X of agent A (XA), a level of cytotoxicity is obtained at a point on the dose-response curve that is above line Z. This level of cytotoxicity is identified as Y. Next, the dose of agent B (XB) that is required to produce cytotoxicity equal to the difference in cytotoxicity at line Z and point Y (identified as C) is determined. The cartesian coordinate (XA, XB) is plotted and becomes a point on the mode 1 line. The entire mode 1 line is constructed in this manner by varying the dose of agent A (for a resulting level of cytotoxicity that falls above line Z) and subsequently calculating the appropriate complementary dose of agent B as described.

Step 5. The mode 2 line is constructed assuming that the two agents have the same mechanism of action. As for mode 1 line construction, exposure to dose X of agent A (XA) results in a level of cytotoxicity identified as Y. The dose-response curve for agent B is then examined. The dose of agent B required for cytotoxicity equivalent to Y is determined and identified as YB. The change in dose of agent B that is required to increase cytotoxicity from YB to line Z is determined and labeled ΔB. The cartesian coordinate (XA, ΔB) is plotted. Similar points are calculated for various initial doses of agent A, and the mode 2 line is formed. The mode 2 line varies in shape depending on whether agent A or agent B is selected first for step 5. Generally, the mode

2 line that results in the greatest separation from the mode 1 line is chosen for the envelope of additivity.

Step 6. The two agents are given concomitantly, and a dose-response curve for concomitant treatment is obtained (typically by holding the dose of one agent constant while varying the dose of the other). The doses of the individual agents that result in combined cytotoxicity equivalent to the level represented by line Z are plotted (J, P).

This procedure allows for characterization of experimental data. The experimental point (J, P) represents an antagonistic interaction if the point falls above the envelope of additivity. The effect of the combination treatment is less than would be expected if the agents had completely independent mechanisms of action. An experimental point that falls directly on the mode 1 line suggests that the agents have independent mechanisms of action and the interaction is additive. An experimental point that falls below the mode 2 line suggests a synergistic interaction between the two agents for the particular concomitant treatment used.

The most difficult result to interpret is an experimental point that falls within the envelope of additivity. In some respects, the envelope of additivity is a misnomer because experimental points that fall in this range display an interaction that is greater than the additive effect that is achieved if the agents function by completely independent mechanisms. The interaction between the agents may be positive if the agents have independent mechanisms of action, or it may be negative if they have identical mechanisms of action.

Although the isobologram analysis is useful, it is somewhat limited because interactions in each analysis are investigated at a single level of cytotoxicity. The investigation of interactions at several levels of cytotoxicity requires the construction of several envelopes of additivity. The ambiguity associated with experimental points that fall within the envelope can be disconcerting and may lead to erroneous conclusions, especially if several levels of cytotoxicity are not investigated. Other mathematical modeling systems have been developed to assess the interaction of agents that cause cytotoxicity. These assessments aim to account for the kinetics of cytotoxicity of the involved agents and to assess multiple levels of cytotoxicity.

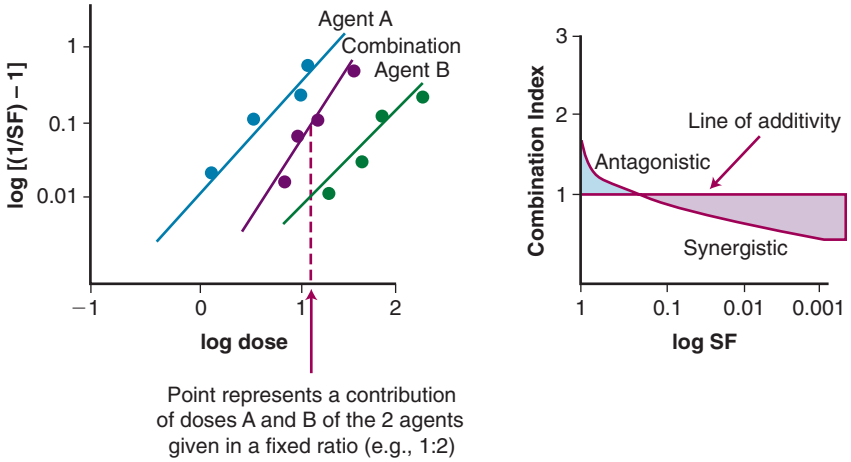

Figure 4-5 The hypothetical graph *(left)* demonstrates the median effect principle analysis for agents A and B given alone or in combination. The combination treatments are given in a fixed ratio so that the individual contribution of each agent to the combined effect can be calculated. The combination index *(right)* is then calculated at various levels of cytotoxicity as measured by surviving fraction (SF). The areas of antagonism, additivity, and synergism are indicated.

Definitions used in the median effect principle include the following:

Mutually exclusive: the agents of interest have similar modes of action and do not act independently.
Nonmutually exclusive: the agents of interest have different modes of action or act independently.
Combination index (CI): the derivation of this index is beyond the scope of this chapter. Calculation of CI allows characterization of an interaction as synergistic (CI <1), antagonistic (CI >1), or a summation (CI = 1). Chou and Talalay[31] provide a full description.

CI can be calculated for any surviving fraction and for mutually exclusive or mutually nonexclusive interactions. For a mutually exclusive interaction,

$$CI = [D_1/(Dx)_1] + [D_2/(Dx)_2]$$

For a mutually nonexclusive interaction,

$$CI = [D_1/(Dx)_1] + [D_2/(Dx)_2] + [D_1D_2/(Dx)_1(Dx)_2]$$

in which

$(Dx)_1 = D_m[(1/SF) - 1]^{1/m}$, solving the general equation for agent 1 given alone in a dose x.
$(Dx)_2 = D_m[(1/SF) - 1]^{1/m}$, solving the general equation for agent 2 given alone in a dose x.
$(Dx)_{1,2} = D_m[(1/SF) - 1]^{1/m1,2}$, solving the general equation for the agents given in combination for dose x, which represents the sum of the doses of the agents given in a fixed combination.
$D_1 = (Dx)_{1,2} \times$ (fraction of the mixture that is agent 1).
$D_2 = (Dx)_{1,2} \times$ (fraction of the mixture that is agent 2).

CI represents the doses of the agents required for a given effect when they are given together, divided by the doses required when the agents are given alone; in this way, CI less than 1 represents a synergistic interaction. A diagram of a CI plot for various levels of surviving fraction is shown in Figure 4-5.

Despite the advent of these robust statistical tools for determining the additivity relationship between treatments, the applicability outside of in vitro models is limited based on time and expense necessary to complete dose response experiments for both drug and radiation. Therefore, preclinical in vivo experimentation typically involves the use of a single drug dose at a concentration that can be achieved clinically.

CHEMOTHERAPY AND RADIATION AND COMBINATIONS OF CYTOTOXIC AGENTS

General Concepts

From the Bench to the Clinic

Occasionally, the process of quantifying interactions of chemotherapy and radiation has frustrated clinicians attempting to interpret in vitro and in vivo laboratory information, as exemplified by Charles Moertel (quoted by Tannock[32]) in his keynote speech at the first International Conference on Combined-Modality Therapy in 1978:

> *Based on the results of various individual studies, I could conclude that it is most ideal to administer the nitrosourea 15 hours before irradiation, 2 hours before irradiation, simultaneously with irradiation, or 6 hours after irradiation. While we will continue to cheer our radiation biology colleagues on from the sidelines, I am afraid that we are not yet at the stage where we can comfortably incorporate their results into our clinical practice.*

This was not meant as disrespect for the radiobiology community but to point out that, at that time, the laboratory models were potentially quite different from the clinical setting. Because it has been difficult to extrapolate from laboratory results to clinical results, many clinicians have used combination treatments on a trial-and-error basis. However, the reverse order of study has occasionally been fruitful, and efficacious combinations of treatment demonstrated in clinical studies have inspired laboratory investigations that revealed interesting molecular bases of interaction.[29,30] Translational research ideally occurs with a concept that arises from laboratory findings and subsequently is shown to have clinical efficacy. However, preclinical model systems have not always allowed investigators to take findings from the laboratory to the clinic, as indicated by the quotation of Moertel and by many of the early hypoxic cell sensitizer studies.

Therapeutic Benefits

Tannock[32] mentioned another problem with translating findings from the laboratory to the clinical setting, emphasizing that investigators must not merely explore combinations of therapeutic agents to find synergistic interactions but must also find interactions that will produce a therapeutic benefit (e.g., provide greater cytotoxicity in tumor cells than in normal cells). To categorize potentially exploitable differences, Tannock[32] described three main categories of biologic diversity between tumor cells and normal cells: tumor cells may display

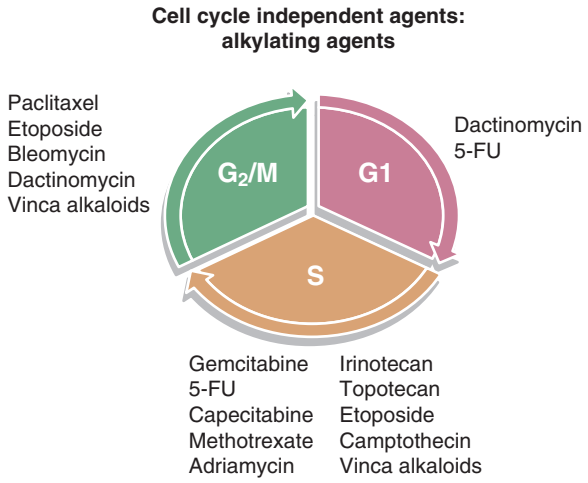

Figure 4-6 Diagram of the cell cycle with the cell cycle phase dependence of various chemotherapeutics.

genetic instability compared with normal tissues; tumor cells and normal cells may be different with respect to cellular proliferation or proliferation that occurs after treatment; and environmental factors such as oxygenation and pH may affect tumor cells and normal cells differently. As findings are translated from the laboratory to the clinical setting, it is important to consider the effects of the host mechanisms on these three areas.

Chemotherapeutic Classes

In the next section, several classes of systemic agents will be presented followed by a brief review of clinical data describing combination treatment of these agents with radiation. There are a host of chemotherapeutic classes that are used in patients that will undergo radiation treatment. Although not all of these agents are used concurrently with radiation, it is helpful to understand their predominant mechanism of action. A brief description of several of the major classes of chemotherapeutics with some information regarding possible means of interaction with radiation follow. In addition, Figure 4-6 summarizes the cell cycle phase specificity of these agents.

Antimetabolites

The origin of antimetabolite chemotherapy dates back to the 1940s when aminopterin was used to treat pediatric leukemia.[33] Since then, a large number of antimetabolite chemotherapeutics have been developed with tremendous success. The targets for these drugs include folate metabolism and nucleoside analogs. The major antimetabolites are presented here.

Fluoropyrimidines: Fluorouracil, Fluorodeoxyuridine, and Capecitabine

The fluoropyrimidines, as the name implies, are halogenated pyrimidines that function as antifolates by inhibiting thymidylate synthesis. As mentioned previously in historical perspectives, 5-FU is one of the most established drugs used in combination with radiation. It has been used in both a bolus infusion as well as a continuous venous infusion when combined with radiation and appears to target the radioresistant cells in S-phase.[16] The two delivery methods have some differences in terms of side effect profile, but both seem to have good efficacy. In a phase III rectal cancer postoperative adjuvant chemoradiation trial, concurrent continuous infusion 5-FU during EBRT was more effective than the bolus delivery.[34] Moreover, data shows that 5-FU plasma levels and intracellular metabolite levels are rather short-lived,[35] also suggesting a need for continuous administration of the drug to be effective with radiation. Because of this, oral formulations have been developed, most notably capecitabine, a fluoropyrimidine carbamate prodrug of 5-FU, which must be converted through the action of thymidine phosphorylase. In addition to the improved patient comfort of taking an oral medication rather than having an infusion pump, another potential advantage of capecitabine in combination with radiation is that it appears that radiation increases thymidine phosphorylase levels in tumors, which allows potential bioaccumulation of active metabolite within irradiated tumor.[36,37]

Gemcitabine

Gemcitabine is an analog of deoxycytidine that specifically functions during the S-phase by preventing the dNTP production. There is both preclinical and clinical evidence demonstrating dramatic radiation sensitizing properties to combined gemcitabine and radiation.[38-41] In fact, a significant amount of toxicity has been demonstrated in clinical trials for pancreatic cancer[42] necessitating either decreased dose of gemcitabine or limited field size for radiation treatment ports.

Antifolates: Methotrexate, Trimetrexate, and Pemetrexed

The antifolate, methotrexate, tightly binds dihydrofolate reductase (DHFR) thereby inhibiting folate metabolism. Through this inhibition, thymidylate synthesis is blocked, and thus, purine biosynthesis. In addition, some amino acid synthesis is impaired through blockade of this enzyme resulting in cytotoxicity.[43] Pemetrexed is a pyrrolopyrimidine that functions as an antifolate that inhibits multiple enzymes including thymidylate synthase, dihydrofolate reductase, glycinamide ribonucleotide formyl-transferase, and aminoimidazole carboxamide formyl-transferase in a cell cycle independent manner. Pemetrexed is effective against many solid tumors and has shown radiosensitizing propertied in preclinical systems.[44,45,46]

Alkylating Agents

Alkylating agents are composed of several classes of electrophilic compounds that share the antitumor characteristic that they form covalent bonds with ("alkylate") DNA bases. Some alkylators interact with a single strand of DNA, whereas others can cross-link two strands. The induced DNA damage leads to the cytotoxicity of these agents. The various classes of alkylators that are potentially used with irradiation are briefly presented here.

Nitrogen Mustard: Chlorambucil and Melphalan

The first of a long series of alkylating agents developed for clinical use, mustard gas was discovered based on clinical observations of people and animals exposed to mustard gas during World War I, particularly the effect on bone marrow.[33,47] Later, nitrogen mustards were developed for lymphoma therapy as mechlorethamine or Mustargen, eventually used in the MOPP (Mustargen, vincristine [Oncovin], procarbazine, prednisone) regimen for Hodgkin's lymphoma. The most commonly used nitrogen mustards are chlorambucil and melphalan (L-phenylalanine mustard) and are principally used for the treatment of chronic lymphocytic leukemia and multiple myeloma, respectively. Because of the bone marrow effect of these drugs, caution should be used when irradiating large volumes of bone marrow.

Oxazaphosporines: Cyclophosphamide and Ifosfamide

The oxazaphosphorines are nitrogen mustard-like compounds that include cyclophosphamide and its structural isomer,

ifosfamide. These agents are used in combination with radiation in both pediatric and adult cancer treatment.

Mitomycin C

Mitomycin C is an antibiotic with alkylating characteristics derived from *Streptomyces*. This agent, is an aziridine ring–containing compound that resembles nitrogen mustard as well. This drug blocks DNA synthesis but also causes cell cycle arrest during G2/M phase transition.[48,49] Mitomycin C has also been shown to function well as a hypoxic cell radiosensitizer,[50] which may help explain why mitomycin C-based chemoradiation is so effective in anal cancer treatment,[51,52] as discussed later in the chapter.

Triazenes: Procarbazine, Dacarbazine, and Temozolomide

Temozolomide has revolutionized the treatment of high-grade gliomas in combination with irradiation. It effectively crosses the blood-brain barrier. (The cerebrospinal fluid [CSF] can achieve 30% of plasma levels).[53] Temozolomide generates DNA damage through methylation of DNA at the O-6 position of guanine. Interestingly, the O-6 methylguanine DNA-methyltransferase (MGMT) is a p53 DNA repair enzyme that can be regulated epigenetically silenced by promoter methylation, which appears to predict for response to temozolomide-based chemoradiation because of the inability of the cancer cell to remove the O-6 methylguanine causing cytotoxicity.[54] Indeed, this DNA alkylation/methylation from temozolomide triggers the mismatch repair pathway with a G2/M phase arrest yielding apoptosis and radiosensitive cells.[55] Ongoing clinical trials are examining the importance of MGMT status and combining temozolomide with other agents.[54,56]

Nitrosoureas: BCNU, Methyl-CCNU, CCNU, and Streptozotocin

Several members of the nitrosourea group of alkylating agents are capable of crossing the blood-brain-barrier and cross-linking DNA. BCNU, or carmustine, has been used to treat brain tumors, predominantly gliomas, but it has also been used for multiple myeloma and high-dose transplant regimens. Gliadel (BCNU impregnated wafer) can be placed in a glioma resection cavity, which biodegrades slowly to release the chemotherapeutic. CCNU, or lomustine, is a related compound with increased lipid solubility also used for brain tumors.[57]

Platinums: Cisplatin, Carboplatin, Oxiliplatin, and Satraplatin

Cisplatin, (cis-Diammine dichloroplatinum[II]), the prototypical and most widely studied member of the platinum family, has been used for decades as an anticancer treatment. Preclinical work in the late 1970s by Soloway et al[58] demonstrated radiosensitization in a murine model of transitional cell carcinoma. Since then, a host of both clinical and preclinical data suggests several mechanisms of interaction between cisplatin and radiation. Potential cooperation between the two modalities can occur at the level of DNA because radiation often causes repairable single-stranded breaks in DNA, which can be converted to lethal double-stranded breaks when they occur close to cisplatin-DNA adducts (intra- and interstrand cross-links). This may also be as a result of the ability of cisplatin to function as a free-electron scavenger that impairs the DNA repair mechanism, thus, "fixing" the radiation-induced DNA damage.[59] In addition, radiation may enhance the uptake of cisplatin into the cell as well as help generate active platinum metabolites.[1] The other family members, carboplatin, oxiliplatin, and the orally active, satraplatin, appear to have similar mechanisms of action though differences among the members may be because of the three-dimensional structure of the DNA adducts that each platinum generates, which influences binding to various polymerases and DNA repair enzymes.[60] For these reasons, the platinums function independent of the cell cycle phase.

Microtubule Targeting

Because microtubule polymerization and depolymerization are critical for spindle formation and chromosome segregation during mitosis, microtubule targeting agents have the ability to enhance radiation effect by creating a cell cycle blockade during M-phase, which is a radiation-sensitive phase of the cell cycle. Moreover, these agents promote apoptosis as well. The three predominant classes of microtubule targeting agents are discussed here.

Estramustine

Estramustine is an interesting hybrid molecule that is derived from both nitrogen mustard and 17β-estradiol. Estramustine effectively blocks microtubules by binding β-tubulin and microtubule associated proteins resulting in destabilization of microtubules. This targets the mitotic spindle and leads to cell cycle arrest during M-phase causing radiosensitization.[61] This drug has been approved for hormone-refractory prostate cancer for almost three decades.

Vinca Alkaloids: Vincristine, Vinblastine, and Vinorelbine

The vinca alkaloids have been used as anticancer agents for more than 40 years and function by targeting microtubules. They are able to force depolymerization of microtubules and, thus, disrupt the mitotic spindle resulting in an M-phase blockade.[62] These drugs have been used for a wide variety of malignancies, both pediatric and adult. In terms of radiosensitization, vincristine, vinblastine, and vinorelbine impact cell cycle effects and DNA damage repair.[9,62]

Taxanes: Paclitaxel, Docetaxel, and Albumin-Bound Paclitaxel

As opposed to the vinca alkaloids, the taxanes stabilize microtubules and promote further tubulin polymerization, which inhibits centrosome mechanics during mitosis. In terms of enhancing radiation effect, the taxanes appear to manipulate several of the factors listed in Table 4-1. First, the taxanes will block the metaphase-anaphase cell cycle checkpoint, which could allow for accumulation of cells in the radiosensitive G2/M phase.[62,63] Furthermore, taxanes can cause tumor shrinkage,[64,65] thereby decreasing interstitial pressure and allowing for improved oxygenation.[18] In addition, taxanes can manipulate signal transduction cascades involved in radiation response.[66]

Epothilones (Epothilone B, Aza-Epothione B [Ixabepilone])

The epothilones are considered next-generation microtubule targeting agents that function similar to taxanes but are derived from mycobacterium. They are able to stabilize microtubules with high potency and halt mitosis similar to taxanes.[62] These drugs were developed to be independent of the p-glycoprotein efflux resistance mechanisms that target taxanes and vinca alkaloids.[62,67] These drugs will likely become a popular choice for concurrent chemoradiation regimens in the future.

Topoisomerase Inhibitors

Topoisomerases are critical enzymes in DNA replication of all cells because of their ability to unwind DNA. There are two major classes of topoisomerases in mammalian cells that are

clinically relevant for oncology therapeutics, topoisomerase I and II. Topoisomerase I (TopI) is involved in DNA replication fork movement and unwinding supercoils during DNA transcription, whereas topoisomerase II (TopII) is important for untangling DNA during transcription and remodeling chromatin.[35,43] These classes are named based on how many DNA strand breaks are created during enzymatic action, a single-stranded break for TopI and double-stranded break for TopII.[43] These breaks are required for TopI and II to unwind and disentangle DNA, but they are temporary because the enzyme will reconnect the broken strands (religation). TopI/II inhibitors have cytotoxicity by disrupting the process and generating DNA double-stranded breaks.

Topoisomerase I Inhibitors (Camptothecins—Irinotecan, Topotecan)

Camptothecin is a naturally occurring alkaloid derived from the plant *Camptotheca acuminata* that was identified in an anticancer drug discovery screen in the 1960s.[68] Camptothecin is believed to form a stable ternary complex that prevents normal DNA religation and a collision of the complex with the replication fork occurs leading to a DNA double-stranded break and cytotoxicity.[69] The S-phase specificity of this drug class provides some of the rationale for radiosensitization. The drug was unsuccessful in the clinic because of severe urinary complications, though camptothecin is still used as a research tool and positive control for cytotoxicity and apoptosis. However, derivatives of camptothecin, notably irinotecan and topotecan, are used as chemotherapeutics. Irinotecan is FDA approved for colorectal cancer, but data related to concomitant administration with radiation has been generated in patients with both small cell[70-72] and non–small cell lung carcinoma.[73,74] Topotecan is approved for ovarian, small cell, and cervical cancer, but it has been combined with radiation in glioblastoma clinical trials.[75,76]

Topoisomerase II Inhibitors

Podophyllotoxins: Etoposide, Etoposide Phosphate, and Teniposide. The plant extract, podophyllotoxin, has microtubule binding activity, yet, the clinically used derivatives do not function through microtubule action but actually are TopII poisons.[77] These epipodophyllotoxins, most notably etoposide and teniposide, are glycoside derivatives that are used in both childhood and adult tumors.[35] In addition, these drugs have been used with radiation in both sequential and concomitant regimens.[78-81]

Anthracyclines: Idarubicin, Doxorubicin, Epirubicin, and Daunorubicin. Anthracyclines are naturally occurring substances that intercalate into the DNA when they target TopII leading to DNA double-stranded breaks.[35,82] These drugs have a wide range of clinical indications, including both liquid and solid tumors. In terms of radiation sensitization, the interaction of doxorubicin and radiation are well known such that concurrent administration is generally avoided. In fact, when doxorubicin is given after radiation, an inflammatory reaction known as "radiation recall" can occur.[83,84]

Others: Mitoxantrone and Dactinomycin. Mitoxantrone is an anthracenedione that was designed to function like an anthracycline but have less cardiotoxicity[85] because it is less likely to form free radicals[35] and may affect calcium release differently.[86] Like anthracyclines, mitoxantrone can intercalate in DNA and poison TopII to form DNA double-stranded breaks. This drug is approved for hormone-refractory prostate cancer. Dactinomycin is a *Streptomyces* derived antibiotic that can intercalate in DNA, block TopII and cause DNA double-stranded breaks.[35] Dactinomycin is used in pediatric sarcoma therapeutic regimens, including rhabdomyosarcoma.

CHEMORADIATION CLINICAL EXAMPLES

An all-encompassing review of the clinical examples of the use of chemoradiation is beyond the scope of this chapter. More comprehensive information regarding disease site-specific trials are included in the individual chapters devoted to each site. What follows is merely a brief account of some of the landmark trials that have demonstrated improved organ preservation, local control, and overall survival in the modern era. Specifically, aerodigestive, genitourinary, gynecological, and central nervous system cancer examples are presented.

Gastrointestinal Cancers

Anal Cancer

A classic example of the evolution of an efficacious interaction of chemotherapy and radiotherapy is combined modality treatment for anal cancer. In the early 1970s, it was discovered that anal cancer could be treated successfully with a combination of 5-FU, mitomycin C (MMC), and irradiation.[52] In 1974, Nigro et al[52] reported on three patients who received variations of these three treatments, with excellent responses to the preoperative therapy (eTable 4-1). This article became a classic in the oncology literature, and the regimen became prominent in the treatment of anal cancer. Because of this regimen, many patients were spared abdominal perineal resection.

After the initial report of Nigro et al,[52] several other groups confirmed the efficacy of chemotherapy and irradiation (without surgery) as the standard treatment for primary anal cancer (Table 4-2).[52,87-89] Subsequently, an intergroup effort was undertaken by the Radiation Therapy Oncology Group (RTOG) and Eastern Cooperative Oncology Group (ECOG) to determine whether MMC could be removed from the regimen because its inclusion resulted in increased toxicity compared with that of 5-FU and radiation without MMC. With 5-FU, however, fewer patients were able to avoid colostomy (see Table 4-2).

Additional attempts at replacing MMC with less toxic concurrent chemotherapy have been undertaken, most notably in the U.S. GI Intergroup study (see Table 4-2) coordinated by RTOG (RTOG 98-11). This trial compared an induction chemotherapy (5-FU and cisplatin) regimen followed by the same chemotherapy concurrently with radiation versus standard concurrent chemotherapy (5-FU and MMC) with radiation. The hypothesis was that the induction chemotherapy would decrease tumor bulk making radiotherapy more effective and thus improving local control and that the additional cycles of induction chemotherapy may improve overall survival (OS) by decreasing distant metastases. However, these hypotheses were disproven because the cisplatin arm not only failed to show a benefit in terms of local control, disease-free survival (DFS), and OS, but was clearly inferior to MMC in terms of colostomy-free survival (CFS).[51] Long-term followup of trial results not only confirmed initial results regarding CFS but, more importantly, demonstrated a statistically significant superior DFS and OS with 5-FU and MMC compared to induction and concurrent 5-FU and cisplatin.[90] Therefore, the combination of 5-FU, MMC, and irradiation remains the standard regimen for anal cancer. IMRT strategies combined with 5FU-MMC based chemoradiation have been investigated by multiple groups and demonstrate a reduction in normal tissue toxicities.[91-93]

Additional text available at https://expertconsult.inkling.com/ for a discussion of how the laboratory investigations followed the clinical data.

eTABLE 4-1 Combined-Modality Treatment for Anal Cancer: A Study of Three Patients

Patient	RT	Chemotherapy	Results
1	34.7 Gy/5 wk	Concomitant 5-FU*/porfiromycin (50 mg)	APR 9 wk after RT, NED
2	30.6 Gy/17 Fx	Concomitant 5-FU*/mitomycin (30 mg)	Clinically free of disease, patient refused APR
3	30 Gy/15 Fx	None	APR 8 wk after RT, NED

Data from Nigro ND et al.[52]

5-FU, *5-Fluorouracil;* APR, *abdominoperineal resection;* Fx, *fractions;* NED, *no evidence of disease;* RT, *radiation therapy.*

**Dose of 1500 mg of 5-fluorouracil in the form of a continuous 24-hour infusion for 5 days.*

The clinical finding of the efficacious combination of 5-FU, mitomycin C, and radiation led to laboratory studies. Dobrowsky et al[94] performed a complex isobologram analysis using the same agents reported by Nigro et al.[52] The assessment by Dobrowsky et al,[94] using an in vitro system of a squamous tumor cell line, illustrated some of the difficulties with the ideal progression of taking laboratory discoveries to the clinic. Two different endpoints were used: colony formation (cells plated after treatment and allowed to form colonies) and viable cells per flask (obtained by multiplying the cell number per flask at 96 hours by the surviving fraction, as stipulated by a standard colony formation assay). In an attempt to duplicate the clinical treatment of Nigro et al,[52] mitomycin C was given as a 1-hour exposure and 5-FU as a 4-day exposure after initial radiation.

The first experiments assessed the interaction of 5-FU and mitomycin C without radiation. Initially, a single dose of mitomycin C (0.5 μg/mL for 1 hour) was combined with various doses of 5-FU. Isobolograms were constructed for the colony formation endpoint at a surviving fraction of 0.04. Isobologram construction showed that the combination treatment resulted in an experimental point below the envelope of additivity at this level of cytotoxic assessment. Isobolograms also were constructed for the viable cells per flask endpoint at the 1% viability level; the experimental point for combined 5-FU and mitomycin C was directly on the mode 2 line. This endpoint was included because it was believed to account for the cytotoxic and cytostatic effects of the treatment.

Because the results of this synergy analysis varied with the endpoint used, the optimal endpoint, whether colony formation or viable cells per flask, is not known. That the use of these slightly different endpoints produced slightly different isobologram results illustrates some of the problems in interpreting in vitro data and in attempting to extrapolate this information to the clinical setting. In the future, it may be possible to assess which endpoints may be most useful for various cytotoxic agents and various tumors on the basis of the relative contribution of cytotoxic and cytostatic effects for a given situation.

On the basis of the experiments without irradiation, specific concentrations of mitomycin C (0.5 μg/mL) and 5-FU (0.15 μg/mL) were selected for subsequent experiments involving radiation[94]; these concentrations resulted in 60% and 80% surviving fractions, respectively. With colony formation as the endpoint, it was discovered that the interaction of irradiation and 5-FU or irradiation and mitomycin C (at the levels of cytotoxicity assessed) produced experimental points below the envelope of additivity. These results corroborated those reported previously by Byfield et al,[95] in which some level of 5-FU cytotoxicity was required for a positive interaction with irradiation. However, the results of radiation in conjunction with mitomycin C were not entirely consistent with those of previous reports, which had suggested that a positive interaction of these agents did not exist.[96]

The previous example illustrates several important points. If the protocol of Nigro et al[52] had been designed on the basis of laboratory studies (if all of the aforementioned studies had existed in 1974), it would have been difficult to assess where to begin. First, the investigator would need to decide which in vitro endpoint would be most relevant to anal cancer (viable cells per flask or colony formation), and this decision would affect whether one believed that 5-FU and mitomycin C interacted synergistically. Second, the investigator would need to decide which assessment of mitomycin C and radiation was most relevant to the treatment of anal cancer because authors disagreed about whether this interaction was synergistic. This example also illustrates the challenges that are faced when interpretations of in vitro or in vivo experimental data are used to guide the design of clinical trials. These challenges can be exciting as we learn more about the significance of various endpoints at the molecular level and how these molecular events may be manipulated in a particular tumor.

TABLE 4-2 Concomitant Radiation and Chemotherapy for Anal Cancer

Study	Regimen	Outcome
Nigro et al[52] (1987), Wayne State University	RT (30 Gy/15 Fx) with CI 5-FU (1000 mg/m^2) for 4 days × 2 cycles and mitomycin C (15 mg/m^2) on day 1	Of 104 patients, 31 required APR
Sischy et al[89] (1989), RTOG/ECOG	RT (40 Gy/20 Fx) with CI 5-FU (1,000 mg/m^2) for 4 days × 2 cycles and mitomycin C (10 mg/m^2) on day 2	Of 79 patients, 8 required APR
Flam et al[88] (1996), RTOG/ECOG	RT (45 Gy/25 Fx) with CI 5-FU during weeks 1 and 4, with randomization to mitomycin C (10 mg/m^2) on days 1 and 29 vs. no mitomycin C	Colostomy-free survival improved with MMC, 71% vs. 59% (p = 0.014)
Bartelink et al[87] (1997), EORTC	RT (60-65 Gy*) alone vs RT plus 5-FU (750 mg/m^2 on days 1-5, 29-33) and mitomycin C (15 mg/m^2) on day 1	Improved event-free survival with RT and chemo compared with RT alone (p = 0.03)
Ajani et al[51] (2008), Gunderson et al[90] (2012); RTOG 98-11 (GI INT)	RT (55-59 Gy) with CI 5-FU CI 5-FU (1000 mg/m^2, for 4 days, wks 1 & 5) and MMC (10 mg/m^2 on days 1 and 29) vs CI 5-FU (1000 mg/m^2) + cisplatin (75 mg/m^2 on days 1 and 29) with induction chemotherapy	(N = 682); Improved DFS and OS at 5 y (67.8% vs. 57.8%; p = 0.006 and 78.3% vs. 70.7%; p = 0.026, respectively) for MMC arm

Esophagus/Esophago-Gastric Junction

Esophageal/esophago-gastric junction cancer remains a challenging cancer to treat, primarily because of the locally advanced stage that is typically found at diagnosis. For nonsurgical approaches to treatment, radiation alone has been shown to be quite limited in terms of controlling the disease. Indeed, chemoradiation has been clearly shown to be the treatment of choice following several landmark trials comparing chemoradiation to radiation alone. The Intergroup trial coordinated by RTOG (85-01) originally published by Herskovic et al[97] and later updated by Cooper et al[98] randomized patients to either 64 Gy radiation alone at 2 Gy/fraction or 50 Gy in 2 Gy/fraction concurrent with 5-FU (1000 mg/m^2/day for days 1-4) and cisplatin (75 mg/m^2 on day 1). In the concurrent arm, the chemotherapy was given every 28 days during radiation and then every 21 days thereafter for two additional cycles. This trial established that radiation alone was inferior to combined modality chemoradiation (5 year OS 0% vs. 26%, p = 0.0001).[98] A meta-analysis by Wong et al[99] confirmed that concurrent chemoradiation was beneficial in terms of survival with a hazard ratio of 0.73, 95% confidence interval of 0.64-0.84, p < 0.0001. Sequential chemotherapy and radiation did not show a statistically significant benefit, however.[99]

The role of trimodality therapy with neoadjuvant chemoradiation followed by surgery has also been investigated. Tepper et al[100] published the results of the U.S. GI Intergroup study (CALGB 9781) that randomized patients to neoadjuvant cisplatin/5-FU/EBRT (50.4 Gy) before esophagectomy versus esophagectomy alone. Although the trial was closed early because of poor accrual, the 56 patients enrolled were analyzed on an intent-to-treat analysis. This revealed a significant difference in median and 5-yr OS with trimodality treatment and surgery alone (median: 54 vs. 21.6 mo.; 5-yr OS: 39% vs. 16%, p = 0.002).[100] More recently, the CROSS group completed a large randomized phase III study of 366 analyzable patients comparing neoadjuvant carboplatin/paclitaxel/EBRT (41.4 Gy) before esophagectomy and esophagectomy alone.[101] Results of this study revealed that preoperative chemoradiation improved OS (median, 49.4 vs. 24 mo.; 5-yr OS 47% vs. 34%; p = 0.003; hazard ratio, 0.657) without significant increases in acute side effects or postoperative complications. Pathologic complete response was noted in 29% of patients with neoadjuvant therapy. A complete resection of the tumor (R0 resection) was accomplished in 92% of patients who underwent neoadjuvant therapy compared to 69% in patients who had surgery alone.

Combining molecularly targeted agents with standard chemotherapies with radiation have also been tested. Most heavily investigated has been the addition of EGFR targeting agents to standard chemoradiation regimens. Results from the SCOPE1 trial, a European multicenter phase II/III trial evaluating the addition of cetuximab to concurrent cisplatin, capecitabine, and radiation (50 Gy), has revealed a lack of benefit and possible detriment with the addition of cetuximab.[102] Initial reports of RTOG 0436, a randomized phase III trial evaluating the addition of cetuximab to concurrent cisplatin, paclitaxel, and daily radiation (50.4 Gy), also confirm these findings with little or no benefit of cetuximab as evidenced by no improvement in OS or clinical complete response.[103]

Gastric

The U.S. GI Intergroup 0116 phase III trial, reported by McDonald et al, compared adjuvant postoperative chemoradiation to surgery alone for patients with resected high-risk gastric or gastroesophageal cancers. Bolus 5-FU/leucovorin was given before EBRT (one 5-d cycle), concurrently with EBRT (2 cycles: 4-d wk 1, 3-d wk 5), and after EBRT (2 additional 5-d cycles). A survival advantage of concurrent chemoradiation was shown (3-yr OS—50% vs. 41%, p = 0.005; 3-yr relapse free survival—48% vs. 31%, p = 0.001),[104] and this treatment has been the standard of care for gastric cancer in the United States. In the United Kingdom, the MAGIC trial established a nonradiation regimen that involves perioperative (neoadjuvant and adjuvant) epirubicin, cisplatin, and 5-FU (ECF) chemotherapy as an appropriate standard of care for resectable gastric cancer.[105] The logical followup study was a postoperative adjuvant U.S. GI Intergroup phase III trial (CALGB 80101) that essentially married the INT-0116 and the MAGIC trial by investigating the role of chemoradiation in the setting of more modern ECF chemotherapy as the experimental arm versus the control arm of GI INT 0116. Although the experimental arm did not improve survival, the ECF regimen had a more favorable toxicity profile.[106]

Rectal

Although rectal cancer is a surgically managed disease, the addition of adjuvant therapy is well recognized as a vital

TABLE 4-3 Randomized Trials of Neoadjuvant Concomitant Radiation and Chemotherapy for Rectal Cancer

Study	Regimen	Outcome
Boulis-Wassif et al[108] (1984)	Preop RT (34.5 Gy at 2.3 Gy/fx) ± 5 FU 10 mg/kg/d day 1-4 followed by surgery	Trend toward improved 5 y OS (59% vs. 46%, $p = 0.06$)
Bosset et al[107] (2006)	4 arm study: preop RT (45 Gy) + S vs. preop CT-RT with 5 FU (325 mg/m^2/d)/LV (20 mg/m^2/day) d1-5, 28-32+ S vs. preop RT + S + adjuvant 5 FU/LV vs. preop CT-RT + S + adjuvant 5 FU/LV	5 y LR was worse in the RT only arm (17.1% vs. 8.7%, 9.6%, and 7.6% in the CT containing arms; $p = 0.002$)
Bujko et al[109] (2006)*	Preop RT (25 Gy at 5 Gy/fx) + S vs. Preop CT-RT (50.4 Gy at 1.8 Gy/fx with 5 FU(325 mg/m^2/d)/LV (20 mg/m^2/day) d1-5, 28-32 + S	No difference in LC, OS, or late toxicity, but CT-RT had more early toxicity (8.2% vs. 3.2%; $p < 0.001$)
Gerard et al[110] (2006)	Preop RT (45 Gy at 1.8 Gy/fx) ± 5 FU (350 mg/m^2/d d1-5 days + LV) followed by S + adjuvant 5 FU (350 mg/m^2/d d1-5 days + LV)	Improved pCR (11.4% vs/ 3.6%; $p < 0.05$) and less LR (8.1% vs. 16.5%; $p < 0.05$) with CT-RT

**Not a true comparison of adjuvant EBRT ± concurrent chemo as used markedly different adjuvant EBRT regimens*

component of therapy. Four randomized trials[107-110] investigating the addition of chemotherapy to neoadjuvant EBRT in Stage II and III rectal cancer is summarized in Table 4-3 (the Bujko trial did not use the same dose/duration of EBRT so it is not a true comparison of EBRT ± concurrent chemotherapy). Furthermore, a meta-analysis reviewed these four trials.[111] Although this analysis showed improved complete pathological response rate and local control with the addition of chemotherapy to preoperative radiation, no benefit was found in terms of sphincter preservation, DFS, or OS. Of note, preoperative chemoradiation was found to produce increased grade 3 and 4 toxicity compared to preoperative EBRT alone.

The current standard of care approach, however, was defined in the phase III German Rectal Trial.[112] Preoperative chemoradiation was shown to be superior to postoperative chemoradiation in terms of local control, sphincter preservation rates, and toxicity.

As in other disease sites, more recent trials are investigating the addition of molecularly targeted agents to the standard preoperative chemoradiation regimen. The antivascular endothelial growth factor antibody, bevacizumab, has shown promising results in phase I/II trial in which all 32 patients showed tumor regression following neoadjuvant therapy with an actuarial 5-year DFS of 75%.[113] In addition, EGFR targeted agents have shown promise in KRAS wild-type tumors.[114,115] However, these agents remain investigational in this setting.

Head and Neck Cancers

Head and neck cancers management for locally advanced tumors were traditionally managed with surgery and postoperative radiation. However, over the past two decades, an explosion of chemoradiation trials shifted the management toward an organ preservation approach (summarized in Table 4-4). One of the most impressive results for a randomized trial in head and neck cancers was that of Intergroup 0099 (RTOG 8817) originally published by Al-Sarraf et al in 1998.[116] In this trial of patients with nasopharyngeal cancer, radiation alone (70 Gy at 2 Gy/fx) versus radiation with concurrent cisplatin with adjuvant cisplatin/5-FU demonstrated a dramatic 67% to 37%, respectively, 5-year OS advantage in favor of the chemoradiation arm. More than 90 randomized clinical trials have been performed examining chemoradiation in head and neck cancers. Several meta-analyses have been published showing an absolute survival benefit to chemoradiation. Indeed, the most recent update of the MACH-NC in 2009 analyzed more than 17,000 patients in 93 randomized trials and showed an absolute OS benefit of 6.5% at 5 years.[117] Although two large randomized trials of neoadjuvant chemotherapy followed by radiation have shown a benefit in terms of laryngeal organ preservation,[118,119] subsequent studies, including RTOG 9111,[120] and the MACH-NC[117] suggest that concurrent chemoradiation is more effective than sequential administration.

As mentioned previously, the RTOG 9111 was a landmark Intergroup trial for patients with what would currently be staged as T2 and T3 glottic and supraglottic squamous cell carcinomas.[120] This trial randomized patients to one OS was not different between the groups, the DFS and local-regional control favored the concurrent chemoradiation arm.[120] This benefit is not restricted to organ preservation studies. Indeed, two trials published in the same issue of the *New England Journal of Medicine* detailed the RTOG[124] and EORTC[123] trials randomizing patients to postoperative radiation with or without concurrent chemotherapy. Although the two trials had slight differences in their inclusion criteria, they both established the importance of adjuvant chemoradiation in the setting of high-risk postoperative patients. A pooled data analysis from the two trials identified positive margins and extracapsular extension as the two significant risk factors for combining chemotherapy with radiation in the adjuvant setting.[127]

Recently, the question regarding whether induction chemotherapy followed by concurrent chemoradiation is superior to concurrent chemoradiation alone in locally advanced head and neck cancers was addressed in the PARADIGM trial.[128] In this study, patients were randomized to receive either induction chemotherapy with docetaxel, cisplatin, and 5-FU followed by concurrent chemoradiation with docetaxel or carboplatin compared to concurrent chemoradiation using cisplatin. Although the trial was terminated early because of poor patient accrual, results suggest no difference in overall survival between the two groups. However, a greater incidence of febrile neutropenia was noted in patients who received induction followed by concurrent chemotherapy compared to concurrent chemoradiation alone.

In 2006, Bonner et al published the results of a randomized phase III trial incorporating a molecularly targeted therapy with radiation in locally advanced head and neck cancers.[125] This trial used cetuximab, which is a monoclonal chimeric (mouse and human) antibody to EGFR. This trial showed not only a local control benefit but also an overall survival benefit when cetuximab was combined with radiation, including altered fractionation schedules. In addition, the incidence of serious toxicity (other than rash and transfusion reactions) was similar between the groups, which is in stark contrast to chemoradiation regimens that invariably have increased toxicity. These results have held up at the most recently published update[126] showing a 49-month median survival in the

TABLE 4-4 Selected Concomitant Radiation and Chemotherapy for Head and Neck Cancers

Study	Regimen	Outcomes
INT 0099 (1998)[116]	RT (70 Gy) vs. RT (70 Gy) + cisplatin (100 mg/m^2 q3 wks × 3) with adjuvant cisplatin (80 mg/m^2)/5-FU (1 g/m^2/d for 96 h q 4wks × 3)	At 5-yr update, PFS (58% vs. 29%), DFS (74% vs. 46%), and OS (67% vs. 37%) favors the CT-RT arm ($p < 0.001$)
Brizel et al (1998)[121]	RT (75 Gy at 1.25 Gy BID) vs. RT (70 Gy at 1.25 Gy BID) with concurrent cisplatin (12 mg/m^2/d) and 5-FU (600 mg/m^2 days 1-5) on weeks 1 and 6.	3-yr LRC favored CT-RT (70% vs. 44%, $p = 0.01$). 3-yr OS trends in favor of CT-RT (55% vs. 34%, $p = 0.07$).
RTOG 9111 (2003)[120]	3 arm trial of glottic and supraglottic cancer patients: RT(70 Gy) vs. sequential chemo (cisplatin 100 mg/m^2 + 5-FU g/m^2/d for 120 h q3wks × 3) then RT(70 Gy) vs. concurrent ChemoRT (cisplatin 100 mg/m^2 q3wks × 3)	No difference in OS but concurrent arm had superior local control (2-yr: 78% vs. 61% sequential vs 56% RT alone; $p \leq 0.003$) and highest organ preservation rate (88% vs. 75% vs. 70%; $p \leq 0.005$)
Adelstein et al (2003)[122]	3 arm trial: RT (70 Gy) vs. concurrent RT (70 Gy) + cisplatin (100 mg/m^2 q3wks × 3) vs. split course RT (30 Gy with cycle 1 and 30-40 Gy with cycle 3) + concurrent 5-FU (1 g/m2/d for 96 h) and cisplatin (75 mg/m^2) q4wks	The concurrent non-split cisplatin/RT arm had superior 3-ry OS (37% vs. 27% in split course CT-RT vs. 23% in RT alone; $p = 0.014$). Concurrent cisplatin/RT had highest rate of grade 3+ toxicity (89% vs. 77% vs 52%; $p < 0.0001$)
EORTC 22931 (2004)[123]	Postoperative RT (up to 66 Gy) vs. postoperative CT-RT (up to 66 Gy with cisplatin 100 mg/m^2 q3wks × 3) for potential high-risk head and neck cancer patients (Stage III/IV except T3N0 or T1-2N0-1 with +margins, +PNI, +ECE, +VSI, OC/OP primary with + LNs at levels 4-5)	Improvement in 5-yr OS (53% vs. 40%; $p = 0.02$), 5-yr PFS (47% vs 36%; $p = 0.04$), and 5-yr LRC (82% vs. 69%; $p = 0.007$) with CT-RT; Grade 3/4 mucositis was higher in CT-RT arm (41% vs. 21%; $p = 0.001$)
RTOG 9501 (2004)[124]	Postoperative RT (up to 66 Gy) vs. postoperative CT-RT (up to 66 Gy with cisplatin 100 mg/m^2 q3wks × 3) for potential high risk head and neck cancer patients (2 or more +LNs, +ECE, + margins)	Improvement in 2-yr DFS (54% vs. 44%; $p = 0.04$) and LRC (82% vs. 72%; $p = 0.01$) with trend toward better OS (63% vs. 57%, $p = 0.19$); Higher rate of grade 3 or greater acute toxicity in chemoRT arm (77% vs. 34%; $p < 0.001$)
Bonner et al (2006[125] and 2010[126])	Once Daily RT (70 Gy at 2 Gy/d), concomitant boost (72 Gy in 42 fxs) or hyperfractionated (72-76.8 Gy at 1.2 Gy BID) ± cetuximab (given 1 week before RT at 400 mg/m^2 then given weekly at 250 mg/m^2 × 7 wks)	Improvement in MS (49 vs. 29.3 months) and 5-yr OS (45.6% vs. 36.4%) in the cetuximab arm (HR of 0.73; $p = 0.018$). No difference in grade 3 or 4 toxicity, including mucositis, (except acneiform rash and infusion reaction).
MACH-NC meta-analysis[117]	Meta-analysis of 93 randomized trials of CT in head and neck cancer, with 17,346 patients.	Concomitant CT-RT provides absolute 5-yr OS benefit of 6.5% whereas induction chemo showed only 2.4% (HR of 0.81; $p < 0.0001$).

cetuximab arm and 29.3 months in the radiation alone arm. Five-year OS was 45.6% in the cetuximab group and 36.4% in the radiation alone group (hazard ratio, 0.73; $p = 0.018$).

Several trials are accruing or recently closed combining cetuximab with chemoradiation including the Phase III RTOG 0522 randomizing patients with stage III and IV squamous cell carcinoma of the oropharynx, hypopharynx, and larynx to cisplatin (100 mg/m^2 every 3 weeks) with or without a 1-week pretreatment (400 mg/m^2) and concurrent (250 mg/m^2/week) cetuximab with accelerated fractionation. Initial reports suggest the addition of cetuximab to concurrent chemoradiation does not improve clinical outcomes.[129] Final results should be forthcoming.

The human papilloma virus (HPV) has been implicated as a major cause of head and neck cancers.[130] Interestingly, patients with HPV-associated head and neck cancers have improved outcomes over patients with cancers not associated with HPV. It has been suggested that this may be as a result of an inherent DNA repair defect in HPV-associated head and neck tumors. Thus, efforts by ECOG and RTOG are under way to deescalate therapy in attempts to reduce the morbidities of therapy. The ECOG E1308 is a phase II trial, which tests the efficacy of reducing radiation doses and using concurrent cetuximab rather than chemotherapy in patients who have achieved a complete response to induction chemotherapy. Initial results are promising, with an 86% overall response rate observed in enrolled patients, and more importantly, decreased toxicities compared to historical controls.[131] The RTOG 1016 is a phase III trial randomizing patients to concurrent chemoradiation or cetuximab/radiation. This study is currently nearing completion of accruing the necessary number of patients.

Non–Small Cell Lung Carcinoma

Non–small cell lung carcinoma (NSCLC) is the number-one cause of cancer death in the United States, which is at least partly the result of the late presentation that typically occurs with this disease. As such, most patients will present with stage III disease or stage IV.

The treatment of stage III NSCLC has evolved over the past two decades. For unresectable stage III patients, EBRT alone produced poor 2-year OS, on the order of 20%. A modest improvement (up to 29%) was achieved with more intense radiation schedules such as the continuous hyperfractionated accelerated radiotherapy (CHART) regimen.[132]

To improve on these outcomes, the approach that was most heavily tested was the addition of systemic agents to EBRT, which is summarized in Table 4-5. Three major trials of

TABLE 4-5 Concomitant Radiation and Chemotherapy for Non–Small Cell Lung Cancer

Study	Regimen	Outcome
Dillman et al[133] (CALGB 8433 updated[141])	Sequential cisplatin (100 mg/m^2 d1 and 29) and vinblastine (5 mg/m^2 weekly × 5) followed by RT (60 Gy) vs. RT alone (60 Gy)	Improved MS (13.7 vs. 9.6 mo.; p = 0.012) with CT-RT
Sause et al[134] (RTOG 8808 updated[142])	Three-arm trial: sequential cisplatin (100 mg/m^2 d1 and 29) and vinblastine (5 mg/m^2 weekly × 5) followed by RT (60 Gy) vs. HyperFx RT (69.6 Gy at 1.2 Gy BID) vs. RT alone (60 Gy)	Improved MS (13.2 vs. 12 vs. 11.4 mo.; p = 0.04) with CT-RT
Furuse et al[138]	Chemo of cisplatin (80 mg/m2 on d1 and 29), vindesine (3 mg/m^2 on d1, 8, 29, and 36), and mitomycin C (8 mg/m^2 on d1 and 29) given either concurrently with split course RT (28 Gy × 2, 10 days apart) or sequentially with RT (56 Gy)	Improved MS (16.5 vs. 13.3 mo.; p = 0.03998) with concurrent CT-RT
Curran et al[137] (RTOG 9410)	Three-arm trial: cisplatin (100 mg/m^2) and vinblastine (5 mg/m^2) given before (Arm 1) or concurrently with once daily RT (Arm 2, 60 Gy), or concurrent cisplatin (50 mg/m^2) and oral etoposide (50 mg BID) with HyperFx RT (Arm 3, 69.6 Gy at 1.2 Gy BID)	Improved MS (17 mo.) in concurrent once daily CT-RT arm (arm 2) va. 15.6 mo (arm 3) va. 14.6 mo. (arm 1) (p = 0.038)
Albain et al[143] (INT 0139)	Stage IIIA patients received two cycles of chemo: cisplatin (50 mg/m^2 on d1, 8, 29, and 36) and etoposide (50 mg/m^2 on d1-5 and 29-33) plus 45 Gy. If no progression, they were randomized to surgery or 16 Gy boost. All patients received 2 adjuvant cycles of cisplatin/etoposide	No difference in MS, or 5-yr OS; improved median PFS in trimodality arm (12.8 vs. 10.5 mo.; p = 0.017); in subset analysis, improved OS in patients who underwent lobectomy vs. CT-RT, but CT-RT was better if patient underwent pneumonectomy.
Thomas et al[144] (GLCCG)	Patients received three cycles of cisplatin and etoposide and were randomized to CT-RT with concurrent carboplatin and vindesine followed by S or S followed by RT alone.	Preoperative CT-RT resulted in increased pathological response but no improvement in PFS. For patients requiring pneumonectomy, preop CT-RT had trend to increased Tx-related mortality (14% vs. 6%; p = 0.14)

sequential chemotherapy followed by radiation were published in the 1990s that showed improvement with the addition of platinum-based chemotherapy.[133-135] Around the same time, a meta-analysis demonstrated a small, but significant improvement with the addition of chemotherapy.[136] However, because the various trials included many different sequences of chemotherapy and radiation, it was unclear what would be the best regimen. Therefore, several randomized phase III trials compared sequential to concurrent chemoradiation.[137-140] In all but one trial,[140] the concurrent arm showed a significant improvement relative to sequential chemotherapy and irradiation. This established concurrent chemoradiation as the treatment of choice. What was not clear, however, was whether adjuvant chemotherapy could be added to concurrent chemoradiation regimens, and if so, if it was better to administer the chemotherapy neoadjuvantly or adjuvantly.

A phase II trial called the Locally Advanced Multimodality Protocol (LAMP) trial attempted to determine what would be the best approach.[145] The three arms in this trial included (1) neoadjuvant chemotherapy followed by radiation, (2) neoadjuvant chemotherapy followed by concurrent chemoradiation, and (3) concurrent chemoradiation followed by adjuvant chemotherapy. Although the concurrent followed by adjuvant arm had the best outcome, the trial had some limitations including insufficient power to determine the best regimen.[145]

Although concurrent chemoradiation is the standard approach for stage III NSCLC, there are certain instances in which surgery can be combined with chemoradiation in a trimodality approach. Two major randomized trials have been published regarding this trimodality approach, which are also included in Table 4-5 (U.S. Lung Intergroup 0139[143] and the German Lung Cancer Cooperative Group[144] trials). Both trials appeared to show that trimodality therapy was feasible, but that preoperative chemoradiation should be avoided if a pneumonectomy would be performed due to excessive treatment related mortality.

Cervical Cancer

One of the clearest clinical examples demonstrating improved outcomes of combined chemoradiation is in locally advanced cervical cancer. Cisplatin-based regimens have had clear success in a series of randomized phase III trials showing not only improvement in local-regional control but in also OS. This series of clinical trials (summarized in Table 4-6) had differing inclusion criteria and various treatment approaches, yet, these trials presented convincing evidence that cisplatin, when combined with radiation, improves outcome in locally advanced cervix cancer. An excellent review of the historical context and remaining controversies regarding these trials is available,[146] so they will only briefly be discussed here.

The Gynecological Oncology Group (GOG) had three positive trials for chemoradiation as a component of treatment. The GOG 85 trial investigated two different concurrent chemotherapy regimens (hydroxyurea and cisplatin/5-FU) with radiation for patients with locally advanced cervix cancer.[147] This trial demonstrated that concurrent cisplatin/5-FU was superior to hydroxyurea (5-yr OS 62% vs. 50%, p = 0.018). GOG 120 was a three-arm trial that compared radiation alone to two different cisplatin containing regimens (one with cisplatin alone and the other with cisplatin plus 5-FU and hydroxyurea).[148] The two cisplatin-containing arms were superior to the control arm (3-yr OS for both cisplatin based arms of 65% vs. 47%, $p < 0.005$). Since the cisplatin alone arm was less toxic than the 5-FU/hydroxyurea combination, the concurrent cisplatin/radiation approach was preferred. The GOG also

TABLE 4-6 Concomitant Radiation and Chemotherapy for Cervix Cancer

Study	Regimen	Outcome
GOG 85 (1999)[147]	IIB-IVA patients; RT + HU (3 g/m^2 twice per week) vs. RT + Cisplatin (50 mg/m^2)/5-FU(4 g/m^2/96 h)	Improved PFS (RR of 0.79, $p = 0.033$) and improved OS (5-yr: 62% vs. 50%, RR of 0.74, $p = 0.018$) in cisplatin containing arm
GOG 120 (1999)[148]	IIB-IVA patients; three arms: Cisplatin (40 mg/m^2/week) vs. Cisplatin (50 mg/m^2)/5-FU (4 g/m^2/96 h) with HU (2 g/m^2 twice per week) vs. HU (3 g/m^2 twice per week)	Improved PFS (RR of 0.57 and 0.55, $p < 0.001$) and improved OS (3-yr: 65% vs. 47%, RR of 0.61 and 0.58, $p < 0.005$) in both cisplatin containing arms
GOG 123[149]	IB (tumors ≥4 cm) patients; RT ± cisplatin (40 mg/m^2/week)	Improved PFS (RR of 0.51, $p < 0.001$) and improved OS (3-yr: 83% vs. 74%, RR of 0.54, $p < 0.008$) in cisplatin containing arm
SWOG 8797 (2000)[150]	I-IIA patients after hysterectomy with high-risk features (positive nodes, positive margins, or parametrial involvement); RT ± cisplatin(70 mg/m^2)/5-FU(4 g/m^2/96 h)	Improved PFS (HR of 2.01, $p = 0.003$) and improved OS (4-yr: 81% vs. 71%, HR of 1.96, $p = 0.007$) in cisplatin containing arm
RTOG 9001[151]	IB-IIA (≥5 cm), IIB-IVA (or positive pelvic nodes) patients; RT ± cisplatin (75 mg/m^2)/5-FU(4 g/m^2/96 h)	Improved 5-yr DFS (67% vs. 40%, $p < 0.001$) and improved 5-yr OS (73% vs. 58%, $p = 0.004$) in cisplatin containing arm
NCIC[152]	IB-IIA (≥5 cm), IIB-IVA (or positive pelvic nodes) patients; RT ± cisplatin (40 mg/m^2/week)	No difference in PFS or OS

5-FU, *5-Fluorouracil;* DFS, *disease-free survival;* GOG, *Gynecological Oncology Group;* HR, *hazard ratio;* HU, *hydroxyurea;* NCIC, *National Cancer Institute Canada;* OS, *overall survival;* PFS, *progression-free survival;* RR, *relative risk;* RT, *radiation therapy;* RTOG, *Radiation Therapy Oncology Group.*

investigated the importance of chemotherapy with radiation for patients in bulky stage IB treated with hysterectomy in GOG 123. In this trial, the patients were randomized to radiation alone versus radiation plus weekly cisplatin before undergoing hysterectomy.[149] Once again, the cisplatin-containing arm was superior (3-yr OS 83% vs. 74%, $p = 0.008$).

In the 1990s, the RTOG also examined the importance of cisplatin with radiation for patients with locally advanced cervix cancer. RTOG 9001 compared extended field radiation alone to pelvic radiation plus cisplatin and 5-FU.[150] The chemoradiation arm was superior to the extended field irradiation (5-yr OS 73% vs. 58%, $p = 0.004$).

The fifth trial to support concurrent cisplatin/radiation was the Intergroup 0107/SWOG 8797, which tested chemoradiation in the adjuvant setting for patients that underwent hysterectomy with high-risk features at time of surgery including positive pelvic nodes, positive margins, and parametrial involvement.[151] Patients were randomly assigned to receive radiation alone or radiation with cisplatin/5-FU. The chemoradiation group was again superior (4-yr OS 81% vs. 71%, $p = 0.007$).

Only one major trial, from National Cancer Institute of Canada (NCIC), failed to demonstrate an OS benefit for this approach.[152] However, that trial has been criticized because of the small size and wide confidence intervals that may have prevented a difference from being detected.

The next generation of chemoradiation trials is adding molecularly targeted agents, including cetuximab and tirapazamine, to standard cisplatin-based regimens.

Genitourinary Cancer

Chemoradiation is established as the standard bladder preserving management strategy for muscle invasive bladder cancer. Shipley et al[153] published a single institution experience using a neoadjuvant chemoradiation approach similar to the larynx preservation trials discussed previously in which a cisplatin-containing chemoradiation regimen is given (following a maximal transurethral resection of bladder tumor [TURBT]), an evaluation for tumor response is then performed followed by either surgery (for anything less than a complete response) or consolidative chemoradiation. With this approach, the 5-year OS is comparable to surgical series at 54%. Bladder preservation rates without invasive local recurrence are ~50%.

Another genitourinary example involving the use of hormone ablation therapy plus EBRT for high-risk prostate cancer demonstrates a local control, DFS, biochemical DFS, and possibly an OS benefit based on both RTOG[154-156] and EORTC[157,158] experience. It has been postulated that androgen-deprivation therapy used in concomitant radiation regimens not only provides a spatial cooperation interaction but also a biological cooperation function. Currently, the RTOG is investigating the addition of TAK-700 (Orteronel), which suppresses adrenal androgen production, to concurrent EBRT and standard androgen deprivation therapy for high-risk prostate cancer patients (RTOG 1115) in attempts to maximally suppress androgen production.

Glioblastoma

The treatment of glioblastoma has dramatically changed in recent years based on the encouraging findings from the phase III trial from EORTC and NCIC. This trial, first published by Stupp et al in 2005[159] and updated with 5-year data,[160] demonstrated a remarkable improvement in median survival (14.6 vs. 12.1 months) and OS (9.8% vs. 1.9% at 5 years; hazard ratio, 0.63; $p < 0.0001$) with the use of concurrent temozolomide and radiation with adjuvant temozolomide. Prognostic[161-163] and possibly predictive[164] information can be garnered from evaluating the MGMT promoter methylation status because it has been shown that patients whose tumors have MGMT epigenetic silencing as a result of promoter hypermethylation do better.

FUTURE DIRECTIONS

Molecular Prediction

One of the current ideals for the medical field is to develop personalized or "precision" medicine for patients. For the oncology field, the identification of biomarkers for prognosis and response to therapy is of critical importance for achieving this ideal. Perhaps the most promising strategy toward personalized medicine in oncology has been the investigation of synthetic lethal interactions between two distinct pathways, which can be exploited therapeutically.[165] This concept of synthetic lethality is one in which mutation or loss of either of the two pathways individually has no effect on survival; however, mutation or loss of both leads to cell death. To this end, inhibitors of poly(ADP)-ribose polymerase (PARP) have come to the forefront for patients with BRCA-associated cancers.[166,167] PARP is involved in the base excision repair of single-stranded DNA

damage, which if left unrepaired, is converted into a double-stranded DNA break that can be repaired by the homologous recombination repair pathway mediated by BRCA. In patients with BRCA-associated tumors, which are homologous recombination repair defective, inhibition of PARP leads to significant cytotoxicity of tumors while sparing normal tissues, which are proficient in homologous recombination repair. This exciting therapeutic strategy has shown promise in multiple clinical trials and exemplifies the ultimate goal of personalized therapy—that is, to maximize therapeutic ratio.

The predominant investigative tools for biomarker discovery are related to genomics and proteomics, the study of global gene expression and protein expression, respectively. An emerging science is that of kinomics in which global kinase activity is determined. These expression or activation patterns of individual tumors can be correlated to outcomes including treatment response and survival endpoints. The hope is that diagnostic tests can be developed that will guide clinicians in selection of therapy. A brief description of each discovery tool is found here.

Genomics/Transcriptomics

The most actively studied component of molecular prediction uses genomic technology. Genomics refers to the genome-wide evaluation of individual gene expression. Pharmacogenomics refers to the study of genetic information to predict treatment response. There are a host of platforms for analyzing genetic information within a biologic specimen. One means is through evaluation of polymorphisms, which refers to a variation within a gene such that at least two alleles occur in 1% or more of the general population. When the variation occurs at a single nucleotide, this is termed a *single nucleotide polymorphism*, or SNP. Several groups have identified SNPs within DNA synthesis/DNA repair genes that could potentially serve as markers of response to radiation,[168] chemotherapy,[169] or chemoradiation.[170] Genome-wide SNP arrays are commonly used these days and have been applied to translational studies. Historically, though, the most widely used approach has been microarray-based, such as the GeneChip from Affymetrix (Santa Clara, CA). These arrays enable the analysis of relative expression of more than 38,000 genes on a single chip. However, with the advent of next-generation sequencing (NGS or "deep sequencing") ushering in lower costs and higher throughput, NGS approaches are largely replacing microarray-based methods. For example, the RNASeq approach can provide gene expression information (transcriptome) but also provide information about genomic alterations (at least for the expressed genome). Focused exome NGS is being used to identify drug-targetable mutations in patient tumors. NGS approaches are now the methodology of choice for The Cancer Genome Atlas (TCGA) project that is cataloging molecular data on 20 tumor types that has already identified many molecular subtypes among several cancer types.[171]

No matter what platform is used, the identification of genomic/transcoptomic differences between good and poor responders may eventually guide therapy decisions. A significant amount of work has been done in predicting breast cancer response to chemotherapy in vivo.[172] Similar studies for radiation and chemoradiation response are in various stages of development.

Proteomics

Proteomics is becoming an established platform for biomarker discovery. The predominant approach involves mass spectrometry to identify levels of proteins based on peptide fragments generated from enzymatic digestion of all of the proteins within a biologic specimen such as a biopsy, tissue sample, blood, urine, etc. This approach has been used for prognostic purposes in NSCLC[173] as well as prediction of sensitivity to chemoradiation in cervical cancer patients.[174] Miniaturization with nanofluidic assays[175] and novel dynamic-proteomics[176] approaches are providing more information and understanding regarding cellular response to drugs.

Kinomics

Although genomic and proteomic strategies are being used in translational components of several clinical trials with RTOG and other cooperative groups, these technologies have significant difficulty in detecting transient signaling events such as kinase activation. This is as a result of the fact that kinases are predominantly regulated posttranslationally, that is, they are subject to phosphorylation events, conformational changes, subcellular translocation, binding partnerships, etc. Kinomics, thus, refers to the global detection of kinase signaling events within a cell or tissue. There is a tremendous amount of preclinical data that demonstrates robust but transient activation of kinase-based resistance pathways downstream of ionizing radiation and chemotherapy.[177-181] Arguably, the most prominent class of next-generation therapeutics for oncology is kinase-targeted agents. In the near future, there may be a large repertoire of available kinase inhibitors that are available for therapy if we could only identify the patients most likely to benefit from them. Kinomic analysis may help guide therapy by identifying the critical kinase activations that predict for sensitivity or resistance to particular drugs. Although this technology is still in its infancy, kinomics may one day provide a complementary clinical tool to the genomic and proteomic strategies that are making their way into oncology practice. Indeed, the TCGA selected reverse phase protein arrays (RPPA) as their platform technology for functional proteomic evaluation of tumors.[182] Other translational research examples include kinomic profiling of pediatric brain tumors,[183] chondrosarcomas,[184] preclinical xenograft treatment response prediction,[185] chemoradiation response prediction in locally advanced rectal cancer patients,[186] and even for identification of novel radiation modulators.[187]

Patient-Derived Xenografts

One potential strategy to improve molecular prediction is to use better preclinical model systems for combination testing. Patient-derived xenografts (PDX, xenolines, or tumor avatars) have been increasingly used as preclinical model systems. PDX appear to more faithfully represent clinical reality because they are passaged within immunocompromised mice rather than cultured in plastic with high levels of serum. "-Omic" characterization and therapy response data have shown considerable promise leading many pharmaceutical companies and some academic institutions to incorporate PDX into their preclinical testing program. Indeed, several companies specializing in PDX production and therapy testing have emerged in recent years. One potential strategy for integrating PDX into therapeutic development is the concept of a "parallel mouse" clinical trial that can be performed in conjunction with an actual human clinical trial. The incorporation of the parallel mouse trial allows for a larger cohort of tumor specimens to be available for molecular characterization and biomarker development. The potential for PDX-informed clinical decision making could be possible with this approach.

SUMMARY

Multimodality therapy has become the mainstay of the vast majority of solid malignancies. Understanding the interaction between chemotherapy and radiation is, therefore, vital to improving patient care. With the addition of biologically targeted agents to the armamentarium of anticancer therapy, it

may be better to refer to chemotherapeutics and biologics simply as systemic agents. It is expected that clinical investigation will help validate as well as generate novel strategies in the laboratory. In addition, the establishment of useful biomarkers will hopefully usher in a new era of personalized oncologic medicine. In this way, exploitable differences between tumor tissue and normal tissue will be optimized for each patient.

CHAPTER

5 Biologics and Their Interactions with Radiation

Timothy V. Waxweiler and David Raben

Over the past decade, radiation oncology researchers have rapidly developed the capability of delivering "targeted" therapy using photon- or proton-based energies with the evolution of intensity-modulated radiation therapy (IMRT) and the incorporation of image-guided motion tracking. During this same decade, advances in molecular pathology have resulted in powerful predictive biomarkers such as KRAS, ALK, and BRAF that have ushered in a new era in cancer therapy, that of personalized cancer therapeutics. Improved understanding of the molecular mechanisms underlying malignant processes has allowed the development of novel therapeutic agents that target specific cellular processes. Molecularly targeted therapeutic agents, or biologics, are a class of agents that have been developed to specifically interfere with functions central to the pathophysiology of the malignant phenotype.

Although initially targeted in the single-agent setting and then with chemotherapy, many of these biologic pathways are also central to the radiation response; this finding raised the likelihood that some biologic agents may be effective radiosensitizers. A radiosensitizing effect has indeed been demonstrated clinically and in model systems. As biologically targeted drugs continue to gain prominence in the cancer therapy landscape, radiation oncologists should be familiar with therapies that their patients are likely to be receiving in conjunction with radiation. Furthermore, the potential for radiosensitization mandates that radiation oncologists become educated regarding the potential for these agents to exacerbate toxicity or improve efficacy in the standard radiotherapy setting. Finally, the potential to take advantage of the new biologics as radiosensitizers offers an exciting opportunity to improve local control for many tumor types treated with radiotherapy.

Before we can move forward we must ask why many of our preclinical studies, that at first glance appear promising, have failed to translate successfully in phase III clinical trials when combined with chemoradiation.[1,2] Over the past decade or so, we have, in fact, only demonstrated success in one phase III trial using an anti-EGFR antibody with radiation alone.[3] Perhaps the optimal preclinical studies were never performed to adequately evaluate optimal sequencing and whether adding a targeted agent to a chemoradiation backbone in fact could be antagonistic. Perhaps some of these targeted drugs might be best used as maintenance therapies after completion of chemoradiation. Perhaps dual targeting of specific pathways might provide improved local-regional control over traditional chemoradiation combinations and should be tested against standard of care. Do we need to dose biologically based approaches in a maximum tolerated drug (MTD) format similar to what we traditionally do with chemoradiation phase I trials? We have even gone as far as adding dual biologics to a chemoradiation backbone with little or no preclinical data to support its clinical translation, resulting in added toxicity.[4-7] These are critical questions that must be answered if we are to realistically move our field forward in a molecular age.

In a previous version of this chapter, the authors emphasized developments in the laboratory and in the clinic related to epidermal growth factor inhibition, antiangiogenesis, proteasome interference, DNA repair inhibitors, mTOR inhibitors, and insulin growth factor receptor inhibitors; and how these factors cooperate with radiation. In this edition, the clinical experience with familiar molecularly targeted drugs and radiation has been updated and streamlined; however, we intend to place an emphasis on selected newer agents that appear promising in a variety of disease sites. These include PI3K/Akt/mTOR pathway inhibitors, PARP inhibitors, and immunomodulating agents. Many additional agents are under investigation including "dirty" biologics, agents such as the multityrosine kinase inhibitors that target multiple pathways, although a detailed discussion of these agents is beyond the scope of this chapter. To provide some perspective, since the previous edition of this chapter was published in 2011, the number of biologics approved by the Food and Drug Administration (FDA) has more than tripled, from ~14 to more than 50 agents (Table 5-1). This update particularly focuses on emerging biologics believed likely to play an increasing role in clinical radiation oncology in the near future. What does the practicing radiation oncologist need to know as we witness a remarkable evolution in our understanding of molecular oncology and develop new insights in to radio-genomics to predict response and toxicity to radiation therapy? Next-generation sequencing is assisting in defining new targets within a cancer to personalize our therapeutic approaches and this information may be valuable in finding the optimal agents to combine with radiation within a specific disease site.

EPIDERMAL GROWTH FACTOR RECEPTOR FAMILY INHIBITORS

Epidermal Growth Factor Receptor Family Biology

The epidermal growth factor receptor (EGFR) family signaling process has captured significant attention clinically over the past 15 years as a targetable pathway that could be used in conjunction with radiation. Why is it important and how does it work? EGFR signaling regulates mesenchymal-epithelial interactions during growth and development, transmitting extracellular cues to intracellular signaling cascades.[10-12] The family has four known members: EGFR, HER2 (erbB2), HER3 (erbB3), and HER4 (erbB4). These membrane-spanning tyrosine kinase receptors contain an extracellular ligand-binding domain, a transmembrane domain, and an intracellular tyrosine kinase domain. These normally quiescent receptors are activated when ligand binds to the extracellular domain of a receptor monomer. Ligand binding induces a structural change that favors dimerization with the same member (homodimer) or a different member (heterodimer) of the family. When dimerized, the tyrosine kinase domains are activated and they phosphorylate key tyrosine residues in the intracellular domain, resulting in activation of several downstream signaling cascades.

The end result of receptor activation, proliferation, differentiation, migration, or survival signaling depends on many factors, including which receptor pairs are formed and for

TABLE 5-1 FDA-Approved Biologic Modifiers[8,9]

Agent	Class	Approved Indication	Key Toxicities
Afatinib[RT] (Gilotrif)	mTKI: HER2, EGFR	Metastatic NSCLC	Skin effects
Aflibercept[RT] (Zaltrap)	VEGFR fusion-protein antibody	Metastatic CRC	Hemorrhage, GI perforation, poor wound healing
Alectinib*	ALK inhibitor	Crizotinib-refractory NSCLC	Fatigue, GI effects
Alemtuzumab[RT] (Campath)	CD52 antibody	B-cell CLL	Cytopenias, infusion reactions
Axitinib[RT] (Inlyta)	mTKI: VEGFR, PDGFR, CKIT	Metastatic RCC	HTN, GI effects, fatigue
Belinostat (Beleodaq)	HDAC inhibitor	Peripheral T-cell lymphoma	Fatigue, GI effects, anemia, fever
Bevacizumab[RT] (Avastin)	Anti-VEGFR antibody	CRC; advanced NSCLC; metastatic RCC; recurrent glioblastoma multiforme; metastatic HER2-negative breast cancer	Hemorrhage
Bortezomib[RT] (Velcade)	Proteasome inhibitor	Multiple myeloma; mantle cell lymphoma	Cytopenias, GI effects, neuropathy
Bosutinib (Bosulif)	Src-Abl TKI	Ph(+) CML	GI effects
Brentuximab vedotin[RT] (Adcetris)	CD30 antibody-drug conjugate	Refractory Hodgkin lymphoma; anaplastic large cell lymphoma	Cytopenias, GI effects
Cabozantinib[RT] (Cometriq)	mTKI: RET, VEGFR, TIE2, MET, TRKB	Metastatic medullary thyroid cancer	Hemorrhage, GI perforation or fistula
Carfilzomib (Kyprolis)	Proteasome inhibitor	Refractory multiple myeloma	Cytopenias, GI effects
Catumaxomab (Removab)	CD3, EpCAM antibody	Malignant ascites	Fever, GI effects
Ceritinib* (Zykadia)	ALK inhibitor	ALK(+) metastatic NSCLC after crizotinib	Fatigue, GI effects, hyperglycemia
Cetuximab[RT] (Erbitux)	Anti-EGFR antibody	Irinotecan-refractory metastatic CRC with KRAS wt; HNSCC	Anaphylaxis, skin rash
CO-1686*	EGFR	EGFR(+) NSCLC with T790M resistance mutation	Hyperglycemia, GI effects, fatigue
Crizotinib[RT] (Xalkori)	ALK inhibitor	ALK(+) locally advanced or metastatic NSCLC	GI effects
Dabrafenib (Tafinlar)	BRAF inhibitor	Advanced melanoma with BRAF mutation	Skin effects
Daratumumab*	CD38 antibody	Refractory multiple myeloma	Cytopenias
Dasatinib[RT] (Sprycel)	mTKI: Src, BCR-ABL, CKIT, PDGFR, TKI	Refractory CML or Ph(+) ALL	Myelosuppression
Denileukin diftitox (Ontak)	CD25-directed diptheria cytotoxin	CD25(+) cutaneous T-cell lymphoma	Infusion reaction, capillary leak syndrome, vision loss
Denosumab (Xgeva)	RANK ligand inhibitor	Bone metastases prevention; giant cell tumor of bone	Musculoskeletal effects
Entinostat*	HDAC inhibitor	Advanced ER(+) breast cancer	Fatigue, neutropenia
Erlotinib[RT] (Tarceva)	EGFR TKI	Chemotherapy-refractory NSCLC; advanced pancreatic cancer with gemcitabine	Skin rash, diarrhea
Everolimus[RT] (Afinitor)	mTOR inhibitor	Advanced RCC; progressive neuroendocrine tumors of pancreatic origin; subependymal giant-cell astrocytoma in tuberous sclerosis; advanced breast cancer with exemestane	GI effects
Gefitinib[RT] (Iressa)	EGFR TKI	Advanced or chemotherapy-refractory NSCLC	Skin rash, diarrhea
Ibrutinib*	Bruton TKI	Mantle cell lymphoma; Waldenstrom macroglobulinemia; CLL	GI effects
Ibritumomab (Zevalin)	CD20 RIT	Relapsed or refractory low-grade or follicular B-cell NHL; follicular NHL with response to first-line chemotherapy	Infusion reactions, cytopenias, mucocutaneous reactions

Continued

TABLE 5-1 FDA-Approved Biologic Modifiers—cont'd

Agent	Class	Approved Indication	Key Toxicities
Imatinib[RT] (Gleevec)	BCR-ABL TKI	Philadelphia chromosome–positive CML or ALL; GIST; dermatofibrosarcoma protuberans; myelodysplastic/myeloproliferative disorders; systemic mastocytosis	Myelosuppression
Ipilimumab[RT] (Yervoy)	CTLA-4 antibody	Advanced melanoma	Autoimmune reactions
Lapatinib[RT] (Tykerb)	mTKI: EGFR, HER2	Refractory HER2 overexpressing advanced breast cancer with capecitabine	Rash, diarrhea
MPDL3280A*	PD-L1	Metastatic bladder cancer	Auto-immune reactions
Nilotinib[RT] (Tasigna)	BCR-ABL TKI	Ph(+) CML	QT prolongation
Obinutuzumab* (Gazyva)	CD20 antibody	CLL	Infusion reactions, cytopenias, PML
Ofatumumab* (Arzerra)	CD20 antibody	Refractory CLL	Cytopenias, GI effects
Palbociclib*	CDK4, CDK6	ER(+), HER2(–) advanced breast cancer	Cytopenias
Panitumumab[RT] (Vectibix)	Anti-EGFR antibody	Irinotecan-refractory metastatic CRC without KRAS mutation	Anaphylaxis, skin rash
Pazopanib[RT] (Votrient)	mTKI: VEGFR, PDGFR, CKIT	Metastatic RCC; advanced soft tissue sarcoma	Hepatotoxicity
Pembrolizumab* (aka lambrolizumab)	PD-1 antibody	Advanced melanoma	Autoimmune reactions
Pertuzumab[RT] (Perjeta)	Anti-HER2 antibody	HER2 overexpressing breast cancer with trastuzumab or docetaxel	Cardiomyopathy, embryo-fetal toxicity
Radium-223 (Xofigo)	Calcium mimetic	Castration-resistant prostate cancer with bone metastases	GI effects
Ramucirumab (Cyramza)	VEGFR	Advanced or metastatic gastric or gastroesophageal adenocarcinoma	GI effects, HTN, headaches
Regorafenib (Stivarga)	mTKI: VEGFR, PDGFR,KIT, RET, TIE2, FGFR, RAF, MAPK	Unresectable or refractory GIST; previously treated CRC	Hepatotoxicity
Rituximab[RT] (Rituxan)	CD20 antibody	Non-Hodgkin lymphoma; CLL	Infusion reactions, tumor lysis, mucocutaneous effects, PML
Romidepsin[RT] (Istodax)	HDAC inhibitor	Cutaneous T-cell lymphoma	GI effects
Temsirolimus[RT] (Torisel)	mTOR inhibitor	Advanced RCC	Rash, asthenia, GI effects
Tositumomab I-131 (Bexxar)	CD20 RIT	Relapsed or refractory follicular NHL	Hypersensitivity, cytopenias
Trametinib[RT] (Mekinist)	MEK inhibitor	Advanced melanoma	Cardiomyopathy, skin effects, GI effects
Trastuzumab[RT] (Herceptin)	Anti-HER2 antibody	HER2-neu overexpressing breast cancer	Cardiomyopathy
Sorafenib[RT] (Nexavar)	mTKI: VEGFR, PDGFR, Raf, c-KIT	Unresectable hepatocellular carcinoma; advanced RCC	Rash, diarrhea, HTN
Sunitinib[RT] (Sutent)	mTKI: VEGFR, PDGFR, c-KIT, Flt3	Advanced RCC; GIST; pancreatic neuroendocrine tumors	Rash, diarrhea, HTN
Vandetanib[RT] (Caprelsa)	mTKI: RET, VEGFR, EGFR	Unresectable or metastatic medullary thyroid cancer	QT prolongation
Volasertib*	Polo-like kinase inhibitor	AML	Cytopenias
Vorinostat[RT] (Zolinza)	HDAC inhibitor	Cutaneous T-cell lymphoma	GI effects
Vemurafenib[RT] (Zelboraf)	BRAF kinase	Unresectable or metastatic melanoma with BRAF mutation	Photosensitivity and other skin effects

[RT]Concurrent trials with radiation are ongoing or have been completed.

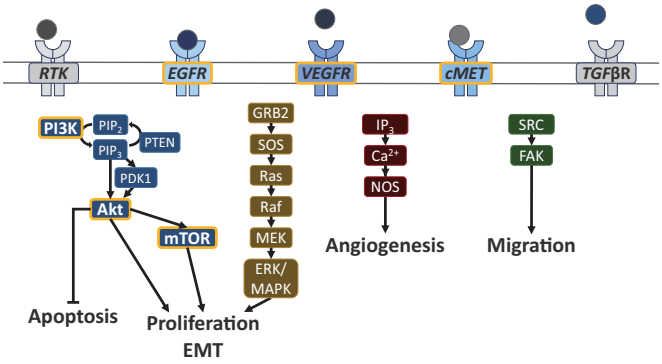

Figure 5-1 General overview of major signaling pathways involved in oncogenesis (many of the molecular targets emphasized in this chapter are outlined in yellow). Cell surface receptors (e.g., EGFR, VEGFR, cMET) normally bind various growth factors and small molecules initiating cell signaling pathways, which lead to maintenance of various cell processes. Mutations involved in up-regulated oncogene or down-regulated tumor suppressor activity lead to inhibition of apoptosis, cell proliferation, epithelial mesenchymal transition (EMT), angiogenesis, migration/invasion, and a variety of additional pro-oncogenic processes.

how long they are activated.[13] This in turn depends on which receptors are predominantly present in the cell and which ligand is involved in activation. There are two ligand families that activate the EGFR family receptors, the EGF-like and heregulin families.[14,15] The EGF-like family includes EGF, TGF-α, amphiregulin, betacellulin, and HB-EGF. The heregulin (neuregulin) family includes many proteins resulting from splice variations of two different genes, all designated as heregulin with different subtypes. The ligands exhibit preference for particular receptors and induce different receptor combinations. HER2 has no known ligand. Instead, HER2 is the favored partner of the other receptors when ligand binds to EGFR, HER3, or HER4.[16] This complex interplay of receptors is important for understanding and interpreting the effect of an inhibitor of a single member of the EGF family.

The effect of receptor activation also depends on which downstream signals are activated involving DNA synthesis and repair, apoptosis evasion, growth factor signaling, and proliferation. EGFR family members signal via a diverse network of signal transduction pathways, including the protein kinase C (PKC), Ras-Raf-ERK, PI3K-Akt, and STAT pathways[17] (Figure 5-1). Furthermore, various receptor pairs recruit different downstream effectors. For instance, HER3 contains multiple PI3K-binding motifs, resulting in strong signaling via PI3K, which plays a role in cell survival, invasion, and proliferation. Interestingly, HER3 alone among the receptors has an inefficient kinase domain, requiring heterodimerization with other family members to become phosphorylated. The need for heterodimerization juxtaposes the PI3K signal emanating from HER3 with the Ras-Raf-ERK or STAT signal emanating from EGFR, HER2, or HER4.

EGFR Family and Tumor Pathogenesis

In 1986, the Nobel Prize was awarded to Stanley Cohen for the discovery of growth factors, resulting from his work in identifying EGF and its receptor.[18] EGFR was first identified as a proto-oncogene because of its homology to the avian erythroblastosis (v-erb) oncogene.[19] Aberrant function of EGFR or HER2 occurs frequently in human tumors; gene amplification results in massive overexpression in a proportion of gliomas and breast cancers.[20-22] Alternatively, dysregulation occurs at more modest levels of expression when the receptor is activated as the result of autocrine stimulation, in which the tumor produces its own ligand to activate the receptor. This type of dysregulation occurs frequently in cancers of the head and neck, gastrointestinal system, and prostate gland.[23-26] Another mechanism of dysregulation is the development of mutations in the kinase domain that render the kinase activity more potent, most clearly demonstrated in lung cancer.[27] Likewise, mutations in the ligand-binding domain can cause the receptor to be constitutively active even in the absence of ligand, as occurs in a significant proportion of gliomas.[28] Dysregulation via mechanisms other than amplification may not always result in overexpression as detected by standard immunohistochemical techniques, raising the issue of how best to identify all tumors in which EGFR dysregulation promotes tumor proliferation and resistance to therapy.

EGFR Family Inhibitors

The frequent dysregulation of the EGFR family in tumors makes the family an attractive target for exploitation. Remarkable progress has been made in the development of EGFR family inhibitors.[29] Many antibodies directed against the extracellular domains of EGFR and HER2 and small-molecule tyrosine kinase inhibitors have now been approved by the FDA for clinical application, and many more are in various stages of development.[8,30]

The first EGFR family–targeted agent to be approved with radiation was cetuximab (Erbitux), an anti-EGFR monoclonal antibody that binds to the extracellular domain of EGFR, interferes with ligand binding and, hence, dimerization and activation.[31] Cetuximab has modest activity as a single agent but gives more encouraging results when it is combined with cytotoxic therapy. Cetuximab is typically given intravenously on a weekly schedule. When combined with radiation therapy, a loading dose is given the week before initiation of radiation treatment. Cetuximab has gained FDA approval for use in treating metastatic colorectal cancer and in locally advanced head and neck cancers. Initial approval for cetuximab in treating metastatic colorectal cancer was based largely on the results of a positive trial including 329 patients randomized to receive either cetuximab and irinotecan or cetuximab alone.[32] Further molecular analysis demonstrated that patients with KRAS mutations in codons 12 or 13 did not respond to cetuximab with survival benefits seen only in patients with wild type KRAS; this is presumably related to alternate activation of signal transduction pathways.[33,34] In head and neck cancers, we have yet to determine biomarkers that predict response to anti-EGFR therapy. This finding underscores the complexity of cancer biogenetics and marks an important turning point toward an era of personalized cancer therapy.

The anti-Her2 antibody trastuzumab and more recently pertuzumab, an antibody that inhibits Her2 heterodimerization, have been shown to improve outcomes for patients with Her2 overexpressing breast cancer.[35-37] These agents are currently recommended for combined use by the National Comprehensive Cancer Network (NCCN) in a variety of stages and settings. Additional investigations are ongoing in other cancers with Her2 overexpressing, including esophageal and salivary duct tumors.

Further discussions regarding the use of EGFR inhibitors alone or with chemotherapy are beyond the scope of this chapter, however, we provide references related to these avenues.[38-44] Our focus is a review of the use of these agents with radiation preclinically and the successes and failures in the clinical arena. One of the most frustrating aspects of this combination is the fact that we still struggle with a lack of predictive biomarkers related to response to EGFR inhibitors. Is it the ligand presence that predicts response? Does the

presence of an EGFR mutation always predict response to EGFR inhibitors in diseases like lung cancer, or do we need to dig deeper?[45] Is it based on gene amplification or high gene copy numbers in EGFR wild type cancers?[46]

Several small-molecule tyrosine kinase inhibitors targeting EGFR have gained FDA approval: gefitinib (Iressa), erlotinib (Tarceva), afatinib (Gilotrif), and lapatinib (Tykerb). These compounds specifically inhibit the tyrosine kinase activity of an EGFR family receptor while relatively sparing the other EGFR family members and related tyrosine kinases. Gefitinib and erlotinib act on EGFR; lapatinib is active against HER2; and afatinib targets both EGFR and HER2. These small-molecule agents have shown modest benefits in patients with advanced malignancies (primarily in patients with EGFR mutations); however, they have yet to demonstrate any significant benefits in phase II/III clinical trials with irradiation. One phase II trial of erlotinib with temozolomide and radiation in patients with newly diagnosed glioblastoma multiforme (GBM) exhibited unacceptable toxicity with multiple treatment related deaths and no evidence of increased efficacy.[47]

The primary toxicity of both gefitinib and erlotinib occurs in the skin, similar to cetuximab, and as diarrhea. However, infrequent cases of serious, life-threatening interstitial lung disease have also been reported for both agents, as well as anaphylactic reactions in approximately 3% of patients treated with cetuximab. Because these reactions can be life threatening, careful monitoring is required with these agents.

EGFR Family and Radiation Response

EGFR family members play an important role in radiation response. Preclinical studies showed that cells made to express v-erb were rendered radioresistant.[48] Similarly, breast cancer cell lines become more radioresistant when made to overexpress HER2, and head and neck cancer cell radioresistance correlates with EGFR expression levels.[49-52]

Clinical studies also suggest that EGFR family dysregulation influences radiation response. A study of 170 gliomas treated with primary radiotherapy demonstrated lower response rates in tumors that overexpressed EGFR; the response rate was 33% in EGFR-negative tumors, 18% in EGFR-intermediate tumors, and 9% in EGFR-positive tumors.[53] In smaller series of patients with head and neck cancers, locoregional recurrence after radiotherapy was associated with EGFR overexpression.[54,55] In breast cancer, a case-control series of patients with in-breast tumor recurrence after breast-conserving surgery and radiotherapy found that the proportion of patients with HER2 overexpression was higher in the recurrence group than in the controls.[56]

Preclinical Studies of EGFR Family Inhibitors as Radiosensitizers

The role of EGFR family members in radiation response was further clarified by studies using newly developed EGFR family inhibitors. In virtually every study, EGFR or HER2 inhibitors demonstrated modest radiosensitization.[57-59] Radiosensitization is more pronounced in vivo than in vitro and with fractionated-dose than with single-dose irradiation. The understanding of the mechanisms underlying enhanced radiosensitization is evolving.[60-62] In every case, the combination of EGFR or HER2 inhibitors and radiation resulted in increased cell cycle arrest, predominately in the G1 phase, but with a substantial decrease in S phase, which translates in vivo to decreased proliferation. Radiosensitization with EGFR family inhibitors also causes decreased angiogenesis. It is not yet clear whether this is an additive result of combined antiangiogenesis effects from both radiation and EGFR inhibitors, or whether the EGFR inhibitors further increase the susceptibility of the vascular elements of the tumor to radiation. The combination of EGFR inhibitors and radiation increases apoptosis in some, but not all, models. Finally, EGFR inhibitors appear to directly interfere with EGFR induced DNA-PK-dependent nonhomologous end joining repair of radiation-induced DNA damage.[63,64] What is lacking in past studies were designs that actually mimicked what we do in the clinic, including comparing chemoradiation to chemoradiation plus an EGFR inhibitor for example in the disease setting to be clinically studied rather than extrapolating from another tumor type. These types of studies, albeit performed in somewhat artificial systems, might have provided valuable information as to the best way to move forward in a clinical trial.

Clinical Studies of EGFR Family Inhibitors as Radiosensitizers

Promising preclinical studies with EGFR family inhibitors have translated into improved patient outcomes in randomized controlled trials when added to radiation alone primarily in patients with locally advanced head and neck squamous cell carcinoma (LA-HNSCC). The most mature of these is a phase III trial that compared the efficacy of standard radiotherapy with standard radiotherapy plus the anti-EGFR antibody cetuximab. In this study, 424 patients with LA-HNSCC of the oropharynx, hypopharynx, or larynx were stratified by T stage, nodal status, and performance status and then were randomly assigned to receive radiotherapy alone or radiotherapy plus weekly concurrent cetuximab. Radiotherapy was delivered using one of three fractionation regimens (stratified): a once-daily regimen (2 Gy × 35 fractions over 7 weeks), a twice-daily regimen (1.2 Gy × 60 to 64 fractions over 5 to 5.5 weeks), or a concomitant-boost regimen (1.8 Gy × 30 fractions with a second daily fraction of 1.5 Gy for the last 12 treatment days over 6 weeks). Concurrent chemotherapy was not allowed. Two-year local control was 56% in the radiotherapy-plus-cetuximab arm versus 48% in the radiotherapy-alone arm, with a median duration of local control of 36 months versus 19 months, respectively ($p = 0.02$).[65] Overall survival was also significantly enhanced with combined therapy. A recent update reported 45.6% 5-year overall survival in the radiotherapy-plus-cetuximab arm versus 36.4% in the radiotherapy-alone arm, with median survival of 49 months versus 29 months, respectively ($p = 0.018$).[3]

Although concern for unwanted normal tissue effects when combining targeted drugs against EGFR and radiation therapy alone is justifiable, the additional morbidity of this approach appears minimal based on the experiences in the clinic to date. In the study by Bonner et al,[65] the improvement in outcome was associated with an increase in acute skin, but not mucosal, toxicity. Furthermore, there were no differences between the groups on standardized quality-of-life assessment scores. Interestingly, a grade 2 or greater acneiform rash correlated with better survival rates (HR 0.49, $p = 0.002$). This correlation, seen in other studies in multiple disease sites, has been hypothesized to be reflective of an anticancer immune response.[66,67] In a separate trial, concurrent administration of adjuvant radiotherapy with trastuzumab in patients with early-stage breast cancer did not increase the incidence of acute radiation toxicity.[68]

Results have been mixed in trials of EGFR inhibitors added to combination chemotherapy and radiation. RTOG 0234, a phase II randomized trial comparing radiation plus cetuximab and either weekly cisplatin or weekly docetaxel in patients with LA-HNSCC, suggest that both regimens are feasible with outcomes superior to results from RTOG 9501 that used high-dose cisplatin on days 1, 22, and 43.[69] Grade 3 to 4 myelosuppression was observed in 28% (cisplatin) and 14% (docetaxel) of patients. Dermatitis was seen in 39% of patients in each

group. The rates of grade 3 or higher mucositis were 37% and 33% in the cisplatin and docetaxel arms, respectively; these rates seem low but are encouraging compared with historical controls. The 2-year distant metastasis rate was 13% in the group that received docetaxel and cetuximab versus 26% with cisplatin and cetuximab. One of the conclusions from this trial is that perturbing growth factor signaling may allow us, under the right circumstances, to reduce administration of high doses of standard chemotherapy and reduce patient morbidity. The addition of cetuximab to the current standard of cisplatin and radiotherapy for LA-HNSCC was evaluated in the phase III RTOG 0522 with abstract only results thus far showing no improvement in progression-free survival (PFS) or overall survival (OS), equivalent overall grade 3 to 5 toxicities, and increased grade 3 or higher mucositis and skin reactions in patients receiving chemoradiation with cetuximab versus chemoradiation alone.[1] In the phase II trial ACOSOG Z4051, 70 patients with locally advanced esophageal adenocarcinoma received preoperative therapy with the EGFR monoclonal antibody panitumumab added to docetaxel, cisplatin, and radiation.[7] Despite 54% of patients showing at least a near pathologic complete response, nearly half of all patients had grade 4 or higher toxicities making this regimen unsuitable for further study. To our knowledge, this type of combination was not studied preclinically to assess its efficacy and safety before going forward into a clinical trial.

An alternative strategy is to evaluate the use of induction chemotherapy before combination EGFR inhibition and radiation. The TREMPLIN study, a phase II randomized trial, directly compared the addition of cisplatin versus cetuximab to radiation for 116 patients with LA-HNSCC of the larynx/hypopharynx with a greater than 50% response following three cycles of traditional induction chemotherapy.[70] Larynx preservation at 3 months, larynx function at 18 months, and overall survival at 3 years demonstrated equivalent outcomes. Local failures were slightly higher in the cetuximab arm (8 vs. 5), but only the patients in the cetuximab arm eventually underwent salvage surgery (7 vs. 0). Grade 3 or higher rates of mucositis were similar between arms, and skin toxicity was roughly doubled in the cetuximab arm; however, acute renal toxicity was substantial in the cisplatin plus radiotherapy arm. This suggests that perhaps by using induction chemotherapy we may be able to study combinations of biologically targeted agents without the added toxicity of conventional chemotherapy agents, assuming the preclinical studies support this approach. An additional trial, the Gruppo di Studio Tumori della Testa e del Collo (GSTCC) trial, employed a 2×2 factorial design for 421 patients with LA-HNSCC randomized with and without induction chemotherapy and randomized to concurrent radiation with either cetuximab or cisplatin.[71] Abstract results showed similar response rates, PFS, and OS between patients receiving cetuximab versus cisplatin. Toxicity rates were also similar between the two groups and patients receiving cetuximab actually required more treatment interruptions with a median radiation therapy (RT) duration of 8 weeks versus 7 weeks in the cisplatin arms. Additional retrospective analyses examining cetuximab versus cisplatin have suggested that cisplatin provides better local control but similar overall survival outcomes.[72,73]

Why the failures to date? As mentioned at the beginning of this chapter, perhaps the optimal preclinical studies were never performed. Often, biologic agents like EGFR inhibitors are combined with radiation in the laboratory and the assumption is made that this will be just as effective, if not more so, when combined clinically with chemoradiation. Preclinical studies must seek to optimize clinically relevant standards to truly understand the optimal sequencing and combinations for integrating EGFR inhibitors with, and perhaps without, radiation, chemotherapy, and additional biologics. Currently, multiple RTOG trials continue to address these issues in head and neck cancers in the setting of intermediate or high-risk postoperative settings (i.e., 0920, 1216) and oropharynx cancers that are positive for human papillomavirus (HPV) (i.e., 1016). Additional RTOG trials examining EGFR targeting concurrently with radiation include RTOG 0839 using panitumumab in locally advanced NSCLC, RTOG 0974 with trastuzumab for Her2 positive breast ductal carcinoma in situ, and RTOG 1010 employing trastuzumab for locally advanced esophageal adenocarcinoma. These are a handful of examples of the ongoing efforts needed to cull out which patients benefit from targeting a particular pathway such as epidermal growth factor signaling and which patients, based on specific mutations, may need interference with Akt, mTOR, or DNA repair pathways in addition to or in lieu of traditional chemotherapy approaches.

ANGIOGENESIS INHIBITORS

Angiogenesis and Tumor Pathogenesis

All tumors require development (or expansion) of blood vessels to promote further tumor growth and nutritional support beyond a 2-mm diameter.[74] Molecules such as vascular endothelial growth factor (VEGF) mediate stimulation of angiogenic signaling and neovascularization. Elevated levels of specific isoforms of VEGF and other indirect markers predict for a worse prognosis in many types of cancer, including those of the gastrointestinal tract, such as pancreatic and esophageal cancers.[75,76] VEGF expression is affected by both the genetic aberrancies of the particular cancer as well as the microenvironmental changes, including hypoxia.

Once VEGF binding activates VEGF-receptor signaling, a cascade of transcriptional signals to promote blood vessel formation is set in motion (see Figure 5-1). Tumors develop a nutritional support system by borrowing existing blood vessels, growing new vessels from surrounding endothelium, and entrapping circulating endothelial stem cells. In contrast to mature vessels, developing tumors display vessels that are immature and chaotic, with a resultant lack of cohesion within the vessel matrix. As a result of increased permeability, blood perfusion through the tumor can be heterogeneous. This can lend itself to areas of hypoxia, which in turn results in activation of pro-angiogenic molecules such as HIF1 and nuclear factor kappa B (NFκB). Transcriptional activation occurs with further production of VEGF and additional pro-angiogenic proteins such as cyclooxygenase (COX)–2, Tie-2, osteopontin, histone deacetylase, and hepatocyte growth factor. An autocrine and paracrine cascade is created to further tumor growth and invasion.

Angiogenesis Inhibitors

Three main strategies under preclinical or clinical investigation exemplify the important concepts underlying angiogenic inhibition: (1) small-molecule tyrosine kinase inhibitors (TKIs) that target vascular endothelial growth factor receptor (VEGFR) signaling, (2) agents that directly target the tumor vasculature, or vascular targeting agents (VTAs), and (3) agents that inhibit VEGF.

Multiple VEGFR-TKIs have now gained FDA approval including sorafenib (Nexavar), sunitinib (Sutent), axitinib (Inlyta), pazopanib (Votrient), regorafenib (Stivarga), vandetanib (Caprelsa), and cabozantinib (Cometriq). Many of these biologics target multiple TKIs in addition to VEGFR signaling. They are indicated for treatment of a variety of cancers including unresectable hepatocellular carcinoma, advanced or metastatic renal cell carcinoma, metastatic colorectal cancer,

gastrointestinal stromal tumors, advanced soft-tissue sarcomas, and metastatic medullary thyroid cancer based on positive results of phase III randomized studies. Vandetanib and cabozantinib are active against VEGFR, EGFR, and more specifically RET kinase, a mutation present in the majority of patients with sporadic or inherited medullary thyroid cancer. These drugs have now been FDA approved for advanced or metastatic medullary thyroid carcinoma following phase III trial results with each significantly prolonging PFS.[76-80]

Agents that target the microtubule formation of intratumoral vasculature, thus destabilizing vessels and causing rapid necrosis within the central part of the tumor, might be effective compounds to combine with radiation. The rationale for pursuing agents that attack intratumoral vessels is based on the premise that endothelial cells in tumors display a different growth pattern than those in normal tissues; it is a chaotic, rapidly expanding pattern. VTAs were developed to take advantage of this differential to selectively occlude or destroy tumor blood vessels. Little progress has been achieved in clinical trials with VTAs, in part because of issues related to cardiac toxicity; however, this remains a potentially promising approach.

An alternative approach, inhibiting VEGF using an anti-VEGF monoclonal antibody is akin to scooping up the keys rather than blocking the lock. Antibodies against VEGF have shown anticancer activity in a variety of preclinical models.[81] Bevacizamab (Avastin) is a recombinant humanized version of the murine antihuman VEGF monoclonal antibody rhuMAb VEGF. Bevacizumab is FDA approved for use in patients with metastatic colorectal cancer when used in combination with 5-fluorouracil (5-FU). Two separate clinical trials demonstrated superior response rates, PFS, and OS in patients treated with combined 5-FU–based therapy with bevacizumab compared with others treated with 5-FU–based therapy alone in either the first- or second-line setting.[82,83] The addition of bevacizumab to carboplatin and paclitaxel also improved overall survival in chemotherapy-naïve patients with metastatic or recurrent, nonsquamous non–small cell lung cancer (NSCLC) and has been approved for use in patients with recurrent GBM, based on trials demonstrating good rates of radiographic response and stable to decreased corticosteroid requirement.[84,85] Improvements in PFS have also been demonstrated in patients with renal cell carcinoma and breast cancer receiving combinations of traditional systemic therapy and bevacizumab.[86] These promising clinical results in the advanced setting have prompted further investigations in the locally advanced setting with radiation.

Preclinical Studies of Angiogenesis Inhibitors as Radiosensitizers

At first glance, one might hesitate to consider blocking angiogenesis from a radiation oncology perspective. If sequencing is not optimal, blocking angiogenesis might to lead to increased hypoxia and reduced tumor control. In fact, the last 10 years have demonstrated the opposite effect: enhanced radiation sensitivity with anti-VEGF agents in the laboratory. Early work by Teicher et al[87-90] demonstrated enhanced radiation cytotoxic effects in a variety of antiangiogenic models. Antiangiogenic agents may enhance the effect of radiation by stabilizing tumor vasculature, thereby enhancing tumor oxygenation.[91] By inhibiting proangiogenic signaling, regulation of antiapoptotic proteins such as amplified NFκB may be improved. Many of these molecules, including VEGF, are activated by radiation, so reversing this process seems logical.

In the clinical trial setting, we have typically combined antiangiogenic agents with chemoradiation; however, we struggle with determining the optimal sequencing. To this end, there have been preclinical studies looking at this issue. ZD6474, a dual VEGFR/EGFR inhibitor, was evaluated with radiation in a xenograft model bearing EGFR-TKI–insensitive NSCLC Calu-6 tumors.[92] Two combined treatment schedules were examined: (1) a concurrent schedule using ZD6474 (50 mg/kg) dosing given 2 hours before the first dose of radiation, and (2) a sequential schedule using ZD6474 dosing given 30 minutes after the last dose of radiotherapy. The sequential approach was superior in terms of the time for treated tumors to quadruple in volume (RTV4) from their pretreatment size ($p < 0.0001$). Importantly, the reduced RTV4 (30 ± 1 day) in the concurrent schedule was also significantly better than either ZD6474 or radiation alone ($p < 0.02$). Nevertheless, clinical trials tend to simply combine these agents concurrently with chemoradiation, ignoring preclinical results.

Similar to studies showing enhanced radiation effects with VEGFR signaling interference, studies combining anti-VEGF antibodies with radiation confirmed that although exposure of human tumor xenografts to radiation promoted induction of VEGF expression, inhibiting VEGF with anti-VEGF antibodies supplanted this effect and resulted in increased endothelial cell killing and synergized antitumor effects in murine tumor model systems.[93]

Clinical Studies of Angiogenesis Inhibitors as Radiosensitizers

Unfortunately limited success has been realized in the clinic. In locally advanced rectal adenocarcinoma, initial phase I studies by Willett et al[94] in rectal cancer brought to light clinical evidence of the vascular normalization hypothesis in which regulation of tumor vasculature may impair entry of metastatic cells into circulation while improving drug delivery and tumor oxygenation for radiosensitization. Multiple subsequent trials have examined the efficacy of either anti-VEGF or anti-EGFR therapies added to standard preoperative chemoradiation regimens for rectal cancer with modest pathologic complete response (pCR) rates ranging from ~10% to 20%.[5,95,96] One recent phase I/II trial examined the combination of bevacizumab and erlotinib with 5-FU and radiation in this setting with an encouraging pCR rate of 33% (9/27) although ~47% of patients experienced at least one grade 3 to 4 toxicity.[5]

In patients with GBM, two recently published major randomized phase III trials examined the addition of bevacizumab versus placebo to standard temozolomide and radiation in newly diagnosed patients.[97,98] Both RTOG 0825 ($n = 637$) and AVAglio ($n = 921$) showed a significant PFS improvement of ~4 months with bevacizumab, but similar overall survival outcomes between arms with a median survival of ~16 to 17 months. MGMT status did not influence response rates between arms in both trials. In the RTOG trial, patients receiving bevacizumab showed higher rates of decline in neurocognitive function and quality of life; whereas in the AVAglio trial, quality-of-life outcomes were improved in patients receiving bevacizumab. Adverse events were modestly increased in the bevacizumab arms of both trials. In the context of these results, the role of bevacizumab in upfront GBM treatment remains unclear.

Results have been more cautionary in combining bevacizumab with EGFR targeting and radiation in lung cancer. Based in part on promising results with bevacizumab and erlotinib in patients with metastatic NCSCL, several phase I/II trials in locally advanced lung cancer have been completed. Bevacizumab and chemoradiotherapy were associated with a concerning incidence of tracheoesophageal fistula and aerodigestive hemorrhage in 3 of 29 patients with small cell lung cancer and NSCLC.[99] A more recent phase I/II trial treated 45

patients with stage III NSCLC with induction, concurrent, and consolidative regimens of bevacizumab and erlotinib with radiation and chemotherapy.[4] Both PFS and OS results were not significantly different from current published results with standard chemoradiation, and on the downside, a significantly higher than expected 29% of patients on this trial had grade 3 to 4 esophagitis. Of note, the radiation in this trial treated elective mediastinal lymph nodes and used three-dimensional conformal radiotherapy to a total dose of 74 Gy (a dose recently shown to have inferior OS when compared to the standard 60 Gy by RTOG 0617); these combined factors likely contributed at least partially to the increased esophagitis rate.[100] The SWOG trial S0533 also attempted to integrate bevacizumab with chemoradiation in a three-step design with administration with docetaxel in the consolidation phase after cisplatin-etoposide and radiation.[101] Because of poor accrual and Cancer Therapy Evaluation Program (CTEP) warnings regarding toxicity, the trial was stopped early. Two of seven patients in the high risk cohort experienced grade 5 hemoptysis.

Bevacizumab as a radiosensitizer has also been studied in cervical cancer with a recently completed RTOG 0417 trial giving the agent every 2 weeks for three cycles during concurrent cisplatin and radiotherapy in 49 patients with stage IB-III disease.[102] With primary endpoints focused on adverse events, this trial noted minimal protocol-defined toxicity with 13 patients (26.5%) having grade 3 toxicities; 5 patients (10.2%) experiencing grade 4 toxicity; and no grade 5 toxicities. The majority of all toxicities were hematologic. In terms of efficacy, 3-year rates showed an 81% OS, 69% disease free-survival, and 23% loco-regional failure.[103] These outcomes are on par with published major trials using standard chemoradiation in cervical cancer.[104]

Thus, in 2014, we are still searching for successful clinical combinations of antiangiogenic agents with radiation in a multitude of disease sites with no positive phase III trials to demonstrate that this strategy is working. Jackson et al[105] further discuss the current use of bevacizumab in combined modality settings with an emphasis on cervical cancer in their recent review, providing the reader with a comprehensive discussion of current and future avenues.

PI3K/Akt/mTOR PATHWAY, INHIBITORS, AND RADIOSENSITIZATION

One of the most important pathways related to cancer cell survival, the PI3K/Akt/mTOR kinase pathway (see Figure 5-1), is a central regulator of cell metabolism, proliferation, and survival by preventing apoptosis. Furthermore, PI3K/Akt/mTOR is up-regulated in many tumors and can also be up-regulated with radiation.[106] Selective and pan-PI3K inhibitors, PI3K and mTOR dual inhibitors, Akt inhibitors, and mTOR inhibitors are all being developed. Given the variety of targets and specificities of these agents, current research has focused on their efficacy, resistance, and toxicity profiles in a wide range of tumors, especially those with pathway alterations (e.g., loss of PTEN, KRAS mutations, and TSC1/2 alterations).[107]

The agents furthest along in development to date are mTOR inhibitors, primarily rapamycin analogs. These include temsirolimus and everolimus, which block signal transduction downstream of mTOR and facilitate apoptosis, suggesting effectiveness as radiosensitizing agents. Currently these two drugs are approved for clinical use in advanced renal cell carcinoma, and everolimus is also approved for pancreatic neuroendocrine tumors, subependymal giant-cell astrocytomas, and advanced breast cancer with exemestane.[108-110] Their clinical role as radiosensitizers is less established but is an active area of research.

To date, preclinical cancer cell models have demonstrated radiosensitizing effects of mTOR inhibitors.[111,112] Temsirolimus is as effective as cisplatin in radiosensitizing HNSCC lines, and triple-combination therapy did not provide additional cooperative effects over temsirolimus with radiation.[112] The in vivo effects were more dramatic partly because of an antiangiogenic byproduct of mTOR inhibition.

The radiosensitizing role of mTOR inhibitors continues to be investigated through clinical studies with mixed results. In a phase I trial of temsirolimus combined with palliative thoracic radiation in patients with NSCLC, dose-limiting toxicities included sudden death, pneumonitis, and pulmonary hemorrhage; however a safe maximum tolerable dose level was achieved.[113] Three separate phase I trials have examined the combination of radiation, temozolomide, and an mTOR inhibitor (i.e., temsirolimus or everolimus) in patients with GBMs, and infectious complications and stomatitis were the primary toxicities.[114-116] These trials have provided the basis for the phase I/II RTOG 0913 trial (i.e., everolimus with radiation and temozolomide up front and in combination with adjuvant temozolomide in GBMs) and the phase II EORTC 26082 (i.e., temsirolimus versus temozolomide in both the concurrent radiation and adjuvant settings for patients lacking methylation of the MGMT promoter with gliomas). In LA-HNSCC, the mTOR pathway has been shown to mediate expression of eukaryotic protein synthesis initiation factor 4E (eIF4E), with elevated eIF4E expression in histologically cancer-free margins associated with increased risk for recurrence. Based on this evidence, Fury et al[117] performed a phase I trial adding everolimus to standard of care concurrent cisplatin and radiation therapy in 13 patients with LA-HNSCC. Three patients experienced dose-limiting toxicities (i.e., two with mucositis, one with failure to thrive), and lymphopenia was the most common grade ≥3 adverse event seen in 12 patients (92%). Overall, a tolerable everolimus dose of 5 mg daily was found, and at 19.4 months follow-up, only 2 patients (15%) had experienced recurrent disease. Translation of these results into phase II and III trials and beyond is anticipated.

The remaining classes of PI3K/Akt/mTOR pathway inhibitors are still in their infancy with many additional phase I/II trials under way.[118] Several investigations are specifically examining their potential as radiosensitizers in both curative and palliative settings including LA-HNSCC, NSCLC, and malignant gliomas. Emerging data in HPV-positive head and neck cancers suggest an increased prevalence of PI3 kinase (PI3K) pathway mutation and copy number alterations.[119] In HPV-positive tumors harboring PI3K mutations mTOR appears activated rather than AKT downstream and thus may be a reasonable target to combine with radiation for this subgroup of patients.[120] A phase I trial of BKM120 or buparlisib, an oral PI3K inhibitor with cisplatin-radiation, is in the process of opening in patients who are HPV positive with locally advanced head and neck cancers.[8] Next-generation sequencing is a powerful tool that continues to deliver new information on the genomic landscape of many cancers including head and neck and should lead to more personalized cancer care.[121]

DNA REPAIR INHIBITORS: FOCUS ON PARP

PARP and DNA Repair

Up-regulated DNA repair within cancers contributes to radioresistance and is a concept across all histologies. DNA damage from radiation or chemotherapy results in a variety of mechanisms that attempt to fix both single- and double-stranded breaks quickly, so cancer cells can continue to replicate and grow. To counteract this repair, one promising strategy incorporates the use of poly(ADP-ribose) polymerase (PARP)

inhibitors. The PARP family consists of 17 proteins with PARP-1, 2, 3, and 4 and Tankerase 1 and 2 playing key roles in posttranslational modification of proteins involved in multiple pathways.[122,123] PARP-1 is the most heavily studied of these enzymes and is activated by base damage, single-stranded DNA breaks, and double-stranded DNA breaks caused by insults, including chemotherapy and ionizing radiation.[124] Activation leads to poly(ADP-ribosyl)ation of PARP-1, nicotinamide adenine dinucleotide (NAD+) consumption, a localized negative charge, and direct enzyme interactions with subsequent interaction of multiple pathways involving DNA repair (especially XRCC1), chromatin restructuring, and cell-cycle check points (Figure 5-2).[125]

Initial interest in PARP inhibition in oncology stemmed from the concept of synthetic lethality in which cancer cells with preexisting deficiencies in homologous-recombination pathways (e.g., BRCA mutations) exhibit selective cytotoxicity to single agent PARP inhibitors. Although many complex interactions occur with PARP inhibition, these cancer cells' susceptibility is in part attributed to their reliance on PARP-dependent DNA repair pathways such as base excision repair.[126] Remarkable activity has been observed in patients with BRCA1/2 mutations in a phase I study using olaparib (AZD2281), an orally bioavailable PARP inhibitor.[127] Importantly, minimal toxicity was observed in doses up to 600 mg twice a day. Objective antitumor activity was reported only in mutation carriers (22/60 patients entered, all of whom had refractory ovarian, breast, or prostate cancer). Two subsequent international phase II trials in patients with metastatic BRCA1/2 mutated breast ($n = 57$) and ovarian cancers ($n = 54$), respectively, treated two cohorts with the oral PARP inhibitor olaparib at doses of 400 mg twice daily (i.e., the maximum tolerated dose) and 100 mg twice daily.[128,129] These trials saw objective response rates of ~30% to 40% in the high-dose groups and ~10% to 20% in the low-dose groups. Both trials reported mostly low grade toxicities with grade 3 to 4 toxicities limited to fatigue, nausea, vomiting, and anemia.

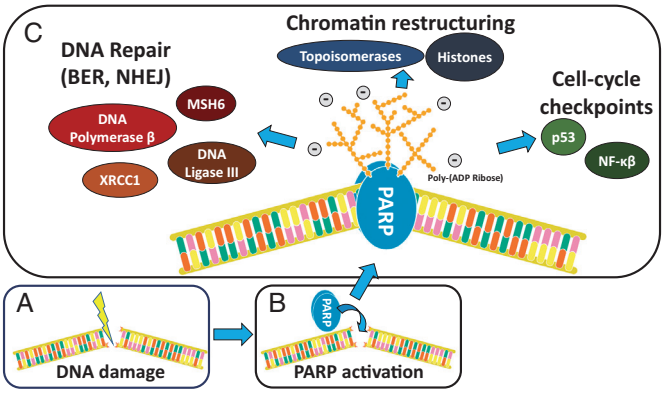

Figure 5-2 Overview of the role of poly(ADP-ribose) polymerase (PARP) activation in response to DNA damage from chemotherapy or irradiation. Activation of PARP triggers various DNA repair pathways, cell cycle regulation, and regulation of gene expression facilitated by chromatin restructuring.

Beyond synthetic lethality, PARP inhibitors show promise as chemosensitizers and radiosensitizers by directly preventing cancer cells from repairing induced DNA damage. In the preclinical setting, many groups have shown the ability of PARP inhibitors to sensitize a variety of histologies, both p53 wild type and null, to radiation in both in vitro and in vivo settings.[130-136] These results are rapidly being translated into the clinic with open phase I and II trial using a variety of PARP inhibitors with radiation and additional systemic agents in sites including central nervous system (CNS), head and neck, breast, lung, esophagus, pancreas, and rectum (Table 5-2).[8] Additional trials have focused on PARP inhibitors with DNA damaging chemotherapies, particularly temozolomide. Specifically, the current RTOG 0929 trial is exploring the use of the oral PARP inhibitor ABT-888 with temozolomide for patients with recurrent GBMs.[137] In development through the NRG (National Surgical Adjuvant Breast and Bowel Project (NSABP), the Radiation Therapy Oncology Group (RTOG), and the Gynecologic Oncology Group (GOG)) cooperative group mechanism is a trial that will evaluate this compound with radiation in patients with newly diagnosed GBM. Of note is the fact that PI3K inhibitors can down-regulate BRCA1/2, suggesting a possible dual targeting approach with these agents and PARP inhibitors to prevent homologous recombination and DNA damage repair.[138]

CHK1 and WEE1

In addition to PARP inhibitors, recent investigations into targeting DNA repair related cell-cycle proteins CHK1 and WEE1 have begun to generate excitement for their role as radiosensitizers. In response to DNA damage, these proteins help mediate both the S and G_2 phase checkpoints.[139] Both CHK1 and WEE1 are up-regulated in P53 mutated cancers, which already bypass the G1 checkpoint.[140] Theoretically, inhibition of either CHK1 or WEE1 would render P53 mutant cancer cells susceptible to DNA damaging treatments such as radiation resulting from critical checkpoint failures, while allowing normal tissues, with intact G1 checkpoints, to remain relatively unaffected. Although lacking preclinical data, several phase I

TABLE 5-2 Select PARP Inhibitors Currently Undergoing Clinical Trials[8,9]

Agent	Manufacturer	Sites
BMN-673	Biomarin	BRCA(+) breast, solid tumors, hematologic malignancies
CEP-9722	Cephalon	NSCLC
E7449	Eisai Incorporated	Advanced solid tumors or B-cell malignancies
Iniparib	Sanofi	Breast, NSCLC
Niraparib	Tesaro	Ovarian, BRCA(+) breast
Olaparib	AstraZeneca	BRCA(+) ovarian, gastric, NSCLC, glioblastoma, esophagus, HNSCC, CRC
Rucaparib	Clovis Oncology	Ovarian, fallopian tube, peritoneal,
Veliparib	Abbott Labs	Pancreatic, ovarian, cervical, breast, NSCLC, DPG, SCLC, liver, prostate, melanoma, metastatic solid tumors, leukemia, myeloma,

CRC, *Colorectal carcinoma;* DPG, *diffuse pontine glioma;* HNSCC, *head and neck squamous cell carcinoma;* NSCLC, *non–small cell lung cancer;* SCLC, *small-cell lung carcinoma.*

trials are evaluating WEE1 inhibitors with concurrent radiation and chemotherapy in patients with recurrent GBMs, cervical cancer, and unresectable pancreatic adenocarcinomas.[8]

IMMUNE TARGETED BIOLOGICS

Cancer and the Immune System

In the past decade, increasing research emphasis has been placed on understanding the role the immune system plays in preventing and controlling cancers and the system's response to radiation. Despite maintaining a multitude of distinctly nonself-antigens among clonal cell populations, many cancers still develop the capability to circumvent the immune system's surveillance of nonself-antigens. Recent research has elucidated that these cancers reach a state of immune tolerance through halting the immune system at immune checkpoints and preventing T-cell activation through alteration of both stimulatory and inhibitory signaling.[141] Two clinically significant regulators of the immune checkpoint are cytotoxic T-lymphocyte associated antigen 4 (CTLA-4), which inhibits initial T-cell activation, and programmed cell death protein 1 (PD-1), which suppresses subsequent T-cell activity in peripheral tissues and tumors.[142-144] Evolving quickly in many different disease sites, we may be entering a new frontier of durable responses never quite seen before in deadly diseases. Can the efficacy of immunologic strategy be amplified with radiation?

CTLA-4 Inhibitors

Ipilimumab, a CTLA-4 antibody, is the first FDA-approved targeted therapy to specifically promote the body's antitumor immune response, rather than directly targeting cancer cells. This human monoclonal antibody's approval for use in unresectable or metastatic melanoma was based on results from two recent phase III trials.[145,146] One trial in 676 patients with metastatic melanoma saw a 3.6-month improvement in median OS from 6.4 months with placebo to 10.0 months with ipilimumab, regardless of whether patients received an additional vaccine that was also part of the study.[145] The 2-year OS nearly doubled for patients on ipilimumab versus placebo (23.5% vs. 13.7%). Regarding toxicity, 14 treatment-related deaths occurred and 10% to 15% of patients had grade 3 to 4 immune-related adverse events. A subsequent trial tested the addition of ipilimumab versus placebo to dacarbazine in 502 patients with metastatic melanoma and again saw a significant improvement in OS.[146] Patients receiving dacarbazine with ipilimumab versus placebo had median OS of 11.2 months versus 9.1 months and 3-year OS of 20.8% versus 12.2%. Although no drug-related deaths occurred, grade 3 to 4 adverse events occurred in 56% of patients in the ipilimumab arm versus 27.5% of those in the placebo arm. As previously seen, this difference was primarily as a result of increased immune-related events including skin, gastrointestinal, and hepatic toxicity. Another CTLA-4 inhibitor, tremelimumab, also underwent multiple phase I-III trials but was not approved because of dose levels inducing unacceptable toxicities and lack of a proven survival advantage.[147]

Ipilimumab, Radiation, and the Abscopal Effect

First proposed in 1953, the abscopal effect has since been elucidated as an immune-mediated systemic cancer response induced by localized radiotherapy.[148,149] Since ipilimumab's FDA approval in 2011, at least four cases have been published linking its use with radiation to the abscopal effect.[150-152] In each case, the patients received ipilimumab either before, concurrent with, or subsequent to stereotactic body radiotherapy or radiosurgery. The high doses of radiation given to each patient have been postulated as necessary to induce sufficient tumor necrosis to allow for an immune response.

A group from Memorial Sloan-Kettering initially reported on a case of a woman with metastatic melanoma who received ipilimumab for four doses followed roughly 1 year later by palliative radiotherapy to a pleural-based spinal para mass to 2850 cGy in three fractions. Following one additional ipilimumab dose 2 months after radiation, the patient was noted to have radiographic regression of both the irradiated lesion and multiple additional distant metastases that were previously progressing.[150] This same group subsequently reported on a patient with metastatic melanoma receiving radiation to an internal mammary lymph node with regression of distant, nonirradiated, left axillary lymph node metastases. In a separate report, a patient with metastatic melanoma received stereotactic radiosurgery to a brain metastasis with concurrent ipilimumab and had a complete clinical response of all metastatic lesions.[151] Notably, his titers of melanoma autoantibodies to melanoma antigen A3 increased from 1:300 to 1:700 following radiation and ipilimumab, supporting a systemic immune response. A Stanford group noted a complete systemic response in a patient with metastatic melanoma receiving stereotactic radiotherapy to two of eight hepatic lesions sandwiched in the middle of four cycles of ipilimumab.[152] Despite the promise of these cases and the growing use of radiation and ipilimumab in patients with melanoma, the abscopal effect remains a rare phenomenon. Ongoing research is investigating the optimal radiation and ipilimumab dosing and timing and the possibility of a biomarker indicating which patients will be most suitable for these treatments. Currently, the National Cancer Institute reports six clinical phase I or II trials hoping to further elucidate the underlying immune mechanisms of the abscopal effect and possibly finding a consistently reproducible method of inducing this phenomenon.[118]

PD-1 and PDL-1 Inhibitors

In a similar but separate immune suppressing vein, the primary effect of PDL-1 binding of PD-1 is suppression of the cytotoxic T-cell response in peripheral tissues and tumors.[153] This mechanism was initially elucidated in the setting of chronic viral infections and inflammatory states, but in the past decade, basic and translational research has shown that PD-1 pathway activation provides an alternative approach to CTLA4 through which cancers can achieve a durable state of immune tolerance.[144,154,155] Notably, cancers have been shown to activate this pathway via two different mechanisms. In one method, a tumor develops constitutive overexpression of PDL-1 on its membrane providing immune suppression regardless of tumor microenvironment. Separately, tumor cells can be induced to express PDL-1 by cytokines (e.g., interferon-γ [IFN-γ]) in a local inflammatory state.[156]

Several molecular therapeutics targeting PD-1 or its ligand PDL-1 are currently under investigation in multiple disease sites with published results appearing promising to date. Three separate phase I studies of more than 600 total patients with advanced cancers of eight separate disease sites receiving an anti-PD-1 or anti-PDL-1 antibody showed objective responses in ~10% to 50% of patients with grade 3 to 4 toxicities in the range of 10% primarily involving immune-related complications.[157-159] In each study, a subset of patients was noted to have durable response off therapy. A recent report notes two patients who achieved eventual durable complete responses lasting more than 3 years off therapy and one patient with 16 months of a stable off-therapy partial response, eventual relapse, and subsequent partial response for at least

16 months following reinduction of anti-PD-1 therapy.[160] In a subset immunohistochemical analysis of tumors for one of these trials, only those tumors expressing PDL-1 by immunohistochemical analysis achieved a response.[159] Based on results of one of these trials focusing on melanoma patients, pembrolizumab (previously lambrolizumab) has gained expedited FDA approval through the FDA Breakthrough Therapies program.[9] In addition, many more trials are ongoing, and further research with these agents is needed to determine optimal dosing and timing; whether patients can be selected for these therapies based on molecular studies; whether these agents can be combined with complementary immunomodulatory biologics such as ipilimumab; and whether these agents have a role in conjunction with radiation including the interesting possibility of an alternative mechanism for generating an abscopal effect. A more in-depth review of immune-targeted biologics by Pardoll et al is provided for reference.[141]

FUTURE DIRECTIONS

Several other classes of agents have not yet received FDA approval but have significant potential as radiosensitizers. The central role of signal transduction, DNA repair, and cell cycle control in radiation response leads to obvious interest in investigating agents that selectively perturb these processes in tumor cells as radiosensitizers.[161,162] Additionally, newer agents targeting cancer stem cells (CSCs) may help impair tumor resistance and relapse following radiation, surgery, and systemic therapies. Here we briefly discuss the bright future of several of these classes.

c-MET

c-MET, another receptor tyrosine kinase, binds hepatocyte growth factor (HGF) and has been associated with a variety of oncogenic pathways including angiogenesis, cell proliferation, DNA damage repair, epithelial-mesenchymal transition (EMT), and the related metastatic capabilities of cell motility and invasion.[163,164] Recent in vitro and in vivo studies have shown that c-MET is up-regulated in many cancer histologies and also up-regulated further in irradiated cells possibly also playing a role in radioresistance.[165,166] At present a variety of these biologics are in varying stages of development as far as phase III trials; however, minimal clinical applications have attempted to use these in conjunction with radiation. Further preclinical investigations examining the radiosensitizing effects of these agents will be necessary before reaching the clinical stage as radiosensitizers.

TGF-β

An intriguing area of anticancer research that is associated with chronic inflammation and potentially tied into the immune-modulating story is the transforming growth factor β (TGF-β) pathway.[167] The TGF-β pathway is found in abundance in solid tumors and is associated with malignant progression through a variety of interactions on the tumor cell and in the surrounding microenvironment. What is its specific mechanism of action? TGF-β1 signaling occurs primarily through a heteromeric complex of type II and type I TGF-β receptors that activates the Smad pathway by TβRI-mediated phosphorylation of Smad2 and Smad3. Subsequent nuclear relocation of receptor-associated phosphorylated Smads bound to Smad4, results in activated TGF-β-driven transcriptional responses.[168] The TGF-β receptor complex can also signal via non-Smad pathways to affect cell survival and EMT.

The paradox lies in the fact that TGF-β actually demonstrates tumor suppressive effects that cancer cells attempt to get around; yet later, TGF-β promotes cancer cell proliferation and invasion once the suppressor activity is blocked (Figure 5-3). Evidence exists that radiation can activate the TGF-β signaling pathway with cross-talk activation of COX-2.[169] This phenomenon has been observed in normal tissue injury in patients treated with radiation.[170] For a wonderful overview of TGF-β signaling and its association with cancer progression as well as opportunities to exploit this pathway for improved anticancer effects we point you to an extensive review by Dancea et al.[171]

Targeting Cancer Stem Cells

In the CSC model, a select group of CSCs drive the renewal, differentiation (including epithelial-to-mesenchymal transition), invasion, and often treatment resistance of an overall heterogeneous population of a cancer.[172] Notch, WNT, and the hedgehog (HH) pathways play central roles in the livelihood

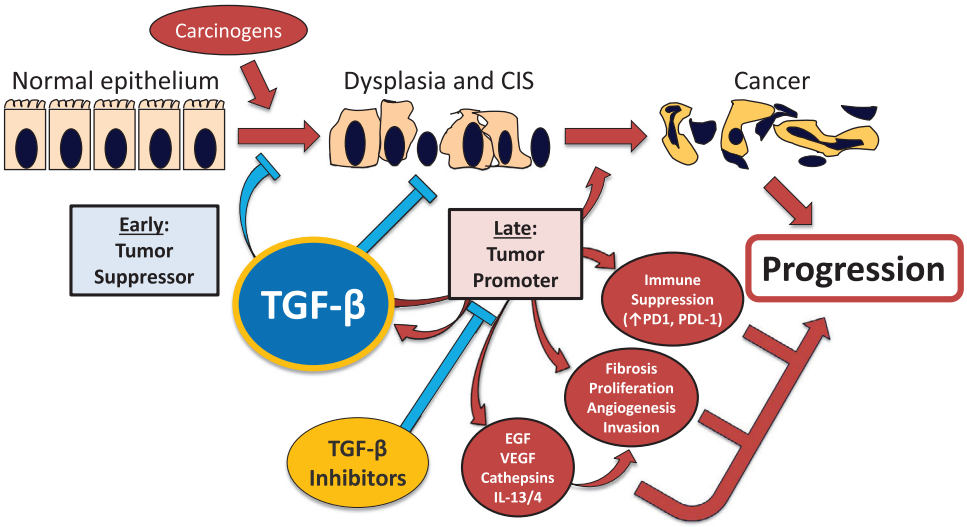

Figure 5-3 The TGF-β pathway exhibits tumor suppressive effects through cell cycle regulation and apoptosis early on in carcinogenesis. Eventually, cancer cells bypass the inhibitory signaling, and TGF-β becomes tumor promoting via a variety of hallmark oncogenic pathways, while concurrently up-regulating TGF-β production.

of these CSCs, offering a handful of promising biologic targets. Multiple phase I and II clinical trials testing inhibitors of these pathways are under way in a variety of solid tumors with early results showing general tolerability but mixed efficacy.[173-175] Furthermore, the potential to impair repopulation makes CSC pathway inhibitors attractive agents as radiosensitizers, especially in the setting of cancers known to exhibit radiation-induced accelerated repopulation such as HNSCC. An early in vivo study presented at ASCO 2014 found that the combination of a HH antibody with radiation in mice with primary cervical cancer xenografts led to better tumor growth delay, reduced lymph node metastasis, increased survival, and had no overt toxicity when compared to radiation alone.[176]

The heterogeneous population of cancers and CSCs may be responsible for the mixed efficacy of biologics previously discussed in this chapter. Nevertheless, this challenge offers an opportunity founded in the hypothesis that cancers may be more vulnerable to combined modality therapies including combinations of complementary biologics, not necessarily limited to CSC pathway inhibitors.[172] In the clinical setting, increased expression GLI-1, a zinc finger protein induced in HH pathway activation, was recently shown to be associated with increased metastasis, progression, and overall survival independent of stage and EGFR expression in a retrospective analysis of HNSCC tumors from patients treated on RTOG 9003.[177] Subsequently, Keysar et al[178] showed that in vitro and in vivo HH pathway inhibition drove HNSCC cells into an EGFR-dependent state thereby preventing cetuximab resistance and significantly impairing tumor growth when combined with cetuximab. A better understanding of such cross-talk signaling pathways among CSCs and the collective cancer cell population will be critical in determining the most clinically effective and tolerable combinations.

Designing Clinical Trials

If the past few years are any indication, we can expect continued exponential growth of targeted therapeutic agents in oncology. With endless permutations of dosing, timing, and combinations of these agents and modern radiation and chemotherapies, increasing emphasis must be placed on careful design and implementation of clinical trials. The NCI and RTOG recently released collaborative strategic guidelines for early stage development of radiosensitizers.[179] The guidelines highlight multiple hurdles in the development of radiosensitizers including difficulties in translating preclinical studies, poor endpoints such as tumor response rates which are expected to occur with radiation alone, and attributing toxicity to an agent versus radiation in a single-arm phase I trial. Furthermore, they provide recommendations for optimizing radiosensitizer trials including rigorous evaluation of preclinical and single-agent clinical data; avoidance of redundant pharmacokinetic studies; efficient methods of dose-escalation; and accurate assessment of expected toxicities. Given the extensive costs of these modern targeted therapies, we must continue to investigate biomarkers for optimal selection of patients whose tumors are most likely to respond to a specific intervention. This sentiment has been echoed by ASCO's recent Choosing Wisely recommendations and recently pursued by large-scale screening efforts.[180,181] Large-scale phase III trials in unselected patients are an inefficient and extremely costly means for scientific progress in our field. A notable alternative to the current trial design paradigm is the concept of the basket study design. In this setting, trials would test targeted therapies in patients with specific mutations regardless of cancer site or histology or within a specific disease site such as lung or rectal cancer with therapy directed based on the mutation status of each patient. Advances in next-generation sequencing will play a central role in making these types of trials feasible.

In addition, and very exciting, is the recent discoveries using cancer personalized profiling by deep sequencing (CAPP-Seq), an efficient and relatively inexpensive ultrasensitive method for quantifying circulating tumor DNA (ctDNA). As an example, Diehn et al[182] at Stanford applied CAPP-Seq for NSCLC with a design covering multiple classes of somatic alterations that identified mutations in >95% of tumors. Subsequently, they detected ctDNA in 100% of patients with stage II-IV NSCLC and in 50% of patients with stage I, with a remarkable 96% specificity for mutant allele fractions down to ~0.02%. Importantly, the measured levels of ctDNA were highly correlated with tumor volume and were accurate in distinguishing between residual disease after radiation and treatment-related imaging changes by computed tomography (CT) or positron emission tomography (PET). ctDNA levels also assisted in determining earlier response to therapy compared to radiographic measurements that can often be difficult to assess. This type of emerging technology offers a glimpse into future possibilities when combining novel agents with radiation and will help us determine if patients are developing resistance to a particular drug. Additionally, integrating radiation into this new framework would need to account for site-specific targeting and toxicity factors (Figure 5-4). With less than 15% of current phase I trials involving radiation, much

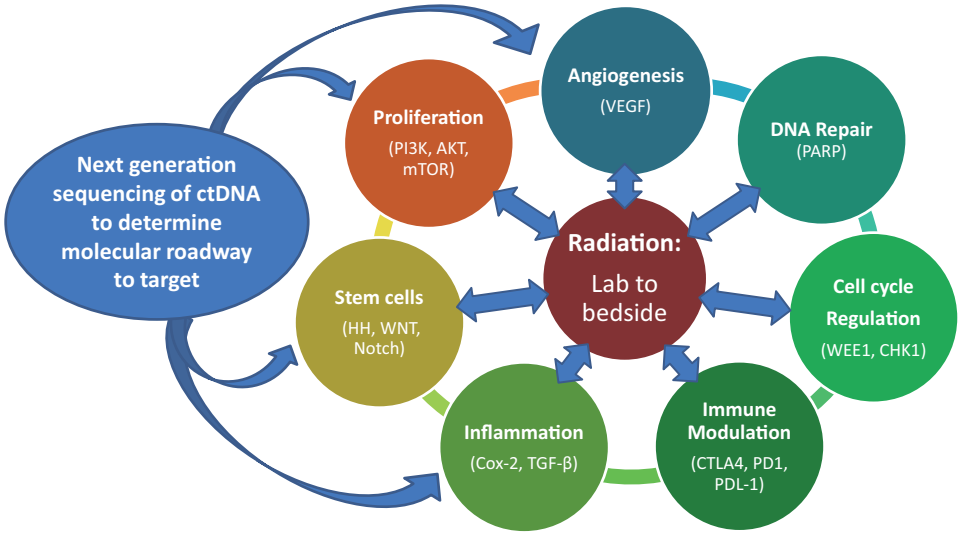

Figure 5-4 Preclinical studies leading to clinical translation using molecular discoveries such as next-generation sequencing to rationally tailor and sequence various biologics during and after radiation therapy for locally advanced disease—getting away from traditional chemoradiation approaches.

work lies ahead for our field toward better understanding the role of targeted therapeutics as radiosensitizers, presenting exciting opportunities to improve treatment results.[118]

CHAPTER 6

Radiation Oncology Physics

J. Daniel Bourland

Radiation oncology is a physical medical modality by which radiative energy is delivered to a target volume to effect palliation or cure. An understanding of the particles and processes involved in imparting radiation energy to matter is fundamental to the clinical application of radiation to patients.

In the irradiation of a biologic system, physical and biologic events occur in the following order:

1. *Physical events:* Physical interactions (e.g., photoelectric, Compton, collisional) result in ionizations and radiation dose.
2. *Chemical events:* Ionizations result in broken atomic and molecular bonds or chemical changes.
3. *Biological events:* Changes in the chemistry of molecules mean that there are changes in biological function (i.e., cells have improper or changed function).
4. *Clinical events:* Biologic alteration may result in clinical changes such as tumor regression, cancer induction, and tissue fibrosis.

MATTER AND PHYSICAL DEFINITIONS

Atomic and Nuclear Structure, Particles, and Nomenclature

Matter is made up of atomic and nuclear particles that have interaction and binding energies from 1 to 10 million electron volts (MeV). The smallest structural subunit that retains the character of an element, the atom, has a nucleus consisting of one or more protons and zero or more neutrons and a surrounding cloud of orbiting electrons. In an atom with zero net electrical charge, the number of orbital electrons equals the number of protons. A simplistic representation shows the atom to be neatly arranged with neutrons and protons in the nucleus and electrons in uniform orbits (Figure 6-1). In reality, the atom is a dynamic structure with defined energy states for the electron orbits and the nucleus. Detailed atomic and nuclear models have been formalized.[1,2]

Neutrons and protons are the building blocks of the nucleus; hence, they are called *nucleons.* The two particles have similar rest masses (the mass of the particle at rest, when kinetic energy is zero) but different electrical charges. The neutron, symbolized by *n,* has no charge (neutron for neutral) and the proton, *p,* has a charge of +1. The electron, *e,* has an atomic mass about $\frac{1}{2000}$ that of a proton or neutron and has a charge of –1. Besides the neutron, proton, and electron, other particles exist with unique masses and properties (e.g., spin). These include neutrinos, pions, muons, and others. The neutrino was first proposed as the neutral accompanying particle emitted in beta decay. There has been great interest in determining the mass of the neutrino because the cumulative neutrino mass may account for the "missing mass" in the universe, with great cosmologic implications. More recently it has been determined that the neutrino mass, inferred through observed oscillations in the neutrino state,[3,4] is finite and also small (close to zero). However, even with nonzero mass, the total amount of neutrino mass is estimated to be insufficient to make up for the "missing" mass. The universe is now stated to be made up of matter (4.6% the material "stuff" we are familiar with), dark matter (23%), and dark energy (which comprises more than 70% of the total mass-energy content of the universe).[5] These "dark" components are unknown entities.

Particles are classified by their mass as leptons or hadrons. Leptons, which include the electron and neutrino, are "lightweight" particles with mass comparable to that of the electron and spin of ½. Hadrons are heavy particles with two subclasses called *mesons* (middleweight, spin 0 or 1) and *baryons* (heavyweight, spin ½ or ⅜). Fundamental, or elementary, particles are those that have no subparts and cannot be divided. All leptons are elementary particles; however, the neutron and proton are not and are instead made up of three fundamental particles each, called *quarks,* which have been observed through high-energy physics experiments. Quarks have positive or negative charge in integer increments of ⅓, spin of ½, and other properties with whimsical, quark-deserving names.[1] Combinations of quarks yield the neutron, proton, and all other hadrons. For instance, a proton is made of two up quarks and one down quark, whereas a neutron is made of one up and two down quarks, which explains their similar mass but difference in charge. Antimatter is real, and an *antiparticle* is defined as a particle with identical mass but opposite charge to the particle. An antiparticle for a neutral particle has opposite spin or internal charge (i.e., quark) compared with the particle.

Matter is held together by four fundamental forces that operate over certain ranges and with certain particles. They are the strong, electromagnetic (coulomb [C]), weak (there are two), and gravitational forces, with respective relative strengths of 10^{1}, 10^{-2}, 10^{-13}, and 10^{-42}.[1] Each force acts by exchange of its respective mediator particle: the gluon, the photon, the W and Z particles, and the graviton (which has not yet been discovered). Counting mediators, leptons, hadrons, and their antiparticles, there are about 170 fundamental and composite particles that make up matter.[1] The model in which matter consists of fundamental particles as described previously is called the *standard model.*[1] Table 6-1 summarizes the fundamental particles in the standard model, which are six quarks, six leptons, six antiquarks, six antileptons, and also the four known forces. Of conceptual importance is the 2012 discovery of the "Higgs boson," predicted in 1964 by Higgs, which is a heavy particle (~125 GeV in energy)

responsible for the character of matter we have named "mass." The Higgs boson is placed by itself alongside the other entries to the standard model as the description of fundamental particles that make up matter (Table 6-1). How fundamental particles fit together to make up other particles continues to be studied. A relatively new theory called *string theory* is a descriptor of how quarks and other fundamental particles are assembled with vibration (energy) states for stringlike entities that give each fundamental particle its unique character.[6] However "flexible" they may be, the strings still need additional dimensions called "branes" (after "membranes") to enable their full character to be described.[7,8] Clearly, the fundamental properties of the universe continue to be studied in basic physics research.

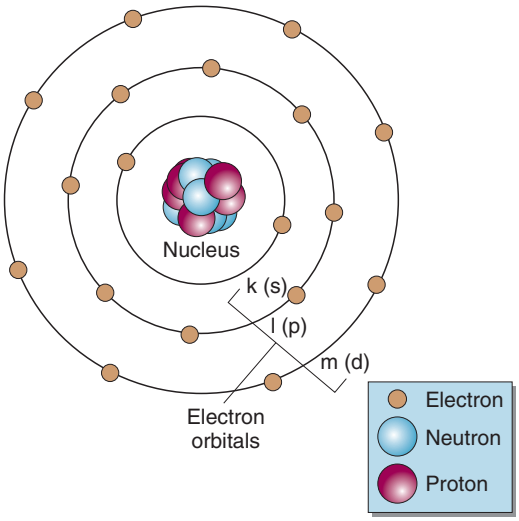

Figure 6-1 The atom has a nucleus composed of protons and neutrons. The nucleus is surrounded by a cloud of electrons in distinct energy levels called *orbitals* named s, p, d, and so on by chemists or called *shells* named k, l, m, and so on by physicists.

TABLE 6-1 The Standard Model of Matter: Fundamental Particles and Mediators

	Generations			
	I	II	III	Mediator (Force)
Quarks	Up	Charm	Top	Photon (electromagnetic)
	Down	Strange	Bottom	Gluons (strong)
Leptons	ν_e	ν_μ	ν_ν	Z (weak)
	e	μ	τ	W+, W– (weak)
Higgs Boson				Responsible for particle mass

Particle mass can be expressed as the atomic mass unit ([amu]; 1/12 of the mass of the carbon nucleus) or in units of energy by conversion with Einstein's formula, $E = mc^2$. Table 6-2 gives the symbol, charge, mass, and stability for the electron, proton, neutron, and other particles of interest.

Combinations of nucleons form a variety of nuclei and determine the physical character of an atom. The number of protons in the nucleus, *Z*, is called the *atomic number* and determines the chemical properties of an atom and the atom's identity as an element. The atomic number also equals the number of electrons in the neutral atom, with one electron per proton. The number of neutrons in the nucleus, *N*, is called the *neutron number.* Whole protons and neutrons constitute the nucleus, and *Z* and *N* have integer values. An atom's mass number, *A*, is the sum of its neutrons and protons. The mass number (an integer) has a value close but not equal to the actual nuclear mass. Their values are similar but must not be confused. Nuclear mass is the noninteger sum of the masses of the individual particles minus their binding energies. Definitions for *Z*, *N*, and *A* are summarized in Table 6-3.

Nuclides and Radionuclides

Nuclides are atomic species made of different combinations of nucleons, and they may be classified by their number of protons, neutrons, or nucleons (*Z*, *N*, or *A*) and by their energy state. Nuclei with the same *Z* but different *N* are called *isotopes* (p for proton), and they exhibit identical chemical characteristics (they are the same elements). Nuclei with the same *N* but different *Z* are called *isotones* (n for neutron). Nuclei with the

TABLE 6-3 Atomic Nomenclature

Symbol	Item	Definition		
Z	Atomic number	Number of protons in the nucleus and the amount of nuclear charge (+Z); also equal to the number of electrons in the neutral atom		
N	Neutron number	Number of neutrons in the nucleus		
A	Mass number	Total number of nucleons: A = Z + N		
Class	**Z**	**N**	**A**	**Examples**
Isotopes	Same	Different	Different	^{1}H, ^{2}H, ^{3}H; ^{125}I, ^{131}I
Isotones	Different	Same	Different	$^{8}He_6$, $^{9}Li_6$; $^{137}Cs_{82}$, $^{138}Ba_{82}$
Isobars	Different	Different	Same	^{60}Ni, ^{60}Co; ^{137}La, ^{137}Ba, ^{137}Cs
Isomers	Same	Same	Same	^{99}Tc, ^{99m}Tc (Δ energy state)

TABLE 6-2 Physical Characteristics of Selected Atomic and Nuclear Particles

Name	Symbol	amu	MeV	m_e	Charge	Lifetime
Electron	e^-	0.000549	0.511	1	–1	Stable
Positron	e^+	0.000549	0.511	1	+1	10^{-6} s
Proton	p	1.007276	938.256	1836.1	+1	Stable

Pion	±Π	0.14990	139.578	273.2	(±1	Unstable

amu, *Atomic mass unit.*

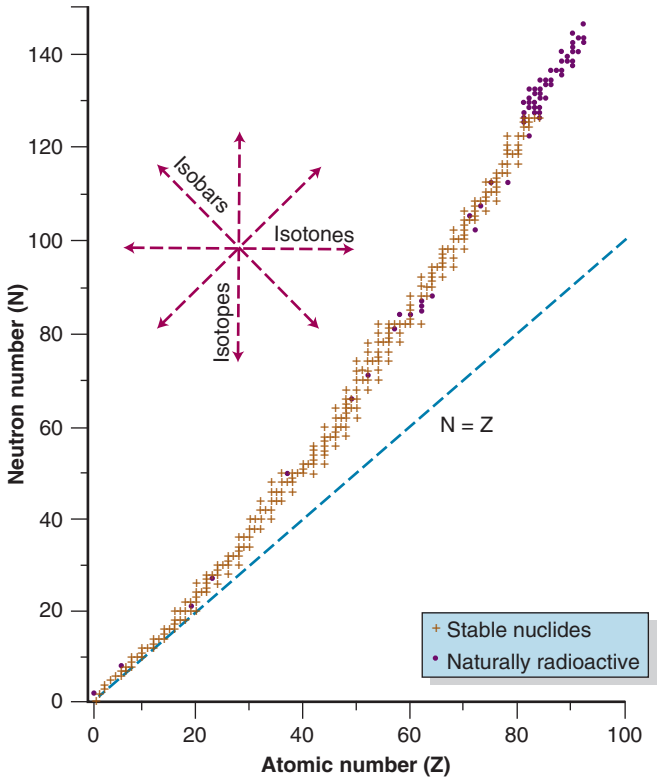

Figure 6-2 Distribution of stable and naturally radioactive nuclides. *Data from Radiological health handbook. Bethesda, MD, U.S. Department of Health, Education, and Welfare, 1970.*

same A but different Z and N are called *isobars*. In a last category, nuclei with the same Z and N, and therefore A, but different nuclear energy states (i.e., excited versus ground) are called *isomers*. Table 6-3 shows these classifications and example nuclides. A nuclide, or nuclear species, X, is denoted as

$$^{A}_{Z}X_{N}$$

in which X is the chemical symbol for the element with atomic number Z, N is the neutron number, and A is the mass number. Because $A = Z + N$, the N value is often dropped to give the following form:

$$^{A}_{Z}X$$

Because the atomic number determines the element's name, represented by the chemical symbol X, the Z is also dropped to give the form ^{A}X. An alternative nomenclature uses the nuclide's name followed by the mass number, such as hydrogen-3 and iridium-192.

Not all combinations of Z and N exist in nature or can be manufactured. Instead, certain combinations are possible, whereas other combinations cannot occur. Figure 6-2 shows the distribution of stable nuclides as a function of the number of neutrons and protons. Notice that at low Z, the ratio of neutrons to protons (N:Z) is about 1.0. Above $Z = 20$, stable nuclides have more neutrons than protons ($N/Z > 1.0$). At higher Zs, the stability of nuclei tends toward neutron-rich nuclides. It has been observed that nuclei with 2, 8, 20, 28, 50, 82, or 126 nucleons (protons and neutrons combined) are stable. These stability "magic numbers" relate to the filling of nuclear energy levels, similar to the complete filling of electron shells. Pairing of like nucleons also results in increased nuclear stability. There are 165 stable nuclei with an even number of both protons and neutrons, 57 stable nuclei with an even number of protons and odd number of neutrons, 53 stable nuclei with an odd number of protons and even number of neutrons, but only 6 stable nuclei with an odd number of both protons and neutrons.

Some nuclides are unstable and eventually transform to stable states by the emission of particles or energy. These nuclides are called *radionuclides* or *radioactive species* because a particle or energy is given off during the nuclear transition. Unstable nuclides lie off the line of stability and will have a neutron or proton excess relative to the stable nuclide. In Figure 6-2, isotopes lie along a vertical axis, isotones lie along a horizontal axis, and isobars lie at 45 degrees to either axis, perpendicular to the line of $N = Z$. Modes of radioactive decay depend on the type of nucleon excess, whether neutron or proton, and are discussed later in more detail.

Stable nuclides include ^{1}H, ^{12}C, ^{33}P, ^{34}S, and ^{59}Co. Radioactive nuclides for these elements include ^{3}H, ^{14}C, ^{32}P, ^{35}S, and ^{60}Co. Other radionuclides of interest to the medical field include ^{99m}Tc, ^{125}I, ^{131}I, ^{137}Cs, and ^{226}Ra.

Photons and Other Definitions

Interactions of ionizing radiation occur at the atomic and nuclear level, where binding energies are small compared with macroscopic realms. Electromagnetic radiation, or photons, are particles that have wavelike qualities with zero mass, which transfer energy from one location to another by propagation of an electromagnetic wave at the speed of light, c ($c = 3 \times 10^{8}$ m/s). Photons are also the mediators of charged particle bonds. A photon has wavelength λ, frequency ν, speed $c = \lambda\nu$, and energy $E = h\nu$; c is the speed of light, and h is Planck's constant ($h = 6.626 \times 10^{-34}$ m^2/kg/s). The electromagnetic spectrum consists of photons with wavelength, frequency, and energy ranges more than 10 orders of magnitude (the range is really infinite). From low to high energy, there are radar waves, microwaves, infrared, light (visible photons), ultraviolet, x-rays, and gamma rays. Photons are named by their wavelength (e.g., radar waves, microwaves), character (e.g., "purple"), and origins (e.g., x-rays from the atom, gamma rays from the nucleus) (Table 6-4).

RADIATION PRODUCTION AND TREATMENT MACHINES

External beam radiation therapy machines produce ionizing radiation by (1) radioactive decay of a nuclide or (2) electronically by the acceleration of electrons or other charged particles such as protons. The basic purpose is to create an intense beam of ionizing radiation with known and predictable characteristics that can be aimed at a patient from a certain distance away (most commonly 100 cm). This beam of radiation with a source outside the patient is the "external beam." The most commonly used radionuclide for external beam radiation therapy has been ^{60}Co. Although once quite common as the first widely used device for external beam radiation therapy, ^{60}Co treatment machines in the United States and other developed nations have been replaced over the past 20 to 30 years by linear accelerators, which produce high-energy x-rays and electrons by electronic means. Basic components of all external beam treatment machines include a radiation source, a collimating system to form and direct a radiation beam, inherent or added shielding for radiation protection, a control system to turn the beam on and off, a light field to delineate visibly the radiation field to be treated, a means to rotate the beam or otherwise change its direction, and a support assembly for the

TABLE 6-4 Physical Definitions

Item	Symbol	Definition
Atom	a	Smallest subunit of an element retaining the character of that element; composed of a nucleus of protons and neutrons and orbital electrons
Electron	e^-	Particle with a charge of –1 and mass of 0.511 MeV; used for radiation treatment when accelerated to energies capable of ionization
Photon	hν, γ, x	Particle with zero charge and mass consisting of electromagnetic radiation; used for radiation treatment at energies capable of ionization
Gamma ray	γ	Photon (electromagnetic radiation) originating from within the nucleus as a result of nuclear transformations
X-ray	x	Photon (electromagnetic radiation) originating from within the atom as a result of atomic transformations
Ionization		Removal of an electron from an atomic shell, leaving the atom with a charge of +1
Ionizing radiation		Radiation of sufficient energy to cause ionization on interaction
Ion	X^-, X^+	Atom of element *X* with an electron deficit, as is formed after ionization, or an electron excess
Nonionizing radiation		Radiation of insufficient energy to cause ionization on interaction
Electron volt	eV	The energy gained by 1 electron when it is accelerated through an electrical field potential of 1 V
Kiloelectron volts	keV	1000 electron volts; used to denote the energy of a monoenergetic particle or photon, as in "100-keV photons" or "10-keV electrons"
Million electron volts	MeV	1 million electron volts; used to denote the energy of a monoenergetic particle or photon, as in "1.17-MeV gamma rays" or "7-MeV electrons" (see Figure 6-7)
Million volts	MV	Million volts; used to denote a spectrum of polyenergetic particles or photons with a maximum energy, as in "18-MV x-rays." In this example, the x-rays have a maximum energy of 18 MeV and a continuous energy distribution of photons from 0 up to 18 MeV (see Figure 6-7).

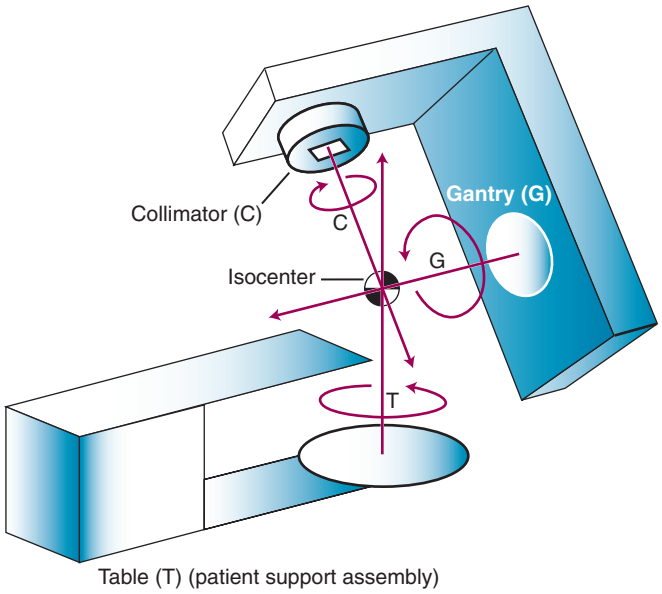

Figure 6-3 Treatment machine geometry for gantry-based linear accelerator or teletherapy unit. Three rotational axes intersect at a point called the *isocenter*. The table surface can translate three directions for a total of 6 degrees of freedom.

patient. These components are assembled for modern conventional treatment machines in an isocentric geometry (Figure 6-3). The isocenter is a point in space at which the treatment machine rotational axes all intersect. Any mechanical rotation is about an axis that passes through the isocenter. With many common components, ^{60}Co teletherapy units and linear accelerators differ primarily in the method of photon production: radioactive source versus electronic source. In current configurations linear accelerators also offer a wide range of sophisticated control systems for control of radiation beam shape, intensity, and trajectory (discussed later).

Radiation Production by Radioactive Decay

Teletherapy is the use of radioactive material, such as ^{60}Co, for production of an external beam of gamma rays for treatment at a distance from the radioactive source (*tele,* meaning "at a distance"). The term is historical and is in contrast to brachytherapy, in which the radioactive source is placed in or on the treatment volume (*brachy,* meaning "close"). Gamma rays are emitted from a daughter nucleus formed after radioactive decay of an unstable parent nucleus. Each gamma ray has a unique energy that relates to the immediately preceding nuclear transformation, and this unique energy can be used to identify the daughter (and therefore the parent). ^{226}Ra, ^{137}Cs, and most commonly ^{60}Co have been used for teletherapy. ^{137}Cs and ^{60}Co are manufactured and became available by neutron activation and as a byproduct of fission after the invention of the nuclear reactor. Use of ^{60}Co as a source of gamma rays for treatment was pioneered by H. E. Johns[9] and represented a major step in obtaining high-energy photons above 1 MeV, "megavoltage" photons. At that time, electronic means of photon production from high-energy x-ray tubes was limited to 300 keV maximum because of electrical arcing at higher accelerating potentials. Specialized particle accelerators were required to produce potentials above 300 keV (e.g., betatrons[10] and van de Graaff accelerators[11]).

Although of historical interest for most readers, ^{60}Co teletherapy units have lower cost and a relatively simple design with lower requirements for their operating environment compared with linear accelerators. For these reasons ^{60}Co teletherapy devices are used worldwide in regions with limited resources for funding and operating infrastructure. A disadvantage is the constantly decreasing dose rate as a result of the decay of the ^{60}Co source and the requirement for eventual replacement of the source. In a conventional ^{60}Co teletherapy unit (Figure 6-4), a cylindrical sealed-source capsule about 3 cm in diameter and 5 cm high contains pellets of ^{60}Co. In each transformation a ^{60}Co nucleus decays to ^{60}Ni, with the prompt emission of two gamma rays at 1.17 and 1.33 MeV each (1.25 MeV average). Typical activity is 6000 to 9000 Ci (2.22 to 3.33 × 10^{14} Bq) for dose rates of approximately 2 to

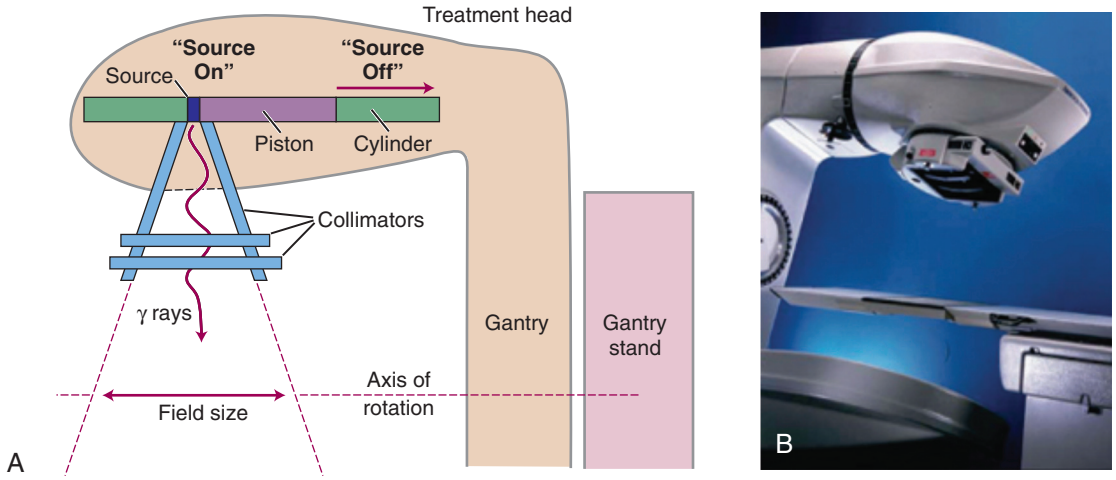

Figure 6-4 In a typical ^{60}Co unit, the source moves from the shielded position (Off) into an unshielded position (On) to produce a treatment beam. ***B,*** *Courtesy Best Theratronics, Ltd., Ottawa, Ontario, Canada.*

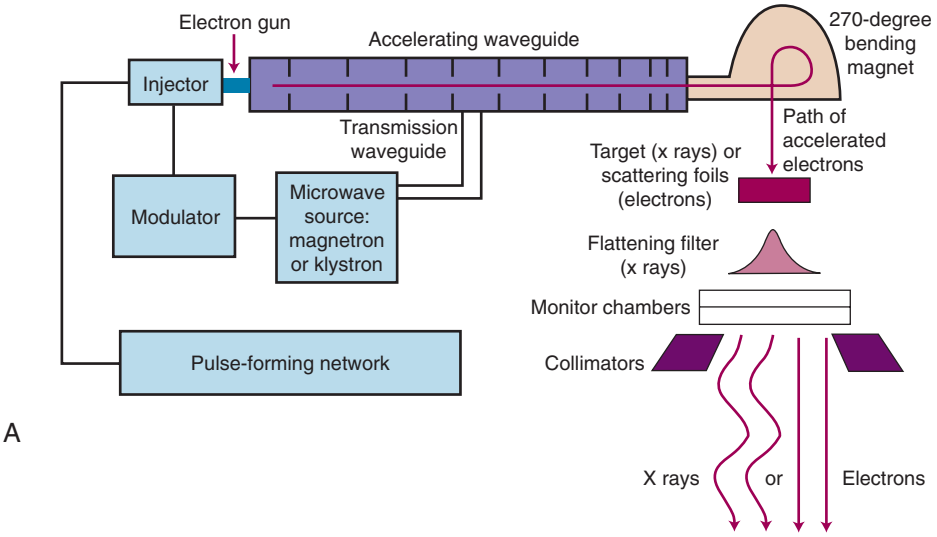
3 Gy/min at 80 to 100 cm from the source. The source decays with a half-life of 5.263 years and is replaced every 5 to 7 years when the dose rate becomes "too low"; treatment times may be excessive and radiobiological effect for treatment efficacy may be compromised below 1 Gy/min.

In one of the most commonly available teletherapy unit configurations (Theratron Phoenix, Best Theratronics Ltd, Ottawa, Ontario, Canada) the source is stored in a shielded head of the machine, mounted on the end of a movable piston in a horizontal cylinder (see Figure 6-4). On the initiation of treatment, the source is moved pneumatically to a position over an opening in the shield that allows a treatment beam to exit. A collimator consisting of interleaved bars of a high *Z* material is used to define the field size as the beam exits the shield port. Trimmer bars, additional collimator bars closer to the patient surface, can be used to reduce the beam penumbra, which is large because of the relatively large source size of approximately 1.5 inches. Maximum field size is 35×35 cm^2 at 80 or 100 cm from the source. Irradiation time is measured and controlled by two independent timers. An end effect caused by the mechanical movement of the source, for which the effective irradiation time is less than the timer setting, is inherent and can be measured. Cross-hairs and a field light are used to delineate the central ray and field dimensions. There is a source-to-surface indicator. Source movement is designed so that in the event of treatment termination or device failure the source is automatically returned to the shielded condition. An emergency pushbar (T-bar) can be used to manually return the source to the shielded position, if necessary.

The machine has a rotatable gantry allowing 360-degree rotation of the source and a nominal isocenter position of 80 cm from the source. Later models have a 100-cm isocenter and treatment distance. An additional degree of freedom is provided by a head swivel mechanism that allows the beam direction to be rotated away from isocenter, if desired. A beam stopper may be used to intercept the beam for additional shielding of the exit beam. The beam stop also acts as a counterweight for the head of the machine. There is a patient support assembly (treatment table) with vertical, longitudinal, lateral, and rotation motions. Beam modifiers include custom or standard field blocks and mechanical wedges for producing angled isodose distributions or tissue compensation.



One manufacturer (Best Theratronics, Ltd., Ottawa, Ontario, Canada) states that as of the year 2010 there were 45,000 daily radiation treatments delivered worldwide using this conventional ^{60}Co teletherapy device.

Radiation Production by Linear Accelerators

In a linear accelerator, electrons are accelerated to high energy and are allowed to exit the machine as an electron beam or are directed into a high *Z* target to produce x-rays by the bremsstrahlung interaction. The linear accelerator enables convenient production of megavoltage x-rays in a relatively small device, and its existence is directly related to the invention of the magnetron and the klystron during the development of radar in World War II. Linear accelerators are quite versatile, with x-ray and electron modes, multiple energies, and computer controls. These capabilities have led to the replacement of most ^{60}Co teletherapy machines in the United States with linear accelerators.

The principle of operation for linear accelerators is to accelerate electrons through a waveguide by use of alternating microwave fields.[12] Two basic waveguide designs exist: standing wave and traveling wave. Waveguide length is a function of the maximum acceleration energy (longer is higher energy) and the frequency of the microwave field. The most common frequency for gantry-based linear accelerators (see Figure 6-5, *B*) is 2.998 GHz (S-band microwaves); however, specialized, shorter waveguides are possible at 9.3 GHz (X-band microwaves) that produce megavoltage energies above 6 MeV with acceptable dose rates for treatment. Major electronic components are described in Table 6-5 and are shown in Figure 6-5 for gantry-based linear accelerators, the most common design.

Major mechanical components are similar to those for teletherapy. A rigid, floor-mounted stand holds high voltage, microwave transport guides, cooling and control components, and supports a rotatable gantry holding the waveguide to allow 360-degree rotation of the source at an isocenter of 100 cm to enable multiple beam directions (see Figure 6-3). In an alternative barrel-type design the entire accelerator—including waveguide, high voltage, microwave transport guides, and other components—is contained within a large rigid cylinder and the cylinder and all its contents rotate on a horizontal axis about the isocenter (this design not shown). A set of one or two pairs of high Z collimators ("jaws"), depending on the manufacturer's design, provides at least 99.9% attenuation of the primary beam (0.1% transmission) and defines the length or width of the rectangular x-ray radiation field. A maximum field size of 40×40 cm^2 at 100 cm (isocenter) is common, with 180- to 360-degree rotation of the entire collimator assembly about the isocenter (see Figure 6-3). Collimator settings are continuously variable, and jaw pairs can be

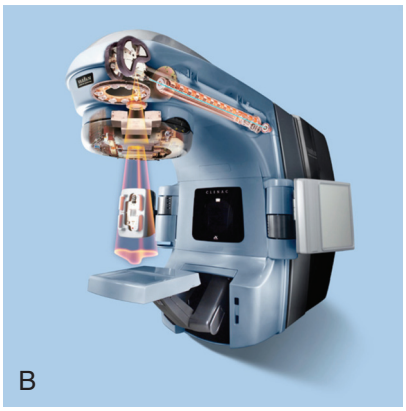


Figure 6-5 Electron linear accelerator schematic. Key components are shown that allow a beam of electrons to be accelerated, producing a treatment beam of electrons or x-rays.

TABLE 6-5 Major Electronic and Beamline Components of Linear Accelerators

Component*	Purpose
Electron gun	Source of electrons to be accelerated
Microwave source	Provides accelerating potential and amplitude (power). Typically, magnetrons are used for ≤10 MV; klystrons are used for >10 MV and for most dual-energy machines
Pulse-forming network	Synchronizes electron bunches with microwave phase
Transmission waveguide	Carries microwave power from its source to the accelerating waveguide
Injector	Injects pulses of current to the electron gun (i.e., drives electron gun)
Accelerating waveguide	Location of electron acceleration through multiple coupled cavities in a linear geometry (i.e., the linear accelerator)
Bending magnet	Used in horizontally oriented accelerating waveguides to redirect the electron beam, for electron energy selection, and for beam focusing
Target (for x-rays)	Placed in electron beam for x-ray production on electron impact
Scattering foils (for electrons)	Scatter electrons to produce a uniform beam of electrons for treatment
Flattening filter (for x-rays)	Flattens the highly peaked x-ray beam exiting the target to produce a uniform beam of x rays for treatment
Monitor chambers	Ionization chambers that monitor the amount of radiation in the beam; count dose and turn machine off when set dose is reached; monitor beam flatness and symmetry
Collimators (secondary)	Provide rectangular field shaping for x-rays and set field sizes for electrons
Accessories and beam modifiers† Interlocks†	Define or modify beam shape or intensity. With other control systems, ensure proper operation of linear accelerator for dose assurance and safety

**Components are shown in Figure 6-5.*
†Components are not shown in Figure 6-5.

operated in coupled mode to produce symmetrical and asymmetrical axis. Cross-hairs and a field light are used to delineate the central ray and field dimensions, and there is a source-to-surface indicator.

Although rarely used for linear accelerators, a beam stopper may be used to intercept the beam for additional shielding of the exit beam when facility shielding is limited. Otherwise, internal counterweights provide balance to the gantry to offset the weight of the accelerator waveguide and high-density shielding required around the x-ray target. There is an isocentric patient support assembly (treatment table) with vertical, longitudinal, lateral, and rotational motions. Fine tolerances for the rotational axes and isocentricity of the gantry, collimator, and table are important for accuracy in patient treatments. The combined variation in rotation and coincidence of the three axes is typically maintained within a 1-mm diameter sphere. The patient support assembly is usually the most difficult rotational axis to set for isocentricity.

Accessories and beam modifiers for conventional geometry linear accelerators are important for customizing the external beam field to an individual patient and include custom or standard shielding blocks to shape a patient's treatment fields to minimize the amount of normal tissue treated or protect critical structures; electron applicators for defining electron fields at the patient surface; physical (made of steel) and "virtual" or "dynamic" wedges for producing angled isodose distributions; and compensators for shaping the dose distribution within a patient for desired dose uniformity. Custom block manufacturing for shaping of patient-specific fields was once common, using high Z alloy materials to provide primary beam

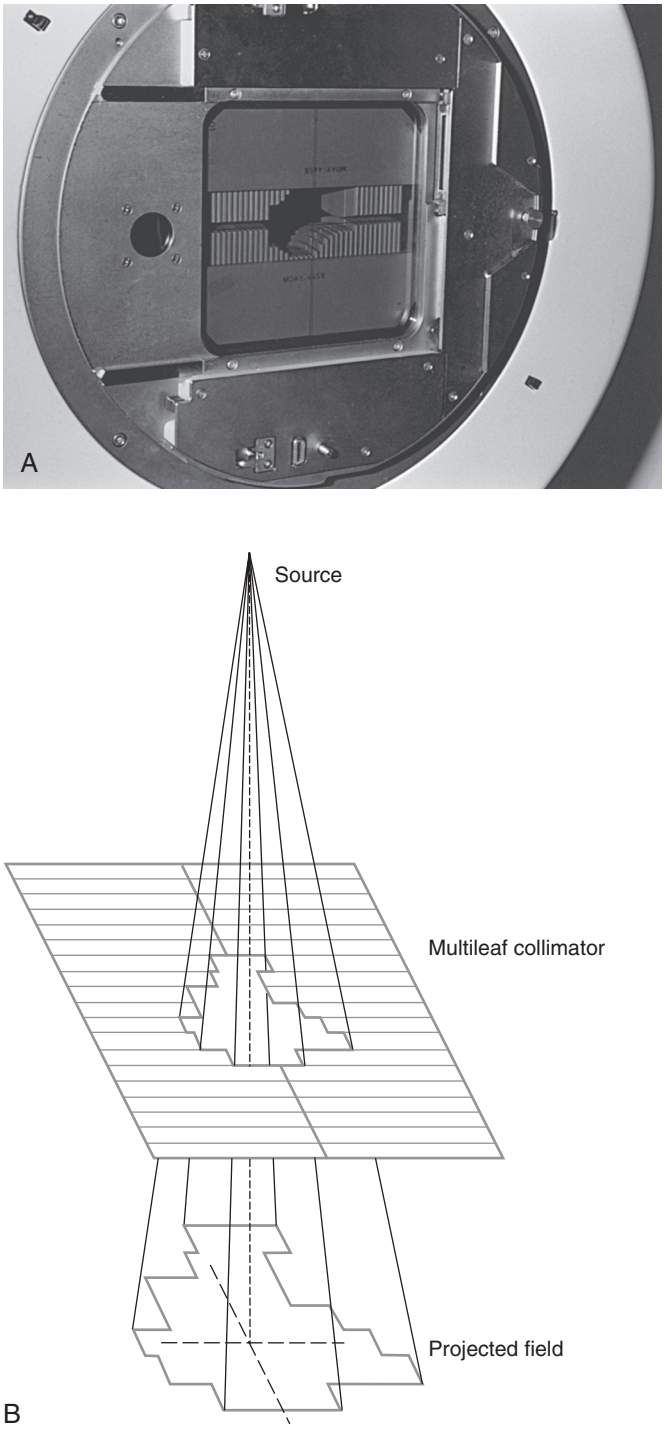

Figure 6-6 The multileaf collimator. **A,** Installed 80-leaf device for a Varian 2100C linear accelerator. **B,** Schematic of beam definition.

attenuation of at least 97% (five half-valve layers). The use of custom blocks has been almost totally replaced by a versatile collimator design called the *multileaf collimator* (MLC), which is now available from all linear accelerator manufacturers (Figure 6-6). The MLC provides field-shaping capabilities, replacing standard manual or custom blocks by the use of a large number of adjustable high *Z* vanes, or leaves. The desired beam outline is shaped as a series of steps by positioning each leaf to approximate a continuous field edge (Figure 6-6, *B*). Different manufacturer's MLC designs include singly and doubly focused leaf ends, where the leaf ends match beam divergence either across the direction of leaf travel (single) or both across and with the direction of leaf travel (double), and projected widths at the isocenter of 3 mm, 4 mm, 5 mm, or 10 mm.[13] MLCs also have capabilities for dynamic treatment, as discussed later for intensity-modulated radiation therapy (IMRT).

Linear accelerators and their supporting technologies have become computer controlled, enabling better-optimized dose distributions, rapid treatment setup, and in-room verification of target location through remote sensing and image-guided approaches. In particular, most modern linear accelerators are hybrid imaging treatment devices fitted with a gantry-mounted kV or MV x-ray imaging device that is coincident with the treatment isocenter. This imaging device provides "in-room" imaging to confirm patient and target position immediately before treatment, in the process termed *image-guided radiation therapy* (IGRT). A wide range of IGRT designs is possible, as discussed later.

Although linear accelerators typically have had an isocentric rotating gantry, there are other commercialized megavoltage accelerator designs available that also have integrated image guidance for treatment. One design, called *tomotherapy*, uses a highly stable computed tomography (CT)-like ring gantry around which an X-band linear accelerator rotates, always pointed toward the rotational center (an isocenter).[14] A binary ("on" or "off") multileaf collimator intensity-modulates a 6-MV x-ray fan beam as the accelerator waveguide is rotated. The treatment table is advanced in a stepwise or continuous motion for either slice by slice or helical fan beam treatment. Another ring gantry design uses a cone beam megavoltage x-ray beam with full MLC, along with kV imaging for image guidance. This entire unit is gimbaled to enable noncoplanar beam geometries outside of the default device orientation.

Another unique geometry uses a nonisocentric format with an X-band linear accelerator fixed on the end of a high-precision robot that is computer controlled for a range of motions with multiple degrees of freedom.[15] This device produces a circular 6-MV x-ray beam that can be pointed at the target from various "nodes" in space—using a relatively large collection of irradiation nodes generates the cumulative dose distribution at the target.

Three differences in radiation sources for teletherapy and linear accelerator devices are fundamental. First, a ^{60}Co teletherapy source is always "on," emitting radiation. Radioactive decay always occurs and cannot be interrupted; to initiate an irradiation the source must be moved from the shielded condition to an unshielded condition (see Figure 6-4). With a linear accelerator, no source is present until the unit is energized; the irradiation is on or off with the flip of an electronic switch initiated by the operator with a key or button at the treatment console. Second, their photon spectra are different (Figure 6-7). In a ^{60}Co unit, two monoenergetic gamma rays are emitted with every decay to produce a discrete spectrum with peaks at 1.17 and 1.33 MeV. In contrast, a linear accelerator produces a continuous x-ray spectrum through the bremsstrahlung interaction. The spectrum has a maximum energy of E_{max} (i.e., accelerating potential) and all other photon energies down to zero. An average x-ray energy of approximately one third E_{max} can be determined and is consistent with theoretical predictions for the continuous bremsstrahlung spectrum (Figure 6-7). Third, a linear accelerator can produce a treatment beam of electrons as well as photons. The accelerated electron beam is allowed to exit the machine under controlled conditions of scatter. Although ^{60}Co gamma rays occur because of an immediately preceding beta decay, the beta particles (electrons) are stopped by the radiation source enclosure, a metallic capsule that contains the radioactive material, and cannot be otherwise harnessed for treatment.

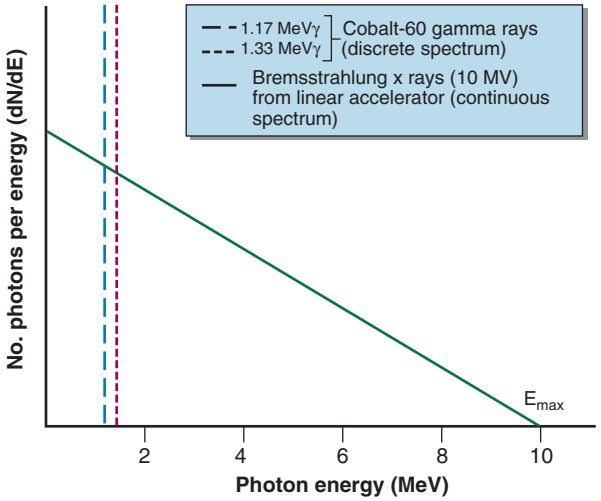

Figure 6-7 Discrete and continuous photon spectra. The discrete spectrum is characteristic of photons emitted by radioactive material. The continuous spectrum is characteristic of polyenergetic bremsstrahlung x-rays emitted by a linear accelerator. E_{max}, 10 MeV.

Radiation Production by Other Accelerators

Other accelerator techniques have been used to produce a variety of high-energy particles such as electrons, protons, neutrons, and higher Z ions. These techniques include the betatron,[10] van de Graaff accelerators,[11] cyclotrons,[16] the racetrack microtron,[17] and accelerators[18] used for high-energy physics experiments.

Among high-energy particles, protons have become the most attractive for therapeutic uses, where proton energies of 230 to 250 MeV yield treatment depths of up to 30 to 40 cm. Although currently an expensive technology to build ($50 to $150 million) and maintain, the use of high-energy protons for treatment is increasing with approximately 15 operating proton facilities in the United States, 50 sites in other nations (including a few for carbon ions), and 40 sites under construction or in the planning stages worldwide.[19] Typically, a large-scale proton facility has a single cyclotron with a beam line that is split to service two to four treatment rooms, each with either a fixed treatment beam or a movable gantry to aim the proton beam. An alternative design includes the use of a smaller (though still large) cyclotron in a single treatment room (one cyclotron per treatment room) that is mounted on a large double-legged gantry system that enables rotation about the patient. Facility designs and technical aspects for proton therapy are available.[20]

INTERACTIONS OF IONIZING RADIATION WITH MATTER

Photon Interactions

Attenuation and Transmission

When incident on matter, ionizing photon radiation undergoes interactions with atomic electrons or nuclei. Interacting photons are removed from the primary beam, an effect called *attenuation.* Photons that do not interact and instead exit the material are called *transmitted photons.* Attenuation and transmission are illustrated in Figure 6-8. A number, N_0, of monoenergetic x-rays or gamma rays is incident to a slab of material, and a smaller number, N, is transmitted. The attenuated photons, numerically equal to $N_0 - N$, are absorbed in the material or scattered in other directions. In narrow-beam geometry, N-transmitted photons alone reach a detector as shown. In broad-beam geometry, scattered photons also reach the detector.

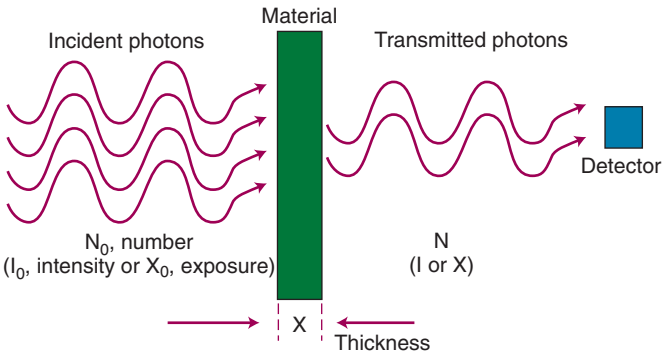

Figure 6-8 Attenuation and transmission. A number, N_0, of monoenergetic x- or gamma rays is incident to a slab of material, and a smaller number, N, is transmitted. The attenuated photons, N_0 and N, are absorbed in the material or scattered in another direction.

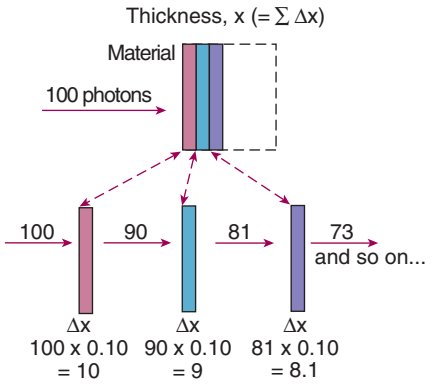

Figure 6-9 Attenuation through successive slabs of material.

Megavoltage photon interaction probabilities are less than 1, typically 2% to 4% per cm in tissue, depending on the incident photon energy, the atomic number of the interaction material, and the interaction type. By physical law, the fractional number of unattenuated photons interacting per unit thickness of a material is constant, such that

$$\frac{\Delta N/N}{\Delta x} = -\mu \quad \text{or} \quad \frac{\Delta N}{N} = -\mu \Delta x \qquad \text{Eq. 1}$$

In the equation, ΔN is the change in the number of photons as the result of attenuation, N is the number of incident photons, μ is a constant that represents the constant fractional attenuation per thickness (called the *linear attenuation coefficient*, with units of length^{-1} [cm^{-1}]), Δx is the thickness traversed by the photons for attenuation ΔN, and the minus sign indicates that the effect is negative, resulting in fewer photons—the attenuation process decreases the number of photons in a beam.

Constant fractional attenuation per unit thickness compounds over successive thicknesses, illustrated in Figure 6-9. This "fraction of a fraction" effect is nonlinear, and the integrated form of Equation 1 yields an important relationship: attenuation in a continuous material is an exponential process:

$$N(x) = N_0 e^{-\mu x} \quad \text{or} \quad \frac{N(x)}{N_0} = e^{-\mu x} \qquad \text{Eq. 2}$$

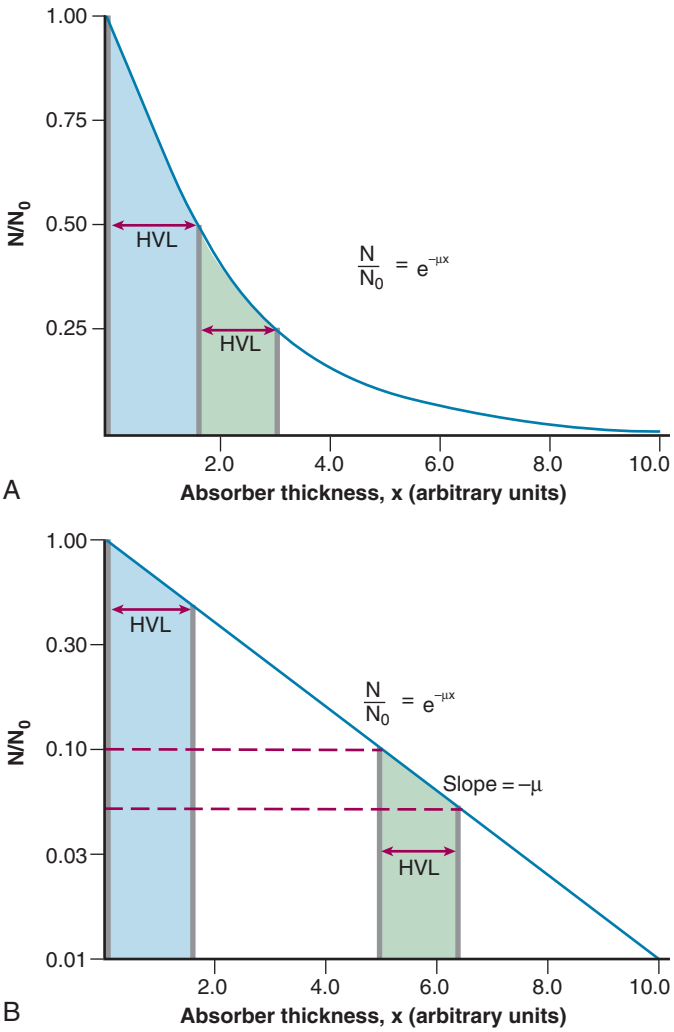

Figure 6-10 Graphic representation of attenuation. **A,** Linear plot. **B,** Semi-log plot. *HVL*, Half-value layer.

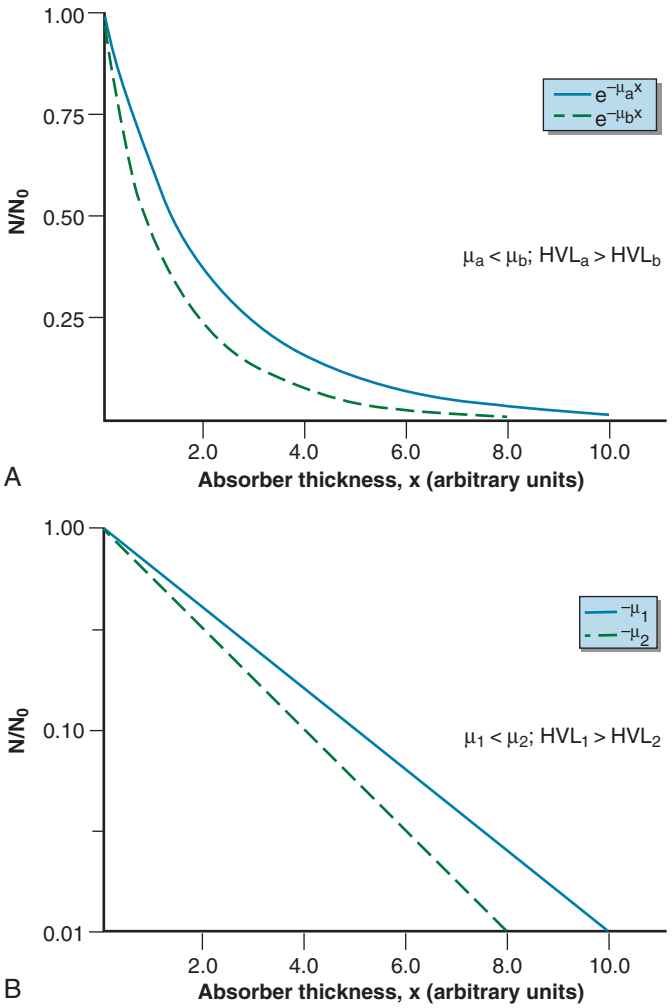

Figure 6-11 Attenuation for two different materials, indicated by the subscripts a and b. **A,** Linear plot. **B,** Semi-log plot. *HVL*, Half-value layer.

In Equation 2, N_0 is the original number of incident photons, $N(x)$ is the transmitted (unattenuated) number of photons, e is Euler's constant ($e \approx 2.7$), μ is the linear attenuation coefficient, and x is the thickness traversed by the photons.

Exponential attenuation is valid for monoenergetic photons and all homogeneous materials in narrow beam geometry and applies to other radiation quantities such as intensity (I) and exposure (X):

$$I = I_0 e^{-\mu x} \quad \text{or} \quad \frac{I}{I_0} = e^{-\mu x} \quad \text{and} \quad X = X_0 e^{-\mu x} \quad \text{or} \quad \frac{X}{X_0} = e^{-\mu x} \qquad \text{Eq. 3}$$

The linear attenuation coefficient is unique for each photon energy and element or material but varies with absorber density. Attenuation coefficients are discussed more fully with radiation interactions.

Equation 2 can be graphed in linear or semi-log form (Figure 6-10). In semi-log form, the attenuation curve is a straight line with a slope of −μ (Figure 6-10, *B*). A smaller attenuation coefficient results in less attenuation and a shallower attenuation curve. Different attenuation coefficients for different materials or different photon energies result in a different amount of attenuation for the same thickness traversed and attenuation curves that differ in their slopes (Figure 6-11).

Beam Quality

Beam quality is a term used to describe the amount of penetration by a photon radiation beam. One indicator of quality is beam energy, defined by accelerating potential, effective energy, or gamma ray energy. Another indicator is the half-value layer (HVL). HVL is the thickness of a material that reduces the transmitted intensity to one half of the original intensity. When $I/I_0 = ½$, the thickness, x, is the HVL, and the attenuation equation becomes

$$\frac{I}{I_0} = \frac{1}{2} = e^{-\mu \text{HVL}} \qquad \text{Eq. 4}$$

Two important relationships come from this equation:

$$\mu = 0.693/\text{HVL} \text{ and } \text{HVL} = 0.693/\mu$$

Thus, given the linear attenuation coefficient, the HVL can be computed, and vice versa. For example, if $\mu = 0.10\ \text{cm}^{-1}$, the HVL = $0.693/0.10\ \text{cm}^{-1}$ = 6.93 cm, and if HVL = 10 cm, μ = $0.693/10\ \text{cm} = 0.0693\ \text{cm}^{-1}$. Notice that the units for HVL are the reciprocal of the units for μ.

Because $e^{-\mu \text{HVL}} = ½$, and given a thickness of material in units of HVL ($x = n$ *HVL*, n equals the number of HVLs), the amount of attenuation can be computed by

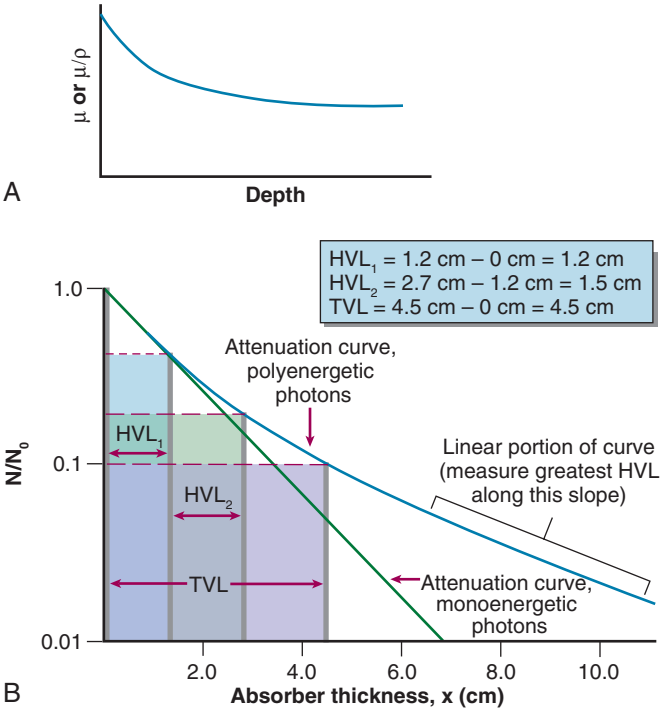

Figure 6-12 Attenuation for polyenergetic photons. **A,** Variation in attenuation coefficient as a function of depth for polyenergetic photons. **B,** Attenuation curve for polyenergetic photons. *HVL*, Half-value layer; *TVL*, tenth-value layer.

$$\frac{I}{I_0} = \left(\frac{1}{2}\right)^n \qquad \text{Eq. 5}$$

In Equation 5, I/I_0 is the fractional transmission, intensity, or exposure and n is the thickness of the material, expressed as the number of HVLs. This equation is valid for positive integer and noninteger values of n (e.g., $n = 1, 2, 5.9, 100.1$, etc).

Similar to HVL, the tenth-value layer (TVL) is the thickness required to reduce the number, intensity, or exposure by a factor of 10:

$$\frac{I}{I_0} = \frac{1}{10} = e^{-\mu TVL} \quad \text{and} \quad \frac{I}{I_0} = \left(\frac{1}{10}\right)^m \qquad \text{Eq. 6}$$

In Equation 6, m is the thickness of the material given in number of TVLs.

HVL can be found graphically from the attenuation curve, whether on a linear or log plot (see Figure 6-10) and for monoenergetic photons can be determined anywhere along the curve because μ is constant; the ratio of the two intensities must be ½. For polyenergetic photons, μ is not constant but instead decreases with increasing depth (Figure 6-12, *A*). The low-energy component of the beam spectrum is attenuated preferentially, compared with high-energy photons because of increased attenuation at low energies. As depth increases, the ratio of high-energy to low-energy photons increases, resulting in increased beam penetration, or "beam hardening." After a large number of low-energy photons are attenuated at depth, additional beam hardening is minimal and μ is essentially constant. The log attenuation curve begins steeply, has curvature, and then becomes linear at depth (Figure 6-12, *B*). Because μ changes with depth, HVL also changes, yielding different first and second HVLs, as defined in Figure 6-12, *B*. The monoenergetic case is shown for comparison. For a polyenergetic beam HVL_1 is always less than HVL_2 because photons incident on HVL_2 have a higher average energy, thus $HVL_1 < HVL_2$. The greatest HVL is found at maximum depth, on the linear portion of the attenuation curve where beam hardening is the greatest. For polyenergetic photon beams, an effective attenuation coefficient (μ_{eff}) can be calculated by determining an effective HVL over a region of interest and then calculating μ_{eff}:

$$\mu_{eff} = 0.693/HVL_{eff}$$

Characteristics of attenuation curves for monoenergetic and polyenergetic photons are summarized in Table 6-6.

TABLE 6-6 Characteristics of Attenuation Curves

Monoenergetic	Polyenergetic
1. Exponential curve on linear scale	1. Complex exponential curve on linear scale
2. Linear curve on semi-log scale	2. Curved on semi-log scale
3. Constant μ	3. Varying μ/μ_{eff} can be determined
4. Constant HVL	4. Varying HVL/HVL_1, HVL_2, TVL, and greatest HVL can be determined

HVL, *Half-value layer;* TVL, *tenth-value layer. See text for other terms.*

Attenuation Coefficients

The linear attenuation coefficient is one representation of photon interaction probabilities. Another form, the mass attenuation coefficient, μ/ρ, is the linear attenuation coefficient divided by the material's density, ρ, and has units of cm^2/g. It is independent of material density and is the form of attenuation coefficient commonly found in physics data tables, presented according to incident photon energy and the attenuating element or material. Its use in attenuation computations requires the density of the material according to

$$\frac{I}{I_0} = e^{-\frac{\mu}{\rho}\rho x} \qquad \text{Eq. 7}$$

Attenuation coefficients can also be expressed in other forms and can be converted from one form to another.[21]

Photon Interactions: X-Rays and Gamma Rays

Attenuation of photon beams is the result of interactions in the intercepting material. There are five most common photon interactions: coherent scattering, photoelectric effect, Compton effect, pair production, and photodisintegration. Each interaction type has an independent interaction probability and contributes to the amount of attenuation. The total linear and mass attenuation coefficients are given by the sum of their components:

$$\mu_{TOT} = \mu_{COH} + \mu_{PE} + \mu_{CE} + \mu_{PP} + \mu_{PD}$$

and

$$\mu/\rho_{TOT} = \mu/\rho_{COH} + \mu/\rho_{PE} + \mu/\rho_{CE} + \mu/\rho_{PP} + \mu/\rho_{PD}$$

In the previous equations, TOT signifies the total coefficient and COH, PE, CE, PP, and PD refer to the respective five interactions. The photoelectric effect, Compton effect, and pair production are the most important interactions for megavoltage photons used for radiotherapy. Detailed presentations of these five interactions have been published.[2,21,22]

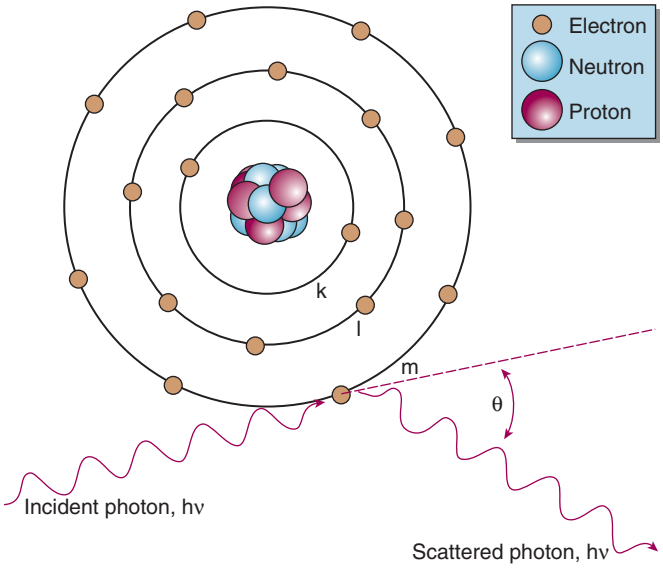

Figure 6-13 Coherent scattering.

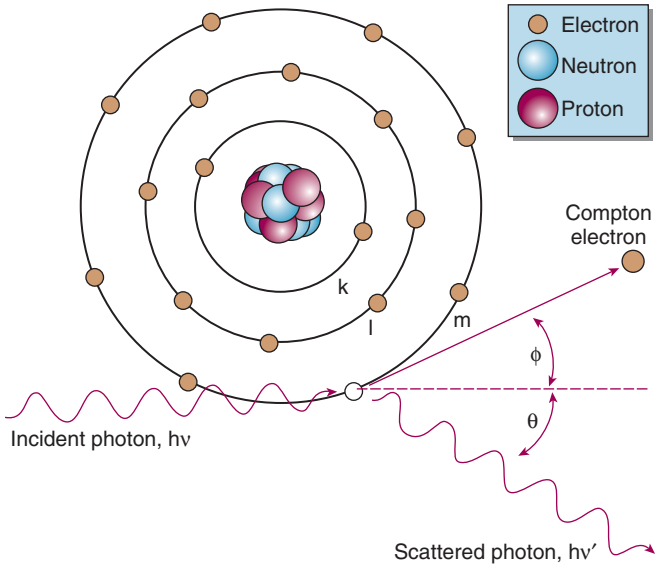

Figure 6-15 Compton effect.

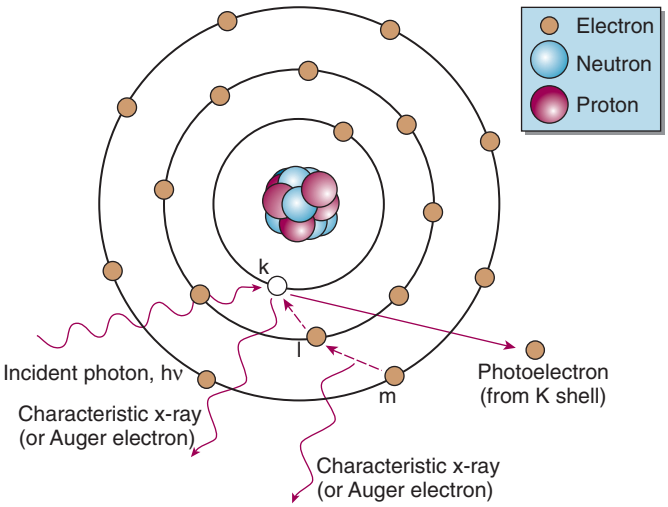

Figure 6-14 Photoelectric effect.

Coherent Scattering

In coherent scattering, a photon is scattered off an outer orbital electron with a change in direction and no change in energy (Figure 6-13). At very low energies (<10 keV), the amount of coherent scattering can be large and attenuation can be high, even though there is no change in photon energy. The amount of coherent scattering is negligible in the diagnostic and therapy energy ranges compared with other principal interactions.

Photoelectric Effect

The following actions occur in the photoelectric effect (Figure 6-14):

1. An incident photon with energy, $E\gamma = h\nu$, interacts with the inner orbital electron with binding energy E_B (most tightly bound). The interaction can occur with other orbital electrons, but the most probable interaction is with the innermost electron.
2. The photon is completely absorbed and no longer exists.
3. The orbital electron, now called the *photoelectron*, is ejected with kinetic energy, E_{pe}, equal to the photon energy minus the binding energy:

$$E_{pe} = E\gamma - E_B$$

If $E\gamma$ is less than E_B, the interaction cannot occur, but the interaction may occur with another orbital electron with a binding energy less than $E\gamma$.

4. Ejection of the orbital electron leaves a vacancy in the inner electron shell. This vacancy is filled by an electron from one of the outer orbitals, with the simultaneous emission of a characteristic x-ray with an energy of E_{cx} equal to the difference of the two electron binding energies (Figure 6-15):

$$E_{CX} = E_{B1} - E_{B2}$$

5. This process leaves a new vacancy in an outer orbital shell, which is filled by an electron from an orbital beyond, with emission of a second characteristic x-ray of lower energy than the first. This cascade of vacancy creation, filling, and characteristic x-ray emission continues until the most outer orbital electron shell has a vacancy that is filled by a "free," or unbound, electron.
6. A competing process to characteristic x-ray emission is the production of an Auger (pronounced "oh-jhay") electron. In this process, the characteristic x-ray energy, E_{CX} , is transferred to one of the nearby orbital electrons with no x-ray emission, and the electron, called an *Auger electron*, is ejected with energy:

$$E_{AU} = E_{CX} - E_{B2} = E_{B1} - 2E_{B2}$$

Characteristic x-rays are so named because their energies are directly related to the unique energy levels of the electron orbits for an element. A material's elemental composition can be determined by detecting its characteristic x-rays. Characteristic x-rays are named for the orbital electron transition that occurred. For instance, a K_α x-ray results in the *L* shell electron filling the K shell vacancy, an M → K transition yields a K_β x-ray, and an M → L transition yields an L_α x-ray.

For an atom with five electron orbitals, the possible electron transitions and their characteristic x-rays after a photoelectric

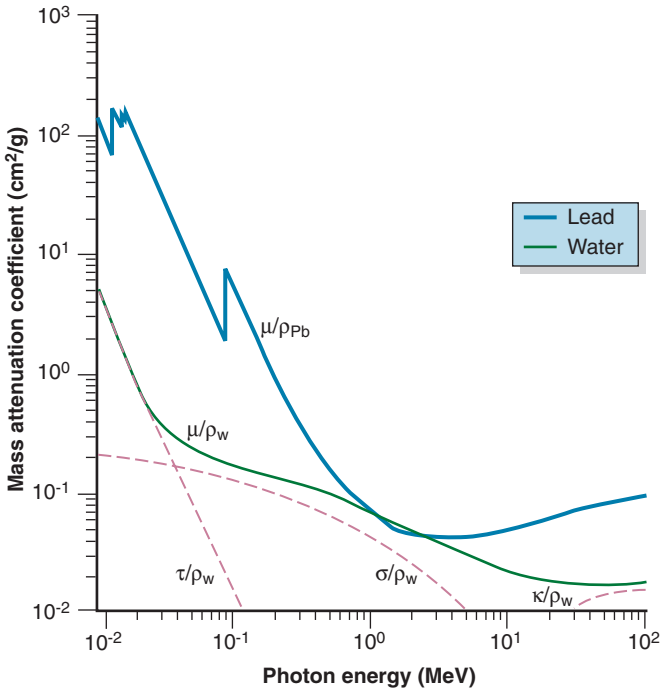

Figure 6-16 Total mass attenuation coefficients for lead and water. Individual interaction coefficients for water *(dashed lines)* also are shown. *Data from Radiological health handbook. Bethesda, MD, U.S. Department of Health, Education, and Welfare, 1970; and Evans RD: The atomic nucleus. Malabar, FL, 1955, Robert E. Krieger Publishing.*

interaction are L → K, M → L, N → M, O → N, M → K, N → K, O → K, N → L, O → L, and O → M. The most probable transitions are those between adjacent orbitals: L → K, M → L, N → M, and so forth. At the same time, Auger electron emission competes with characteristic x-ray emission, at a rate given by w, the fluorescence coefficient.

The photoelectric effect has a strong dependency on photon energy and atomic number of the material. The mass attenuation coefficient varies as $(1/E\gamma)^3$ and Z^3, respectively. Mathematically, this is shown as follows, where CPE is a proportionality constant:

$$\mu/\rho_{PE} = C_{PE} Z^3/(E\gamma)^3 \qquad \text{Eq. 8}$$

These dependencies for water are shown graphically in Figure 6-16. In the photoelectric effect, no interaction is possible until the photon energy is greater than the electron binding energy. After the binding energy is barely exceeded, the probability for interaction increases greatly, leading to a sharp increase in μ/ρ_{PE}, called an *absorption edge*. In Figure 6-16, the *K* and *L* edges for lead are seen, corresponding to photoelectric interactions for the *K* and *L* shell electrons. No absorption edges are shown for water; the binding energies are less than 1 keV and do not show up on the graph.

The dependence on *Z* and E_γ can be used to approximate the photoelectric contribution in a different material, using the formula:

$$\mu/\rho_{PE,2} = \mu/\rho_{PE,1}(E_{\gamma,1}/E_{\gamma,2})^3(Z_2/Z_1)^3 \qquad \text{Eq. 9}$$

If the material *(Z)* is constant but energy is changed, the new photoelectric mass attenuation coefficient is found by:

$$\mu/\rho_{PE,2} = \mu/\rho_{PE,1}(E_{\gamma 1}/E_{\gamma 2})^3 \qquad \text{Eq. 10}$$

If the photon energy (E_γ) is constant but the attenuating material is changed, the new photoelectric mass attenuation coefficient is found by:

$$\mu/\rho_{PE,2} = \mu/\rho_{PE,1}(Z_2/Z_1)^3 \qquad \text{Eq. 11}$$

Compton Effect

In the Compton effect (see Figure 6-15), several events occur:

1. An incident photon with energy, $E\gamma = h\nu$ interacts with a loosely bound, outer orbit electron.
2. The photon is scattered at some angle with reduced energy $E'\gamma = h\nu'$.
3. The orbital electron, now called the recoil or Compton electron, is ejected with kinetic energy, E_{ce}, equal to the difference between the incident and scattered photon energies:

$$E_{ce} = E_\gamma - E'_\gamma$$

4. Because the interaction is with the outer shell electron, which has negligible binding energy, there are no characteristic x-rays or Auger electrons produced.

The distribution of energies and scattering angles for the Compton photon and electron can be described mathematically. The scattered photon has energy $E'\gamma = h\nu'$ given by

$$h\nu' = \frac{h\nu}{1+\alpha(1-\cos\theta)} = \frac{m_o c^2}{1+\left(\frac{1}{\alpha}-\cos\theta\right)} \qquad \text{Eq. 12}$$

In Equation 12, $\alpha = h\nu/m_o c^2$ and represents the ratio of the incident photon energy to the rest mass of the electron, m_o, and θ is the angle of photon scattering as defined in Figure 6-15.

The Compton electron has energy E_{ce} given by the following equation:

$$E_{ce} = h\nu\frac{\alpha(1-\cos\theta)}{1+\alpha(1-\cos\theta)} \qquad \text{Eq. 13}$$

and a scattering angle, ϕ, that depends on the incident photon's energy and its scattering angle, θ:

$$\cos\phi = (1+\alpha)\tan\frac{\theta}{2} \qquad \text{Eq. 14}$$

Selected scattering cases can be considered:

1. The minimum energy transfer occurs for a 0-degree photon scatter; there is no interaction, and the "scattered" photon has the same energy as the incident photon. The electron is scattered at 90 degrees (ϕ = 90 degrees) with zero energy.
2. The maximum energy transfer occurs for a direct hit with a backscattered photon (θ = 180 degrees) and yields a (minimum) scattered photon energy of

$$h\nu' = \frac{h\nu}{1+2\alpha} \qquad \text{Eq. 15}$$

The backscattered Compton photon energy will always be less than and will approach 0.25 MeV (which equals ½ $m_o c^2$) even as the incident photon energy becomes very large. The electron has maximum energy of $E_{ce} = h\nu - h\nu' = h\nu\,(2\alpha/[1+2\alpha])$ and travels in the forward direction.

3. A 90-degree Compton scattered photon has energy:

$$h\nu' = \frac{h\nu}{1+\alpha} \qquad \text{Eq. 16}$$

The 90-degree scattered Compton photon energy will always be less than and will approach 0.511 MeV (which

equals $m_o c^2$) even as the incident photon energy becomes very large. The electron has energy of $E_{ce} = h\nu - h\nu' = h\nu\,(\alpha/[1+\alpha])$, and it travels in a direction that depends on the incident photon energy.

Although isotropically distributed for lower-energy photons, Compton electrons scatter more and more in the forward direction as incident photon energy increases. Their average energy also increases from about 10 keV to 7 MeV as incident photon energy increases from about 100 keV to 10 MeV.[11] The forward-peaked distribution is responsible for the buildup region for megavoltage photon beams, as explained later.

The Compton effect has a slight dependency on incident photon energy, decreasing as energy increases through the megavoltage range, but the interaction probability is essentially constant over most of the megavoltage energy range (Figure 6-16). Compton scattering is independent of atomic number and is dependent on the number of electrons available, or electron density (electrons per gram). The electron density for almost all materials is constant at approximately 3×10^{23} electrons per gram because the N/Z ratio is almost constant. The exception is hydrogen, which with one proton in the nucleus has an electron density of around 6×10^{23} electrons per gram. Except for a small energy dependency and increased interaction probabilities for hydrogen-laden materials, the Compton mass attenuation coefficient is remarkably constant across energy and atomic number, especially for low Z biologic materials such as tissues. Mathematically, this relationship is

$$\mu/\rho_{CE} = C_{CE} \qquad \text{Eq. 17}$$

In Equation 17, C_{CE} is almost a constant.

Attenuation by the Compton effect reduces to the following expression:

$$\left.\frac{I}{I_0}\right|_{CE} = e^{-C_{CE}px} \qquad \text{Eq. 18}$$

For unit thickness of a material, the transmitted amount depends only on material density, not atomic number and photon energy as with the photoelectric effect.

Pair Production

In pair production (Figure 6-17), the following steps occur:

1. An incident photon with energy $E_\gamma = h\nu$ and $E\gamma$ greater than 1.022 MeV passes near a heavy nucleus and spontaneously disappears, creating an electron, e^-, and a positron, e^+, in its place. These two particles are called an *electron-positron pair.* The total kinetic energy of the electron-positron pair, E_{ep}, is equal to the photon energy minus the energy needed to create two electrons, or 1.022 MeV (the rest energy of an electron is 0.511 MeV):

$$E_{ep} = E_\gamma - 1.022\ \text{MeV}$$

   The electron and positron travel off in no particular directions and do not have equal kinetic energies.
2. The electron gradually slows down and is stopped in the material.
3. The positron, the antiparticle of an electron, slows down quickly and annihilates with a free electron, giving off two 0.511-MeV photons (called *annihilation radiation*) that travel in opposite directions (i.e., at 180 degrees).

   The mass attenuation coefficient for pair production varies linearly with atomic number and incident photon energy (when the photon energy is above the threshold of 1.022 MeV):

$$\mu/\rho_{pp} = C_{pp} Z (E_\gamma - 1.022\ \text{MeV}) \qquad \text{Eq. 19}$$

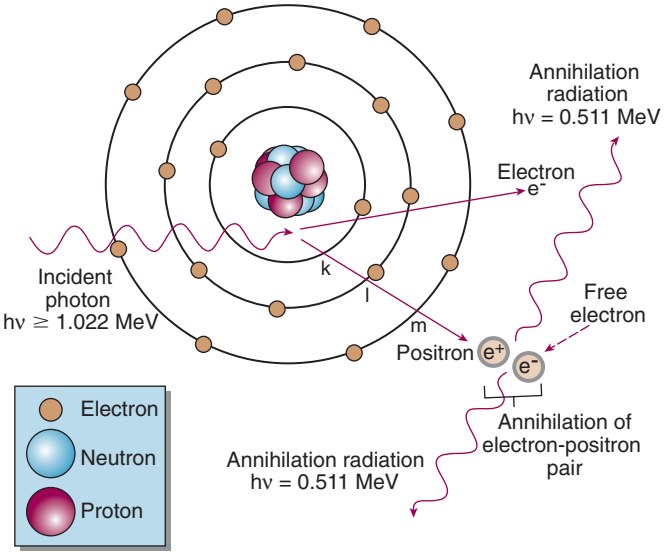

Figure 6-17 Pair production.

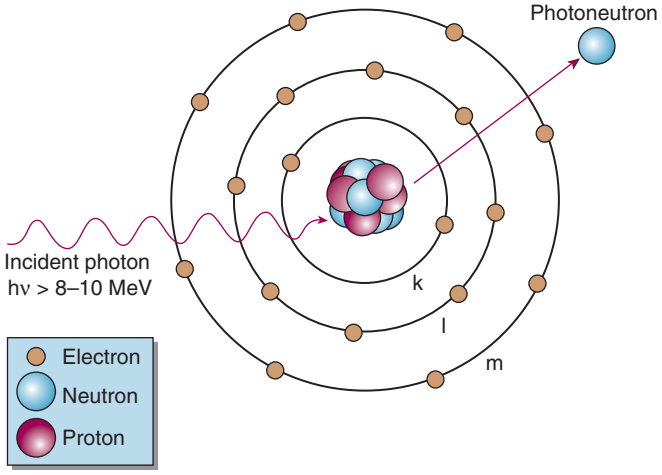

Figure 6-18 Photodisintegration.

Photodisintegration

Several steps occur in photodisintegration (Figure 6-18):

1. An energetic photon of $E\gamma$ greater than 8 to 10 MeV interacts with the atomic nucleus.
2. The photon penetrates the nucleus and is absorbed. The energy deposition results in the emission of a neutron or proton.
3. Neutron emission leaves a fragmented, possibly unstable nucleus (i.e., radioactive), prompting the name *photodisintegration.*

An energy of greater than 8 to 10 MeV is required because the nuclear binding energies for nucleons are 8 to 10 MeV for most materials. Photodisintegration is the interaction responsible for neutron production for photon energies at 10 MeV and greater and can be an important consideration for facility shielding for photon beams of 15 MeV and greater.

Distribution of Secondary Electrons

Electrons released by ionizing photon interactions can travel in any direction from the interaction point and in general have a complex probability for angular spread, depending on incident photon energy and the interaction that occurs. The

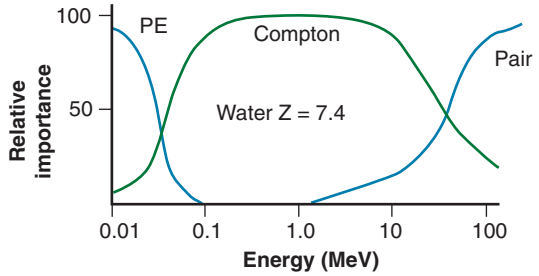

Figure 6-19 Relative importance of photon interactions as a function of photon energy.

probability for forward directions increases with photon energy and is a likely direction for megavoltage photon interactions.[2] As seen later, angular scattering of electrons is responsible for a number of characteristics for megavoltage photon beams, including surface dose, the buildup region, the depth of maximum dose, and the penumbra region.

Total Attenuation Coefficient

Each radiation interaction contributes its part to the total attenuation coefficient. Photons having the same energy can undergo any one of the five interactions when energetically possible. However, the probability for each interaction is different and in a particular energy range a particular interaction will dominate.

In Figure 6-16, the individual interaction and total mass attenuation coefficients are shown as a function of energy for lead and water. Notice the *K* edge in the curve for lead. It can be seen that different energy regions are dominated by particular interactions. For water, the photoelectric effect dominates for photon energies up to 60 keV, the Compton dominates from 60 keV to 10 MeV, and pair production dominates approximately above 10 MeV. For lead, the photoelectric effect dominates up to 700 keV, the Compton effect from 700 keV to 3 MeV, and pair production at 3 MeV and higher. An interaction's region of dominance can be represented graphically to show relative importance as a function of energy (Figure 6-19).

Comparison of interaction dependencies shows why diagnostic energy photons give good contrast for imaging: the photoelectric effect dominates and is quite sensitive to the atomic numbers of the materials being imaged. Materials with even slightly different *Z*s have good subject contrast (and image contrast) because attenuation depends on the cube of the atomic numbers. Radiotherapy portal images, however, have poor contrast because the dominant interaction is the Compton effect. There is no dependence on atomic number, and the effect is constant for most biologic materials (except for hydrogenous materials). Instead of imaging atomic number, the Compton effect images the density of a material, and subject contrast and image contrast are essentially representations of differences in material densities. A comparison of simulator and port images is given later (see Figure 6-49).

Total Absorption Coefficient

Radiation dose relates directly to the amount of energy absorbed at a point, not the amount attenuated, although the two are intimately related. This transfer of energy is done by secondary electrons (photoelectrons, Compton electrons, and the electron-positron pair) that produce a large number of ionizations along their paths until their energy is expended. A portion of the photon energy that is attenuated may escape to other regions as a coherent or Compton scattered photon, an annihilation photon (0.511 MeV), or a bremsstrahlung photon after radiative collision of a secondary electron. The amount of energy absorbed from secondary electrons is less than the amount attenuated as photons, as described by Johns.[21] In a similar fashion to the total mass attenuation coefficient, the total mass *energy absorption* coefficient, μ_{en}/ρ, or simply the mass *absorption* coefficient, describes the energy absorbed resulting from each interaction and is used for computing dose. The value of μ_{en}/ρ is first equal to μ_{TOT}/ρ in the photoelectric region (because all photon energy is transferred to the photoelectron), and then μ_{en}/ρ is less than μ_{TOT}/ρ in the region where the Compton effect dominates (because the Compton scattered photon carries energy away that does not contribute dose to the local region). At very high energies where pair production dominates, μ_{en}/ρ and μ_{TOT}/ρ are almost equal because the fraction of incident photon energy carried off as annihilation photons is negligible compared with the amount transferred to kinetic energy of the electron-positron pair. Over the energy range used for radiotherapy, the amount of absorbed energy at a point in water (tissue) is about one half the amount attenuated at the point. The mass absorption coefficient and dose are discussed more in the next section.

Summary of Photon Interactions

1. Coherent scattering occurs at very low photon energies (<10 keV).
2. The photoelectric effect dominates up to 60 keV in water, with strong dependencies of Z^3 and $1/E^3_\gamma$ for other materials.
3. The Compton effect dominates from 60 keV to about 10 MeV in water, with some dependence on energy or atomic number. Compton scattering depends only on the number of electrons per gram, which is almost constant for all materials ($N_g \approx 3.0 \times 10^{23}$, except for hydrogen, for which $N_g \approx 6.0 \times 10^{23}$).
4. Pair production occurs for photon energies only above 1.022 MeV, dominates above 10 MeV in water, and linearly depends on *Z* and photon energy.
5. Photodisintegration occurs at photon energies above 10 MeV and is responsible for the creation of neutrons in a linear accelerator facility.
6. At diagnostic photon energies, image contrast is determined primarily by differences in atomic numbers of materials being imaged because the photoelectric effect depends strongly on *Z*. Material thickness and density are secondary determinants.
7. At therapeutic photon energies, image contrast is provided by the densities of materials being imaged because the Compton effect depends on the number of electrons per gram, not the atomic number, of a material.
8. The total mass attenuation coefficient describes the amount of attenuation from all processes. A portion of the energy attenuated from the beam is deposited by secondary electrons as dose. The amount of energy absorbed as dose is described by the total mass absorption coefficient, which tracks the total mass attenuation coefficient and is numerically less.

Charged Particle Interactions

Charged particles incident on matter undergo inelastic and elastic interactions with atomic electrons and nuclei, that is, other charged entities.[2,12,13] Inelastic interactions include collisional and radiative processes and result in energy loss by the particle. In an elastic interaction the particle is scattered by an atomic electron or nucleus, resulting in a change of direction for the particle but no energy loss. The interaction probability for charged particles is effectively 1; an incident charged particle interacts at every opportunity. The quotient dE/dx (units of million electron volts per centimeter) is called the *stopping power,* and for charged particles it describes the rate of

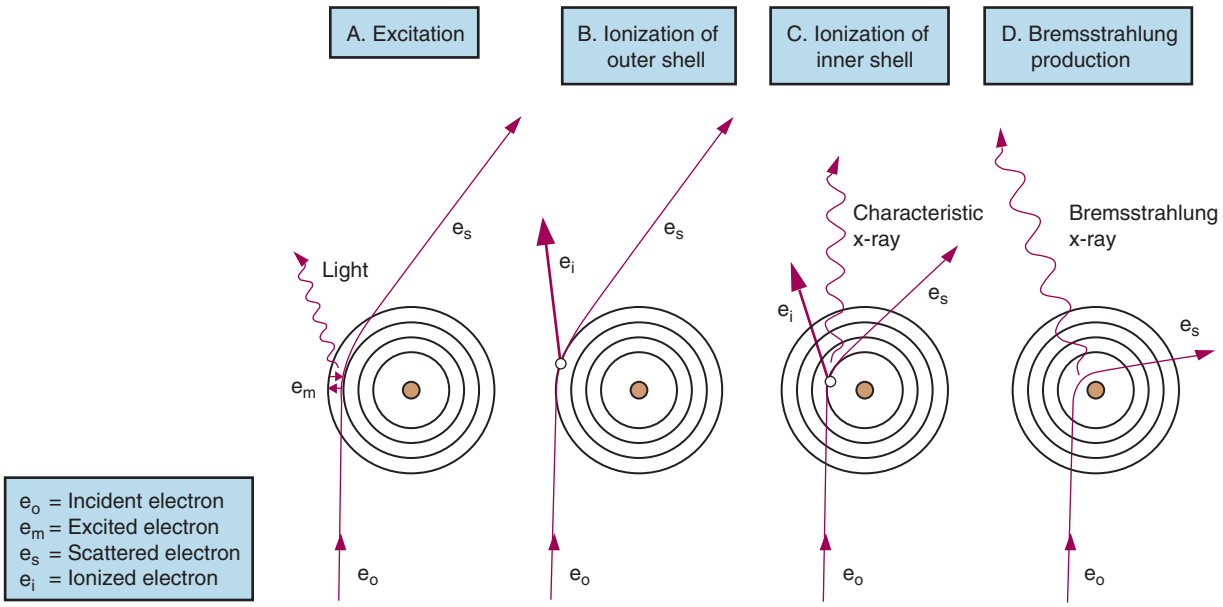

Figure 6-20 Electron interactions. **A,** Excitation. **B,** Ionization of outer shell. **C,** Ionization of inner shell. **D,** Bremsstrahlung production.

energy loss, dE, that occurs over distance traveled, dx, for inelastic collisions. Stopping power is often expressed as the mass stopping power, $dE/\rho dx$ (units of million electron volts per gram per square centimeter), which is independent of the absorber density. Because energy loss is almost continuous and a particle has a particular kinetic energy, E_{KE}, the particle loses this amount of energy and then stops. The distance traveled is finite and is called the *particle range;* the particle can go no farther, and its kinetic energy is zero. For an absorber of density ρ, the particle range, r, can be calculated as follows:

$$r = E_{kE} \frac{1}{\frac{dE}{\rho dx}} \frac{1}{\rho} \qquad \text{Eq. 20}$$

The energy lost through inelastic collisions depends on the particle mass, charge, and kinetic energy and on the mass and charge of the target atom, according to the formula:

$$\frac{dE}{dx} = \frac{2\pi z^2 e^4}{m_o V^2} NZF_Q \qquad \text{Eq. 21}$$

In Equation 21, z is the atomic number of the incident particle of mass M, V is its velocity, e is the electron charge, m_o is the electron mass, NZ is the number of electrons per cubic centimeter in the absorber, and F_Q is a complex function describing energy transfer per interaction.

Collisional energy losses increase by the square of the particle's atomic number and as the incident particle velocity decreases. Increased atomic number results in a greater coulomb force, and decreased velocity increases the amount of interaction time, both leading to increased dE/dx. The energy transfer function, F_Q, is complex and varies with the type of interaction.[2] It accounts for the atomic mass of the absorber, ionization potential, and relativistic effects as V approaches the speed of light.

Light Charged Particle Interactions: Electrons

The electron mass is small compared with any atomic mass, and incident electrons undergo four types of particle interactions with a large amount of scattering.[8] Collisional

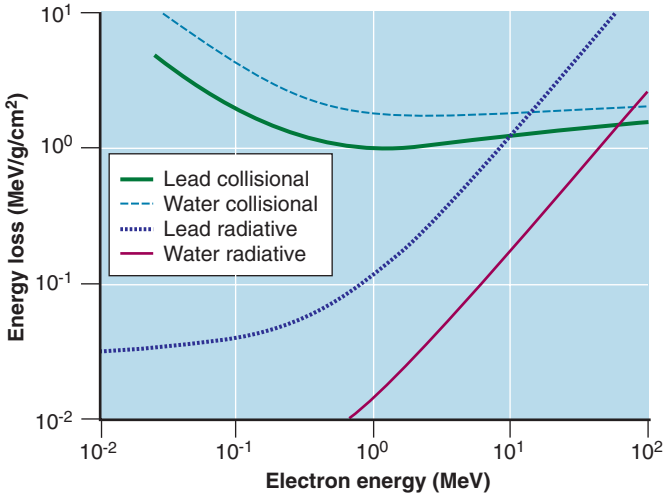

Figure 6-21 Collisional and radiative electron losses as a function of incident electron energy.
Adapted from Johns HE, Cunningham JR: The physics of radiology, ed 3, Springfield, IL, 1978, Charles C Thomas.

interactions result in energy loss of dE_{COL}/dx, causing ionizations or excited states (higher electron orbits) (Figure 6-20). Collisional losses increase as the electron velocity decreases, as stated previously, and decrease as the absorber atomic number increases. The decrease with absorber atomic number results from the decrease in the number of electrons per gram (NZ/ρ) as Z increases. For equivalent mass thicknesses (mass thickness is thickness divided by density, with units of square centimeters per gram), electrons are stopped sooner in low Z than in high Z materials. Figure 6-21 shows these relationships for water and lead.

Radiative interactions result in x-ray emissions. The incident electron penetrates the electron cloud and interacts with the nucleus's positive electrical field, undergoing an abrupt deceleration with energy loss dE_{RAD}/dx and a change in direction (see Figure 6-20, *D*). The energy change, dE_{RAD}/dx, is released in the form of x-rays, called *bremsstrahlung* (or

braking) *radiation.* With an incident monoenergetic electron fluence, a continuous x-ray spectrum is emitted because the probability of any energy loss, large or small, is equal per interaction. Successive bremsstrahlung interactions may occur as the electron loses its energy; a bremsstrahlung x-ray spectrum has a maximum energy equal to the initial electron energy and all other x-ray energies below this maximum to zero (see Figure 6-7). Radiative interactions are important; they are the mechanism by which bremsstrahlung x-rays are produced in diagnostic x-ray tubes and linear accelerators. Bremsstrahlung production increases with incident electron energy and the Z of the absorber (see Figure 6-21).

The probability for collisional and radiative interactions depends on electron energy and the atomic number of the incident material (see Figure 6-21). At electron energies of 100 keV and for high Z absorbers (e.g., x-ray targets), 99% of the interactions are collisional and 1% are radiative (x-ray production), resulting ultimately in heat deposition. At electron energies of 10 MeV, bremsstrahlung is a much more efficient process, and 50% of the interactions are collisional and 50% radiative. At 100 keV, x-ray production is inefficient, whereas at 10 MeV, x-ray production is efficient. Above 10 MeV, bremsstrahlung x-ray production exceeds collisional losses. It has been observed that dE_{COL}/dx increases as electron kinetic energy decreases below 1 MeV (see Figure 6-21). As the electron slows down, it loses energy faster. Above 1 MeV, electrons lose about 2 MeV/cm traveling in water ($dE_{COL}/dx \approx$ 2 MeV/cm). A 10-MeV electron has a range of about 5 cm in water (10 MeV ÷ 2 MeV/cm). Density scaling can be applied for materials different from unit density. For example, a 10-MeV electron travels approximately 3.3 cm in bone of density of 1.5 g/cm^3 (10 MeV ÷ [2 MeV/cm × 1.5]). These relationships use Equation 20 as their basis.

Heavy Charged Particle Interactions

Heavy charged particles, such as protons and alpha particles, experience mainly inelastic collisions. The rate of energy loss is high, resulting in short ranges. Trajectories in water or tissue are in the forward direction with little scattering; the particle mass is similar to that of the interacting material, and few large-angle direction changes occur, in contrast to the large amount of scattering experienced by electrons. Heavy charged particles exhibit rapidly increasing and large energy losses near the end of their ranges because of the dependency on Z^2 and $1/V^2$ discussed previously (see Eq. 21). This increase in energy loss results in a dramatic increase in ionization at the tail of the particle track length after a length of relatively constant loss, a phenomenon called the *Bragg peak.*[2,12,13] Bragg peaks are observable for protons (Figure 6-22) and alpha particles. All charged particles exhibit a Bragg peak, including electrons; however, electrons are light enough such that multiple scatters occur and ionization paths are randomly oriented, blurring any observable effect.

The proton finite range can be modulated through a physical attenuator or other means to decrease the range from the maximum. This process is essentially modulating the incident proton beam energy. If range modulation is done continuously while the beam is on, the Bragg peak will be swept over a range, called the Spread Out Bragg Peak (SOBP), and will produce a high dose plateau (see Figure 6-22). The width of the SOBP dose plateau can be designed to match a tumor size at a certain depth and demonstrates the attractiveness of protons for radiotherapy.

Heavy Uncharged Particle Interactions: the Neutron

Neutrons have no charge and do not undergo coulomb interactions like charged particles. Instead, neutrons interact by inelastic and elastic collisions with nuclei through the strong force. Commonly for lower and middle Z materials, a neutron penetrates the nucleus and is absorbed, followed by the ejection of a proton (the [n, p] reaction). The new nucleus may be radioactive, a process called *neutron activation.* Neutrons may also cause nuclear disintegrations, similar to photodisintegration. For very heavy nuclei, neutrons may cause fission, a reaction harnessed for power production in nuclear reactors. Elastic scattering of neutrons is also common. The type of collision, inelastic or elastic, that a neutron experiences depends on the neutron energy and the absorber atomic number with complex reaction probabilities.[18,21] Neutrons lack charge, thus for higher energy (nonthermal) neutrons their interactions with nuclei are exponential in nature, like photons (see Figure 6-22). Their range can be stated as a mean path length equal to the inverse of the neutron attenuation coefficient.

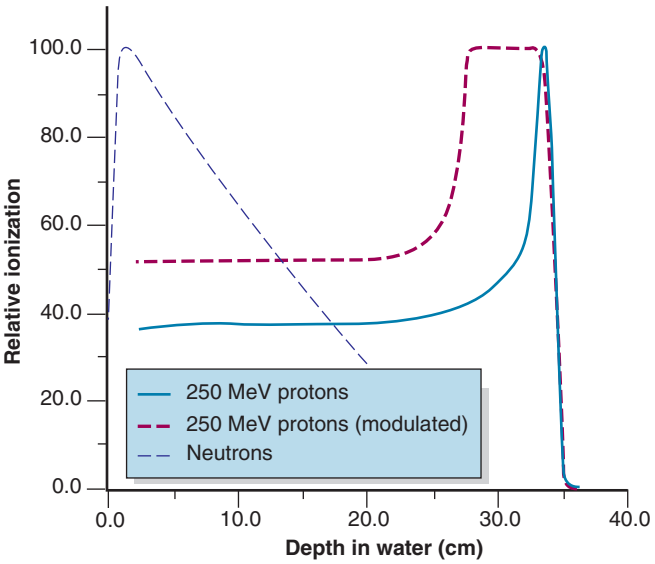

Figure 6-22 Ionization curves for heavy particles. Protons are charged and exhibit a Bragg peak at the end of their range. Neutrons are uncharged and are exponentially attenuated.

Summary of Particle Interactions

1. Particles with kinetic energy have inelastic and elastic interactions with an absorbing material. Inelastic collisions result in loss of energy, whereas elastic collisions do not.
2. Electrons experience inelastic collisions through coulomb interactions with the atomic electrons or the nucleus. Collisional interactions with the atomic electrons result in excitation or ionization. Interactions with the nucleus result in production of bremsstrahlung x-rays.
3. For electrons, collisional energy losses dominate at lower energies, whereas radiative losses dominate at higher energies. Interestingly, collisional energy losses are greater per gram of low Z material than for high Z materials. The material of choice for electron shielding is a low Z material because the stopping power per gram is higher and bremsstrahlung production is minimized.
4. In water or tissue, megavoltage electrons lose about 2 MeV/cm traveled. The electron range is finite, and its length in centimeters is found by dividing the energy (in MeV) by 2.
5. Electron interactions result in a large amount of scattering, caused by the light mass of the electron relative to the nuclear mass of any absorber.

6. Charged heavy particles undergo inelastic collisions mainly through coulomb interactions with the atomic electrons, resulting in excitation or ionization. Nuclear interactions occur only at very high energies and do not include bremsstrahlung production.
7. Charged heavy particles have a finite range and experience a rapid increase in energy loss near the end of their track, dumping much of their remaining energy quickly and producing an ionization curve with a Bragg peak. This is of greatest interest for the use of protons for treatment, using range modulation to create an SOBP that covers a target at depth.
8. Neutrons experience inelastic and elastic collisions with nuclei, resulting in nuclear rearrangements that are followed by ionization events. Neutrons do not have a finite range.

RADIATION QUANTITIES AND MEASUREMENT

Ionization and Its Fate

Ionizing radiation is quantified by measuring the amount of ionization produced. The number of ions is directly proportional to the amount of energy imparted to a material. An average of 33.92 eV is required to produce one ion pair (ip) in air.[23] This number is called the *W value* (W = 33.92 *eV/ip* for air), and it is almost independent of the radiation energy. W for other gases is quite similar to that of air, and its uniformity from material to material relates to atomic energy levels and capabilities for transfer of excitation energy.[2] Note that several values for the W value have been determined over time; these variations are small and are responsible for the slight differences in the coefficients used for conversion of exposure to dose, as reviewed later.[22,23]

In four of the five photon interactions, energy is transferred from incident photons to produce ionization or secondary processes. This energy transfer results in radiation dose, and for each interaction it has origins as follows:

1. In coherent scattering there is no ionization. However, the scattered photon might be able to undergo an ionizing interaction.
2. In the photoelectric effect the inner shell electrons are ionized. The photoelectron is ejected and loses its energy by excitation and ionizations. Characteristic x-rays and Auger electrons are energetic enough to cause ionizations.
3. In the Compton effect the outer shell electrons are ionized. The scattered photons and the Compton (recoil) electrons may be energetic enough to cause ionizations.
4. In pair production there is no direct ionization of the atom. However, the electron and positron each have enough energy to cause ionizations, and annihilation radiation is energetic enough to cause ionizations.
5. In photodisintegration there is no direct ionization of the atom. However, the remaining atom (with one fewer neutron) may be unstable and decay by emission of ionizing particles and the ejected neutron may cause activation of other atoms, resulting in nuclear decay and ionizations.

If these ions are collected and measured, the amount of energy deposited can be determined.

Radiation Quantities and Units

Ionizing radiation is quantified using two important quantities: exposure and dose. A third quantity, kerma, is an important concept that relates to exposure and dose.

Exposure

Exposure, *X*, is the measurement of the amount of ionization produced by photon interactions per mass of air (charge per mass of air). The SI unit for exposure is a charge of 1 coulomb (C) per mass of 1 kilogram (kg): $X = C/kg$. The original unit of exposure, *X*, essentially as the first quantitative definition of radiation dose (circa 1933), is the roentgen *(R)*, named after the discoverer of x-rays, Wilhelm Conrad Roentgen:

$$1R = 2.58 \times 10^{-4} C/kg \text{ of air } (= 1 \text{ esu}/cm^3 \text{ in air})$$

In the previous expression, *C* (coulomb) is a unit of charge (or ionization) such that 1 ip = 1.6×10^{-19} C. The original definition of charge per volume, 1 R = 1 esu/cm^3, was based on the *e*lectrostatic *u*nit and is responsible for the odd units of the roentgen as now defined. Use of the roentgen as a radiation quantity remains quite common, particularly within the radiation protection field.

Several important concepts characterize exposure, *X*:

1. It is defined for all ionizations, primary and secondary, when produced and measured in air.
2. It is defined only for ionizing photons (x- and gamma rays), not electrons or other particles.
3. It is properly measured only under conditions of electronic equilibrium, and it is difficult to measure for photon energies higher than 3 MeV. Above this energy the electron range in air becomes too large for electronic equilibrium to be achieved practically.

Electronic Equilibrium

With electronic equilibrium, ionization lost downstream from a volume of interest is replaced by an equal amount from upstream, producing an equilibrium and an accurate ionization measurement. The concept is illustrated in Figure 6-23. After interaction, ionization (electrons) travels away from the interaction point in the direction of the incident photons and a portion actually leaves the volume of interest. To accurately measure the amount of ionization produced, the lost kinetic energy of the escaping electrons must be replaced by an equal amount that enters the volume from upstream (Figure 6-23). This equilibrium of energy flow is called *electronic equilibrium* or *charged-particle equilibrium* and is a required condition for measurement of exposure.

Dose

Dose, *D*, is the measurement of the amount of energy imparted per mass of material (energy per mass).[11] The unit of dose is the gray *(Gy)*: 1 Gy = 1 J/kg. An earlier dose unit is the rad *(rad)*: 1 rad = 100 erg/g = 0.01 Gy; 1 Gy = 100 rad. Although not an official unit, cGy, is often used because of its numerical equivalency to the rad: 1 cGy = 1/100 Gy = 1 rad. Thus, 100 cGy = 1 Gy.

Dose does not have the restrictions of exposure, and the following two statements therefore apply:

1. Dose is valid for any ionizing radiation at any energy (e.g., x-rays, gamma rays, e^-, e^+, n, p, α, Π).

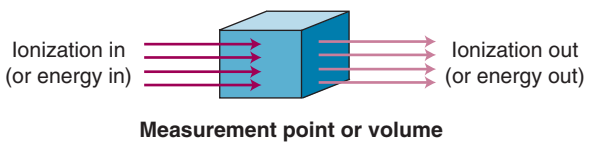

Figure 6-23 Ionization lost downstream from a volume of interest is replaced by an equal amount from upstream, producing electronic equilibrium and an accurate ionization measurement.

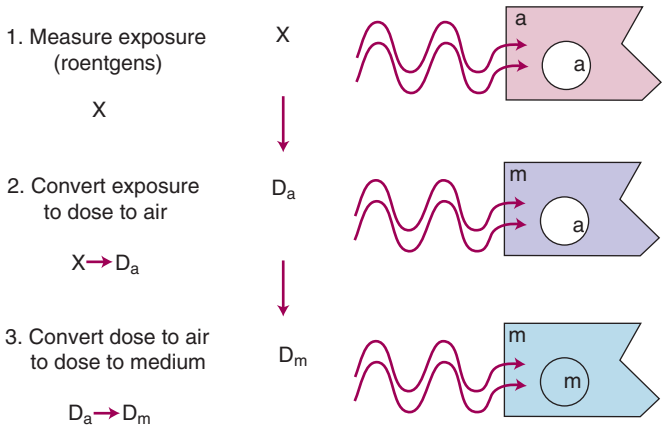

Figure 6-24 The dose measurement process. Exposure to a small mass of air is converted to the dose to medium.

2. Dose is valid for any material and phase: solid, liquid, or gas.

In practice, dose to a medium is determined by measuring exposure and converting it to dose using the W value and the mass energy absorption coefficient, μ_{en}/ρ. The mass energy absorption coefficient is similar to the mass attenuation coefficient, except it describes energy absorbed, not attenuated. The process is illustrated in Figure 6-24 for the following steps, using the original definition of exposure, the roentgen, and with the assumption of electronic equilibrium:

1. Exposure, X, of 1 R is given to a small air-filled cavity contained in a material:

$$X = 1R$$

2. Dose to air in the cavity is computed using the W value and the definition of the roentgen, converting energy units as needed:

$$D_a = WX = 33.92\ \text{eV/ip} \times 1\ \text{R}$$
$$\text{(converting units)} = (33.92\ \text{eV/ip})(1\ \text{ip}/1.6\times10^{-19}\ \text{coul}) \times (2.58\times10^{-4}\ \text{C/kg}/1\ \text{R}) \times (1.6\times10^{-12}\ \text{erg/eV}) \times (1\ \text{kg}/1000\ \text{g})$$
$$\text{(converting to Gy)} = (87.5\ \text{erg/g/R})(0.01\ \text{Gy}/100\ \text{erg/g})$$

so

$$D_a = 0.00875\ \text{Gy/R for an exposure of 1 R} \qquad \text{Eq. 22}$$

The coefficient of 0.00875 Gy/R is called the roentgen-to-gray conversion coefficient and is commonly expressed as the roentgen-to-centigray coefficient of 0.875 cGy/R. The important concept is that an exposure of 1 R, by definition, results in the energy release in air of 0.00875 Gy: 1 R → 0.00875 Gy (in air). This representation of exposure is called "air kerma"; it is the kinetic energies of charged particles released in air. Kerma and the Gray as a unit of dose are discussed later in greater detail.

For X number of roentgens, the dose to air is calculated as follows:

$$D_a = 0.00875\ \text{Gy/R}\ \text{X(R)} \qquad \text{Eq. 23}$$

3. Dose to the material is calculated by converting dose to air, D_a, to D_m. Conceptually, this step replaces the air cavity with an identical volume of the material. It can be shown[21,24] that

$$D_m = Da\left.\frac{\mu_{en}}{\rho}\right|_a^m \qquad \text{Eq. 24}$$

in which

$$\left.\frac{\mu_{en}}{\rho}\right|_a^m$$

is the mass energy absorption coefficient for the material,

$$\left.\frac{\mu_{en}}{\rho}\right|_m$$

divided by

$$\left.\frac{\mu_{en}}{\rho}\right|_a$$

the mass energy absorption coefficient for air.

Combining Equations 23 and 24 yields the following expressions:

$$D_m = \left.\frac{\mu_{en}}{\rho}\right|_a^m 0.875\ \text{cGy/RX(R)} \qquad \text{Eq. 25}$$

and

$$D_m = fX(R) \qquad \text{Eq. 26}$$

in which the f factor, f, is calculated as follows:

$$f = \left.\frac{\mu_{en}}{\rho}\right|_a^m 0.875\ \text{cGy/R} \qquad \text{Eq. 27}$$

For any exposure, $X(R)$, measured in air, the dose to a material substituted at that point can be found by multiplying the f factor by the exposure. In practice, the air-filled cavity is an ionization chamber that is inserted into the radiation beam and the ionization collected in the chamber is converted to dose using exposure-to-dose calibration factors in a prescribed procedure that accounts for the properties of the ionization chamber and particular radiation beam energy and irradiation geometry.

The f factor is an important parameter, and it varies as a function of the material and the photon energy, as shown for water, muscle, and bone in Figure 6-25. By its definition, the f factor for air is always 0.875 cGy/R. Water, muscle, and air have similar f factors because their effective atomic numbers are similar. Bone has a higher atomic number (by a factor of 2) and receives up to four times the dose that soft tissue would receive in the photoelectric region. This effect is responsible for high bone doses received during orthovoltage treatment as well as the contrast seen in diagnostic x-ray images. Notice the decrease in the f factor for fat in the photoelectric region because of its lower Z as a result of its high hydrogen content.

For treatment with ionizing radiation, the amount of energy deposited is quite small per fraction of dose. It takes about 1 million cGy to raise the temperature of 1 cm^3 of water by 1°C. Conversely, for a daily treatment dose of 2 Gy (200 cGy), the

increase in temperature per gram is only 0.0002°C. Thermal effects are non-existent for fractionated and radiosurgical radiation treatment.

Kerma

When photon radiation interacts with a material, energy is transferred to secondary electrons (the photoelectron, Compton electron, pair production electrons) and results in their kinetic energy. This transferred energy is called *kerma* (*k*inetic *e*nergy *r*eleased in *m*edium). Kerma, *K*, is expressed as the amount of energy released per mass of irradiated material and has the same unit as for dose, the gray (J/kg). For example and as reviewed previously, the amount of ionization produced (released) in air for 1 R of exposure is also the "air kerma," with conversion ratios of 1 R = 0.00875 Gy (air kerma) and 1 Gy (air kerma) = 114.3 R. Kerma differs from dose in that kerma is the energy *released* per mass, and dose is the energy *absorbed* per mass. These two quantities may be numerically quite similar, but there are three important aspects to their relationship:

1. The kerma at a point travels (primarily) in the forward direction for megavoltage photons. Secondary particles released at the point deliver their dose downstream from the point, not at the point. Kerma at an interaction point may result in a numerically equal dose at a downstream point of interest.
2. Even if at the same point of interest, kerma will be greater than dose, because secondary electrons may lose some of their energy by the bremsstrahlung process. The bremsstrahlung x-rays carry energy away from the point of interest. $D = K(1 - g)$, in which g is the fraction of energy lost to bremsstrahlung.
3. If electronic equilibrium is satisfied and bremsstrahlung is negligible ($g < 1$), dose equals kerma at the point of interaction. Thus, dose equals kerma, provided there is electronic equilibrium; this concept is key to radiation dose measurements.

Thorough treatments of exposure, dose, kerma, and their relationships are available.[12-14] Much has been studied and written about these and other dosimetric concepts to establish meaningful and consistent definitions. A summary is presented in Table 6-7.

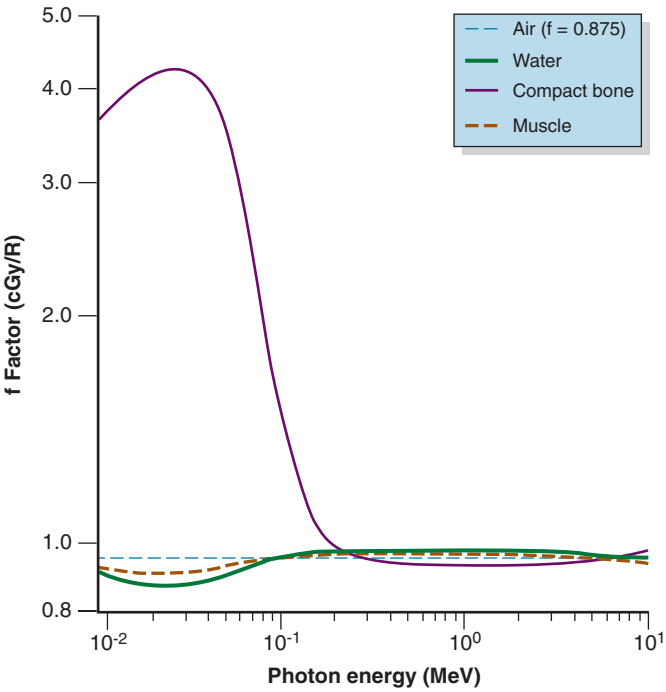

Figure 6-25 The f factor varies as a function of the material and the photon energy.
Data from Radiological health handbook. Bethesda, MD, 1970, U.S. Department of Health, Education, and Welfare.

Radiation Detection and Measurement

There are different types of radiation detection and measurement instruments with particular characteristics that enable measurements of a certain kind to be performed. General classes of instruments are gas-filled detectors, scintillation detectors, other solid-state detectors, absolute dosimeters, and personnel dosimeters.

Gas-Filled Detectors

Gas-filled detectors operate on the basic principle of measuring exposure, that is, collecting ionization in air or a substitute gas. A gas-filled volume is defined as one that contains two oppositely charged plates or wires to collect the charge resulting from ionization in the gas. The reading is in units of charge (coulombs), exposure, or exposure rate. Figure 6-26, *A* shows a simple parallel plate gas-filled detector and its components. As the voltage applied to the electrodes is increased from zero, the amount of charge collected increases (Figure 6-26, *B*). The distinct voltage regions are expanded in Table 6-8. In general, gas-filled detectors require calibration before making radiation measurements.

TABLE 6-7 Radiologic Units

Quantity	What Is Measured	Unit (Symbol)	Value
Exposure	Ionization in air	Roentgen (R)	2.58×10^4 C/kgl_{air}
Dose	Energy absorbed in matter	rad (rad)	100 erg/g
Dose (SI)	Energy absorbed in matter	Gray (Gy)	1 J/kg
Kerma	Kinetic energy released in matter	Gray (Gy)	1 J/kg
Dose equivalent	Biologic effect of energy absorbed	rem (rem)	QF × 100 erg/g
Dose equivalent (SI)	Biologic effect of energy absorbed	Sievert (Sv)	QF × 1 J/kg

TABLE 6-8 Voltage Regions of Gas-Filled Detectors

Region	Description
I	The recombination region. The voltage is not high enough to separate the ion pairs and recombination occurs.
II	The saturation region. The voltage is high enough to collect almost 100% of the ionization (hence, "saturation"). Also called the ionization region.
III	The proportional, or gas amplification, region. The voltage is high enough to accelerate the ionized electrons to an energy that causes additional ionization, amplifying the actual amount of initial ionization by a factor *M*.
IV	The Geiger-Muller, or GM, region. The voltage is high enough that amplification by accelerated ions proceeds so that the entire gas in the detector is ionized each time a photon hits the detector. Whether low or high energy, the amount of ionization that occurs is the same. Thus, a GM counter emits a "click" for each photon seen and is really a photon counting device.
V	The continuous discharge region. The voltage is high enough to spontaneously ionize the detector gas. Once started, the ionization continues and continues. The detector is not useful at this applied voltage.

Ionization Chambers

Ionization chambers operate in region II (see Figure 6-26, *B*) and are an important type of radiation dosimeter as the principal device used for calibration of radiotherapy beams. The design most commonly used for photon beams is the thimble chamber, also called a *Farmer chamber,* which has a cylindrical geometry with central linear and outer cylindrical electrodes (Figure 6-27, *A*). An active volume of 0.6 mL is convention, although chambers with smaller or larger volumes are available for specialized purposes such as small field dosimetry or low-dose-rate measurements. Parallel-plate chambers are also used and are the recommended chamber geometry for electron beam dosimetry (Figure 6-27, *B*). In general, ionization chambers require calibration before use. Ionization currents produced by radiation beams are very small, on the order of 10^{-9} amperes (A), and require a high-precision device called an *electrometer* for accurate measurement. An ionization chamber and electrometer require calibration before use and with a triaxial connecting cable are required tools for radiation beam calibration. Conditions for radiation beam calibrations are set by national protocols such as the Task Group (TG)-51 from the American Association of Physicists in Medicine[15] and by national or state regulatory bodies. A requirement for operation of all ionization chambers is that the chamber be operated under conditions of electronic equilibrium. In disequilibrium conditions, the amount of ionization measured is incorrect, as will be the exposure or dose calculation.

Solid-State Detectors

Thermoluminescent Dosimeters

In a simple model, crystalline solids have two electron energy levels, called the *valence* and *conduction bands.* The valence band holds bound electrons, whereas the conduction band consists of free electrons. Energy states between these two bands are forbidden. When ionized, a bound electron may gain sufficient energy to jump to the conduction band, leaving a positive "hole" in the valence band. The conduction band electron and the hole can move through the lattice and eventually recombine, with the emission of light on recombination. Because of impurities in the lattice, some crystalline materials have the property of having long-lived "traps" that can hold an electron-hole pair in an excited (or unfilled) state. The electron-hole pair is created and excited into the trap by the

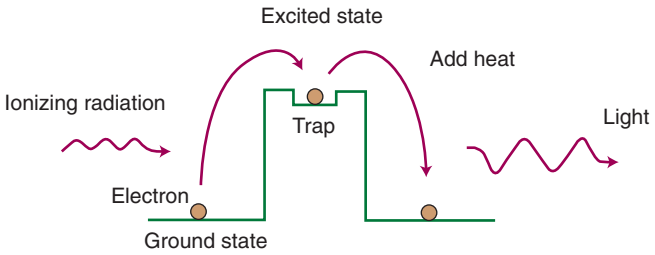

Figure 6-28 Thermoluminescence. Ionizing radiation raises an electron-hole pair to an excited but trapped state. Addition of heat allows de-excitation, which occurs with the emission of light.

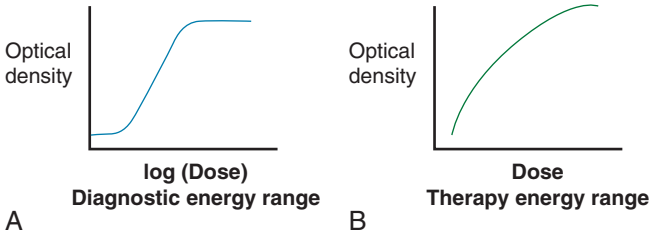

Figure 6-29 Film radiation response varies with film type, photon energy, and dose. **A,** Diagnostic photon energy response. **B,** Therapeutic photon energy response.

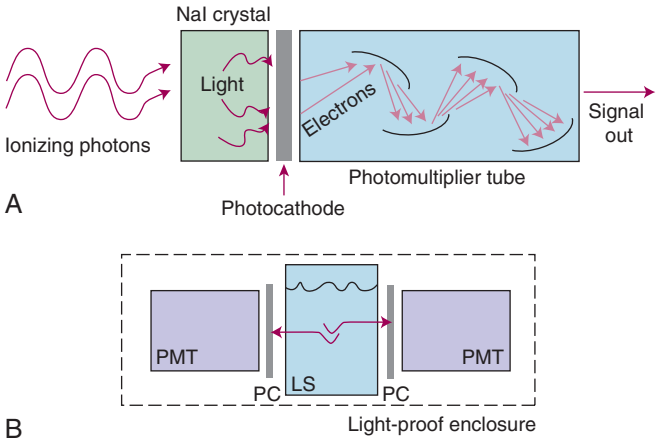

Figure 6-30 Scintillation detectors. Ionizing radiation creates light photons that are converted to electrons and amplified. **A,** Sodium iodine crystal and photomultiplier tube. **B,** Liquid scintillation detection.

absorption of ionizing radiation, which provides the energy to push the pair into the trap (Figure 6-28). Heating the crystal enables the electron-hole pair to leave the trap and return to the de-excited state. With this transition, an amount of light is emitted that is proportional to the amount of radiation dose. Dose is measured by measuring the amount of light emitted. The two most common types of thermoluminescent dosimeter (TLD) are lithium fluoride (LiF, almost tissue equivalent) and calcium fluoride (CaF, not tissue equivalent). A calibration factor must be obtained before use as a dosimeter. TLD is used for in vivo patient dose monitoring during treatment and for personnel monitoring for radiation safety purposes.

Film

Film is a solid-state detector and typically refers to silver-halide films that are sensitive to both light and ionizing radiation. The amount of optical density is proportional to the dose. The response is energy sensitive because film is relatively high Z (the silver content). Response curves are shown in Figure 6-29. Film is used to obtain relative dose distributions (i.e., isodose distributions) for treatment machine quality assurance tests for flatness, symmetry, radiation/light field congruence, and imaging.[16,25] A dose-response curve must be carefully measured, including constant processor control, to enable film to be used to measure actual (not relative) doses. Because of electronic image receptors for digital photography and medical imaging with kV and MV photons (e.g., diagnosis and treatment verification), relatively high cost, and the chemical development process required after exposure, medical uses of silver-halide radiographic film are almost nonexistent, except for specialized imaging applications such as mammography. For physics quality assurance and dosimetry purposes a new type of tissue-equivalent film, called *radiochromic film,* has become a powerful tool. Radiochromic film uses opacity changes from radiation-induced polymerization to indicate dose.[26] This film does not require developing but does have an optimal wavelength of light for reading. A digital flatbed three-channel (color) scanner can be used to read the radiochromic film opacity and through a calibration procedure one- and two-dimensional dose distributions can be obtained. Example uses in therapy beam quality assurance and dosimetry include small beam dosimetry, patient treatment plan verification (such as currently performed prior to a first IMRT procedure), and mechanical and radiologic quality assurance in radiosurgery. Radiochromic film is tissue equivalent and can be used over the full range of x-ray energies. Radiochromic film types are also available for different dose ranges, from 1 Gy up to 50 Gy. Currently, radiochromic film is not an acceptable medical imaging device because of its cost and lack of imaging contrast.

MOSFET Detectors

A semiconductor device called the metal oxide-silicon semiconductor field effect transistor, or MOSFET, can be used as a radiation detector for in vivo dosimetry and physics quality assurance. The p-type device generates electron-hole pairs during irradiation proportional to the dose delivered, and the number of holes, corresponding to dose, can later be read using an appropriate metering device. Advantages include very small size, which enables small field or "point" dose measurements, and the capability for being incorporated into both implantable dosimeters and surface-placed dosimeters for in vivo patient dosimetry.[27] MOSFET dosimeters are primarily used for external beam radiation treatment with photons and require calibration for the photon energy in use. Surface applications require an understanding of the buildup effect for proper assessment of surface dose. Real-time monitoring of brachytherapy dose delivery is also possible.

Scintillation Detectors

Scintillation (light) detectors detect radiation by measuring the amount of light produced in special crystalline materials by the ionizing radiation. The most common material used is sodium iodine (NaI). The NaI crystal is coupled to a photomultiplier tube that amplifies the detection signal coming from the crystal (Figure 6-30, *A*). NaI detectors are extremely sensitive and detect background radiation easily. They are used to detect low-energy or low-activity (dose rate) sources, for instance, in an isotope laboratory within the radiotherapy clinic or a research laboratory using liquid radioactive tracers. These detectors are used in uncalibrated form; a pulse indicates a photon has been detected.

Scintillation materials can also be made in liquid form. With this technique a radiation source (i.e., a sample of radioactive material) is put in direct contact with a liquid scintillator by immersion (see Figure 6-30, *B*). This intimate contact enables

extremely small activities to be detected. Detection limits are in the microcurie and picocurie ranges. This method is used most for detection of very-low-energy beta particles for radioisotope tracer studies, environmental sampling, and isotope analysis of waste or other materials. The liquid scintillator is called a *cocktail* and includes a solvent and the scintillation material. Liquid scintillation detectors require calibration before use, including determination of background count rates.

Semiconductor Detectors: Germanium and Silicon

Germanium (GeLi) and silicon (SiLi) detectors are semiconductor materials that can be used to detect the energies of photons. These detectors are useful only at very low dose rates (i.e., small sample activities or low fluence rates) and are used to measure the photon energy spectrum, not dose.

Absolute Dosimeters

Most dosimeters require calibration in the form of the dose or exposure per reading. Absolute dosimeters *do not* require calibration and instead measure the amount of dose directly.

Calorimetry

All radiation dose, which is energy imparted per mass, eventually becomes heat. If the change in temperature is measured, the amount of dose is known. Temperature changes per gray are quite small as previously stated; thus, a sensitive device called a *calorimeter* is used. Standard-setting bodies, such as the National Institute of Science and Technology, have calorimeters to set the exact calibration factors for radiation beams and instrumentation, and calorimeters are not part of the routine dosimetry instruments used in the radiotherapy clinic.

Chemical or Fricke Dosimeter

The Fricke dosimeter measures chemical changes that are catalyzed by ionizing radiation. The chemical yield of the new product is directly proportional to the radiation dose. The most common reaction used is ferric to ferrous sulfide, such that the amount of Fe^{3+} produced is proportional to the dose delivered. The yield per gray is small, and Fricke dosimeters are typically used in unique geometries and for high dose rates.

Personnel Dosimetry

Monitoring of dose for radiation safety purposes is required for workers who are occupationally exposed to ionizing radiation. Although previously TLD and film have been used, optically stimulated luminescence dosimeters (OSLDs), based on the stimulated luminescence of a thin matrix material of aluminum oxide (Al_2O_3:C) as the dose readout surrogate, is now a primary dosimeter material. The aluminum oxide dosimeter wafer is assembled with other components into a radiation "badge" that is worn at the waist or neck during work. Filters that overlay the dosimeter enable discrimination between electrons or low-energy photons and high-energy photons. Dose readout is accomplished in a light-tight reader and the dosimeter is stimulated with a precision light source to emit light that is proportional to the radiation dose received. Besides personnel dosimeters that must be interrogated with a specialized reader, for high-dose-rate environments there are direct-read dosimeters that can be used for instant readout. Such dosimeters are important for instances of emergency response. Personnel dosimeters are made in holders to enable whole-body and extremity monitoring, based on the work activities being conducted by the user.

References on radiation instrumentation and measurement are available that give detailed theory, design parameters, and operational characteristics for different classes of detectors.[21,22,28]

BUILDUP PHENOMENON

Megavoltage photon beams used for radiotherapy exhibit a phenomenon in which the dose in an absorber is relatively low at the surface but rapidly increases to a maximum during the next few millimeters or tens of millimeters. This region of rapidly increasing dose is called the *buildup region* and is explained as follows. The secondary electrons produced by megavoltage photon interactions travel primarily in the forward direction from the interaction point. The direction and range are represented by the groups of arrows in Figure 6-31. The surface is the first point of interaction, and the dose from these interactions is delivered in the forward direction (point A). Because there are no interaction points upstream from the surface to produce secondary electrons, the surface dose is low. Ignoring attenuation and other small changes to the photon fluence with depth, interactions occur in the next layer of material beneath the surface, with a similar forward dose distribution. These electron tracks overlap (sum) with those from the surface. Additional layers at depth have similar interactions and resulting secondary electron distributions that sum with previous ones. The amount of dose increases rapidly and nonlinearly as successive electron tracks overlap (point B). Given an average, finite secondary electron range, a point is eventually reached where full electron overlap occurs (point D). At this point, the number of summed electron tracks is constant because the electrons being produced match those being lost. A maximum dose, D_m, is reached at a depth called d_m (Figure 6-31), and d_m indicates the average secondary electron range and is the point at which electronic equilibrium is obtained. Because photon attenuation occurs, the number of interactions and resulting secondary electrons decreases with

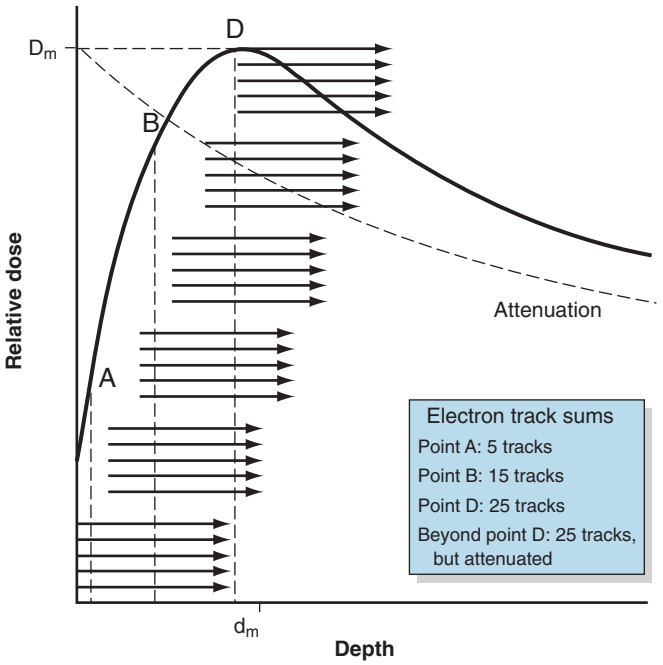

Figure 6-31 Radiation dose buildup. With secondary electrons primarily in the downstream direction, successive electron tracts overlap to produce a rapidly increasing region of dose, called *buildup*. A maximum dose, D_m, reached at a depth called d_m, indicates the average secondary electron range and is the point at which electronic equilibrium is obtained. Because photon attenuation occurs, the number of interactions *(dotted line)* and resulting secondary electrons decreases with the depth from the surface. Attenuation competes with the buildup process, but because buildup occurs more rapidly than attenuation, a net gain of dose results.

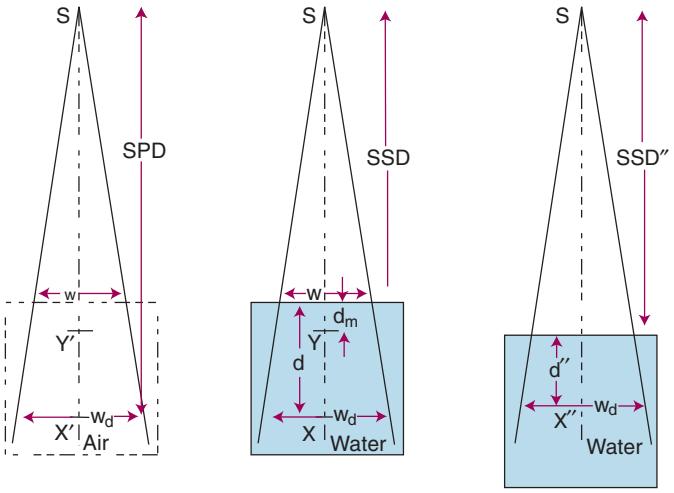

Figure 6-32 Reference irradiation geometries used for measurement of percent depth dose, tissue-air ratio, and tissue-phantom ratio. *Adapted from ICRU Report 24: Determination of absorbed dose in a patient irradiated by beams of x and gamma rays in radiotherapy procedures, Washington, DC, 1976, International Commission on Radiation Units and Measurements.*

depth from the surface. Attenuation competes with the buildup process; however, buildup is more rapid than attenuation, resulting in a net gain of dose. The presence and steepness of a buildup region depend on incident photon energy that governs the type of interaction and the range and distribution of secondary electrons. At higher photon energies, d_m is larger because the average secondary electron range is greater. Beyond d_m, photon attenuation results in transient electronic equilibrium (i.e., energy in is slightly greater than energy out) and a decrease in dose with depth (shown in Figure 6-31 as the dotted line; the difference is exaggerated).

DOSE RELATIONSHIPS FOR EXTERNAL BEAMS

Three mathematical functions that remain important both conceptually and in practice are used to describe the dose characteristics for external radiation beams: percent depth dose (PDD), tissue-air ratio (TAR), and tissue-phantom ratio (TPR).[12,13] These dose functions relate the dose at any point to the dose at a reference point. The irradiation geometry shown in Figure 6-32 illustrates the measurement conditions for the following discussions.[29]

Percent Depth Dose

The PDD is the ratio of the dose at depth, D_d, to the maximum dose, D_m, measured along the central axis of the beam and expressed as a percent. Points X and Y are the locations at depth, D_d and D_m, respectively, in Figure 6-32, *B*. PDD is dependent on the depth, d, reference depth, d_m (the point of maximum dose), beam quality (or energy), E, source-to-surface distance, SSD, and field size at the surface, w. Mathematically,

$$\mathrm{PDD}(d, d_m, E, \mathrm{SSD}, w) = \frac{D_d}{D_m} \times 100\% = \frac{D_X}{D_Y} \times 100\% \qquad \text{Eq. 28}$$

PDD is often expressed as a fraction rather than as a percentage. PDD was the dose function first measured for diagnostic and therapy radiation beams because of the simplicity of measurement, and it remains a basic dose measurement for beam characterization. Inherent in a PDD measurement are the effects of attenuation by the material and the inverse square effect as the distance from the source is changed. PDD is used for photon and electron beams and is often used in tabular form for monitor unit calculations.

Tissue-Air Ratio

Given a fixed irradiation point in space, the ratio of the dose in phantom, D_x, to the dose in air, D_x', at the same point is called the *TAR* (see Figure 6-32, *A* and *B*). TAR indicates how the dose in air is affected when the air is replaced by tissue. The field size at the point and source-to-point distance are constant; the only variable is the depth in phantom:

$$\mathrm{TAR}(d, w_d, E) = \frac{D_X(d, w_d, E)}{D'_X(w_d, E)} \qquad \text{Eq. 29}$$

TAR is essentially independent of SSD because scatter contributions are almost constant for fixed field sizes, regardless of SSD. This independence enables the use of the TAR over a wide range of clinically used SSDs without correction. TAR is used for photon beams only and is not valid for electron beams.

A special case of the TAR, called the *backscatter factor* (BSF), exists when the point of interest is the depth of maximum dose (when $d = d_m$). In this case, the TAR has a maximum value, and

$$\mathrm{BSF}(w_{d_m}, E) = \mathrm{TAR}(d_m, w_{d_m}, E) = \frac{D_Y}{D_{Y'}} \qquad \text{Eq. 30}$$

The BSF takes its name for historical reasons, from a time when low-energy photons were used and the point of maximum dose was on the surface. Any dose scattered to the surface from the phantom or patient was truly backscattered dose.

To determine the TAR and BSF, dose data are acquired at sampled points in phantom and air across and along the radiation beam central axis for the range of field sizes, depths, and SSDs or source-to-axis distances (SADs) clinically relevant.

Tissue-Phantom Ratio

TPR must be used for photon energies above about 4 MV, when in-air measurements required for the TAR are impractical. As with PDD and the TAR, the TPR is the ratio of two doses; however, both doses are made in phantom. The TPR is the ratio of dose D_x, measured at depth d, to dose $D_{x''}$, measured at a reference depth d'' (see Figure 6-32, *B* and *C*):

$$\mathrm{TPR}(d, w_d, E, d'') = D_{X''} \frac{D_X(d, w_d, E)}{(d'', w_{d''}, E)} \qquad \text{Eq. 31}$$

Both measurement points are fixed in space such that the source-to-point distance and field size are the same at each point. The depth of point X is varied to generate TPRs over a range of depths for a particular field size. TPR is essentially independent of SSD because scatter contributions are almost constant for fixed field sizes, regardless of SSD. This independence enables the use of the TPR over a wide range of clinically used SSDs without correction. TPR is used for photon beams only and is not valid for electron beams.

When d'' is the depth of maximum dose, the TPR is called the *tissue-maximum ratio* (TMR). The TPR and the TMR are used in the same manner as the TAR in dose calculations. TMR is the most common data format used for photon monitor unit calculations in second-check computer programs used to

confirm monitor unit results from three-dimensional (3D) radiation treatment planning systems and manual (by hand) calculations.

Primary and Scatter Dose: The Scatter-Air Ratio

Mayneord first proposed that PDD could be separated into primary and secondary (or scatter) components.[12] Later, Clarkson[30] proposed sector integration of scatter components in calculating the PDD at any point inside or outside an irregular field. This concept was later applied by Gupta and Cunningham to the TAR.[31] The concept states that dose at a point is the sum of primary and scatter components. The primary dose results from photons that have interactions at the point of interest. The secondary dose results from photons and electrons that scatter to the point of interest from other interaction points. With this concept, TAR is given by the following expression:

$$\mathrm{TAR} = \mathrm{TAR}_0 + \mathrm{SAR} \qquad \text{Eq. 32}$$

In the equation, TAR_0 is the TAR for zero field size, representing primary dose, and SAR is the scatter-air ratio, representing secondary dose. TAR_0 is found by extrapolation of circular field TARs to zero field size. The SAR is calculated as the difference between the TAR and the TAR_0. For an irregular field, an effective TAR can be found that is the sum of the TAR_0 and an effective SAR for the irregular field:

$$\mathrm{TAR}_{\mathrm{irreg}}(d, W_d, E) = \mathrm{TAR}_0(d, E) + \mathrm{SAR}_{\mathrm{irreg}}(d, W_d, E) \qquad \text{Eq. 33}$$

The irregular field SAR is found by sector integration:

$$\mathrm{SAR}_{\mathrm{irreg}}(d, W_d, E) = \frac{1}{2\pi}\sum \mathrm{SAR}_i(d, W_d, E) \times \Delta\theta \qquad \text{Eq. 34}$$

in which $\Delta\theta$ is the angular increment in radians for each sector. Separation of primary and secondary dose can be applied to any of the dose functions in a similar fashion. For instance, the TMR can be represented as $\mathrm{TMR} = \mathrm{TMR}_0 + \mathrm{SMR}$.

The TAR/SAR and TMR/SMR functions are more commonly used than PDD in dose computation algorithms because fewer inverse square corrections are needed. The TAR and TMR are easily found for isocentric treatment geometries where the size of the treatment field at the isocenter is equal to the treatment field size at the center of the target volume, which simplifies manual (noncomputer) calculations.

Although PDD can be measured with an ionization chamber beyond d_m over the wide range of clinically used photon energies, the TAR cannot be measured when the photon energy exceeds about 3 MV because the range of secondary electrons exceeds the thickness of the buildup cap for the ionization chamber. At these energies, PDD is measured and converted to TPR and TMR by well-known relationships.[21,22] PDD remains the most important and fundamental dose function and performance specification to be measured for almost all physics quality assurance procedures for all external beam treatment devices.

CHARACTERISTICS OF RADIOTHERAPY PHOTON BEAMS

Dose Characteristics

Photon beams used in radiotherapy have dose characteristics that vary primarily as a function of beam energy and treatment machine design. In the standard irradiation geometry (see Figure 6-32, *B* and *C*), PDD measurements are obtained in water along the central axis, beginning at the surface and proceeding to depth. A typical PDD curve shown in Figure 6-33 for megavoltage beams has the characteristics listed in Table 6-9.

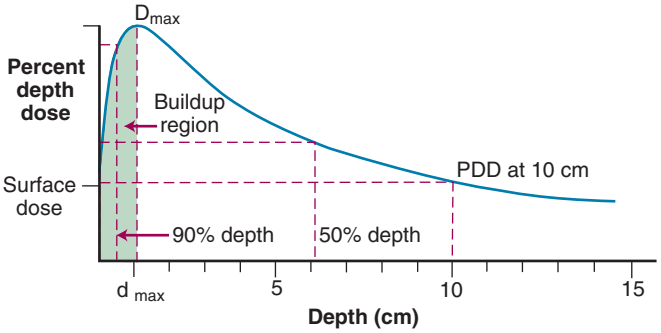

Figure 6-33 A typical photon percent depth dose (PDD) curve is characterized by surface dose, a buildup region, a point of maximum dose, and an exponentially attenuated region. Standard PDD measurements are obtained along the central axis *(dotted lines)*, beginning at the surface and proceeding to depth.

TABLE 6-9 Characteristics of a Typical Percent Depth Dose Curve for Megavoltage Beams

Characteristic	Definition
Surface dose	Nonzero dose at the incident surface
Buildup region	Region between the incident surface and d_{max} where the dose rapidly increase
D_{max}	Maximum dose along the central axis; often used as a reference dose
d_{max}	Depth of maximum dose; often used as a reference point
Percent depth dose	Dose along the central axis of the beam, as a percentage of the d_{max} dose
90% dose depth	Depth from the surface where the dose in the buildup region reaches 90% of D_{max}
50% dose depth	Depth from the surface beyond d_{max}, where the dose falls to 50% of D_{max}
10-cm percent dose	The percent depth dose at 10 cm from the surface, a value often quoted as an indicator of beam penetration

Other important descriptors include an effective attenuation coefficient for depths beyond the maximum depth (d_{max}) and the HVL. The 10 cm PDD in water is most used as an indicator of beam quality, in place of the HVL, because the 10 cm PDD has clinical relevance and the HVL is a better indicator for shielding purposes.

Field size, flatness, symmetry, and sharpness of the beam edge can be measured with a dose profile (Figure 6-34), which is a scanned dose measurement perpendicular to the central axis, across a beam (at a fixed depth, occurring along the horizontal line w_d in Figure 6-32, *B* and *C*). These and PDD measurements are most commonly obtained using a large water phantom with a three-axis scanning system to move a water-immersible ionization chamber or diode detector (Figure 6-35). Dose profiles are normally made at several depths of interest (e.g., d_m, 5 cm, 10 cm, and 25 cm). Beam characteristics from a dose profile are listed in Table 6-10.

The flattening filter and beam steering determine flatness and symmetry in a linear accelerator. Flatness is defined at a reference depth, for instance at a 10-cm depth at the isocenter (SSD = 90 cm). A typical specification is for no more than 3%

dose variation across the useful 80% of the field width (see Figure 6-34). A radiation beam does not have a perfectly sharp edge across the defined beam edge but instead has a gradient from high to low dose with a rounded "shoulder" and "toe." This penumbra region ("penumbra" means "partial shadow") is the result of both the finite source size, "geometric penumbra," and the scattered photons and secondary electrons that cross the beam edge from within the field, "radiologic penumbra." Geometric penumbra can be large because of shadowing of part of the source, as is the case for ^{60}Co teletherapy beams, as a result of a very large (2 cm) physical source size. However, the penumbra region for linear accelerator beams is mostly radiological penumbra because of secondary scatter from within the field and from the collimators. This scattered radiation degrades the beam edge; the dose from the shoulder region scatters outside the beam edge to form the toe. *Penumbra* for radiation fields is defined as the distance over which the dose falls from 80% to 20% of the central axis dose at the same depth, or at the width of the 90% to 10% dose gradient (see Figure 6-34).

Various methods exist to measure a radiation beam along lines of equal dose, called *isodose lines*. In a three-axis water phantom scanner, after determining PDD along the central axis, a certain isodose level is identified in the standard geometry and then tracked to obtain a digital representation of the

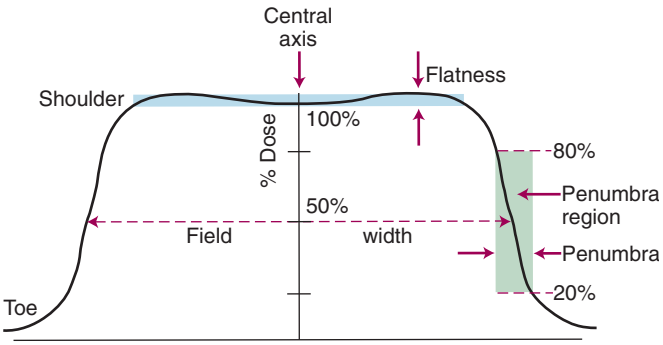

Figure 6-34 The dose profiles of a typical photon beam are characterized by shoulder and toe regions, with definitions for field width, flatness, and penumbra as indicated.

TABLE 6-10 Beam Characteristics From a Dose Profile

Characteristic	Definition
Field size	Distance from field edge to opposite edge at the 50% dose level, with normalization to 100% on the central axis (basically, full-width at half-maximum [FWHM])
Flatness	Deviation in dose level across the width of the field
Symmetry	Deviation in dose level for points symmetrical about the central axis
Penumbra	Dose gradient regions from high to low dose at the beam edge

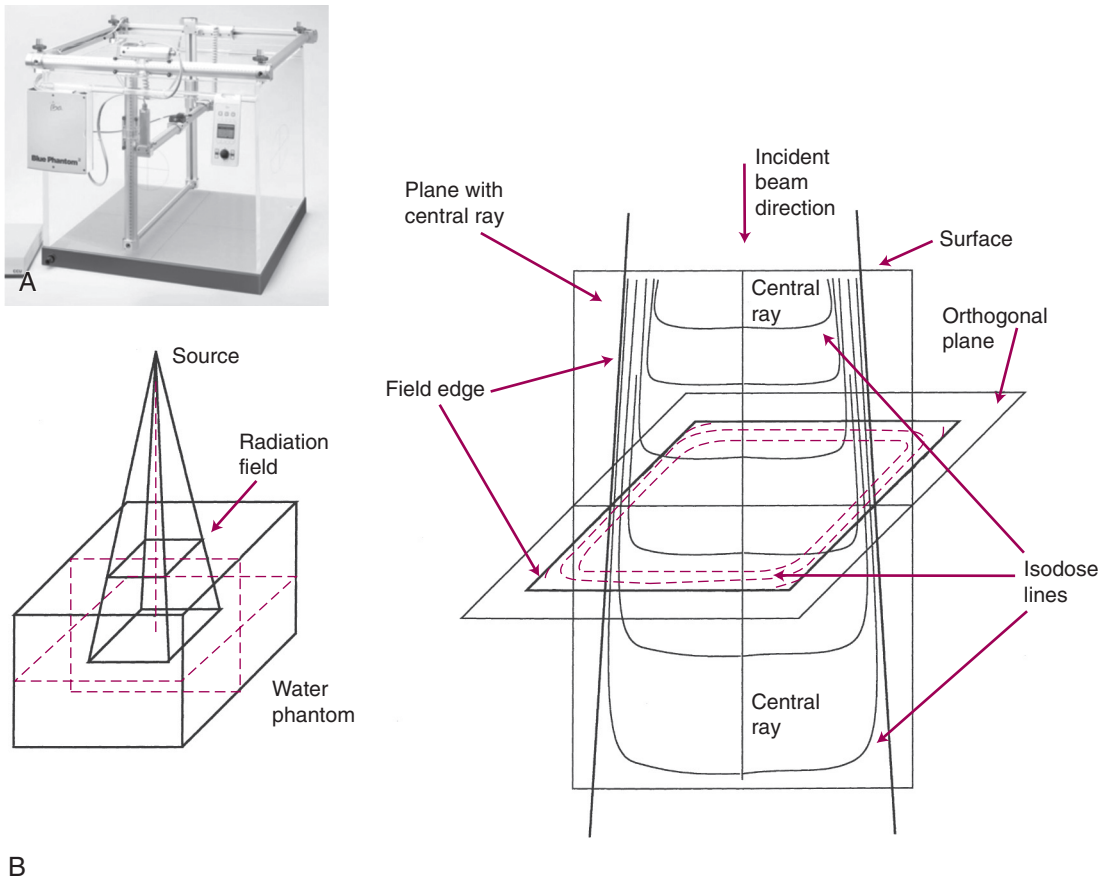

Figure 6-35 Irradiation geometries for isodose measurements. **A,** Beam orientation with phantom. **B,** Planes orthogonal to the central axis and isodose curves.

dosimetric shape of the beam. Figure 6-35 shows sample isodose curves for a plane containing the central ray of a beam and a plane perpendicular to the central ray. The modern water phantom scanning device is computer controlled and has robust software tools for two-dimensional (2D)- and 3D renderings and analysis of acquired dose distribution data.

Effect of Energy

Photon beam characteristics change with beam energy. Representative beam data are presented in Table 6-11, PDDs in Figure 6-36, and isodose curves in Figure 6-37. Several key observations should be considered:

- PDD increases as energy increases. This effect can be represented by the depth of the 50% dose or the PDD at 10 cm and is consistent with the change in the effective attenuation coefficient.
- Surface dose decreases as energy increases. Scattered radiation is more forwardly directed, away from the surface, as energy increases, reducing the dose contribution at the surface. The breakthrough in achieving megavoltage energies is that surface dose decreased from 100% and d_m moved away from the surface, providing "sparing" of skin and superficial tissues.
- The buildup region has a very steep climb of PDD to D_m. Most therapy beams have reached at least 90% of their D_m dose within 1 cm of the surface.
- The d_m is at or near the surface for low energy beams and increases in depth as energy increases. As incident photon energy increases, the effective electron range (photoelectrons and Compton electrons) increases and the scatter component (secondary electrons and Compton scattered photons) is more forwardly directed. The d_m value is directly related to the average energy of secondary electrons produced in photoelectric and Compton interactions; d_m increases with energy.
- D_m is defined as a point, but as energy increases the PDD curve becomes very broad because of a broader spectrum for the scattered electrons. Strictly speaking, D_m is the one point where electronic equilibrium occurs.
- An effective attenuation coefficient can be found that describes the exponential fall-off in dose with depth.
- HVL, measured in lead at megavoltage energies, increases as peak energy is increased until about 6 MV, and it then falls slightly (see Table 6-11). HVL decreases because an increased amount of pair production increases the attenuation coefficient for photon energies above 6 MV (see Figure 6-16). In tissue or water the attenuation coefficient decreases monotonically and the minimum is reached at very high energies, to the far right in Figure 6-16.
- Linear accelerator photon beams have an effective photon energy of approximately one third of the accelerating potential. For example, an 18-MV photon beam (polyenergetic, bremsstrahlung spectrum) has an effective (monoenergetic) value of 6-MeV photons.
- The central axis portion of a megavoltage beam from a linear accelerator is "harder" than the off-axis region because of the use of a flattening filter that is thicker in the central ray than off-axis (see Figure 6-5). Because the flattening filter is designed to produce a flat field at a depth of 10 cm, not d_m, and the off-axis beam is softer than the central axis, a greater beam intensity off-axis is allowed at the depth of d_m to compensate for the increased attenuation of the off-axis beam component. This greater intensity is exhibited as "horns" in the isodose distribution for off-axis regions near d_m (see Figure 6-37, *A*). This effect is greater for lower-energy megavoltage photons than for higher energies.

Effect of Field Size

Field size determines the amount of scatter present in the beam, with the following observations:

- PDD increases as the field size is increased. The effect results from a differential increase in scatter such that points at depth receive a greater relative amount of scatter than does d_m, leading to an increase in PDD. The increased scatter at depth comes from interactions that occur in the increased irradiation volume.
- Surface dose increases as the field size is increased because the amount of scattered radiation from the collimator faces is increased. This scattered radiation includes secondary electrons and scattered photons of lower energy.
- Absolute dose rate, or beam output, increases as field size increases (Figure 6-38). Output increases because there is increased scatter at d_m from the collimator faces as well as from interactions that occur in the increased volume of irradiated material. Figure 6-38 also illustrates the separation of dose into primary and secondary components.
- In a more subtle effect, d_m decreases as the field size increases because of the presence of an increased amount of lower energy photon and electron scatter.

Penumbra

Beam edge sharpness, or penumbra, is typically 7 to 12 mm in width and varies with the amount and energy of secondary electrons and scattered photons. As the amount of scatter increases, penumbra does likewise:

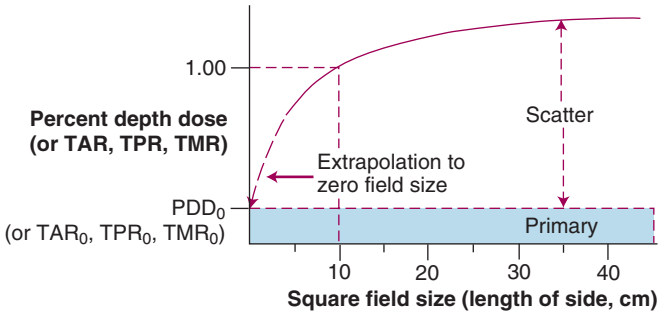

Figure 6-38 Relative dose as a function of photon field size.

- Penumbra increases as depth increases. At depth there is more scatter from the larger irradiated volume upstream, so the penumbra is wider.
- Penumbra increases with field size because of increased scatter from the increased volume of irradiated material and because there is a slight increase in beam divergence (a geometric effect).
- Penumbra increases as SSD increases.
- ^{60}Co has a wide penumbra because the source size is large and the geometric penumbra is large. However, some units have "trimmer" bars that greatly reduce the geometric

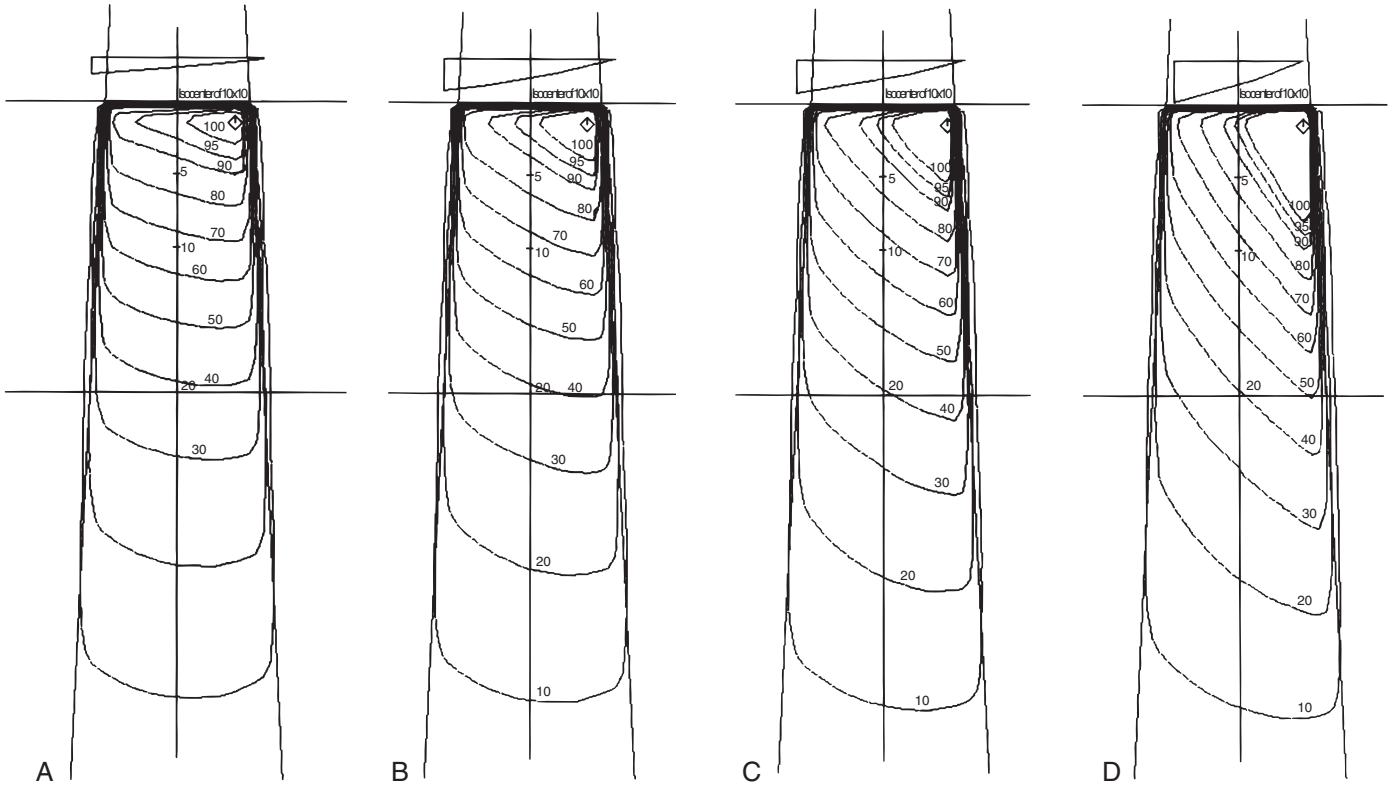

Figure 6-39 Isodose curves with physical wedges, 6-MV photons, and a 10 × 10 cm² field. **A,** A 15-degree wedge. **B,** A 30-degree wedge. **C,** A 45-degree wedge. **D,** A 60-degree wedge.

penumbra component, yielding penumbrae comparable to those of linear accelerations.
- Penumbra increases with energy. Scattered electrons and photons that have a higher effective energy have a corresponding higher lateral range of scatter outside the beam edge. This effect is seen as a degradation of the profile (more pronounced shoulder and toe). This comparison is shown in Figure 6-37, *A* and *B*.

Beam Modifiers

Various devices can be put into a photon beam to modify the shape of the beam and its dose distribution. Collimators and custom blocks are used to shape the field, as previously discussed. Their dosimetric effect is to change the irradiated volume and therefore the amount of scatter.

Physical wedges produce skewed isodose lines at fixed angles across the central ray (Figure 6-39) to compensate for beam angle of incidence, tissue shape, or the trajectory of other treatment beams. Historically, wedge angles of 15, 30, 45, and 60 degrees have been available using physical wedges made of steel or lead. Isodoses show the wedge angle is measured from a perpendicular to the central ray, typically at a depth of 10 cm. A physical wedge produces an attenuated beam that is decreased in absolute dose rate and slightly more penetrating resulting from both attenuation and beam hardening by the thickness of the metal wedge in the beam. A commonly available alternative wedging system uses no physical wedge and produces angled isodose lines by scanning one of the independent collimator jaws across the field while the beam is on. This dynamic method does not result in hardening or attenuation of the beam and is called a *dynamic, virtual,* or *soft wedge.* Another method to produce an angled beam intensity is to use one physical wedge with the maximum wedge angle of 60 degrees that is left in the beam for various fractions of time to produce wedge angles from 0 (no time in beam) to 60 (full time in beam) degrees.

Compensators attenuate the beam in desired locations to provide dosimetric shaping. A variety of methods exist that include simple and complex approaches.[13] Compensators have an important role in dose optimization schemes that include static applications as an alternative to dynamic techniques, including IMRT[32] and whole-body irradiations for bone marrow transplantation.

CHARACTERISTICS OF RADIOTHERAPY ELECTRON BEAMS

Dose Characteristics

Electrons differ from photons in that electrons have a *finite range;* electrons travel a certain distance and then stop, and their kinetic energy is zero. PDD measurements are obtained along the central axis in the standard irradiation geometry as for photons (see Figure 6-32). The one difference in the geometry is that an electron cone is used that requires fixed collimator positions in length and width. A typical PDD curve for megavoltage electrons (Figure 6-40) has many of the same characteristics as do photons, including surface dose, a "buildup region," D_m, and d_m. An electron PDD curve also has the characteristics listed in Table 6-12.

Table 6-13 gives several characteristics for megavoltage electron beams as a function of energy. Although electron beams have some of the same features as photon beams, their finite range and the presence of bremsstrahlung contamination are unique.

Field size, flatness and symmetry, and sharpness of the beam edge for electrons can be measured similarly as for photon beams (see Figure 6-34); however, the measurement depth is typically at d_m or at the 95% dose level beyond d_m. Beam steering, scattering foils, monitor chambers, collimator length and width, and electron applicator design all determine flatness and symmetry for electron beams.[33] These design parameters are important for controlling the distribution and amount of electron scatter. Penumbra is the result mainly of electron scattering from within the defined beam and is defined similarly as for photons.

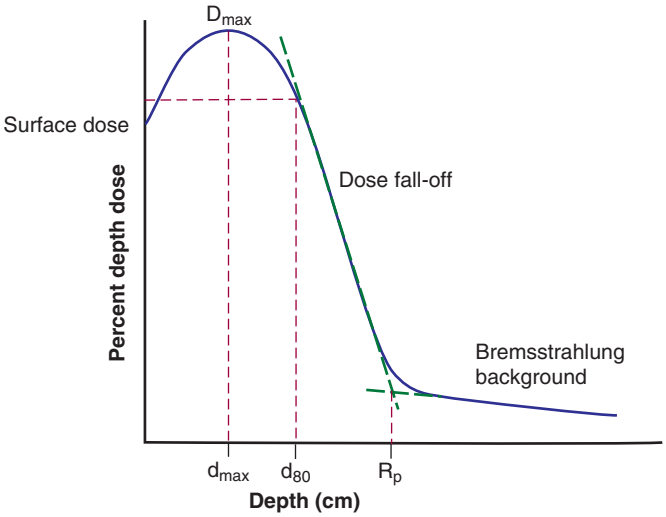

Figure 6-40 A typical electron percent depth dose (PDD) curve is characterized by surface dose, a region of buildup, a point of maximum dose, a rapid dose fall-off, and a tail resulting from Bremsstrahlung background radiation.

TABLE 6-12 Characteristics of an Electron PDD Curve

Characteristic	Definition
Dose fall-off	Region beyond where the dose falls steeply and almost linearly
d_{90}	Depth of the 90% dose beyond d_{max}—a clinically relevant point beyond which dose is not therapeutic
d_{80}	Depth of the 80% dose beyond d_{max}
d_{50}	Depth of the 50% dose beyond d_{max}
R_p	Practical range: the maximum depth to which electrons penetrate; determined by the intersection of the linear part of the dose fall-off curve and the bremsstrahlung background
Bremsstrahlung background	Contamination of the electron beam by bremsstrahlung x-rays created by collisions of the electrons with parts of the machine and with the patient; prevents the dose from going to zero at depth

D_{max}, *Depth of maximum dose;* PDD, *percent depth dose.*

Effect of Energy

Electron beam characteristics change with beam energy. Representative beam data are presented in Table 6-13, central axis PDD in Figure 6-41, and isodose curves in Figure 6-42. Several key observations apply:

- PDD increases as energy increases because the electron range increases with energy. The values for d_{90}, d_{80}, and R_p (see Table 6-12) all increase with energy.
- Surface dose is high, usually in the 70% to 90% range (see Table 6-13), and it *increases* as energy increases (an opposite effect from photon beams) because of changes in the amount of lateral electron scattering and its dose contribution at d_m.
- In general, d_m starts at shallow depths and increases as energy increases because the electron range increases with energy.
- As energy increases, the region around D_m becomes quite broad. In this case d_m is defined at a selected point.
- The steepness of the dose fall-off region lessens with increasing energy. Increased scattering occurs, and a wider

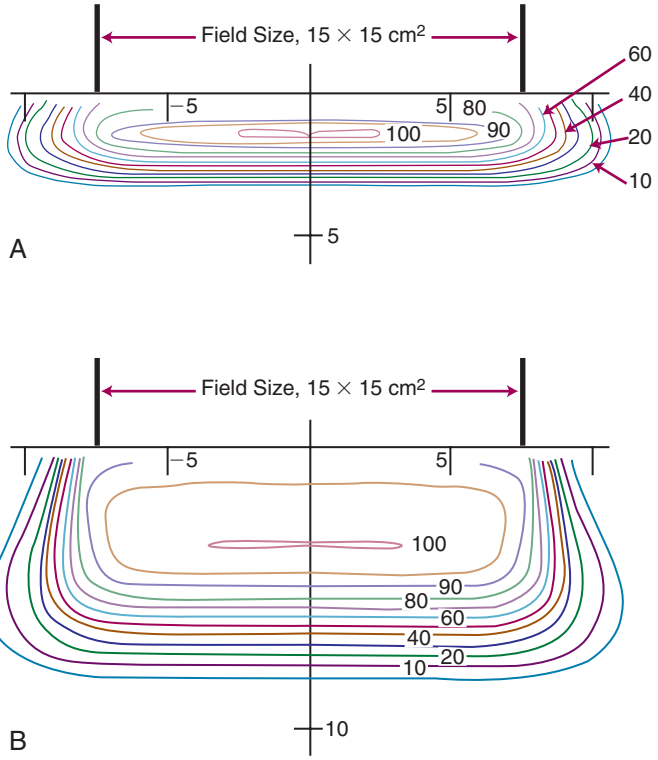

Figure 6-42 Electron beam isodose curves for a field size of 15 × 15 cm². A, 6 MeV. B, 20 MeV.
Data from Hogstrom KR, Steadham RE: Electron beam dose computation. In Mackie TR, Palta JR, editors: Teletherapy: Present and future. Madison, Wlisc., 1996, Advanced Medical Publishing, pp 137-174.

energy spectrum is created with a distribution of electron ranges. The originally monoenergetic electron beam is degraded into a wide spectrum beam with varied practical range.

- The amount of bremsstrahlung contamination increases with energy because the probability for radiative interaction increases with electron energy. Bremsstrahlung contamination can be minimized but not eliminated totally. Structures lying beyond the electron range still receive dose from bremsstrahlung x-rays.
- The approximate d_{80} (depth to the 80% isodose line in centimeters) in tissue can be found by dividing the nominal electron energy (in million electron volts) by 3. The d_{80} of a 9-MeV electron beam is 9/3, or about 3 cm. This number is useful for indicating the largest therapeutic depth, although many clinicians consider the d_{90} as the maximum effective range.

Effect of Field Size

Electron field sizes are changed by using fixed-size applicators to produce square field sizes from approximately 6 × 6 cm up to 35 × 35 cm. Custom cutouts can be used that are inserted into an applicator to provide a shaped field to match a target outline.

- PDD increases only slightly as field size is increased. Scattered electrons have a finite range that is much less than R_p; therefore, for increasing field sizes above 10 × 10 cm or greater, the contribution to the central axis is small. This effect is different from photon beams where scattered photons still have a relatively large mean path length.

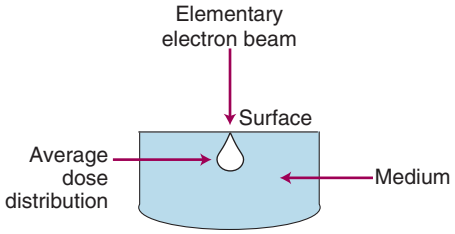

Figure 6-43 Elementary electron scattering kernel.
Adapted from Khan F: The physics of radiation therapy, ed 2, Baltimore, 1994, Williams & Wilkins.

- Surface dose increases slightly as field size is increased because the amount of scattered electrons from the beam path is increased.
- The d_m decreases as field size increases because the amount of lateral electron scatter increases near the surface.
- Absolute dose rate, or beam output, measured at d_m, usually increases as field size increases but can decrease depending on collimator design.

Penumbra

Beam edge sharpness for electron beams varies with measurement depth because of the nature of electron scattering.[22] On interaction at a point, an elementary line of electrons produces a scattering envelope that is teardrop shaped in the forward direction of the beam (Figure 6-43). Electron scattering angles, which initially are primarily in the forward direction, become more randomly oriented at depth.

- Penumbra increases with energy because scattered electrons have a higher effective energy and a corresponding increased range. This effect is seen as a degradation of the profile (enhanced shoulder and toe).
- Penumbra increases as depth increases because of the teardrop shape of electron scattering (see Figure 6-43).
- The field width corresponds to the 50% dose width at d_m, but the shape of the isodose curves changes with increased depth. This effect should be considered during treatment planning.
- Penumbra increases with field size because of increased scatter from the increased volume of irradiated material.
- Penumbra increases as the distance increases from the end of the applicator to the surface. An increased gap allows electrons to scatter laterally before reaching the surface, degrading the field edge.

Other Effects

- Electrons scatter easily, and regions of bone and air greatly change the dose distribution.
- Density scaling can be applied to approximate the electron range in non–unit density materials (see Eq. 20), because mass stopping power is somewhat constant for low Z materials. R_m, the approximate electron range for a material of density p_m, is given by the following equation, in which R_w is the range in water and ρ_W is the density of water (1 g/cm²). For instance, the electron range for a material with a density of 2 g/cm³ is 0.5 times the range in water.

$$R_m = R_w \times \frac{\rho_w}{\rho_m} \qquad \text{Eq. 35}$$

- Electron beams follow the inverse square law, but the reference distance is not the actual source location (i.e., the scattering foil) but instead a virtual source point that is located

along the beam path. This distance is called the *effective source-to-skin distance* (effective SSD) and is usually less than the SAD, for example, 85 cm for a 100 cm SAD linear accelerator. Effective SSD is measured for each energy and applicator and occurs because of multiple electron scatterings along the beam path.

- Use of electron cutouts for field shaping affects scattering conditions and changes output, penumbra, the position of d_{max}, and field homogeneity. These effects are most pronounced when the cutout size is less than one fourth of the applicator dimension or on the order of the electron range.[22] Individual calibration of a cutout or other procedures are required to establish the cutout's dosimetric character when these poor geometric conditions exist.

EXTERNAL BEAM TREATMENT SIMULATION

Purpose

In the "old" days patients were taken to the treatment machine and fields were chosen based on the clinician's general anatomic knowledge and the patient's disease. Diagnostic radiographs were available to help localization. This process is called *clinical setup* because the treatment machine is used with various aids to decide on the beam geometry. Simple fields and manual blocking are used. Clinical setup alone is no longer commonly done, although may be used for emergent palliative treatments. Instead, *simulation* is performed on a special x-ray machine, called a *simulator,* also called a *conventional simulator* (in contrast to a CT simulator). A conventional simulator reproduces all the geometric parameters of the radiotherapy machine and its use has the following advantages:

1. Clinical setup competes with treatment for time on the treatment machine. Simulation on a dedicated simulator does not.
2. Simulators are diagnostic machines with radiographic and fluoroscopic capabilities. Images are of diagnostic quality instead of poor port film quality.
3. The machine can simulate different treatment machine geometries with regard to SSD, SAD, block position, and field size.
4. Simulators are dedicated to the simulation process. Different treatment geometries can be explored without the pressure to turn the room back over for treatment.
5. Simulators can be used to localize and verify brachytherapy implants within the confines of the radiation oncology department (no exposure to outside individuals) and under controlled conditions.

Treatment Setup

There are two basic methods for patient setup: SSD and SAD (Figure 6-44). The SAD technique is most commonly used with today's isocentric treatment devices.

SSD Treatment

If a treatment technique is set up as an SSD treatment, the distance to the patient's skin is recorded in the chart and used as a reference distance for each treatment. The SSD is measured and set to the same point on the patient's surface each time the field is treated. When a different field is treated, the new SSD is set as required before the patient is treated. Each field is independently set and treated. The SSD is standardized to equal the SAD for isocentric machines, so a normal SSD treatment is at 100 cm (80 cm on older treatment machines). The standard SSD is also the distance used for machine calibration. Occasionally, alternative SSDs are used to allow larger field sizes to be used.

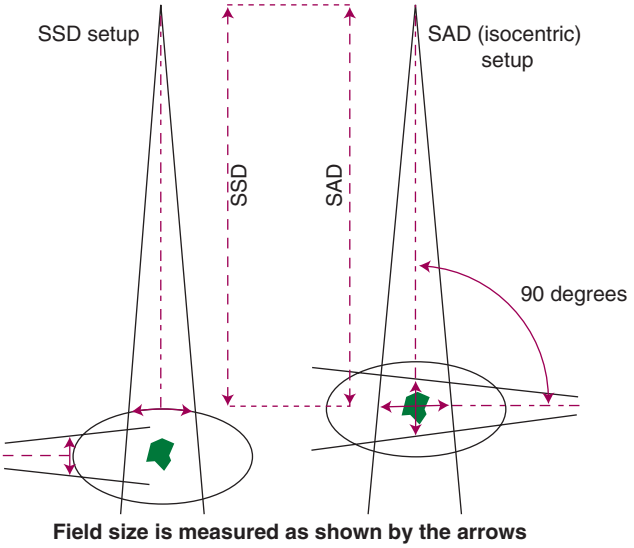

Figure 6-44 Treatment geometries: source-to-skin distance (SSD) and source-to-axis (SAD) approaches.

Compared with SAD treatments, SSD treatments place the target further away from the source. Because the inverse square effect is less, PDDs are greater and larger field sizes may be possible, as when a single field is desired to be used to cover a larger region such as an extremity, the entire spinal cord, or the hemi or whole body. If multiple fields are to be used then the disadvantage is that each treatment field has to be individually set, requiring movements of the treatment couch and patient between successive fields.

SAD Treatment

An alternative to setting the SSD is to set the target volume at the SAD (the isocenter of rotation of the machine). This isocenter is a point in space in the treatment room about which the gantry, collimator, and table all rotate (see Figure 6-3). In this case the SSD is always less than the SAD (SSD < 100 cm). In SAD treatments the target volume always intercepts the beam regardless of gantry, table, or collimator angles.

An advantage is that after one field is set properly, the target is at the isocenter and subsequent treatment fields can be set up rapidly without having to set multiple SSDs. Treatment of a multifield plan therefore is more quickly done because of less setup time, and the target cannot be missed. The disadvantage is that field sizes may occasionally be limited, and there is slightly more inverse square effect.

The advantages of rapid setup and targeting for SAD treatment outweigh those of larger field size and increased PDD for SSD treatments in most cases, and SAD treatments are performed for most patients. This has been especially true because isocenters changed from 80 to 100 cm, providing larger field sizes and less PDD effect, and also because image-guided treatment devices, either orthogonal to or coincident with the central axis of the treatment beam, are designed for rotations around the isocenter, which is most consistent with the SAD treatment technique.

Conventional Radiographic/Fluoroscopic Simulator Description and Components

A conventional radiographic/fluoroscopic (R/F) C-arm simulator unit was originally designed to replicate all of the

mechanical and patient positioning aspects of the radiation treatment unit and has the following components in the geometry shown in Figure 6-3:

1. A fixed gantry stand or base supports the gantry structure that holds the x-ray tube and collimator at one end and the image receptor (flat panel imaging device, film cassette, or image intensifier on the other. The gantry is mounted isocentrically, and the x-ray tube can be positioned to a wide range of SADs or SSDs.
2. The x-ray tube is a diagnostic energy x-ray tube that rides at the top of the gantry. Kilovoltage ranges from 60 to 120 kV(p), and tube current is as much as 1000 mA.
3. The collimator is an assembly that defines the radiographic (image) field size at a given SAD (usually 100 cm). The collimator is isocentric and has field size and rotation capabilities like the treatment machines.
4. Two pairs of field-defining wires are in the collimator, one positioned in the *x* direction and one in the *y* direction. They are used to indicate the size of the treatment field as would be defined by the collimator jaws on the treatment machine. A simulator radiograph shows two radiation fields. The larger field is the actual field imaged as defined by the collimator. The smaller field is the treatment field, indicated by images of the delineator wires. A simulator image shows the treatment field and nearby contextual region.
5. The simulator table is isocentric and has vertical, lateral, longitudinal, and rotational motions. It can be remotely operated from the console, so as to move the patient during fluoroscopy.
6. Hand and console controls allow operation of all of the machine motions from a hand-control unit or the table pedestal in the room, and some of these are duplicated at the control console. All radiographic technique settings are done at the console.

Conventional Simulation Procedures and Immobilization

A patient to be simulated is placed on the conventional simulator table in the treatment position. The supine position is most common, but prone positioning and other geometries are also used. Immobilization devices of various functions and rigidity may be used to maintain patient position, including head holders, thermoplastic face masks, foam molds, cushions and pillows, bite blocks, reflective stereoscopic markers, and vacuum bags. The patient is moved in the treatment position to align the target region or other reference anatomy with the simulator's isocenter. This location is chosen based on available information on the target volume and nearby structures (from planar images, CT, magnetic resonance imaging [MRI], positron emission tomography [PET], clinical examination, surgical reports) or in anticipation of imaging studies for treatment planning. Fluoroscopic imaging or static images are used to determine the location of the isocenter or other reference point in the patient coordinate system. An SSD or SAD setup is chosen, and orthogonal planar images are usually taken to record the patient's position. All geometric information (gantry angle, collimator angle, table position, field size, SSD, SAD) is recorded for each film. Marks are placed on the patient's skin or the immobilization device to indicate the reference field axes.

In conventional simulation, individual treatment field geometries are determined at the time of simulation. All field data are recorded, and simulator images are taken for each field as a record of the intended treatment and for use in designing field shapes. Target and other data are often drawn or annotated on each film or digital image. Images with added contrast agents show certain structures (bladder, rectum). Other data are the clinical examination, surgical reports, surgical clips, markers placed during simulation, and manually transferred contours from CT or MRI images. After the desired data are annotated on the image, a treatment field is drawn that will later be transferred to the shape of the MLC (or custom blocks) for definition of the treatment field aperture on the treatment machine.

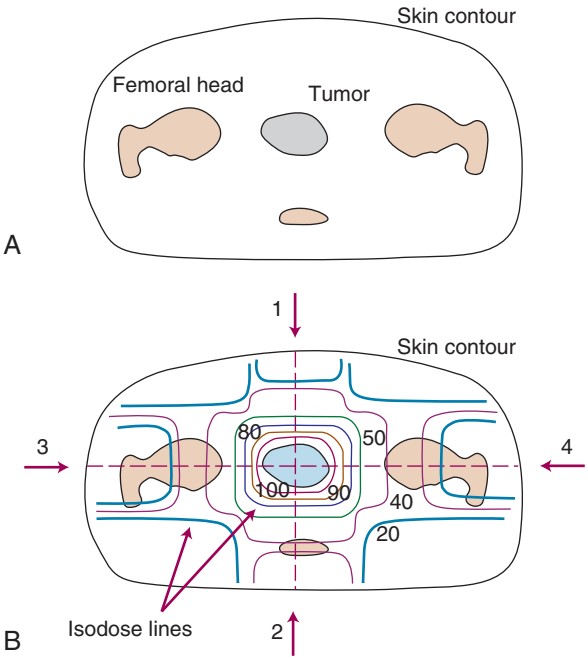
Additional geometric information on the patient is needed if treatment planning is to be performed, such as an external contour and the locations of important internal anatomy, including the target, landmarks, and critical structures. For simple 2D planning at least one transverse contour is obtained; however, sagittal and coronal slices (or obliques) can also be obtained. Sources for patient contours include mechanical methods (e.g., solder wire, tracer device), optical methods (e.g., laser grid, light grid, stereo-shift camera), and CT or ultrasound acquisition.[22] In many practices conventional simulation is used for patients who will be treated palliatively, because treatment complexity is low (for instance, one pair of parallel-opposed fields) and patient setup and data acquisition can be done quickly, followed by simple dose calculations, without the need for full 3D representations of the patient anatomy for higher-level dose computations. Thus, institutions with CT simulation capabilities may often retain the "old" conventional simulator for simple cases or for imaging of brachytherapy cases. However, conventional simulation devices are decreasing in number because of the ready availability and maturity of CT simulation, which enables the rapid identification of structures and incorporation of other 3D digital image datasets.

Computed Tomographic Simulation

CT simulation, also called *virtual simulation*[34] or *computer-aided simulation,* uses a CT volumetric image of the patient in treatment position and computer software to perform patient simulation without a conventional simulator. CT simulation is performed on the patient's CT image set, not the patient, hence the name *virtual* simulation. Work flow may vary, depending on clinic preferences for patient flow; however, general principles are to immobilize the patient in the treatment position, obtain CT scout views to verify positioning and to delineate the range of CT scanning, and then acquire the desired CT image sets, which may include noncontrast and postcontrast images. With the patient still in the treatment position in the CT scanner, the CT simulation process then takes place within the computer where the proposed treatment geometry is designed and viewed on screen. Software tools are used to identify and segment anatomic information within the image set (external contour and volumes such as lung, kidney, cord, and tumor) and determine an isocenter for treatment or other identifying reference point. This information is displayed and the treatment beam geometry is reviewed. Once the isocenter has been selected and marked within the CT image set, the isocenter location (or other reference point) is transferred to the (real) patient or their immobilization device, still on the CT scanner, for permanent marking on the patient or immobilization device. Mechanical or laser light technologies exist for a three-point marking that can be replicated on the treatment machine. Importantly, in most software implementations the CT simulation procedure includes virtual simulation only of the proposed treatment geometry and does *not* include dose calculations.

Dedicated CT simulators as turnkey devices, including a CT scanner and simulation software, exist since first in commercial and are in regular clinical use.[35,36] Large aperture CT simulators offer a greatly improved aperture size from a

standard 70 cm up to 85 or 90 cm, depending on the vendor. This increased size greatly improves the image field of view (FOV), allowing bariatric and off-center patients to be CT simulated, as well as enables access for relatively wide or tall immobilization devices.[37] Other readily available CT simulator improvements include multislice and cone-beam CT scanning for rapid acquisition, and four-dimensional (4D) CT-fluoroscopy techniques for assessment of target motion resulting from physiologic processes such as respiration.[38,39]



Moving simulation to the digital CT simulation approach has allowed a variety of image processing tools to be applied to the process, such as autosegmentation algorithms and 3D renderings, and has enabled the incorporation of registered multimodality images from MRI, PET, and other modalities. Treatment planning techniques, the next important process after simulation, are discussed in the next section.

EXTERNAL BEAM TREATMENT PLANNING AND DOSIMETRY

Purpose and Procedures

After conventional or computer-aided simulation, the simulator images (if any); CT, MRI, and other digital images; beam geometries; and other patient data are transferred to dosimetry for further treatment planning. During treatment planning, possible beam geometries and combinations are investigated. Simulated beams may be fine-tuned or deleted, or new beams may be created; the beam weights may be adjusted, wedges added, beam energy changed, field sizes adjusted, different normalizations used, and compensation checked. The intent is to produce a treatment plan in the form of a 3D isodose distribution overlaid on the reference CT treatment planning images that can be evaluated by the physician and approved or modified. Treatment plans describe the following characteristics about the patient's treatment, as illustrated in two dimensions for simplicity for the static four-field plan shown in Figure 6-45:

1. Prescription isodose (i.e., the 97% line) or depth (at the isocenter or at 3 cm deep) gives the location where the prescribed dose is to be given.
2. Various tumor, target, and normal tissue volumes as specified according to the International Commission on Radiation Units and Measurement Reports 50 and 62 (ICRU 50 and ICRU 62) recommendations for volumes of interest. This information must be represented in some manner to enable plan evaluation (see later). These volumes may be 3D contours or isodose lines or surfaces.
3. Beam weights indicate the relative dose delivered to the prescription or normalization point by each beam.
4. The presence of beam modifiers (i.e., wedge, custom block, compensation filter, dynamic field shaping, or intensity modulation) is specified.
5. The size and shape of each field (i.e., collimator settings) are specified. If the MLC is used for a shaped field or intensity modulation, each MLC leaf has a specified position as a function of the number of monitor units elapsed.
6. The SSD is specified for each field.
7. "Inhomogeneities" are identified. These are volumes that are not water or soft tissue equivalents (e.g., lung, bone, metal prosthesis) for which dose may need to be corrected. In a CT image set each voxel intensity relates to the average electron density for that voxel and most modern-day treatment planning systems are configured to compute the dose distribution based on the voxel-by-voxel electron density information carried in the CT image.
8. Number of monitor units, or amount of beam-on time, must be set on the machine for each beam.

Beam data
1. AP:18MV x rays, SSD = 92.5 cm, weight = 1.0, field size = 8×10, G:0 C:0 T:0

Dose Specification

Components of a dose prescription for a patient treatment course include the patient's name, clinic identification number, treatment site, radiation energy and modality (photons or electrons), prescription point location, dose per fraction, number of fractions, and total dose. These components are recognized standards[40] and are required by most regulatory bodies.[41] The point of prescription defines the location within the patient where dose is to be delivered and therefore defines the geometric point for dose computation. Prescription point selection and additional recommendations for prescribing, recording, and reporting volumes of interest and dosimetric parameters for photon beam treatment are specified by ICRU 50 and ICRU 62.[42,43]

Volumes of Interest

ICRU 50 defines five volumes of interest related to treatment. The following definitions are illustrated in Figure 6-46 for an idealized case:

Gross tumor volume (GTV): The GTV is the volume that contains the gross palpable or visible extent and location of malignant growth. The GTV may be identified on a simple contour, a radiograph, or sectional images.

Clinical target volume (CTV): The CTV is the volume that contains the GTV and any suspected microscopic disease. The CTV is the volume that must receive the prescribed dose to effect cure or palliation.

Planning target volume (PTV): The PTV is a volume that contains the GTV and CTV and that is defined to account for

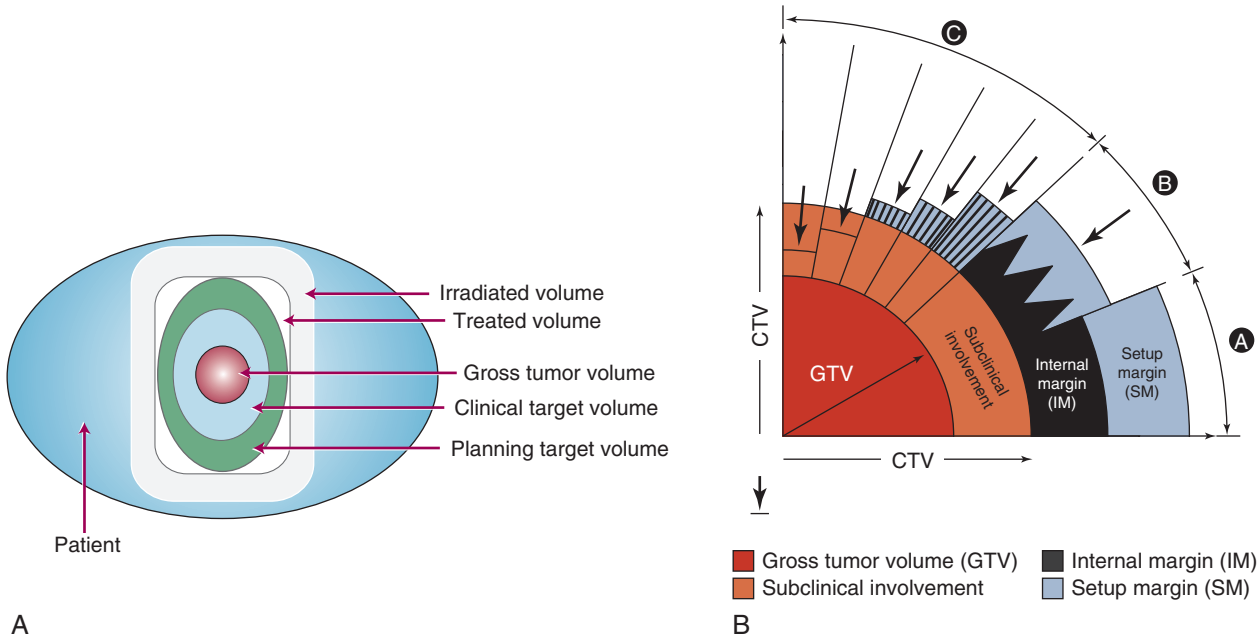

Figure 6-46 **A,** The International Commission on Radiation Units and Measurement Report 50 (ICRU 50) defines five volumes of interest related to treatment. **B,** Schematic representations of the relations between the different volumes (GTV, CTV, PTV, and PRV) in different clinical scenarios. ***A,*** *From ICRU Report 50: Prescribing, recording, and reporting photon beam therapy, International Commission on Radiation Units and Measurements, 1993;* ***B,*** *From ICRU Report 62, Supplement to ICRU Report 50, 1999.*

the irradiation geometry and all uncertainties in treatment, such as organ and patient motions and setup errors. The PTV is a volume that, when covered by the prescription dose, will ensure the delivery of the prescription dose to the CTV. The PTV includes a margin for motion and set-up error but not for microscopic disease. The PTV is a function of treatment geometry, because the number of beams and their orientations may impose limitations on the PTV's shape or scope.

Treated volume (TV): The TV is the volume enclosed by a selected (prescribed) isodose surface and is a function of the treatment geometry required for planning the PTV. For an acceptable plan, the TV is greater than the PTV, although an ideal TV/PTV ratio would be 1.0, indicating perfect conformation (assuming the locations of the volumes were identical).

Irradiated volume (IV): The IV is a volume that receives a significant dose; significance is determined by morbidity or other measures.

ICRU 50 considered radiation target volumes only and did not specify normal tissue volumes that might be relevant for morbidity and avoidance. ICRU 62 addresses this deficiency by specifying organs at risk (OARs) and the planning organs at risk values (PRVs).[43] In ICRU 62 the GTV, CTV, and PTV remain and new defined volumes are the following:

Internal target volume (ITV): The ITV is an expansion of the CTV to account for motion of the CTV, for instance caused by respiratory or digestion motions. Motion may be in a preferential direction such that the expansion of the CTV through internal margins (IMs) may not be isotropic and can be nonuniform.

Organ at risk (OAR): The OAR is a nearby normal tissue or critical structure at risk for radiation-induced morbidity, based on the recognition that normal tissue response is radiation treatment limiting. Thus, relevant OARs are to be identified for purposes of morbidity assessment and assignment of dose constraints. Tissue physiologic organization of OARs as serial or parallel units, or combinations of the two, are considered to aid risk assessment.

Planning organ at risk volume (PRV): The PRV is an expansion of the OAR as a result of possible motion. However, incorporating motion into the OAR can be a challenging process.

Dose Recording and Reporting

The ICRU recommendations for dose include a point for dose computation and indicators of dose homogeneity. The *reference point* is a point within the PTV at which dose is specified. There are several criteria for selecting the reference point:

- The dose at the point is clinically relevant and representative of dose in PTV.
- The point is easily defined by anatomy or geometry.
- The point is a location where dose can be accurately determined.
- The dose gradient at the point is not steep.

With these criteria, suitable point locations include the center of PTV, near the central axis, or where tumor cell density is a maximum. In many cases the isocenter has these characteristics and serves as the reference point, because for nondynamic fields the isocenter is most commonly placed within the target. However, the isocenter may not properly serve as the reference point for IMRT plans because dose constraints for nontarget volumes determine the dose distribution and may result in a nonhomogeneous dose distribution in the target, including a dose gradient through the isocenter.[44]

Dose homogeneity is also to be reported and is represented by the maximum and minimum doses in the PTV. Together, the reference, maximum, and minimum point doses represent the dose to the PTV as well as the variation in that dose.

Dose Reporting for Different Techniques

ICRU 50 demonstrates its recommendations for three levels of complexity: single plane plans, multiple planes, and 3D

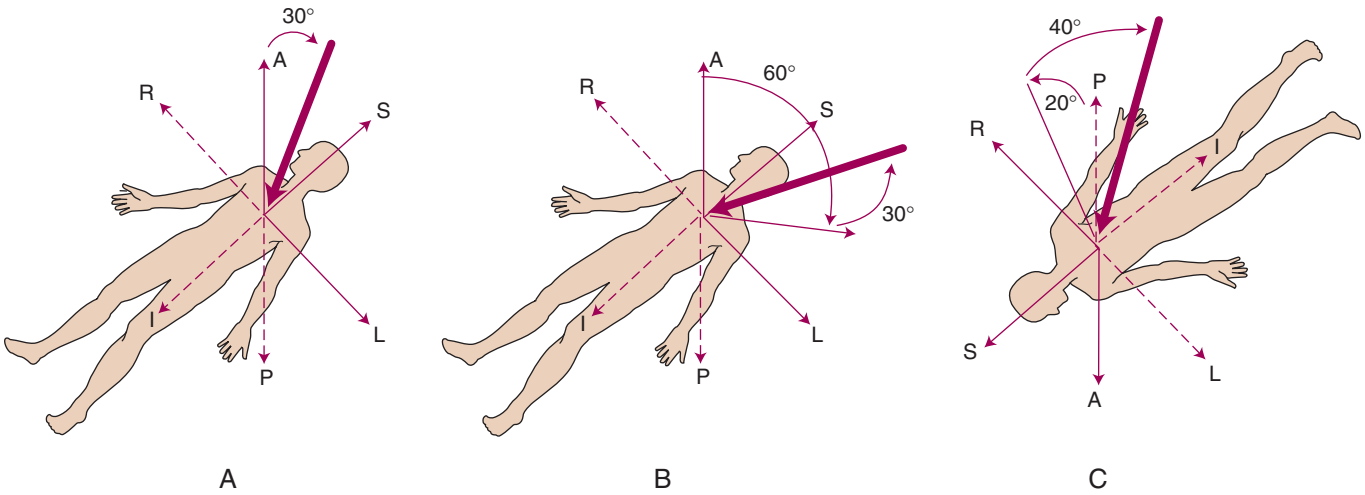

Figure 6-47 Three-dimensional beam nomenclature. Beams are named in reference to the patient coordinate system. **A,** The A30S beam is 30 degrees superior from the anterior axis. **B,** The A60L30S beam is 60 degrees left from the anterior axis and 30 degrees superior. **C,** The P20R40I beam is 20 degrees right from the posterior axis and 40 degrees inferior.

volume studies. In each case the reference point dose is computed and the maximum and minimum point doses are estimated or computed. Isodose distributions are computed if a contour plane or multiple planes are acquired. In the highest complexity, dose evaluation tools such as dose-volume histograms are recommended.

Together the ICRU 50/62 recommendations create a standardized, consistent set of definitions for target and normal tissue volumes, to enable the comparison of treatment plans across institutional and international boundaries. Institutions use the ICRU 50/62 recommendations, and they have been adopted by national protocol groups.

Beam Nomenclature

When using complex field arrangements it can be difficult to describe the precise beam orientation. A system has been developed to allow this description to be done simply.[45,46] The suggested nomenclature defines a coordinate system that corresponds to the patient's anatomic position (Figure 6-47). The axes are labeled *A, L,* and *S* (for anterior, left, and superior) and *P, R,* and *I* (for posterior, right, and inferior). A beam name begins with the closest cardinal axis and then gives the angle of rotation from that axis to the beam central axis. Simple beams with no off-axis rotation are named after their anatomic positions. Examples include *A, P, R,* and *L* for the beam orientations commonly called *AP, PA, right lateral,* and *left lateral*, respectively. Beams with off-axis rotations include the angle of rotation. For instance, A30S indicates an anterior beam that is angled 30 degrees to the superior and A60L30S indicates an anterior beam that is angled 60 degrees to the left then angled 30 degrees superior (see Figure 6-47). This nomenclature is in clinical use in several institutions, and its use removes ambiguities in beam identification. An advantage over naming conventions based on machine coordinates (e.g., the GTC system, for gantry, table, and collimator) is that beam names are reported in the patient coordinate system and can be readily interpreted with respect to the patient position.

Radiotherapy Planning

Two-Dimensional Treatment Planning

Treatment plans such as those shown in Figure 6-45 are the results of 2D treatment planning. The patient contour, whether manually obtained at the time of simulation or obtained from a particular CT slice, must contain the central ray and one collimator axis of the beam; the beam must be coplanar with the contour plane. Beam orientations with central rays outside the contour plane are not permitted. Uses and limitations of 2D treatment planning have been thoroughly discussed[47,48] and very few 2D-only treatment systems are now in use.

Three-Dimensional Treatment Planning

With 3D treatment planning, radiation beam geometries are not constrained to lie in an image plane. Instead, beam trajectories are possible over all solid angles, greatly increasing the number of potential beam paths (see Figure 6-47). Software tools enable target and volume of interest localization/segmentation, image reconstructions, automatic and beam's eye view field designs, 3D dose calculations, and visualization techniques and metrics for plan evaluation. Advantages of 3D treatment include better target localization resulting from image-based planning, more accurate field delineation to include target and exclude critical and normal structures, and improved dose calculation models that consider the 3D shape of the patient and composition. Chapter 16 presents 3D treatment planning in detail, and comprehensive reviews are available.[49-52]

Dose Computation Algorithms

Photon dose calculation methods can be classified as one of four types: (1) empirical or semi-empirical models (e.g., broad beam methods based on the TMR and SMR), (2) analytic models based on first principles, (3) convolution models that use dose kernels and pencil beams, and (4) random sampling or Monte Carlo models that directly calculate the dose. Broad beam methods have been reviewed,[48] and work continues on higher fidelity models.[49,50,53-55] A clinically implemented electron calculation model with acceptable accuracy has been published and further developed.[56] Advances include convolution pencil beams and full Monte Carlo methods, which account for the 3D electron density distribution of the irradiated volume, radiation transport, and the spectral components of megavoltage photon and electron beams.[57] Convolution models for photon beams are well studied and implemented in every commercial treatment planning system. They compute dose based on the electron densities of the individual CT voxels traversed, using "density scaling" across non–unit density voxels. Thus tissue inhomogeneity or other "corrections" are

not needed, as they are for broad beam models, to compensate for inadequacies in the computation model. Physics requirements for dose calculation systems include calibration of the CT scanner intensity values (CT numbers) and proper commissioning of the treatment planning system using measured beam data to confirm dose computation accuracy over the range of irradiation geometries and electron densities clinically encountered. In the relatively near future, photon and electron doses will be computed rapidly, using graphics processing units (GPUs) or other fast hardware, and with the greatest accuracy possible using Monte Carlo algorithms that account for all unique aspects of the patient dataset.[58,59]

Treatment Plan Evaluation and Optimization

Evaluation of a treatment plan to determine clinical acceptability is a process that depends on the patient geometry, target dose coverage, protection of normal structures, and other clinical criteria. A treatment planner (dosimetrist) can provide several "reasonable" plans under physician guidance, but acceptability is a clinical decision by the radiation oncologist. One tool that aids quantitative plan evaluation is the dose-volume histogram (DVH).[60] A DVH represents a treatment plan by graphically indicating the fractional amount of a volume of interest that receives a specified dose (or more). Two histograms are possible: the differential DVH (dDVH) shows the fractional volume receiving a specified dose whereas the cumulative DVH (cDVH) is the integral form and shows the fractional volume receiving a specified dose or more. Both forms are shown in Figure 6-48 for hypothetical target and normal tissue volumes. The cDVH is the form most commonly used. Although DVHs show dose coverage of a volume, a disadvantage is that spatial information of the dose distribution is lost. For instance, inadequate coverage of a target volume may be indicated by the shape of the DVH but the location of the poorly covered region is not indicated; the treatment plan must be viewed to determine the location.

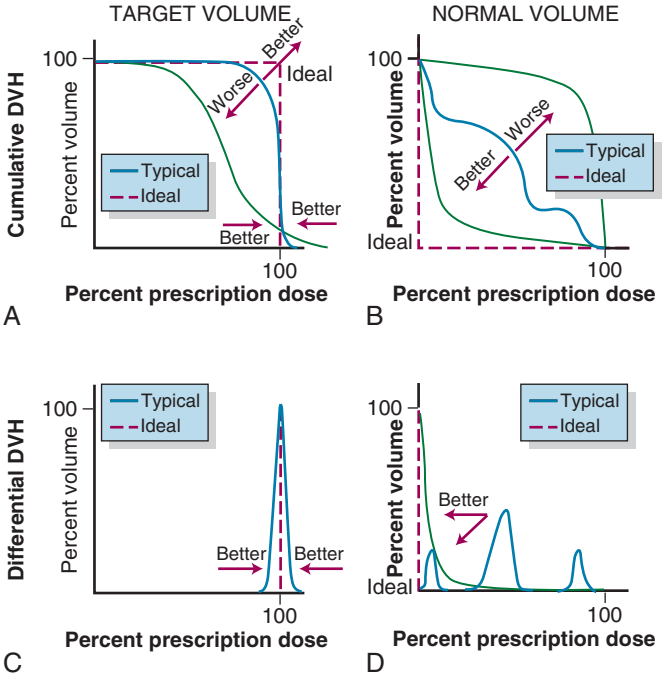

Figure 6-48 Dose-volume histograms (DVHs). **A,** Cumulative DVH for the target. **B,** Cumulative DVH for normal tissue. **C,** Differential DVH for the target. **D,** Differential DVH for normal tissue. Ideal DVHs are shown by the *dashed lines*. Indications for better or worse DVHs are shown.

Optimization of treatment plans depends on quantification of optimization criteria and may include dosimetrics (dose constraints at points or regions), permitted and prohibitive beam geometries, DVH indices, and approximations to biologic response functions such as tumor control probability (TCP) and normal tissue complication probability (NTCP) or other indices.[53,54] Mathematical optimization does not necessarily equate with clinical acceptability; optimization criteria may be improperly selected or otherwise limited. Similarly, rank-ordered, mathematically optimized plans may yield numerous clinically equivalent plans. Continuing work in treatment planning, research, and development requires clinical trials to show efficacy of the techniques. Various trials are under way, as discussed in Chapter 16.

Monitor Unit Calculations

Treatment planning data include beam parameters and weights that indicate the dose contribution of each beam to the prescription point. The setting on the treatment machine that controls dose delivery, either monitor units (MUs) or timer setting, must be computed so that the proper dose for each beam will be delivered. Typically, the MU or timer setting is calculated by the treatment planning system, particularly so for 3D treatment planning systems and for IMRT plans. As an independent check of the planning system and for simple irradiation geometries, the MU or timer setting is validated by performing a second-check calculation using treatment machine data tables of PDD, TMR, and other parameters—a TMR-based algorithm using measured data for each beam is an almost universal practice. Generally, this calculation is based on a broad beam model with homogeneous media (water, based on acquisition of beam data in a 3D water phantom), or the water-equivalent path length for heterogeneous media; thus calculations may give poor agreement (outside of ±5%) for complex irradiation geometries with heterogeneous media, strong surface or interface perturbations or small beams. This simple model is not appropriate for an independent check for IMRT fields without having a model that accounts for the contribution of each beamlet to the prescription point.

In a second-check MU calculation system and for applicable irradiation geometries the MU or timer setting can be calculated with the basic equation:

$$\text{Setting} = \frac{\text{Dose}}{\text{Dose rate}} = \frac{D}{\dot{D}} \qquad \text{Eq. 36}$$

in which the dose, D, is the desired dose (in centigrays) to the prescription point from the beam (target dose), and the dose rate, $\dot{D}$, is the dose per MU (centigrays per MU), or dose per time (centigrays per minute), that the beam delivers to the prescription point. Dose rate is relative to $\dot{D}_0$, the calibrated dose rate of the treatment unit, which is obtained for a reference geometry (depth = d_{max}, 10 × 10 cm^2 field size at 100 cm SAD) and material (water) using a national consensus protocol (in the United States, TG-51, American Association of Physicists in Medicine).

Equation 37 is used for calculation of monitor units (for linear accelerators):

$$\text{MU} = \frac{D(\text{cGy})}{\dot{D}(\text{cGy/MU})} \qquad \text{Eq. 37}$$

Equation 38 is used for timer calculations (for teletherapy devices):

$$T(\text{min}) = \frac{D(\text{cGy})}{\dot{D}(\text{cGy/min})} \qquad \text{Eq. 38}$$

The real work comes in determining the dose rate at the prescription point, $\dot{D}$, for the particular treatment geometry being calculated. $\dot{D}$ (Gy/MU or Gy/min) can be found from the reference dose rate, $\dot{D}_0$, by the following equation:

$$\dot{D} = \dot{D}_0 \times \text{PDD(or TMR or TAR)} \times \text{OF} \qquad \text{Eq. 39}$$

The term *OF* represents *other factors*, including attenuation factors for beam modifiers such as field shapes (use of MLC or custom blocks), wedges, and compensators; output factors for field sizes; off-axis dose rate factors; an inverse square term if needed; transmission and buildup factors for immobilization devices (molded sponges, thermal plastic masks, arm or breast boards, stereotactic frames); and any other devices or parameters that must be considered. As stated, in most cases the beam weight and $\dot{D}$ are computed by the treatment planning system, yielding a completed MU calculation for treatment. As explained here the simple MU calculation is performed as an independent, second check for confirming the treatment planning dose computation. Any MU calculation system must be thoroughly understood and defined to ensure its appropriate application to computation of the correct dose to the patient. MU calculations have been formalized in consensus documents in the United States[61] with similar formats in other countries.

EXTERNAL BEAM TREATMENT VERIFICATION

Treatment Portal Imaging

External beam treatments are verified by validating setup data such as beam geometries, including SSD measurements, and through comparison of simulator and treatment portal images. The use of portal images (originally performed with film) has been shown to have a positive impact on treatment,[62] and common practice is to obtain portal images at the beginning of treatment and for each week thereafter. The image quality of megavoltage port images is poorer than the quality for companion simulator images or kV-equivalent digitally reconstructed radiographs (Figure 6-49) because of poor subject contrast[63] caused by the dominance of the Compton effect. However, improvements to portal image quality have included design of more sensitive films; enhancement of image capture by the use of specifically designed screens, cassettes, or film-screen-cassette systems; combination diagnostic and therapy imaging; image enhancement of digitized portal films; and especially digital acquisition of the portal image, which is the current state-of-the-art.[63-65] Digital portal imaging systems, referred to as *electronic portal imaging devices* (EPIDs) were originally designed with at least five types of EPIDs,[63] depicted schematically in Figure 6-50: mirror-based video systems, fiberoptic video systems, liquid ionization chamber systems, scanning ionization chamber systems, and static solid-state systems—the flat-panel image receptor. This last design, using primarily amorphous silicon (aSi) as the detector element, has become the industry standard and is used by all linear accelerator manufacturers (see Figure 6-5). The use of EPIDs in clinical practice includes simple replacement of film, treatment verification by manual comparison with digital reference films, image enhancement by digital techniques such as adaptive histogram equalization for improved structure recognition, automatic determination of patient positioning to permit or prohibit treatment, dynamic monitoring of conventional treatment, dynamic monitoring of dynamic treatment (e.g., IMRT), and verification of treatment dose delivery.[64] These applications depend on the design and operational characteristics of the devices, such as image sampling and refresh rates (as needed for fluoroscopy), signal-to-noise ratio, detector resolution, detector radiation sensitivity, size of the active imaging area, software for image processing, physical size, and ease of use.

In Vivo Dosimetry

Dosimetric verification of treatment is sometimes required for unique patient geometries or critical situations such as total-body irradiation. Techniques for in vivo dose measurements include the following:

1. Optically stimulated luminescent dosimeters (OSLD) or thermoluminescent dosimeters (TLD) can be packaged in capsules or protective bags and placed in cavities, directly on the skin surface, and under extremities or bolus. Evaluation of results can be challenging for geometries where buildup is not complete. OSLD has replaced TLD as a commonly used method for in vivo dosimetry, although TLD remains a quite valid method.
2. Diode or MOSFET detectors with integral buildup may be placed superficially or intracavitarily. Diode and MOSFET systems can be set up rapidly and results are immediately

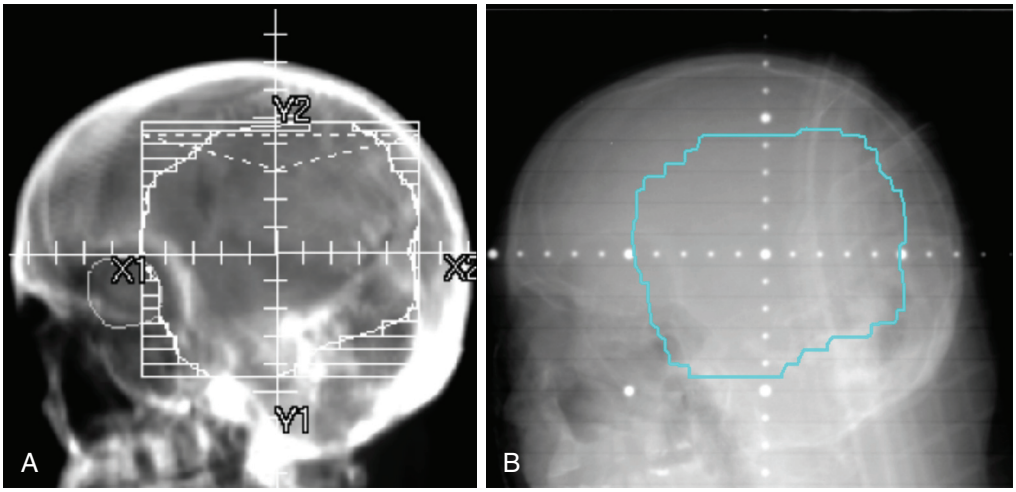

Figure 6-49 Imaging with diagnostic and high-energy photons. **A,** Simulator film of a brain tumor patient, with a block indicated by the outline. **B,** Port film of the patient in **A** shows the blocked area and context around the treatment region. Contrast is much higher in **A** because of increased amount of photoelectric effect. Contrast is poorer and of more limited range in **B** because of dominance of the Compton effect.

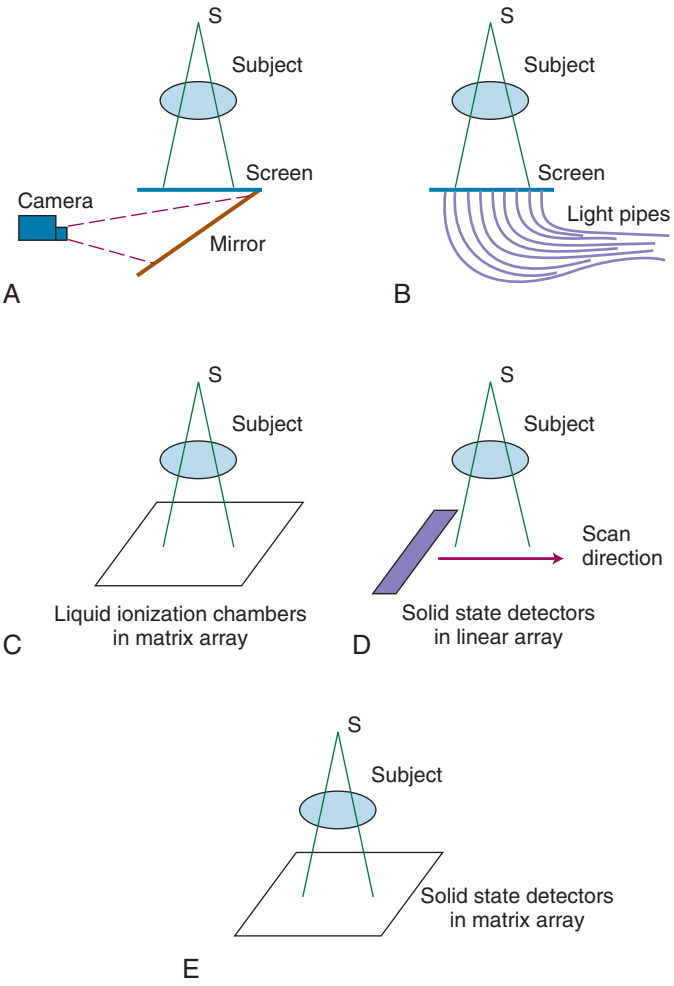

Figure 6-50 Five methods for electronic portal imaging. **A,** Fluorescent screen, mirror, and camera. **B,** Fluorescent screen and light pipe carrier. **C,** Direct irradiation of the matrix array of liquid ionization chambers. **D,** Direct irradiation of the linear array of solid-state detectors, with scanning. **E,** Direct irradiation of the matrix array of solid-state detectors.

available. They have gained popularity because of their ease of use compared with TLD. Designs exist with direct electronic connection to an in-room readout device or detectors alone that after irradiation are inserted into a readout device.

3. Radiochromic film can be used in a patient-equivalent phantom in the replicated patient treatment geometry. Film density is read with a calibrated digital scanner and with a film dose-response curve enables the readout and evaluation of isodose lines to yield a qualitative indicator of the relative dose distribution delivered.
4. A patient-equivalent phantom is tissue equivalent and includes internal structures such as bone, lung, and airways. Some phantoms are sectioned into transverse slabs and can accept radiochromic film, OSLD, TLD, or even ionization chambers at a particular anatomic level. Anatomic phantoms differ in shape or anatomy from the real patient but are useful for studying treatment geometries.
5. Ionization chambers rarely are used for in vivo dosimetry but may be placed with a protective sleeve in vivo superficially or in intracavitary locations, such as for monitoring a high-dose-rate brachytherapy procedure.
6. EPIDs can be used for transmission dosimetry for integrated or real-time measurement of dose when the patient geometry is known. Developing uses include static field and IMRT dosimetry.
7. Remote reporting MOSFET detectors are now available, with primary use in the breast or prostate. These solid-state detectors can be interstitially implanted and interrogated remotely to measure dose in situ. Such devices are biocompatible, relatively small, and can be visualized with kilovoltage imaging.

EXTERNAL BEAM TREATMENTS: GENERAL TECHNIQUES

Target depth, size, anatomic site, and proximity of critical structures all influence the choice of treatment modality (photons or electrons) and the technique to be used. Technique includes the number of beams; beam energy; beam weight (the relative amount of dose delivered by a beam); field shape; irradiation geometry; and use of bolus, wedges, compensators, or other special devices. Treatment planning techniques have been well studied and presented.[66,67] General practice is that photons are almost always used in a combination of two or more fields (i.e., parallel opposed, wedged pair, three field, four field, more field, or arc) and electrons are used as single *en face* fields (perhaps junctioned with other electron fields to cover a larger area). Example photon plans demonstrate these principles for the parallel-opposed, wedged-pair, three-field, four-field, and arc techniques in Figures 6-51 to 6-56. As the number of fields increases, there are two observations: The high-dose region becomes more conformal to the target, and the peripheral dose decreases but the volume of tissue covered by peripheral dose increases.[21] Current-day radiotherapy uses from one field (as delivered in a simple unidirectional treatment) up to effectively several hundreds or thousands, as delivered with IMRT or dynamic arc treatment. Electron treatment planning is less mature than photon planning and even now is often not performed at all, although pencil beam and even Monte Carlo calculation algorithms are available with accuracies that are clinically acceptable.[56,57] Commonly enough, electron treatment plans are based on graphic or tabulated measured data as previously shown (see Figs. 6-42 and 6-43).

THREE-DIMENSIONAL CONFORMAL RADIOTHERAPY

The goal of delivering dose to the target volume and minimal dose elsewhere was not easily approached with the limitations of early treatment technologies, because volumetric images (CT, MRI), beam shaping/modulation techniques, and computerized treatment planning were not available or were primitive. The 3D problem was understood, but tools did not exist to allow solution. Development and maturation of 3D treatment planning tools have rapidly enabled workers to consider the search for an "optimal" treatment plan, reasonably thought of as a plan with a dose distribution that "conforms" to the target volume (Figure 6-57). For many clinical sites conformal radiation treatment is the state-of-the-art, through the use multiple static, shaped fields, static or dynamic IMRT, or other computer-controlled approaches. Conformal radiation treatment is reviewed in Chapter 16.

Conformal radiotherapy plans are realized by using a large number of beams of various weights, sizes or shapes, and orientations to hit the target. If enough beams of the proper kind are used, a dose distribution can be created with a shape

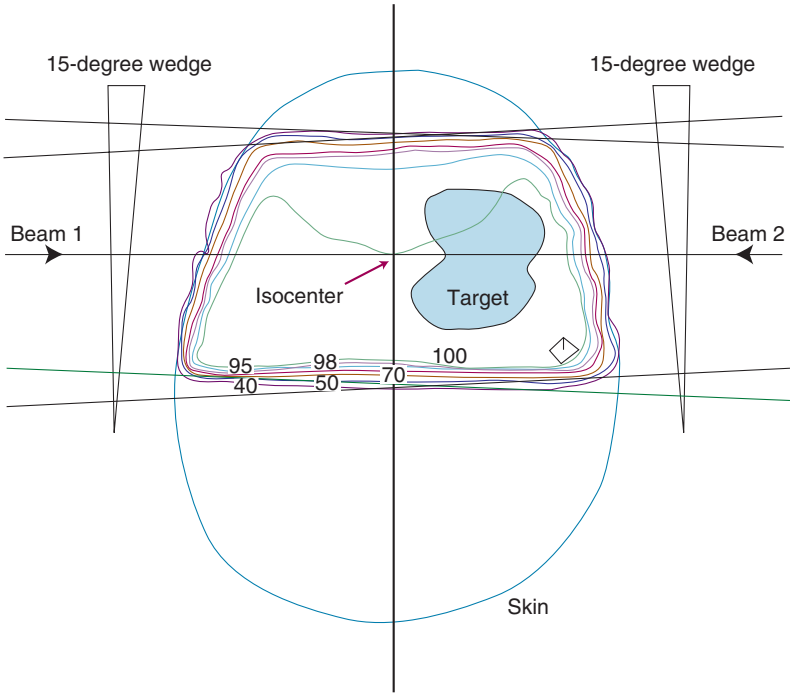

Figure 6-51 Parallel-opposed plan for treatment of a target in the head or neck.

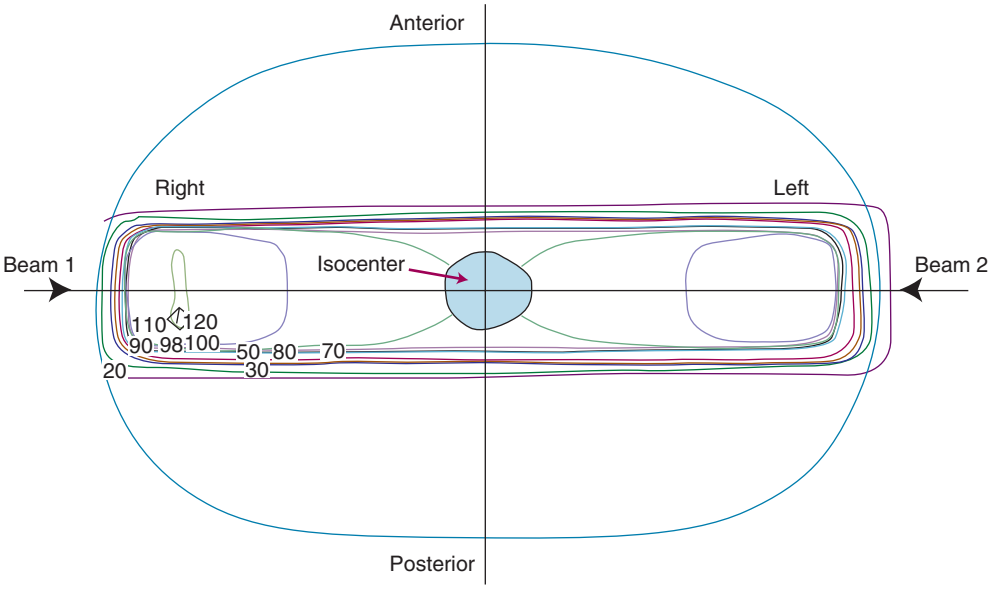

Figure 6-53 Parallel-opposed plan for treatment of a target in the pelvis.

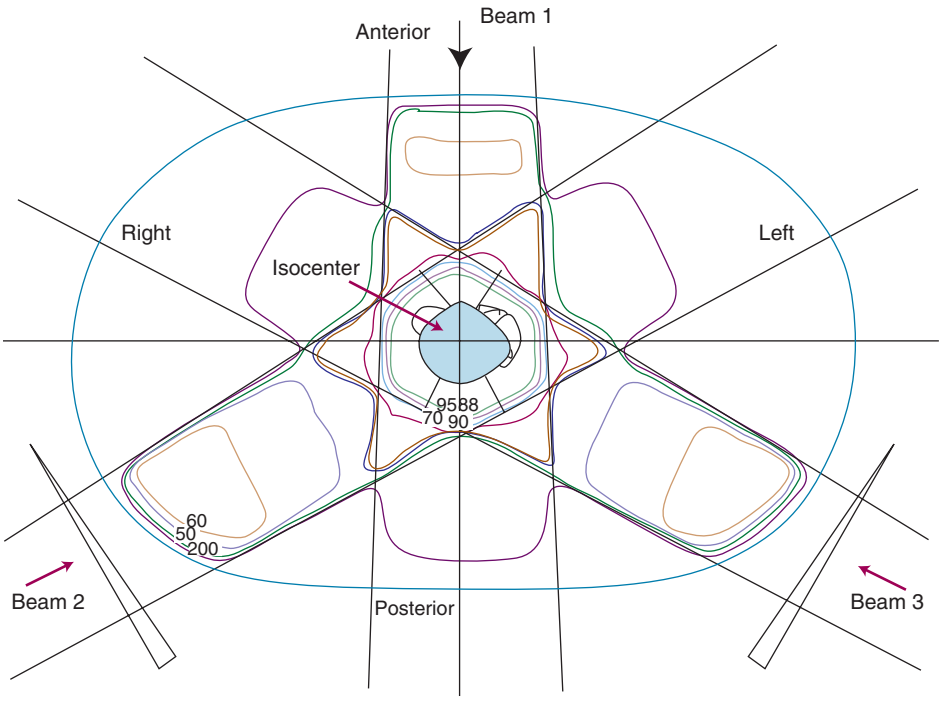

Figure 6-54 Three-field plan for treatment of a target in the pelvis.

that conforms to the target volume. This technique was recognized early[21] and is the reason multiple fields are used. In this regard, all radiotherapy treatment plans are conformal; however, the degree of conformation greatly varies based on the irradiation technique.

Conformal delivery techniques include a variety of approaches. Multiple static fields for 3D conformal radiation therapy (3D CRT) can be shaped by custom blocks, MLCs, miniature MLCs,[68] and custom stereotactic collimators.[69] Dynamic fields using arcs of gantry motion can be delivered using fixed field shapes[70] or variable field shapes[71] for each arc path. IMRT has several delivery approaches and can be delivered using static fields with 3D compensators[32] or by dynamic techniques using a binary collimator[13,72] or MLCs.[73,74] Some of these approaches are used for single-fraction radiosurgery techniques and others for fractionated treatment.

IMRT has become an important treatment approach over the past 15 years for curative treatment as well as for challenging irradiation geometries.[75-77] In IMRT the shaped outline of the radiation beam at a particular gantry angle is subdivided into a large number of beamlets, with the intensity of each beamlet set during an optimization procedure to give a particular dose. Beamlet width is set by the projected width of an individual MLC leaf. With a nonbinary MLC the length of each beamlet is variable and depends on the required dose and dose gradient needed and the technical specifications of the MLC device. The reconstruction of a conformal dose distribution for IMRT is the same process as CT image reconstruction from transmission profiles.[75] If an optimized plan is one that is conformal, solving the inverse radon transform will provide a solution that is optimal. However, it can be shown that a solution cannot be found that will give an exactly

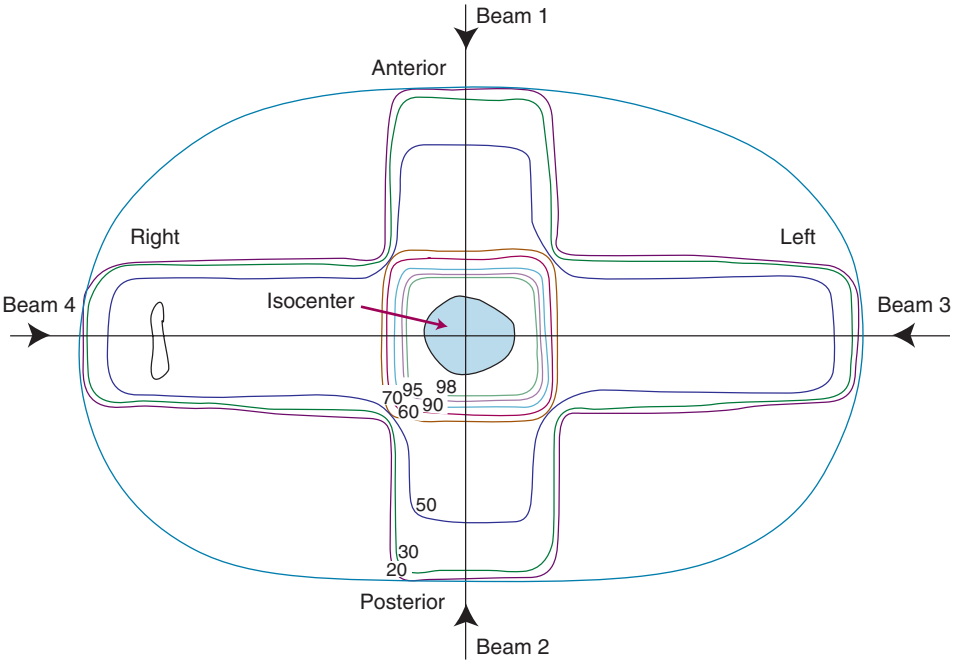

Figure 6-55 Four-field plan for treatment of a target in the pelvis.

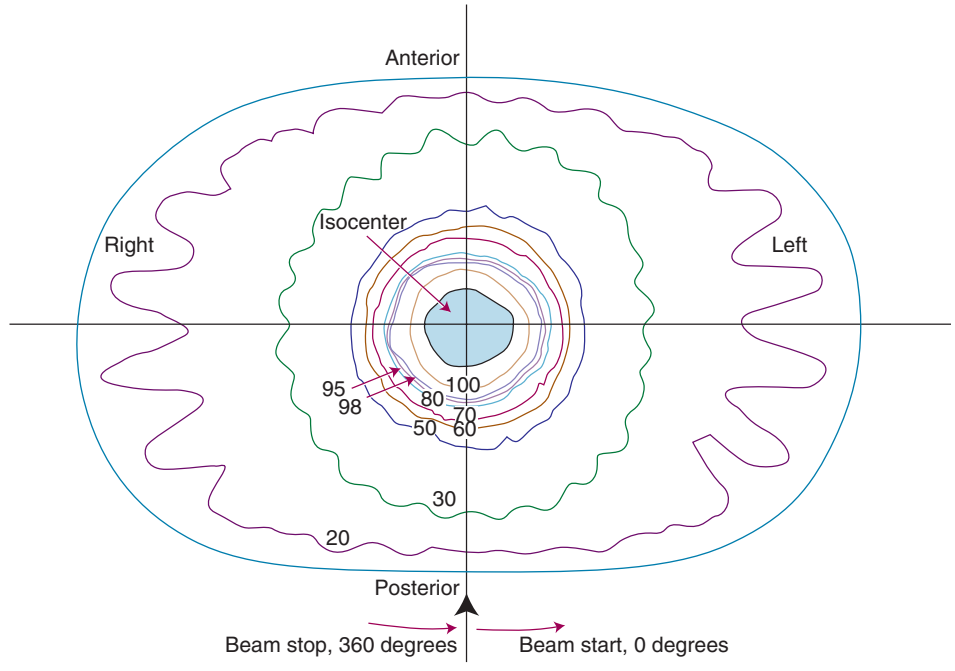

Figure 6-56 Arc plan for treatment of a target in the pelvis.

conforming distribution because negative beam weights (use of negative energy) are required but are not possible. The approach is to find an approximate solution to the inverse radon transform through iterative techniques. Also, importantly, dose constraints are set for both target (minimum dose to a point or volume) and normal or critical structures (maximum dose to a point or volume), and these constraints drive the automated dose optimization process. A thorough review of the conformal problem and its solutions is published,[54] and the field continues to develop with new approaches, faster optimization algorithms, and integrated plan evaluation tools. In a newer technique, rotational IMRT is delivered, using the conventional C-arm linear accelerator design, with simultaneous motions of the MLC leaves and gantry (arc movements). This technique is called intensity-modulated arc therapy (IMAT) or volumetric-modulated arc therapy (VMAT).[78] An intensity-modulated conformal plan is shown in Figure 6-58, and Chapter 16 gives additional information.

IMAGING IN RADIOTHERAPY

Radiotherapy procedures have become image based, and image-guided interventions, whether for surgery, lesion ablations, embolization of vascular defects, radiotherapy, or other therapies, are increasing in number.[56-58,77,78] The contributions of advanced imaging for radiotherapy include two primary areas: imaging for verification of treatment delivery and

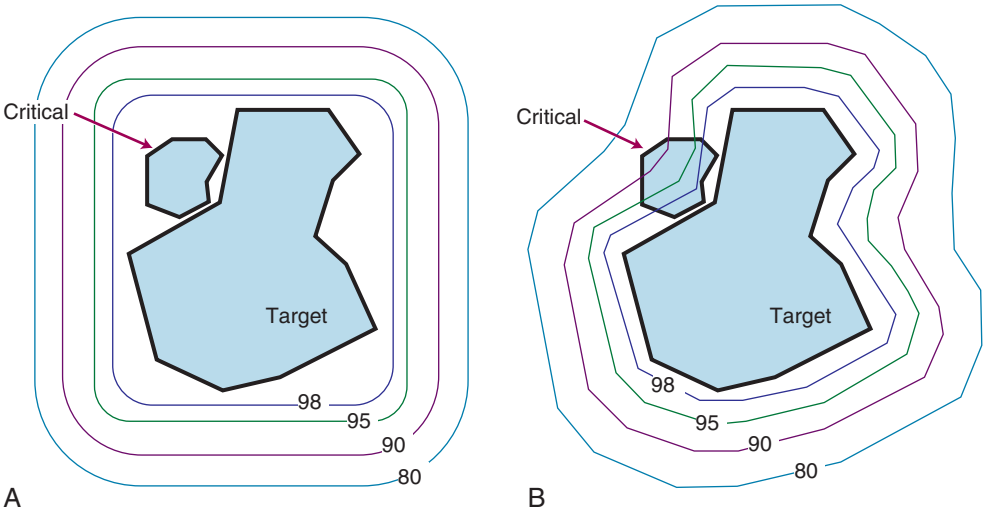

Figure 6-57 The conformal problem. A conventional plan **(A)** treats the target quite well but also treats a nearby critical structure. A conformal plan **(B)** treats the target well and spares part of the critical structure. Is the conformal plan better than the conventional plan?

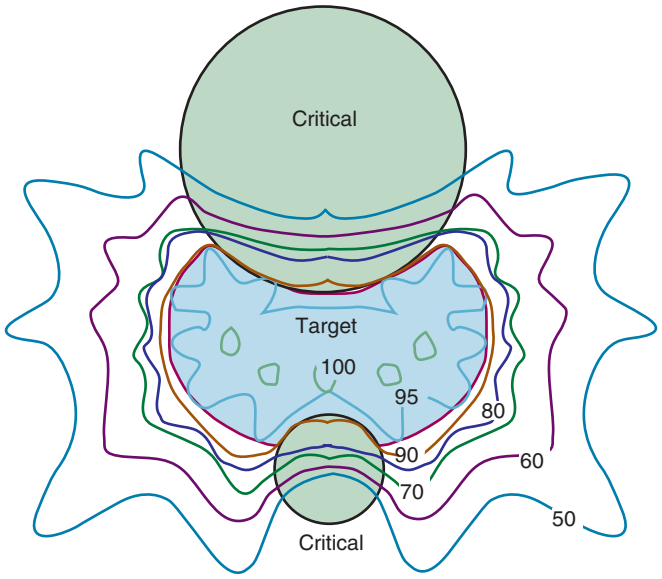

Figure 6-58 Example of a conformal plan. Intensity-modulated plan for a target located between two critical structures.

imaging for better understanding of the biology of cancers and normal tissues.

Image-Guided Radiotherapy

Image-guided interventions have been developed for a multitude of medical procedures, including radiotherapy.[79,80] The main justification has been the development and use of highly conformal radiotherapy plans, which carry risk for their implementation—in general, 3D CRT and IMRT plans use small fields that if delivered with geometric miss to the wrong location increase the likelihood of CTV underdoses. Thus, use of highly conformal radiotherapy techniques has heightened the need for image-based verification of treatment delivery on a more frequent basis than just the weekly portal images. This need has led to IGRT in which daily in-room imaging is performed immediately before each radiation treatment fraction. IGRT approaches that use in-room imaging include isocentric ultrasound imaging, CT-on-rails, radiographic and fluoroscopic projection imaging, kV cone beam CT, MV cone beam CT, and MV fan beam CT.[81,82] These devices are integrated with the MV treatment device to form a hybrid imaging-treatment unit. Implementation issues include image quality, imaging dose, image interpretation, manual versus automated comparison of daily and reference images, revisions to treatment plans based on observed daily variations of position and anatomy compared to a reference treatment plan, and image archival and retrieval.[81-83]

Imaging for treatment simulation and IGRT techniques have made possible the study of target motion, to assess if a target moves outside the radiation field such that a geometric miss might occur.[84] Target motion is primarily because of the respiratory cycle; however, bladder and bowel filling or emptying or other noncyclic motions may also cause target motion. The main approach is to perform a motion study of the target, using (typically) CT and possibly PET, using a variety of image acquisition and reconstruction techniques. A common method is to acquire images at the same time that the respiratory cycle is tracked, over a time period of several respiratory cycles. Each image is correlated with the respiratory phase at the time of acquisition and then rebinned with that corresponding phase. A "playback" of the images over time yields a coherent set of dynamic images on which target motion can be observed and measured as a function of time. This technique is possible for 4D CT and PET imaging modes,[84] with 4D MR under investigation. At the time of treatment planning and treatment any observed target motion can be accommodated by one of several techniques: using a larger treatment field, gating the treatment to match a particular phase of the respiratory cycle, real-time tracking of the target using a surrogate fiducial marker detected by optical means or rapid radiologic imaging, or optical patient surface tracking.[82,84] Motion assessment and compensation techniques continue to be developed, and techniques that use optical and remote monitoring show promise for being fast in detecting motion and changes in patient position.

Although optical methods tend to be limited to detection of visible surfaces, in one technique real-time remote monitoring of target position is performed before and during

treatment, using interstitially implanted glass-encapsulated transponders and an in-room remote readout device.[85] At least three transponders are implanted into the target and their relative positions are determined from the treatment planning CT scan and the remote readout unit, with geometric reference to the isocenter position. Each day patient position is set based on the planning CT scan and then monitored in real-time to ensure treatment delivery to the correct location.[85,86] Accuracy is high, transponder migration is typically small although possible, and imaging modalities should be considered for the best information flow with minimal image artifact.[86,87]

Biologic Imaging

Biologic imaging is imaging of physiologic, metabolic, and functional processes to noninvasively measure the biologic character of tumors or normal tissues. Important biologic aspects of tumors to be imaged include metabolite content, the presence of hypoxia, and cell proliferation. Methods with biologic imaging potential include PET and PET/CT with novel radionuclides and ligands for specific receptor targeting, MR spectroscopy, functional MRI (fMRI), MR diffusion and perfusion imaging, ultrasonography, and optical methods for targeted receptors.[80] Biologic and molecular imaging techniques have increased tremendously over the past 10 years, and their applications include preclinical basic science research, the use of imaging as a biomarker, and studies of clinical responses to radiotherapy. Molecular imaging applications in radiation oncology are in active development.[88]

As a biomolecular imaging example, brain tumors have been studied using magnetic resonance spectroscopy (MRS) to measure the spatial distribution of metabolites that correlate with tumor grade.[59,60,84,85] Choline, creatine, *N*-acetyl-aspartate (NAA), lactate, and other metabolites relevant to the type of tumor (in this case, brain tumors) are determined by MRS. The ratio of choline to NAA is determined by spectroscopic peak height analysis and mapped on a contrast-enhanced MR image (Figure 6-59, *B*). One observation is that the spatial distribution of metabolite values and ratios for brain tumors differ in size and shape from that of (conventional) contrast-enhanced MRI.[89,90] Figure 6-59 shows the problem for targeting with radiation: metabolite ratios or other tumor-specific information from biologic imaging modes will redefine how oncologic targets are determined. Anatomic methods that image endogenous contrast or contrast-enhanced regions will be complemented with advanced biologically based imaging techniques. These multimodality images will be used for targeting. The information is greater than having two different imaging modalities such as CT and MRI; it is the addition of patient-specific imaging to determine tumor character and environment. The validation of these new imaging techniques is important to ensure the understanding of the image information content, that is, the meaning of an intensity value for a voxel and how the image should be used as part of the radiation planning process.[89,91]

Biologic imaging and methods for IGRT will continue to mature over the next decade. Biologic imaging will contribute especially to the understanding of cancer and normal tissue biology. Costs, technologic aspects of implementation, and clinical benefits of multimodality imaging remain to be solved for biologic imaging and its uses in radiation treatment planning and the evaluation of patient response to treatment.[79,92] For instance, dedicated PET/CT and MR simulators have been implemented to facilitate the uses of these advanced imaging modalities for radiation oncology patients.[93] Also, the development of hybrid imaging-treatment devices for IGRT continues with MR-linear accelerator and MR-gamma teletherapy designs now being brought into clinical use.[94,95]

STEREOTACTIC RADIOSURGERY AND RADIOTHERAPY

High accuracy and precision radiotherapy can be performed using stereotactic image-guidance and rigid immobilization or remote monitoring and positioning systems. The *stereotactic* component of these techniques refers to immobilization or fixation of the patient with a rigid or otherwise stable system

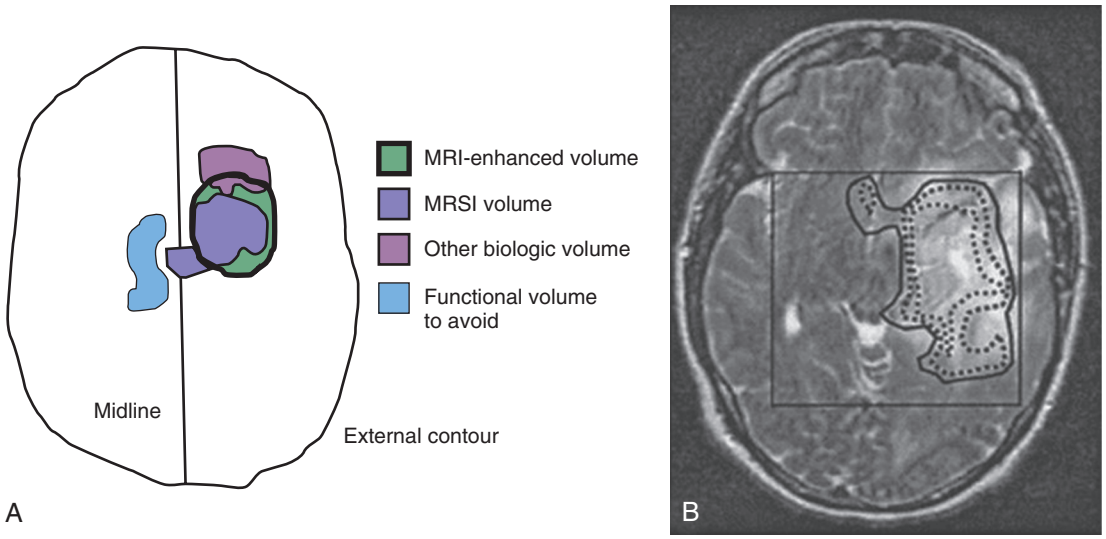

Figure 6-59 Biologic target volumes. **A,** Schematic shows the possible arrangement of three representations of a brain tumor: contrast-enhanced magnetic resonance imaging (MRI, *green*), magnetic resonance spectroscopic image (MRSI, *purple*), and other biologic volume *(violet)*, such as proliferation and receptor density. A region of avoidance *(blue)* is represented as may be obtained by functional MRI. **B,** From inner to outer shells, successive iso-ratio lines for choline-*N*-acetyl-aspartate (NAA) metabolite ratios (cho/ NAA) of 6 *(dotted line)*, 4 *(dotted line)*, and 2 *(solid line)*. coupled with same-day imaging, to establish a patient-specific image-based coordinate system for the entire treatment process. *Stereotactic radiosurgery* (SRS) refers to the use of single-fraction, small-field, high-dose (12- to 24-Gy margin dose), focal radiation for treatment of relatively small intracranial or extracranial tumors.[96] By two SRS techniques, a gamma radiosurgery unit[97-102] or specially designed linear accelerator systems,[68-70,103-107] a large number of small circular or shaped radiation fields are aimed accurately from multiple directions to intersect a common point at which a target is positioned. In contrast, *stereotactic radiotherapy* (SRT) refers to the use of more than one fraction, typically two to five fractions (hypofractionation), using similar techniques with small fields and relatively high dose per fraction. SRT techniques include noninvasive and replaceable patient fixation,[108] extracranial treatment,[109,110] static or shaped fields,[69,111] intensity-modulated treatment with large- or small-width collimators, treatment with robot-controlled x-ray units,[14,112] shape-based planning,[113] and other optimization algorithms. In particular, stereotactic body radiotherapy (SBRT), which uses a relatively large number (e.g., 7, 9, or 11) of shaped, static fields and hypofractionated dose regimens, has become quite common for small lung targets and liver metastases, possibly including 4D motion accommodation and always using IGRT.[109,110,114,115] Gamma radiosurgery, linear accelerator radiosurgery, and stereotactic body radiotherapy (SBRT) are covered in detail in Chapter 17.

TOTAL-BODY PROCEDURES

Total-body irradiation (TBI) is an irradiation procedure performed as part of bone marrow transplantation and requires special physics measurements for implementation of treatment.[116] The patient is irradiated in the anterior-posterior/posterior-anterior or lateral-opposed directions at an extended distance from the treatment machine using large photon fields to encompass the whole body (Figure 6-60). The goal is to provide dose homogeneity within ±10% of the prescription dose at the patient's midline. Dose compensation for narrow-width regions of the body and protection of the lungs with shielding blocks is required, depending on the technique used. Radiation beam data, such as beam profiles, depth dose or tissue-maximum ratios, and reference dose rates, must be obtained at the extended distance used. Data obtained for conventional treatment at the isocenter may not apply to large fields at extended distances, because of changes in scattering conditions. Higher beam energies are used for lateral techniques, matching the increase in patient thickness compared with anteroposterior geometries.

Total-skin electron treatment (TSET) is similar to TBI except that electrons are used instead of photons. Considerations for this technique, which is used for skin cancers such as mycosis fungoides, have been delineated and include measurement of beam data (e.g., beam profiles, depth dose, and reference dose rate), measurement and any required reduction of bremsstrahlung contamination, and methods for ensuring relatively homogeneous irradiation of the patient surface. In particular, the irradiation geometry must avoid overdoses to thin anatomic regions such as the hands and fingers and prevent underdoses to anatomic regions that might be shielded by skin folds or extremities.[117] Typically, a six-field approach with six different patient positions is recommended. The set up techniques are described in more detail in Chapter 18.

BRACHYTHERAPY

Brachytherapy is a term that comes from *brachy* ("short"), combined with *therapy*, meaning short-distance therapy. The contrast is *teletherapy*, meaning therapy at a distance, as with ^{60}Co or linear accelerator machines, where the radiation source is 80 to 100 cm from the patient. In brachytherapy radioactive sources of small physical size are placed very close to or in the tumor for surface mold, interstitial, or intracavitary treatment. Several terms are defined:

1. *Surface mold:* sources are fixed to an applicator, or mold, that conforms to the patient surface. The surface applicator positions the sources in the desired geometry and is placed on the skin surface to irradiate a superficial target. This technique is not commonly performed, except for purposes of treatment of ocular melanoma.

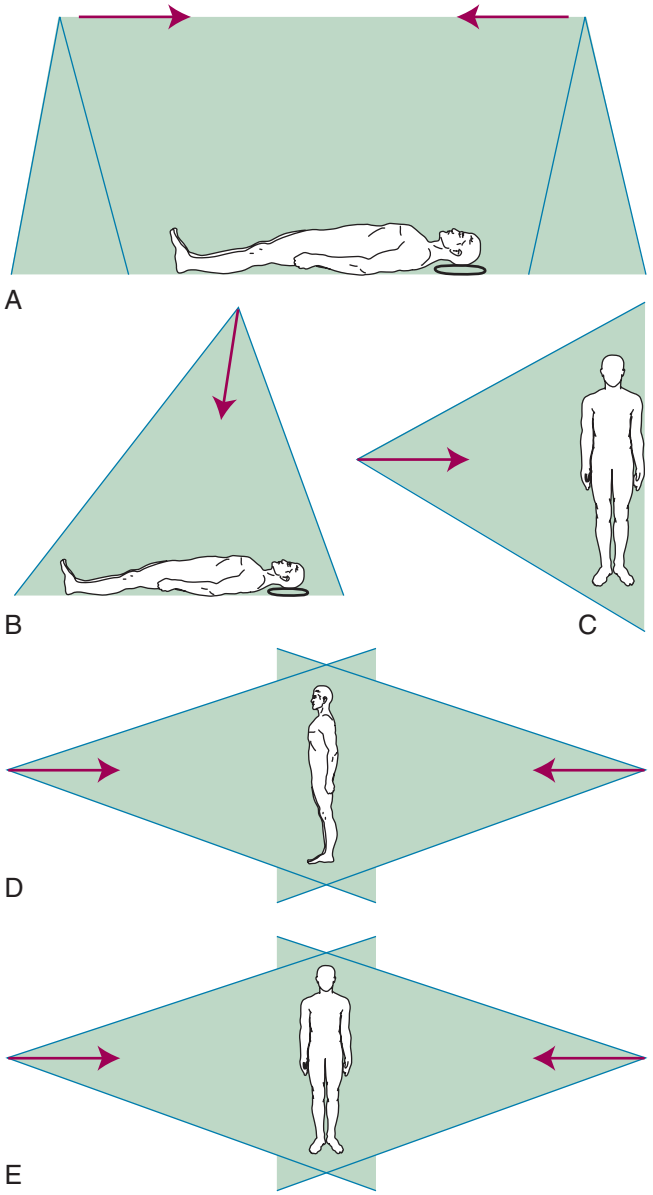

Figure 6-60 Irradiation geometries for total-body irradiation. **A,** Moving-source technique, with the patient on the floor. **B,** Large-field irradiation, with the patient on the floor. **C,** Single, large, lateral field, with the patient erect. **D,** Opposed, large, anterior and posterior fields, with the patient erect. **E,** Opposed, large, lateral fields, with patient erect.
A *to* ***C,*** *From AAPM RTC Task Group 29: Report 17: The physical aspects of total and half body photon irradiation. College Park, MD, 1986, American Association of Physicists in Medicine.*

2. *Interstitial treatment:* sources are implanted in tissues directly or within catheters that are first implanted within the target volume.
3. *Intracavitary or intraluminal treatment:* sources are inserted into body cavities by means of applicator devices. Sites include the oral, rectal, vaginal, and uterine cavities and the tracheal and bronchial lumina.

Brachytherapy has several advantages compared with external beam treatment:

1. The inverse square law dominates the decrease in dose rate and dose as the distance from a source increases. The dose fall-off is steep so that the dose delivered near a source is quite high (thousands of centigrays), whereas a few centimeters away the dose is low (tens of centigrays). The steep dose gradient confines the high-dose region to a small volume.
2. The photons emitted by brachytherapy sources have relatively low energies and greater attenuation in tissue compared with photons used for external beam treatment. This increased attenuation concentrates dose near the source and minimizes dose at a distance.
3. In conventional brachytherapy, prescription dose rates are relatively low, about 0.40 Gy/hr up to 0.80 Gy/hr, and it takes several days to deliver the prescribed dose. This approach may allow treatment of all cells in each phase of the cell cycle for a radiobiologic advantage. High dose rate remote afterloading brachytherapy is now commonly used, with dose rates of approximately 2 Gy/min at the prescription point, comparable to external beam dose rate.

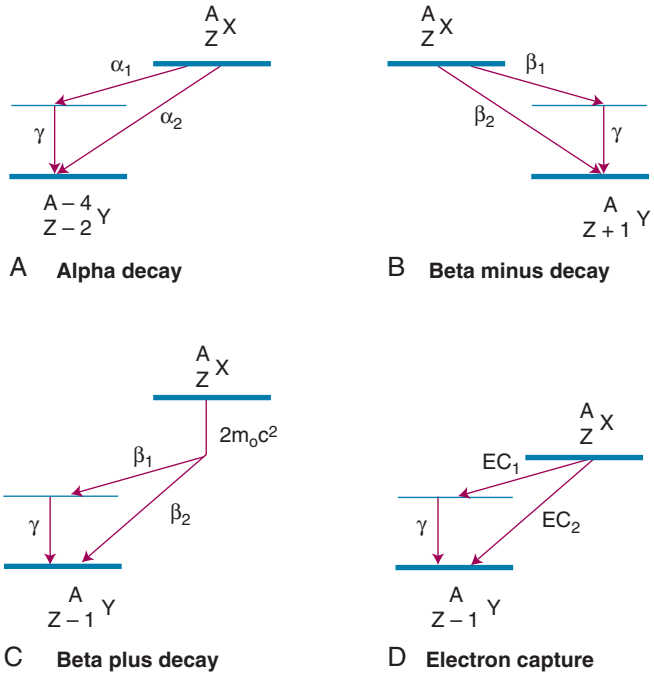

Figure 6-61 Modes of radioactive decay. **A,** α Decay. **B,** β⁻ Decay. **C,** β⁺ Decay. **D,** Electron capture.

Radioactive Decay

The atomic nucleus contains protons and neutrons that prefer certain configurations for stability, as discussed previously. Those configurations that are not stable undergo spontaneous transformation to another nuclear species that may or may not be stable. This spontaneous transformation is called *radioactive decay.* The mode of radioactive decay, meaning the type of transformation and emitted particles, depends on the parent species' nuclear composition. For a particular parent nuclide, a decay mode is allowed or prohibited, and it is one of the following types[2,12,13] (nomenclature is as defined previously, and particles are defined in Table 6-2):

1. In alpha decay (Figure 6-61, *A*), the nucleus gives off an alpha particle, $^{4}\alpha^{2+}$ (2 protons and 2 neutrons—a helium nucleus), resulting in a daughter nucleus of mass A-4 and atomic number Z-2. Alpha particles are monoenergetic and tend to have 4 to 8 MeV in kinetic energy.

$$^{A}_{Z}X \rightarrow {}^{A-4}_{Z-1}Y + {}^{4}\alpha^{2+} + Q \quad 2n \rightarrow 2p + {}^{4}\alpha^{2+} + Q$$

Secondary processes after alpha decay include gamma ray emission (or internal conversion, yielding characteristic x-rays or Auger electrons), which may occur after alpha decay as the daughter de-excites to the ground state. Radionuclides undergoing alpha decay tend to have high Zs and include ^{216}Ra, ^{222}Rn, ^{218}Po, ^{235}U, ^{239}Pu, and ^{241}Am.

2. For beta decay, a single nucleon (neutron or proton) transforms from one type to the other in the nucleus. The nucleus gives off an electron, called a β particle because of its nuclear origin, and a neutrino. There are two types of β particles, one with negative charge, β^-, which is a "regular" electron, also called a *negatron,* and one with positive charge, β^+, the antiparticle to the electron, also called a *positron.* Radioactive decay modes with emission of a β^- or β^+ are possible.
   a. For β^- decay (i.e., negatron decay) (see Figure 6-61, *B*), a neutron transforms into a proton in the nucleus. The nucleus gives off a β^- particle and an antineutrino. The resulting daughter nucleus has the same mass *A* and increased atomic number of *Z* + 1. The β^- particles have a distribution of energies less than or equal to Q (the antineutrino carries off the remainder). The average β^- energy is about one third Q.

$$^{A}_{Z}X \rightarrow {}^{A}_{Z+1}Y + \beta^- + \bar{v} + Q \quad n \rightarrow p + \beta^- + \bar{v} + Q$$

Secondary processes after β^- decay include gamma ray emission (or internal conversion, yielding characteristic x rays or Auger electrons), which may occur after β^- decay as the daughter de-excites to the ground state. The β^- decay occurs for neutron-rich nuclides over all Zs. Example nuclides include ^{3}H, ^{14}C, ^{32}P, ^{60}Co, ^{89}Sr, ^{99}Mo, ^{131}I, ^{137}Cs, and ^{198}Au.

   b. For β^+ decay (i.e., positron decay) (see Figure 6-61, *C*), a proton transforms into a neutron in the nucleus. The nucleus gives off a β^+ particle and a neutrino. The resulting daughter nucleus has the same mass *A* and decreased atomic number of *Z* – 1. The β^+ decay requires that 2 $m_o c^2$, or 1.022 MeV, be available between the parent and initial daughter energy states to be possible. If this energy difference is not available, β^+ decay is prohibited and electron capture may occur. The β^+ particles have a distribution of energies less than or equal to *Q* (the neutrino carries off the remainder). The average β^+ energy is about one third *Q* but is higher than the average β^- energy for the same *Q* because of repulsion by the nucleus.

$$^{A}_{Z}X \rightarrow {}^{A}_{Z-1}Y + \beta^+ + v \quad p \rightarrow n + \beta^+ + v + Q$$

Secondary processes occur after β^+ decay. The positron, β^+, has a short lifetime before annihilation. There is a small chance that the β^+ will hit an electron and annihilate in flight. The greater probability is that the β^+ slows down (through coulomb interactions) and combines

with a free electron. The combined β^+/e^- (or e^+/e^-) species is called *positronium.* Positronium exists for about 10^{-10} seconds before annihilation and the creation of two 0.511-MeV photons (i.e., one photon for each electron mass). A longer-lived state of positronium (10^{-7} seconds) yields three simultaneous annihilation photons. Gamma ray emission (or internal conversion, yielding characteristic x-rays or Auger electrons) may also occur after β^+ decay as the daughter de-excites to the ground state. The β^+ decay occurs for proton-rich nuclides over lower and intermediate Zs. Example nuclides include ^{11}C, ^{15}O (used in positron emission tomography), and ^{22}Na.

3. In electron capture (see Figure 6-61, *D*), the nucleus captures an orbiting electron, increasing the nuclear mass by 0.511 MeV and transforming a proton into a neutron. Electron capture is similar to β^+ decay because the daughter has mass Z-1 and a neutrino is emitted. Most often, the K shell electron is captured. Electron capture occurs for proton-rich nuclides over lower and intermediate Zs when there is not sufficient energy (2 m_oc^2, or 1.022 MeV) for β^+ decay to occur.

$$^{A}_{Z}X + e^- \rightarrow {}^{A}_{Z-1}Y + v + Q \quad p + e^- \rightarrow n + v + Q$$

Secondary processes occur after electron capture. Because an orbital electron is captured, subsequent filling of the electron shell results in the emission of characteristic x-rays after an electron capture event. Gamma ray emission (or internal conversion, yielding characteristic x-rays or Auger electrons) may occur after electron capture as the daughter de-excites to the ground state. Nuclides decaying by electron capture include ^{22}Na, ^{40}K, ^{51}Cr, ^{57}Co, and ^{192}Ir (also with β^-).

The term *Q* in each decay equation represents the total energy given off as kinetic energy of the ejected particles (α, β^-, β^+, $\bar{\nu}$, ν), the remaining nucleus, or both. The neutrino, with a mass of almost zero, was first postulated for existence because of the observed continuous energy distribution for β^- and β^+ energies in beta decay. Without a third reaction product, the β^- or β^+ energies would be monoenergetic and almost equal to Q, reflecting the discrete energy levels in the nucleus.

Secondary Decay Processes

Each of the primary decay modes can leave the daughter nucleus or atom in the ground state or excited state. If an excited state exists, the additional energy is given off in various ways to yield a ground-state daughter.

1. *Isomeric transition by fast gamma emission:* with an excited daughter nucleus, the excitation energy may be given off by photons called *gamma rays.* The gamma ray energy is equal to the difference between the initial and next energy state of the nucleus. Because energy states are fixed for particular nuclei, gamma emissions are fixed and unique for a particular nucleus. Gamma rays identify their nucleus of origin in the same way characteristic x-rays identify their atom. Gamma emission may result in a ground state nucleus by a single gamma emission or by successive gamma emissions through several energy states. The release of energy by gamma emission is fast—the excited state exists for no longer than 10^{-6} seconds—gamma emission is immediate after α, β^-, β^+, or electron capture decay. Although the phrases "^{60}Co gamma rays" and "^{137}Cs gamma rays" are used, these gamma rays are really from the daughter nuclei. Gamma rays from ^{60}Co are really ^{60}Ni gamma rays and gamma rays from ^{137}Cs are really ^{137}Ba gamma rays. However, the terminology is based on the parent nuclide's name.
2. *Isomeric transition from a metastable state:* when an excited nuclear state exists for greater than 10^{-6} seconds before gamma emission, the state is called a *metastable state.* Metastable states sometimes exist long enough to enable the separation of the metastable species from the parent, as is the case for ^{99m}Tc, with a half-life of 6 hours. The "m" refers to metastable. ^{99m}Tc decays to ^{99}Tc (an isomeric transition) by the emission of two gamma rays in succession.
3. *Internal conversion:* an excited nucleus can de-excite without gamma emission by the process of internal conversion. Instead of a gamma ray, the excitation energy is used to eject an orbital electron, usually from the K shell. The ejected electron is called a *conversion electron* and has energy equal to the gamma energy minus the electron binding energy. The usual cascade of characteristic x-rays and Auger electrons follows. Internal conversion competes more with gamma emission as Z increases. The pathways of gamma emission and internal conversion are parallel to the competing processes of characteristic x-ray and Auger electron emission; a photon carries off the excitation energy, or the energy is transferred to an electron that is then ejected.

Radioactive decay is characterized by the following observations:

- All nuclei above $Z = 82$ are radioactive.
- For nuclei below $Z = 82$ some are naturally radioactive (e.g., ^{14}C and ^{40}K).
- High *Z* nuclei tend to undergo alpha decay; their nuclei have an abundance of protons and neutrons that may be emitted as coupled pairs (i.e., an alpha particle).
- Alpha particles tend to have 4 to 8 MeV in kinetic energy.
- Middle-range *Z* nuclei tend to undergo β^- (i.e., negatron) decay.
- Low *Z* nuclei tend to undergo β^+ (i.e., positron) decay.
- In general, if the decay rate is high (i.e., short half-life), the decay particles are energetic.
- In general, if the decay rate is low (i.e., long half-life), the decay particles are low energy.

Radioactive Decay Mathematics

Radioactive decay occurs spontaneously but also with a distinct probability for each radioactive nuclide. The number of transformations occurring per unit time, *A(t)*, is called *activity* and is given by the following equation.

$$A(t) = \lambda N(t) \qquad \text{Eq. 40}$$

in which *N(t)* is the number of atoms of the radioactive species at time *t* and λ is a proportionality constant called the *decay constant.* The SI unit for activity is the becquerel, equal to one transformation per second. The original unit of activity is the curie, which is 3.7×10^{10} transformations per second (3.7×10^{10} s^{-1}), an amount equal to the number of disintegrations occurring in 1 g of ^{226}Ra. λ is called the *decay constant,* which is unique for a nuclide and is equal to ln(2) divided by the half-life, $t_{1/2}$:

$$\lambda = \frac{\ln(2)}{t_{1/2}} = \frac{0.693}{t_{1/2}} \qquad \text{Eq. 41}$$

in which $t_{1/2}$ is the amount of time required for the activity or the number of nuclei to decay to one half of the original value. The relationship between λ and *t* looks like the relationship between HVL and λ.

The half-life, and, hence, the decay constant, is constant and unique for a nuclide, and its measurement can be a means

for identifying a species. Depending on the species, the half-life can be large or small and governs the lifetime over which decay occurs. The equation that radioactive decay obeys is:

$$N(t) = N_0 e^{-\lambda t} \text{ or } A(t) = A_0 e^{-\lambda t} \qquad \text{Eq. 42}$$

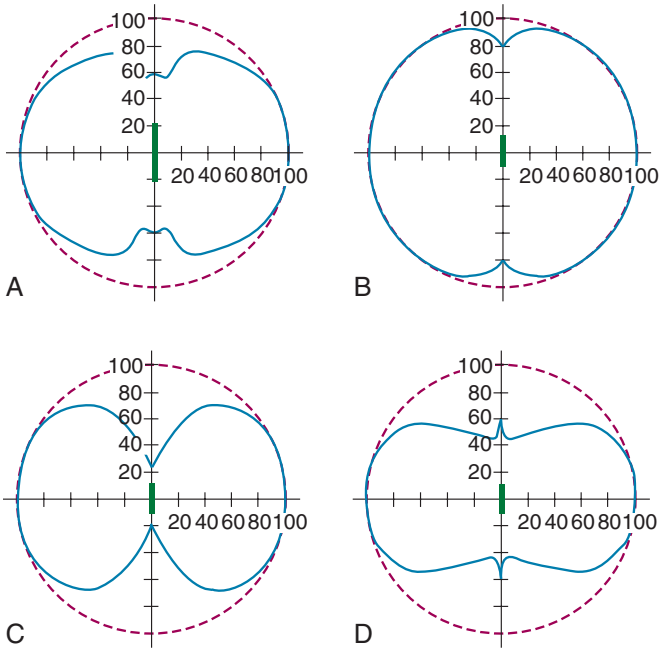
where $N(t)$ and N_o are the number of nuclei at time t and $t = 0$, respectively, and $A(t)$ and A_0 are the activities (in becquerels or curies) at time t and $t = 0$, respectively. Decay is exponential and can be represented in linear or semi-log form (Figure 6-62).

Properties and Applications of Isotopes

Table 6-14 lists isotopes, their properties, their physical forms, and their therapeutic applications. As seen, brachytherapy sources may be constructed as sealed sources in the forms of needles, tubes, or seeds. The solid radioactive material, in a metallic, stable inorganic or organic chemical form, adsorbed onto a material, or possibly as a liquid or gas, is sealed into a metal source capsule by welds or other means that prevent leakage of the material. Most radioactive sources are beta emitters, and the useful radiations for treatment are the gamma rays or characteristic x-rays emitted after beta decay. Besides containment of the source material, the metal encapsulation stops all beta (or alpha) emissions and allows only the gamma or x-rays to be transmitted. Sources can also be used for their beta emissions when encapsulated in a thin-wall enclosure (i.e., ^{90}Sr) or in unsealed (liquid) form.

Dose distributions from sealed sources have a shape that reflects the rapid fall-off with dose because of the inverse square law, the source energy, the distribution and amount of activity within the source, and the source encapsulation. Source encapsulation in particular affects the apparent activity, active length, and shape of the dose distribution through attenuation by the source capsule walls and ends. Sealed-source dose distributions are anisotropic, not uniform, because of increased encapsulation thickness and self-absorption along the length of the source (Figure 6-63). Investigators have performed measurements and applied Monte Carlo techniques and other models to determine brachytherapy source dose characteristics.[118,119]

Radioactive decay and its energetics are represented by decay schematics (see Figure 6-61). Horizontal lines represent



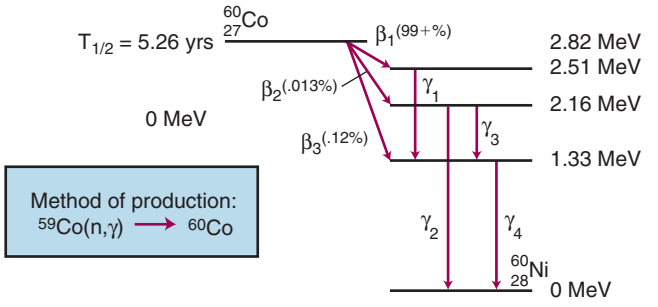


Figure 6-63 Brachytherapy source anisotropy. **A,** Relative dose rate using a 2-cm radius, ^{226}Ra tube, and 1.35 active length. **B,** Relative in-air fluence for ^{192}Ir seed. **C,** Relative in-air fluence for ^{125}I seed, model 6711. **D,** Relative in-air fluence for ^{103}Pd.

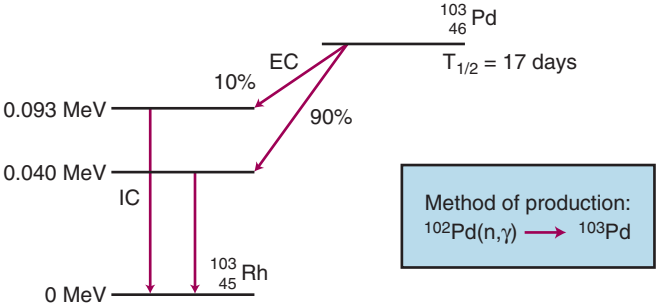
the relative nuclear energy levels of the parent and daughters. Branches from the parent to the daughter represent the type of decay, whereas the horizontal spacing of each species represents the atomic number, Z. A branch to the left indicates a transition where Z decreases (α, β^+, or electron capture) (see Figure 6-61, *A* to *D*). A branch to the right indicates a transition where Z increases (β^- decay) (see Figure 6-61, *B*). Elevated horizontal lines above the ground state indicate excited nuclear levels. Vertical arrows from one excited level to a lower one or the ground state indicate gamma emission. Fractional or percentage amount of time a transition occurs is indicated, as are the absolute energies of levels, particles, and photons. Decay schemes for the medical isotopes listed in Table 6-14 are presented in Figures 6-64 to 6-71 and web-only eFigures 6-1 and 6-2, available on the Expert Consult website. It is observed that the nuclear configurations and transitions for these isotopes are simple for some and complex for others. For instance, ^{60}Co decays by β^- decay to ^{60}Ni, which de-excites by the emission of two gamma rays, one at 1.17 MeV and one at 1.33 MeV (see Figure 6-64). ^{125}I decays by electron capture to ^{125}Te, with the emission of one gamma ray (35 keV) and two characteristic x-rays (27.3 keV, 31.4 keV) (see Figure 6-67). After decay, the resulting daughter nucleus itself may be radioactive, resulting in an additional decay or decays. The decay chain for ^{226}Ra has nine decays (and daughters) until stable ^{206}Pb is reached (eFigure 6-2).



Source Strength

Source strength, that is, the amount of radiation or dose given off per unit time, is an important physical and clinical parameter because dose rate must be known to enable a prescribed dose to be delivered. Source strength has been specified as the amount of milligrams of ^{226}Ra (mg-Ra), the equivalent amount

of milligrams of ^{226}Ra (mg-Ra eq, for ^{226}Ra substitutes such as ^{137}Cs or ^{192}Ir), the actual activity encapsulated, the apparent activity, and the exposure rate at a distance. These historical representations of activity have been replaced by the current day recommended source strength specification of air kerma strength[120] (S_K) with units of μGy/m²/hr. S_K is based on the air kerma rate in free space, $\dot{K}_1$, which gives the kerma rate in air in micrograys per hour at a fixed distance from the source, measured radially from a point source or along the perpendicular bisector for a linear source. Kerma equals dose with

less than 1% difference for brachytherapy photon energies, so $\dot{K}_1$ essentially gives the dose rate in air at the reference distance. Although air kerma strength is adopted as a standard, multiple specifications for source strength are still in use by source manufacturers and treatment planning systems. The same convention of source strength must be used for the radiation source and the planning system to ensure correct computations of dose rate and dose. Additional guidance is available on source strength specification, and other brachytherapy planning issues.[120-122]

Brachytherapy Applicators and Afterloading

When first used in the early 1900s brachytherapy sources were directly implanted into the patient for interstitial or intracavitary treatment. To reduce personnel doses and allow greater flexibility in determining source configurations without having to handle "hot" sources, a technique called *afterloading* was developed in the 1950s, first for intracavitary treatments and later for interstitial applications. With afterloading, the source configuration is determined using nonradioactive "dummy" sources and the actual sources are efficiently loaded at a later time. Afterloading techniques require the use of specialized source applicators to position the dummy sources and allow accurate (re)placement of actual sources. A variety of applicators and techniques have been developed to facilitate implantation of the isotopes shown in Table 6-14, and these are reviewed in a later chapter and elsewhere.[123,124]

Preplanning can be used in brachytherapy to optimize the source locations and activities. For implantation, physical templates may help maintain the intended source geometry and are recommended when possible. Once the applicators are in place, adjustments to the implant geometry are limited to number of sources per applicator, spacing, and activity. Dummy sources are loaded, and each source location is determined by obtaining orthogonal images. These images are best obtained for an applicator(s) that matches the imaging device. Applicators exist that are compatible with either a conventional radiographic/fluoroscopic simulator, a CT simulator, or (more rarely) an MR simulator. A magnification indicator may be needed depending on the imaging method. On the images each source location and anatomic and dosimetry points of interest are identified and digitized. Planning determines the position, activity, and insertion time for each source based on the chosen point of prescription. A plan is represented by isodose distributions that show dose rate (typically, Gy/hr).

Brachytherapy Treatment Planning

Planning for brachytherapy treatments initially was nonexistent, but beginning in the 1920s various systems were developed that provided rules and guidelines for implantation geometries and specifications for prescription. Initially, ^{226}Ra was the only radionuclide used for brachytherapy because of its natural abundance, and systems were developed that were specific to ^{226}Ra source configurations of needles and tubes. Other radionuclides for brachytherapy became available in the 1950s through neutron activation in a nuclear reactor or as byproduct material. The radium systems were modified for the physical characteristics of these nuclear-age radionuclides.

Gynecologic Implants

Three systems using different applicators, source strengths, and treatment times were developed for intracavitary implants of the cervix and uterus.[123] The first two, the Paris and Swedish systems, were modified and became known as the Manchester system, the most widely used brachytherapy system. In the Manchester system, four points of interest are anatomically defined (Figure 6-72):

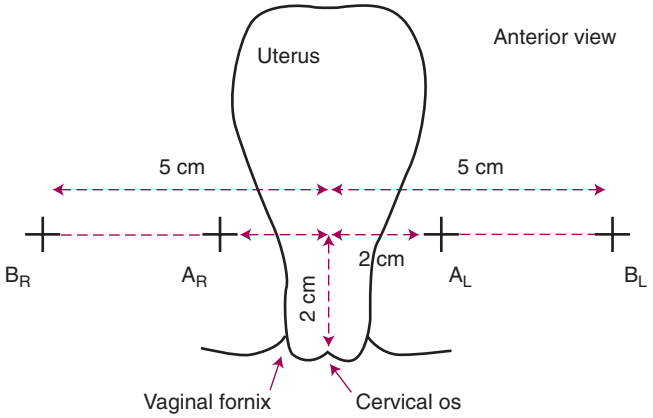

Figure 6-72 Gynecologic anatomy and definitions for points A and B.

1. *Point A* is 2 cm superior to the external cervical os, and 2 cm lateral to midline. Point A is specified on the right and left and indicates the location where nominally the uterine vessels and ureters cross.
2. *Point B* is 2 cm superior to the external cervical os and 5 cm lateral to midline. Point B is specified on the right and left and indicates the presumed location of the obturator lymph nodes.
3. A radiographically defined point indicates the dose of relevance to the *bladder.*
4. A radiographically defined point indicates the dose of relevance to the *rectum.*

The Manchester system prescribes dose to point A using a dose rate of 55.5 R/hr, delivering 8000 R in 144 hours in two 3-day sessions over 2 weeks. Point B gives an indication of peripheral dose at the obturator nodes, and the bladder and rectum points indicate the dose at these dose-limiting structures. The classic gynecologic implant uses three 2-cm sources in a line, or *tandem,* in the uterus and two 2-cm sources, one on either side of the cervix, as shown in Figure 6-75. With activities of 15, 10, and 10 mg (of ^{226}Ra, or mg-Ra eq of ^{137}Cs) in tandem and 15 mg each in the lateral vaginal fornices, for a total of 65 mg-Ra eq, a well-known pear-shaped dose distribution results (see Figure 6-73). Variations to the Manchester system are readily apparent. Implant duration and dose, number of sources, source activity (dose rate), source geometry, applicator design, number of implants, and primary versus boost treatment can all be varied. Gynecologic implant approaches have been reviewed.[123-125]

Interstitial Implants

The Manchester system of implantation rules and dose prescription, also called the Paterson-Parker system after its authors,[126,127] has formed the basis for interstitial implant approaches and was originally developed for ^{226}Ra needles. This system specifies source distribution rules for planar and volume implants. The system is based on the concept of using a relatively uniform distribution of sources having differing linear activities to deliver a dose distribution with homogeneity of ±10% of prescription. Rules include the distribution of activity, that is, the percentage of activity to load in the implant center versus the periphery, for planar targets, and cylindrical, spherical, and cubical implant volumes. A fixed source spacing of 1 cm is specified. The Quimby system was developed and used in the United States and is based on the concept of using a uniform distribution of sources of the same linear activity throughout the implant volume (^{226}Ra needles were available

in the United States with constant linear activity). Source spacing is uniform, with 1- to 2-cm source intervals. The modern Paris system is based on the use of ^{192}Ir wire. Sources are arranged in parallel fashion in planes, the linear activity is constant for all sources, and source spacing is uniform.[128] Target coverage is specified as an isodose surface that encompasses the target volume, relative to a reference point at the implant center. An example of a single-plane implant is shown in Figure 6-74. Combinations of implant planes enable an entire target volume to be treated to a particular dose surface. Table 6-15 summarizes some of the rules for the Manchester, Quimby, and Paris systems. More complete reviews are available and required for complete details for each system.[128,129]

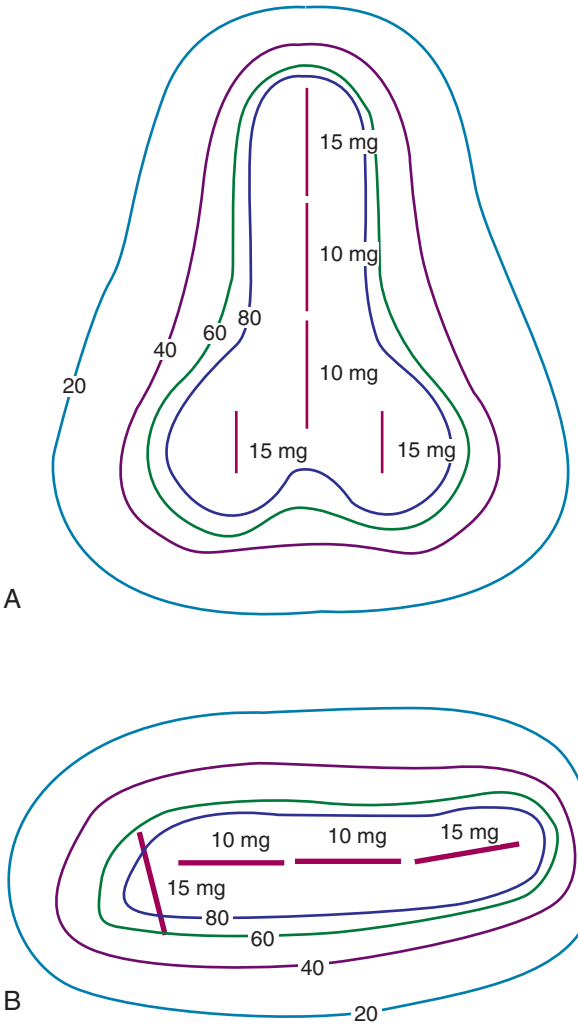

Figure 6-73 Typical gynecologic implant. **A,** Coronal plane. **B,** Sagittal plane. Source arrangement coincides with anatomy shown in Figure 6-73. Isodose values are in units of centigrays per hour.

High-Dose-Rate Remote Afterloading

High-dose-rate (HDR) remote afterloading devices use a single, large activity (10 Ci, ^{192}Ir) source that is stored in a shielded container within the base of the unit and then inserted into implanted applicators or catheters under remote control from outside the treatment room[130-132] (see Figure 6-75). The source position is known continuously and can be moved to various locations within an implanted applicator to build a desired dose distribution. The amount of dwell time in one location

Isodose values are in centigrays per hour. *Data from Interstitial Collaborative Working Group: Interstitial brachytherapy: Physical, biological, and clinical considerations, New York, 1990, Raven Press.*

TABLE 6-15 Manchester, Quimby, and Paris Systems

	System		
Parameter	**Manchester**	**Quimby**	**Paris**
Dose	6000-8000 R	5000-6000 R	6000-7000 R
Dose rate	40-60 R/hr	60-70 R/hr	25-90 cGy/hr
Prescription point	10% above absolute minimum	On bisector (planar) or periphery (volume)	85% of minimum central dose
Linear activity	Variable	Constant	Constant
ACTIVITY DISTRIBUTION			
Single plane	Varies with area	Uniform	Uniform
Volume implant	Varies with shape	Uniform	Multiple, uniform planes
Source spacing	Constant at 1 cm	Constant, 1-2 cm	Constant, 0.5-2 cm
Crossing needles	Yes	Yes	No

determines the amount of dose delivered. Multiple catheters or applicator connections are possible to enable an entire implant volume to be treated with a single source, in step-by-step fashion. Almost all intracavitary and interstitial implants just described have been replicated using HDR techniques, and primary implant sites are breast, gynecologic, and prostate[130-132] (Figure 6-76). In a novel technique, local, partial breast irradiation is delivered to the breast, using a balloon catheter that positions the HDR source in one or more dwell positions within the postlumpectomy surgical cavity (see Figure 6-76, *A*).

HDR advantages include shorter overall treatment times, opportunities for fractionated treatment, advanced imaging techniques for improved treatment planning, improved treatment planning by customization of the ^{192}Ir source dwell times, and reduced radiation exposure to the implant team. Radiation safety considerations are important for HDR treatment because of the high dose rate of the source. Pre- and post-HDR radiation room surveys must be conducted to ensure proper source storage and radiation safe conditions for both the patient and personnel.[130-132]

Computerized systems have facilitated customized planning for brachytherapy treatments. Planning systems now perform image-based planning and include tools for automated source localization and optimization of the dose distribution. HDR planning systems, in particular, have provided optimization schemes to determine source dwell times to provide a desired dose distribution. A planning system must use the source strength convention for the source being applied (i.e., apparent activity or air kerma strength) and must account for radial and axial anisotropies in the dose distribution,[133] such as the anisotropies shown previously (see Figure 6-63).

Dose Specification

An implant system specifies dose or dose rate at a point or points (e.g., point A) or possibly to a plane or volume of interest that contains the implant. The ICRU has recommended

TABLE 6-16 Quality Factors for Radiation Protection

Radiation	Quality Factor
X-rays, gamma rays, and electrons	1
Thermal neutrons	5
Neutrons and heavy particles	20

TABLE 6-17 Exposure Limits for Radiation Protection

Exposed Region or Site	Occupational (mSv)	General Public (mSv)
ANNUAL EXPOSURE LIMITS		
Whole body; head and trunk; active blood-forming organs; lens of eyes; gonads	50	1 (frequent exposure) 5 (infrequent exposure)
Hands and forearms; feet and ankles	750	75
Skin of whole body	300	30
ADDITIONAL EXPOSURE LIMITS		
Nonoccupational areas: <0.02 mSv/h (0.02 mSv/h ≈ 50 mSv/yr if exposed year round) <1 mSv/wk (≈ 0.006 mSv/hr for continuous exposure)		
Fetal dose: <5 mSv during the gestation period		
MORTALITY RISK		
Population risk from exposure: risk is approximately 2.5×10^{-2} deaths/person/Sv or 2.5×10^{-4} deaths/person/cSv. There are approximately 2.5 deaths if 10,000 people receive 0.01 Sv (1 cSv) each.		

that dose be reported to a reference volume and points of interest for gynecologic implants and for mean central and peripheral dose for interstitial implants.[134,135] The recommendations are similar to the ICRU's specification of volumes for use in external beam therapy in ICRU 50 and ICRU 62,[42,43] and it is recommended that ICRU's nomenclature be used in clinical practice.[136]

Other Brachytherapy Techniques

Brachytherapy applications have also included molds for ocular melanoma using ^{125}I seeds, biliary stent implantation with ^{192}Ir, ultrasound-guided prostate brachytherapy using ^{103}Pd or ^{125}I, and once popular procedures such as endovascular brachytherapy (^{90}Sr, ^{192}Ir, and other nuclides), and treatment of pterygium (^{89}Sr).[122,137] Development of new radionuclides for specific applications continues, particularly for liquid forms of radionuclides.

RADIATION PROTECTION

Radiation protection practices are important in the radiation oncology clinic for protection of the patient, radiation oncology personnel, ancillary staff, and the general public. Recommendations by international bodies are enacted into law and serve as dose limits for occupationally exposed individuals and the general public.[138] The dose-related quantity of interest for radiation protection purposes is called the *dose equivalent, H*:

$$H = D \times QF \qquad \text{Eq. 43}$$

In the equation, H is the dose equivalent (in sieverts [Sv], with units of J/kg), D is the dose received (in grays, with units of J/kg), and QF is the quality factor (unitless) of the exposing radiation.

The quality factor indicates the biologic effect of the radiation type, relative to x-rays, and varies with linear energy transfer. High linear energy transfer radiations, such as particle radiations, have a high quality factor (Table 6-16). The units of the sievert are still joules per kilogram, as for the gray; however, the meaning of the sievert is different than that of the gray. Given photon and fast neutron exposures of 1 Gy each, the dose equivalent (meaning the biologic effect) for each is different: the photons deliver 1 Sv; the fast neutrons deliver 20 Sv.

Exposure limits for occupational exposure and the general public are given in Table 6-17. A safety factor of 10 is applied to the general public limits compared with the occupational limits for whole-body exposures. However, for annual whole-body exposures the general public is limited to $\frac{1}{20}$ the occupational limit if exposure is frequent. This lower limit (0.1 rem or 0.001 Sv) is the regulatory limit for exposure of the general public in the United States. Exposure limits for occupational radiation protection are based on laboratory studies and observed effects for irradiated human populations and are believed to give equivalent risk as in other safe occupations.

Radiation protection principles are based on three factors: time, distance, and shielding. To reduce any dose, minimize the time of exposure, maximize the distance away from the sources, and maximize the shielding between the sources and the point of exposure. The degree to which each of these principles is exercised for a particular exposure scenario depends on the type of radiation source; its physical properties such as energy, intensity, collimation, and beam orientation; the presence of barriers; distances to points of interest; the potential time of exposure; and the category of individual exposed (occupational or general public). Common protection practices in radiation oncology include the use of heavily shielded vaults for protection of linear accelerator operators and the public, administrative controls that limit access to radiation sources, physical barriers to room entry during exposure, interlocks that prevent irradiation during unsafe conditions, use of long-handled tools when handling brachytherapy sources, afterloading equipment such as source applicators and dummy sources to negate the need to load sources "hot," remote afterloading devices operated under remote control, the use of lead aprons and shielded control consoles during radiographic or fluoroscopic procedures, and assessment of fetal dose for patients or occupationally exposed personnel. A body of literature addresses specific situations that may be encountered.[138-140]

Even though radiation protection exposure limits exist, in general, radiation protection philosophy incorporates the ALARA principle: *as low as readily achievable.* This philosophy holds that although dose rates may be within the legal (acceptable) limits given previously, all exposures should be reduced as much as possible, given practical constraints of money, time, and human and material resources. Examples of ALARA in practice might be the relocation of clerical personnel away from a radiation source storage area, developing a more efficient method for source handling in a busy brachytherapy practice, or the addition of another HVL of shielding to a linear accelerator room ceiling during a time of renovations to further reduce doses to an upstairs pediatric playroom.

Ownership, use, receipt, and transfer of radiation sources are governed by national or state laws and are authorized or licensed under the supervision of institutional committees and state and national regulatory agencies. The Nuclear Regulatory Commission (NRC) regulates radioactive materials only

(e.g., ^{60}Co, ^{137}Cs), and its laws are published in the Code of Federal Register and in regulatory guidance documents.[141,142] These rules apply to all states and U.S. territories. However, the NRC does not regulate electronically produced radiation sources (x-ray tubes and linear accelerators). Some states have agreed to implement the NRC rules as part of their state radiation control program, and these states are called *agreement states*. Radiation users in agreement states are inspected by the state, not the NRC. Radiation users in nonagreement states are inspected directly by the NRC for their radioactive materials. Nonagreement states may have their own state radiation control programs for electronically produced radiation sources. About 75% of U.S. states are agreement states, and the remaining 25% are nonagreement states. Other regulatory agencies with radiation-related regulations include the U.S. Department of Transportation, the U.S. Environmental Protection Agency, and possibly other state or local agencies.

General provisions for radiation sources are specified in a license that is granted to an individual or institution by the appropriate regulatory authority. Radiation source licenses cover a variety of classes of sources and generally require adequate administrative controls by the user. For instance, academic institutions with medical and research uses of radiation sources must have a radiation safety program that specifies items such as educational and experience requirements for users, radiation control procedures, and the administrative chain. Institutional radiation safety programs include a radiation safety committee for oversight and a radiation safety officer for implementation of policy.

Recent events in the United States, where patients were injured or died as a result of overdoses from both radiologic imaging and treatment procedures,[143] have highlighted the need for continued vigilance for radiation safety for patients. The issues relate to the computer-controlled automation of imaging and treatment procedures and the understanding of operators and radiological professionals on the radiation dose and other performance aspects for the equipment being used. The imaging or treatment devices were operated with unknown and incorrect parameters or with a partial malfunction that still enabled radiation delivery. National standards are now being formulated for quality assurance procedures, operator training, and other aspects. Importantly, besides errors in radiologic procedures, a great concern has been stated by the National Council on Radiation Protection and Measurements (NCRP Report 160)[144] about the average collective effective dose in the United States; there has been approximately a twofold increase in the average yearly collective effective dose, from 3.6 to 6.2 mSv over about a 15-year period from 1982 to 2006, owing to a large increase in the amount of dose from radiologic medical imaging, mainly CT, and followed by nuclear medicine imaging. Clearly, the radiologic community must be cognizant of the ionizing radiation dose being delivered by both imaging and treatment procedures, to ensure no dose is given without an intended benefit.

QUALITY ASSURANCE

Radiation machines and sources, beam modifiers, measurement instrumentation, and treatment planning computers must be regularly verified for proper operation and characteristics to ensure quality and consistency of dose. A basic quality assurance program for dose-related items entails daily, weekly, monthly, and annual tests with satisfactory results within specified tolerances. Recommendations and standards for quality assurance exist for machines, sources, instrumentation, and treatment planning computers.[40,145-147] References also are available on the general quality assurance process.[148-150] Dose verification by an independent, accredited radiologic physics center is a desirable service and is required for participation in many cooperative protocol groups.

The age of computerized and automated radiation treatment planning, delivery, and verification presents new challenges for quality assurance of treatment. Treatment processes may now be wholly contained within commercially provided "black boxes" of computer software and automated treatment machines, such that important quality assurance tests may be difficult to design and perform or provide results that are difficult to readily interpret. The radiation imaging and treatment errors mentioned previously are examples of the "black box" syndrome and failed quality assurance procedures. The implication is that high technology approaches to quality assurance will also be needed with redundant methods for ensuring and proving the correct delivery of treatment. Quality assurance and safety in high-technology radiation therapy remain high priorities for those individuals who are prescribing, delivering, and ensuring quality for the benefit of radiation treatment patients.

CHAPTER

7 Radiation Physics: Stereotactic

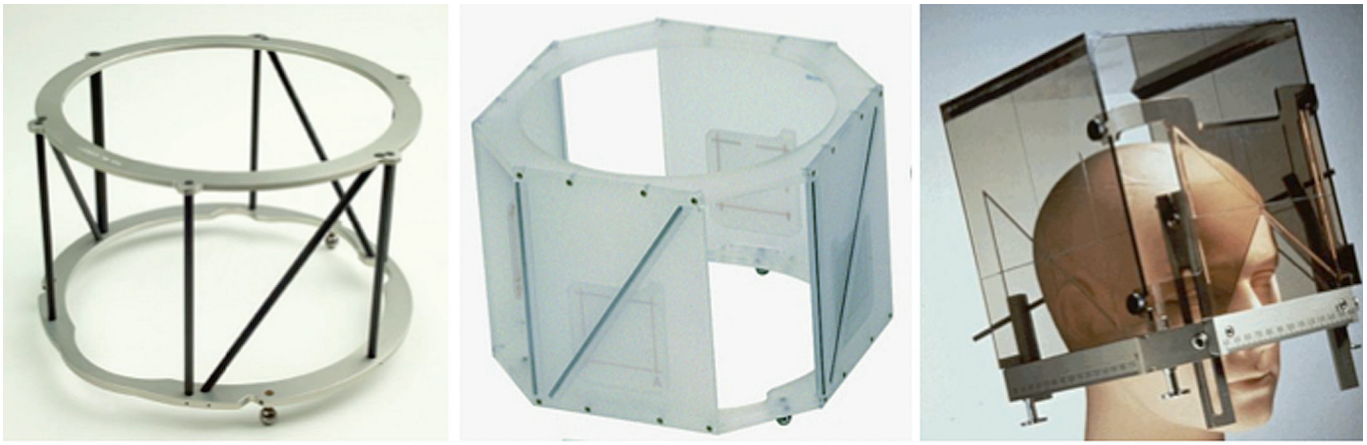
Timothy D. Solberg, Paul M. Medin, and Brian A. Hrycushko

The field of stereotactic radiosurgery is now more than 60 years old. The intervening decades have seen numerous technical developments, facilitating clinical success in numerous disease sites throughout the brain and body. Yet the fundamental principles remain largely unchanged:

- the delivery of an ablative dose of radiation that is biologically distinct from conventional fractionation;
- the use of many nonoverlapping beams converging on a target from many directions to create a conformal and compact dose distribution, effectively minimizing damage to intervening tissue;
- the assiduous requirement for localization accuracy, facilitated through the use of a stereotactic frame, or more recently, though image guidance; and
- the unique characteristics of radiosurgery beams—small field size, step gradients, loss of lateral equilibrium—that place rigorous demands on beam measurement, commissioning, and quality assurance.

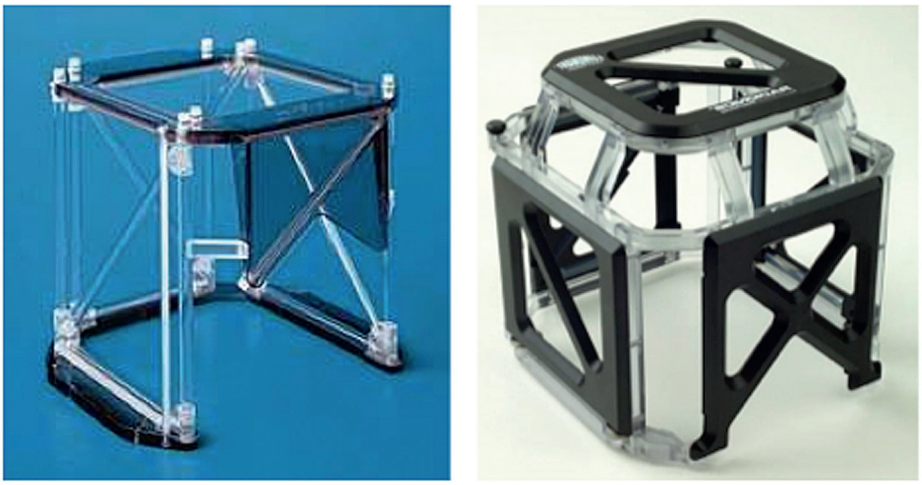
The chapter provides covers the principles of stereotactic localization, the physics associated with small photon beams, selection of appropriate detectors, and the processes for commissioning stereotactic radiosurgery systems.

HISTORY OF STEREOTACTIC IRRADIATION



The field of stereotactic irradiation owes its origins to parallel development in two disparate medical disciplines dating back more than a century, stereotactic surgery and external beam radiation. In the late 1800s, surgeons and anatomists began exploring quantitative methods for studying the structure and function of the brain. The methodology, known as stereotaxis, relies on external fiducials to define a three-dimensional frame of reference in which targeting can be performed. Historically the fiducials consisted of a head frame that was rigidly attached to the skull. Because the skull and cranial structures remained fixed with respect to the frame, the external fiducials served as an appropriate surrogate for intracranial localization. The stereotactic method was pioneered by Horsley and Clarke, who devised an instrument for producing lesions at exact locations within the brains of nonhuman subjects.[1,2] Other early efforts included those of Mussen and Kirschner.[3,4] Routine clinical application of stereotactic surgery in humans is credited to the team of Speigel and Wycis.[5] Lars Leksell subsequently developed a frame based on polar rather than Cartesian coordinates, providing maximum flexibility in choosing entry point and trajectory.[6] The commercial Leksell frame (Elekta AB, Stockholm, Sweden) remains identical in function to the 1949 device. Other developments in stereotactic frames included the efforts of Talairach; Narabayashi; Reichert and Mundinger; and Brown, Roberts, Todd, and Wells.[7-14] Brown's modifications to the original Wells-Todd device resulted in the Brown-Roberts-Wells (BRW) coordinate system that is available commercially from Integra Radionics (Burlington, MA) and BrainLAB (Feldkirchen, Germany).[12,14] Examples of commercial stereotactic localization devices are shown in Figure 7-1. In the era of image guidance, the skull serves as its own set of fiducials, and head frames are no longer required.[15-18]

The discovery of x-rays by Wilhelm Roentgen in late 1895 is well known. Throughout the subsequent decades, efforts to increase the penetration ability of x-rays produced with conventional tubes met with modest success, with tube potentials limited to approximately 200 kV. In the early 1950s, Leksell realized that external forms of energy such as ultrasound and ionizing radiation could be coupled to a stereotactic frame. In 1951, Leksell proposed the term *stereotactic radiosurgery* (SRS) to refer to the delivery of a single high dose of radiation accurately directed to an intracranial target. The principles of dose localization require irradiation "through a large number of small portals . . . which all meet and cross in the structure in question."[19] Leksell also appreciated the limitations imposed by low energy x-rays, and his subsequent efforts, as well as those of groups located in Boston, Massachusetts, and Berkeley, California, used beams of protons and other light ions.[20-25] In the mid-1960s, Leksells' colleagues at the Karolinska Institute in Stockholm, Sweden, began efforts on what would become the first dedicated radiosurgery device. The initial Gamma Knife, installed in Sofiahemmet Hospital in 1967, used 179 rectangular-collimated cobalt-60 sources; subsequent commercial versions were implemented with 201 circular-collimated sources.[26,27] The Perfexion unit, consisting of 192 cobalt sources arranged in eight independent sectors, was introduced by Elekta in 2007. Each sector can move to one of four locations to choose between blocked, 4-, 8-, and 16-mm circular collimation.[28] Figure 7-2 shows the evolution of the commercial Gamma Knife, from the Model U to the present Perfexion.



The development of technology for linear accelerator-based radiosurgery began in the early 1980s, with the first radiosurgery patient treated on a modified linac in 1982.[29] All early linac systems used hardware modifications designed to facilitate stereotactic frames and improve targeting accuracy to overcome shortcomings with the treatment couch.[29-31] Subsequent improvement in linac couches allowed the stereotactic frame to be affixed directly to the couch top. Subsequent developments included linacs dedicated for radiosurgery, including the CyberKnife (Accuray, Sunnyvale, CA), 600SR (Varian Medical Systems, Palo Alto, CA), Novalis (BrainLAB AG, Heimstetten, Germany), and C-arm multi-rotation-axis linac (Mitsubishi Electric Ltd., Tokyo, Japan).[32-36] Modern linacs such as the TrueBeam STx and EDGE (Varian Medical Systems, Palo Alto, CA), and Axesse and Versa HD (Elekta AB, Stockholm, Sweden) have localization and dosimetric characteristics that make them well suited for radiosurgery applications. Figure 7-3 shows the evolution of the radiosurgery linacs, including the original Betti device, an early floor stand, the original CyberKnife, and several commercial linac systems.

PRINCIPLES OF STEREOTACTIC IRRADIATION

There are several key principles that make SRS distinct from conventional radiotherapy. First, the procedure involves the delivery of an ablative dose of radiation that overwhelms the capacity of the irradiated cells to survive. The biological processes associated with high-dose delivery are quite different

Radionics CT | BrainLAB CT/Angio | Leksell CT

Radionics MR | Leksell MR

Figure 7-1 Commercial localization devices for defining stereotactic coordinates.

than those occurring at ~2 Gy per fraction, and an increasing number of investigators have alluded to these *threshold effects*.[37] The ablative intent implies that the approach is meant to treat gross disease exclusively and not microscopic extension. The accompanying need for tight margins places demands on both physical and dosimetric accuracy. The superior contrast resolution provided by magnetic resonance necessitates its use in most cranial indications, albeit with careful consideration of potential spatial distortions.[38-41]

Second, the accuracy and precision of both spatial and dosimetric localization is essential. Before the advent of computed tomography (CT), stereotactic localization was performed using a pair of projection radiographs. Fiducials located on the entrance and exit surfaces of the localization device facilitated calculation of both target location and magnification from a pair of radiographs (Figure 7-4). Studies have demonstrated that the target point can be determined to within 0.3 mm over a large range of source-to-target and source-to-image distance and projection angles using such a technique.[42,43] The obvious shortcoming of the approach is that it cannot adequately reconstruct a target volume.

The principle of stereotactic localization based on tomographic images is illustrated in Figure 7-5. The superior-inferior dimension *(z)* is defined by measuring the in-plane distance between diverging fiducials *(y)* and applying simple geometry:

$$z_i = y_i / \tan\theta \quad (1)$$

With modern imaging and head frames, localization accuracy on the order of 1 to 2 mm is achievable.[44-47] There are numerous sources of geometric uncertainty, including mechanical and radiation device isocentricity, imaging resolution, target delineation, as well as the stereotactic frame itself. The report of American Association of Physicists in Medicine (AAPM) Task Group 42 specifies an overall localization uncertainty of 2.4 mm (1σ), providing the planning images use a sufficiently thin slice thickness.[48]

Dosimetric localization requires the delivery of many beams from many directions, overlapping only at the target of interest. Ideally the intensity of any individual beam is sufficiently low that little damage occurs along the beam path, except at the point all beams intersect. Conformality of the high dose and target volumes is essential, as is compactness of the overall dose distribution. Because the intermediate dose volume increases rapidly as a function of target size, single fraction cranial applications are largely limited to lesions smaller than 4 cm.[49]

DOSIMETRY OF RADIOSURGERY BEAMS

Dosimetric integrity, that is, the ability to accurately deliver the intended dose distribution to the desired volume, is a critical element of radiosurgery. Dosimetric integrity begins with

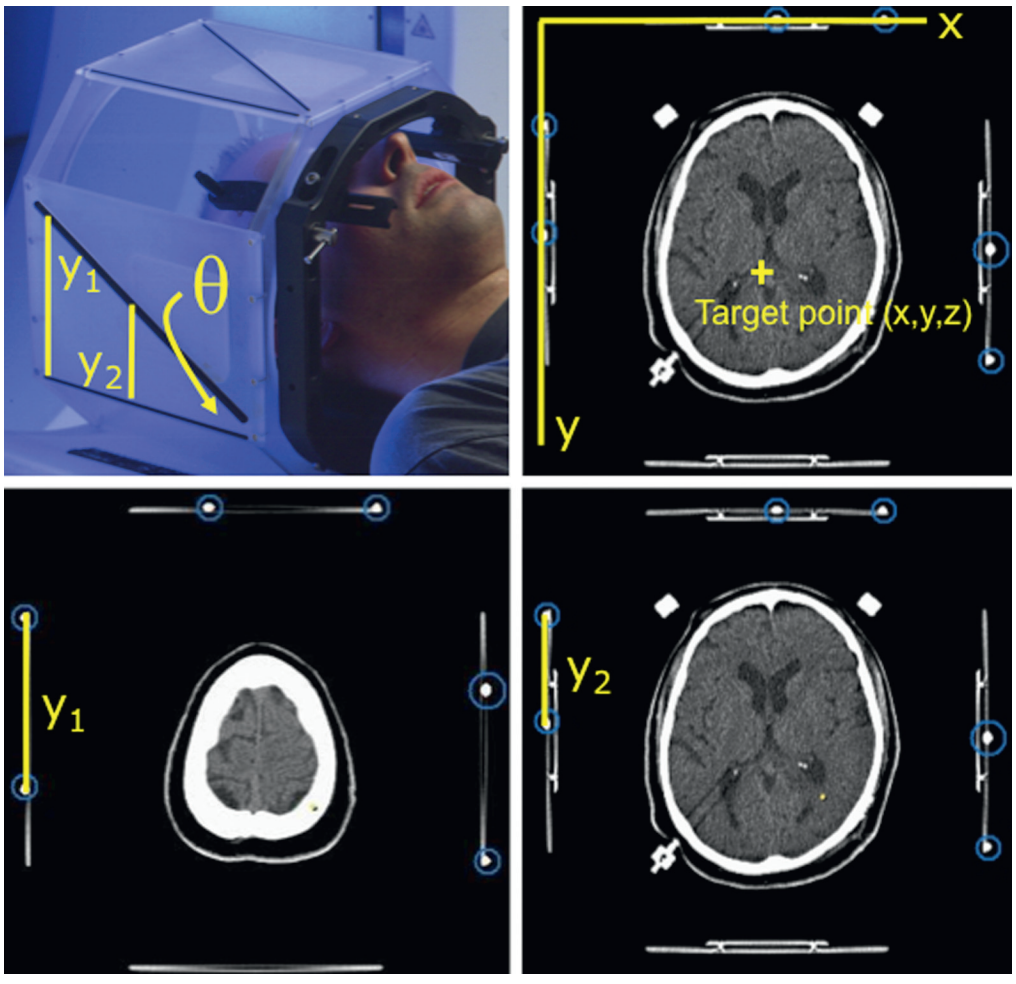

Figure 7-5 Principles of stereotactic localization using computed tomography.

the accurate measurement of photon beam characteristics.[50] In general, SRS planning systems require the measurement of percent depth dose, off-axis profiles, and relative output factors. For systems equipped with a micro-MLC, measurement of leaf transmission and dynamic leaf gap is also required. Historically, radiosurgery planning systems used highly simplistic dose algorithms, ignoring both surface irregularities and tissue heterogeneities.[51,52] For cranial targets, these approximations introduced clinically insignificant errors on the order 1% or less, provided beams are not placed through air cavities.[53,54] Subsequent development of pencil beam algorithms facilitated CT-based dose calculation.[55-57] The current GammaPlan system offers the original water-based dose calculation (TMR10) as well a CT-based convolution algorithm. Modern linac systems provide both pencil beam and Monte Carlo options.[58-63] For commissioning Monte Carlo algorithms, additional beam measurements, including central and off-axis profiles and output factors in air, are often required.[62,64] In-air scans require a brass build-up cap suitable for the beam energy used.

Considerations in Small Field Dosimetry

The measurement of beam characteristics (relative output factors, percent depth doses, and profiles) in small fields is challenging because of their inherent steep-dose gradients. A misunderstanding of detector requirements or misinterpretation of measured beam data can lead to injurious or even life-threatening consequences.[65,66] There is no accepted criterion defining a "small field," but in general, a small field can be labeled so depending on the electron range in the irradiated medium, the detector dimensions, or partial obstruction of the radiation source through collimation.[67]

Lateral electronic equilibrium becomes compromised when the beam radius is comparable in size to the maximum electron range. The maximum electron range depends on the photon beam energy and the irradiated medium composition (i.e., density and atomic number). At this point, electrons leaving the central portion of the field are insufficiently replaced by electrons scattered from the surrounding medium. Output factors for small fields are difficult to measure in these conditions as a result of spectral differences causing stopping power ratios and correction factors to be unclear. AAPM Task Group 65 recommends a general rule of thumb for the lateral electron range being about one third of the forward range, and in a 6 MV x-ray beam, electron disequilibrium has been shown to occur for radii <1.0 cm.[68,69] Below a certain field size, collimating devices can partially block the radiation source from the detector's field of view. Clearly the output from the partially blocked source will be reduced compared to fields in which the detector views the complete source. The partially obscured focus also leads to the field size, as defined by the 50% isodose, to reduce more rapidly than the collimated aperture.[67]

The measurement of small field beam characteristics requires a small detector. The rationale for selection of an appropriately small detector size and the consequences of using too large a detector differ for relative output factor, depth dose, and beam profile measurements. Relative output factors are commonly defined as the ratio of dose for a field size of interest (a small field) over a reference field size (a larger field) at a fixed depth in medium. Relative output factors are specified on the central axis. The detector of choice must be placed on the central axis and must only intercept central-axis fluence. This is easily achieved for a large reference field size with a flat beam profile around the central axis, but much greater consideration is necessary for a small field with steep-dose gradients in close proximity to the central axis. The cross-sectional dimensions of the detector cannot be

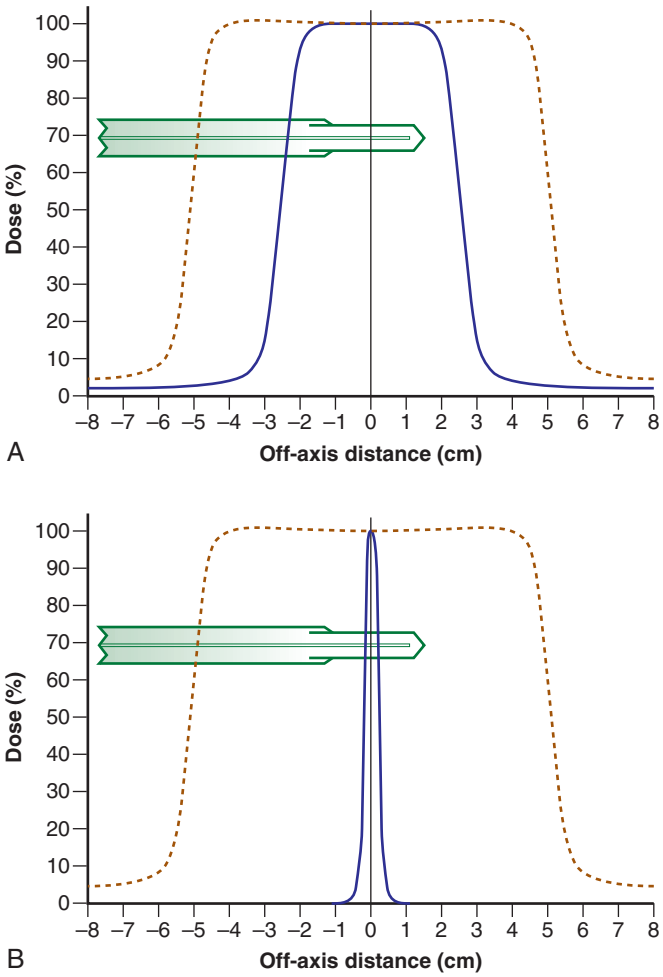

Figure 7-6 A standard air ionization chamber in **(A)** a 5 × 5 cm² field and **(B)** a 0.5- cm diameter circular field relative to a 10 × 10 cm² reference field.

larger than the flat portion of the beam profile (crossline and inline) around the central axis. Appropriate detector selection for a relative output factor measurement of a 5 × 5 cm² field normalized to a 10 × 10 cm² reference field is illustrated in Figure 7-6, *A*. The air ionization chamber fits within the flat portion of the beam profile around the central axis for both fields. Figure 7-6, *B* illustrates an inappropriate detector selection for a relative output factor measurement of a 0.5-cm diameter circular field normalized to a 10 × 10 cm² reference field. The air ionization chamber is much longer than the flat portion of the beam profile around the central axis of the 0.5-cm diameter field and the chamber intercepts the shoulder and tail of the beam profile in addition to the central axis. This results in an output factor measurement that is much smaller than reality and, if used clinically, will result in an overdose to patients. Relative output factors measured with a Farmer-type air ionization chamber and a silicon diode for square fields from 6 to 80 mm are presented in Table 7-1 for comparison. Output factors must be measured for each system independently, and values in Table 7-1 should not be used as a standard. When selecting a detector to measure relative output factors, one should always confirm that the detector dimensions are at least as small as the flat portion of the beam profile around the central axis. For SRS and SBRT beams, AAPM Task Group 101 recommends use of a detector with a maximum dimension of 1 mm.[70]

TABLE 7-1 Relative Output Factors Measured in Small Photon Fields. The Farmer-Type Ionization Is Much Larger Than the Beam, Averaging over the Shoulder and Tail of the Beam Profile in Addition to the Central Axis, and Resulting in Grossly Underestimated Output Factor

Square Field Size (mm)	Output Factor	
	Stereotactic Diode	Farmer-Type Chamber
6.0	0.599	0.126
12.0	0.775	0.420
18.0	0.824	0.647
42.0	0.907	0.900
60.0	0.945	0.940
80.0	0.988	0.975
100.0	1.000	1.000

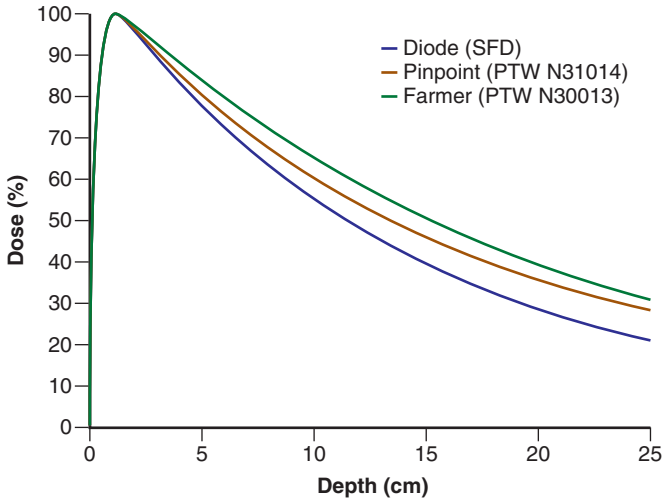

Figure 7-7 Percent depth dose for a 6-mm diameter circular field scanned using a 0.6-cc Farmer-type air ionization chamber, a 0.015-cc pinpoint air ionization chamber, and a stereotactic diode.

Percent depth dose (PDD) measurements for small fields require small detectors because, by definition, PDD describes the change in relative dose with depth on the central axis only. As in the case of relative output factor measurements, a detector wider than the flat portion of the beam profile (see Figure 7-6, *B*) at any depth will give an inaccurate PDD by including the central-axis fluence as well as the shoulder and tail regions. Figure 7-7 shows PDD scans for a 6-mm diameter circular field scanned with, (1) a 0.6-cc Farmer-type air ionization chamber (30013, PTW), (2) a 0.015-cc pinpoint air ionization chamber (31014, PTW), and (3) a silicon diode (SFD, DEB050, IBA Dosimetry). Larger chambers overmeasure the PDD at depth as a result of integration of dose lateral to the central axis.

Small detectors are required to accurately measure beam profiles of small fields to resolve steep-dose gradients in the penumbra region. Figures 7-8, *A* (crossline) and 8B (inline) show beam profiles for a 6.0-mm diameter circular field measured with a Farmer-type air ionization chamber (dashed) and a stereotactic diode (solid). The larger air ionization chamber smears out the profile (penumbra broadening) because it integrates ionization over its 0.6-cc (6-mm diameter, 24-mm length) measurement volume, whereas the diode integrates over its 0.6-mm cross-section. The shape of a beam profile ultimately affects the apparent dose coverage of a target. Over-correcting the shoulder region to achieve target coverage will increase the dose delivered to surrounding tissues.

Detectors for Small Field Measurements

Radiographic and radiochromic film are commonly used in beam data collection for small fields. Film is ideal in spatial dose mapping for relative dosimetry and is recommended for profile measurements with the Gamma Knife radiosurgery system.[48] The superior resolution of radiographic film is inherently limited by the silver halide grain size, typically ranging from 0.1 to 5 µm; however, the practical spatial resolution is limited by the pixel dimensions of the film digitizer. The use of film for small field relative dosimetry is justified as the high spatial resolution provides for a more accurate delineation of the sharp dose gradients within the penumbra region. Although dependencies on irradiation conditions have been observed, reproducible film processor conditions allow radiographic film to be used for output factor corrections for small fields.[71] Radiochromic film has the same benefits for small field dosimetry as radiographic film but exhibits less energy dependence, a greater dynamic range, and no need for film processing.[72]

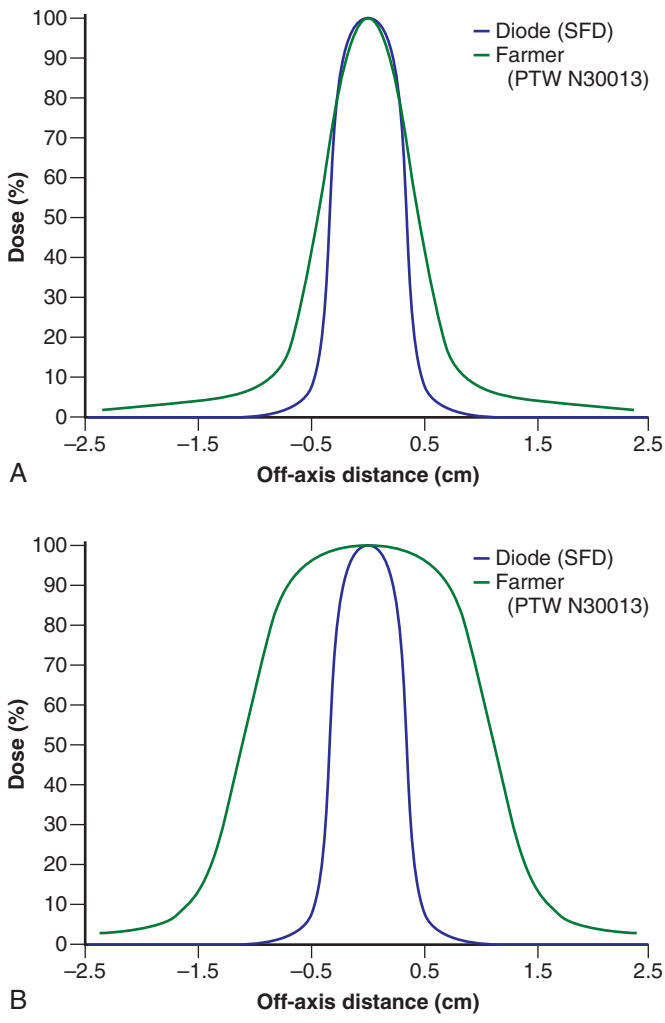

Figure 7-8 Crossline **(A)** and inline **(B)** beam profiles for a 6.0-mm diameter circular field measured using a Farmer-type air ionization chamber *(green curve)* and a stereotactic diode *(purple curve)*.

Semiconductor diamond detectors have been used to characterize SRS photon fields because of their small size.[73] A near soft-tissue equivalence, excellent mechanical stability, and a high signal-to-noise ratio are attractive properties of diamond detectors that are useful for small field dosimetry. The water-to-diamond mass attenuation coefficients and stopping power ratios are relatively constant over the energy range of clinical photon beams making diamond detectors well-suited for relative dosimetry. Measurement of PDD has compared well with diode detectors; however, a significant dose-rate dependence has been observed.[74]

Solid-state silicon diode detectors are the most commonly used detectors for small field dosimetry measurements. Several commercial diode detectors approach the 1-mm maximum dimension recommended by AAPM Task Group 101. P-type silicon diode detectors have the smallest cross-sections among commercially available detectors for radiation therapy applications. Silicon diodes produce approximately 18,000 times the current of an air ionization chamber of equal volume making them useful as a radiation detector at very small sizes (cross-sections from 0.6 to 1.2 mm) while creating sufficient signal.[75] Dieterich et al summarized the physical characteristics and response of seven commercial diode detectors and observed a small interdetector variation that appeared to be systematic with packaging.[76] Diode response has been observed to change with orientation, temperature, radiation damage, energy, and dose rate.[75,77-79] The effect of orientation on response has been investigated with the diode stem oriented parallel versus perpendicular to the beam axis. Although there is the potential benefit of increased resolution with a perpendicularly oriented diode stem, the penumbra width is underestimated because of a decreased electron range in the diode material and skewness can be introduced in profiles, dependent on the scanning direction.[77,78] Scanning with the diode stem oriented parallel with the beam axis is recommended.[77,78] Temperature has been observed to change the response of diodes, but this should not be a significant problem for relative beam data measurements collected in the relatively constant thermal environment of a water bath.[75] Ionizing radiation damages diodes over time, causing a diode's response to decrease as the total dose increases. It is common to preirradiate diodes to minimize the effect of radiation damage.[75] When measuring relative output factors with a diode, it is important to frequently remeasure the output of the reference field to determine if the sensitivity of the device has changed over the course of measurements. Diode response is energy dependent as a result of the atomic number of silicon (Z = 14) and any surrounding high-Z materials (i.e., protective housing or buildup material) being much larger than that of tissue or air. For this reason, diodes may not respond uniformly in fields with nonuniform photon spectra. To minimize the effect of energy dependence in relative output factor measurements, an approach known as "daisy chaining" has been employed in which diode and air ionization measurements are referenced to an intermediate field size. This technique has been described in depth by Dieterich et al.[76] Energy dependence can also affect PDD and profile measurements because of differences in the number of low-energy scattered photons with depth and location within a radiation field. The effect of energy on PDD and profile measurements is dependent on field size and detector design and needs to be verified for a given situation. Heydarian et al measured off-axis factors for circular fields with radii from 7 to 23 mm using a diode and observed good agreement with Monte Carlo simulations.[78] The group also measured PDDs in square field sizes of 10.0, 3.0, and 0.5 cm^2 and observed that the diode produced values less than predicted by Monte Carlo calculations with increasing difference at greater depth. This disagreement was likely predominantly due to a dose-rate effect.

Small Field Beam Data

In Figure 7-9, PDD, off-axis profiles, and relative output factors are shown as a function of field size for both circular and MLC-shaped square fields for a 6 MV beam. The PDD curves exhibit the familiar dependence on field size, that is, the distal slope becomes increasingly shallow at larger field sizes. By overlaying PDD curves for different sized fields on a single plot, errors in detector alignment for small fields will become quite apparent. In addition, a slight shift of the depth of maximum dose (D_{max}) toward shallower depths for the smallest fields can be observed. This is as a result of the absence of lateral electronic equilibrium, which at 6MV occurs for fields smaller than approximately 3.0×3.0 cm^2.[80] For a 6-MV beam with a nominal D_{max} of 1.5 cm at a 10×10 cm^2 reference field, D_{max} may shift to 1.2 cm for a 4-mm diameter circular collimator.

Off-axis profiles are characterized by a sharp lateral falloff. For tapered circular collimators, the 80% to 20% penumbra at 6-MV ranges from ~1.5 to 2.0 mm for 4 to 20 mm in diameter.[81] Measured single beam penumbra on the Gamma Knife have similar values, between 1 and 2 mm.[52] Although the shorter SSD of the Gamma Knife should provide for a smaller penumbra relative to linac systems, the lower energy and finite size of the Co-60 sources act to increase penumbra slightly. Similarly, for micro-MLC the 80% to 20% penumbra at 6-MV ranges from ~2.5 to 5.0 mm for 6 to 30 mm square fields.[81,82]

Relative output is defined as the ratio of dose for a given depth, field size, and source-to-surface distance to that for a reference depth, field size, and source-to-surface distance. Relative output factors are characterized by a decrease with decreasing field size, with a sharp falloff at small fields (Figures 7-9, *C*, and 7-9, *F*, for square and circular fields, respectively). Because there is a greater loss of lateral electronic equilibrium at higher beam energies, relative output decreases with increasing energy, for a given field size.[80] For the same reason, the magnitude of the shift in D_{max} described also increases with energy. These effects are exacerbated at higher energies, thus small field irradiation at energies above 10 MV is not recommended.[48,70,83]

RADIOSURGERY COMMISSIONING AND QUALITY ASSURANCE

Isocentric Accuracy: The Winston-Lutz Test

The Winston-Lutz test is commonly used for assessing isocentric accuracy of linac SRS systems.[30,84] A small radio-opaque sphere is positioned at the isocenter, a series of beams-eye-view images are obtained at various gantry, couch, and collimator combinations (Figure 7-10), and the offset of the sphere is measured relative to the radiation field. For radiosurgery systems that use both circular collimators ("cones") and MLC, the Winston-Lutz test should be evaluated for both field-defining devices. Modern linac systems are capable of results averaging better than 0.75 mm over the full range of gantry, couch, and collimator settings.[64] It is important to perform a Winston-Lutz assessment on a daily basis and after service to the linac or lasers.[66]

End-to-End Target Localization

Although the Winston-Lutz test is essential for characterizing isocentric accuracy, there are various aspects of the treatment process, incorporating imaging, planning, and localization, that must be assessed in an integrated manner. Assessing the ability of the treatment planning system (TPS) to correctly translate the mechanical parameters (i.e., stereotactic coordinates, gantry, couch, and collimator angles, etc.) to the

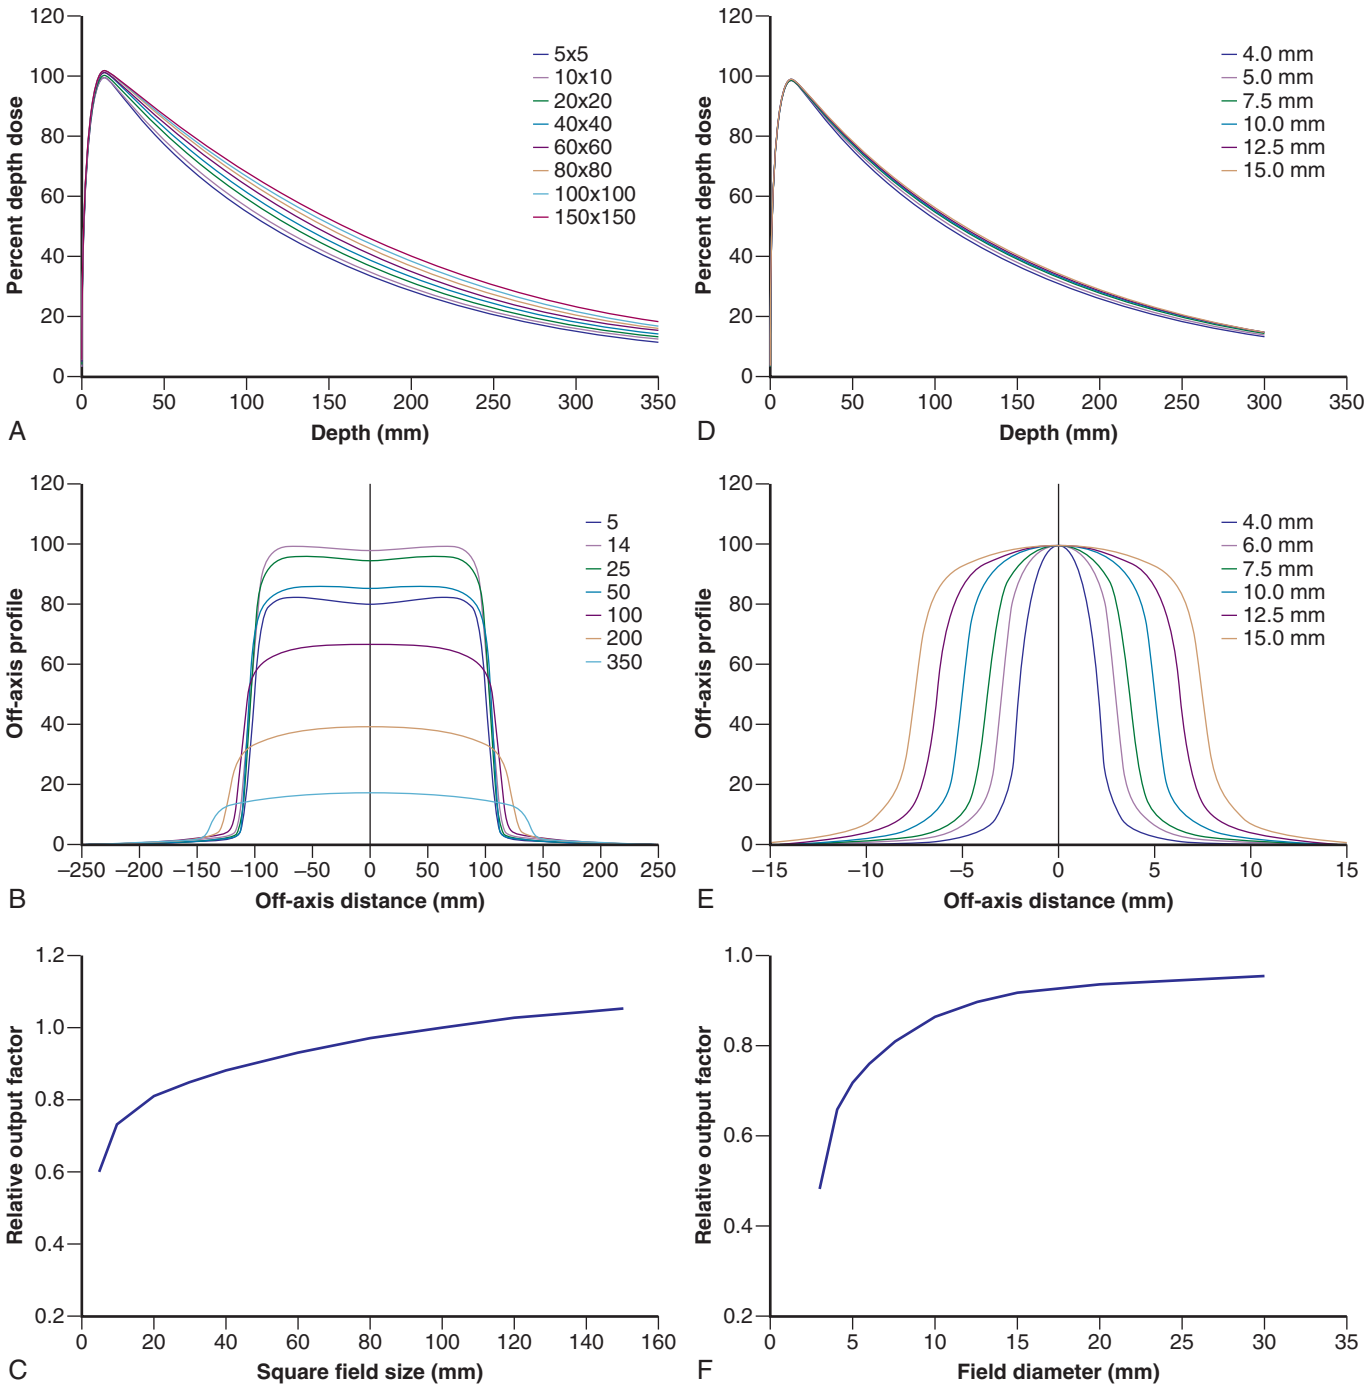

Figure 7-9 Percent depth dose, off-axis profiles, and relative output factors for **(A-C)** MLC-shaped square fields and **(D-F)** circular fields for a 6-MV beam.

treatment device is a critical test of any radiosurgery system. This is illustrated in Figure 7-11 using the Radionics QMP Phantom (Integra Radionics, Inc., Burlington, MA). Within the TPS, an isocenter is placed at the tip of the cone. Using the printed positioning templates, the phantom is localized in the treatment room. If the overall targeting process is working properly, the room lasers should intersect with the tip of the cone.

A hidden target test is also essential for assessing end-to-end capabilities that incorporate imaging, planning and localization aspects. The process of a hidden target test is illustrated in Figure 7-12. In this example, a small, radiopaque ball was placed in an anthropomorphic head phantom, which was in turn fixed in a stereotactic head frame. A CT was obtained and the center of the sphere was identified and defined as an isocenter. In the treatment room, the phantom was aligned to the lasers using templates provided by the treatment planning computer. AP and lateral beams-eye-view films were obtained using a 10-mm circular collimator. Accuracy was subsequently assessed by measuring the offset of the ball within the projection of the field. Hidden target tests can also be used in conjunction with image guidance systems to assess image guided radiotherapy (IGRT) accuracy. Modern systems are capable of end-to-end accuracy on the order of ~1.0 ± 0.5 mm.[46,85-89]

Dosimetric Commissioning

Once targeting accuracy has been confirmed, and beam data has been measured and verified, thorough dosimetric commissioning of the radiosurgery treatment planning system must be performed to ensure that the monitor units and other parameters calculated deliver the intended dose within the desired volume. The process of TPS commissioning is a standard radiotherapy task and has been described is several AAPM reports and elsewhere.[90-92] Because radiosurgery has several unique characteristics relative to conventional radiotherapy—for example, large dose per fraction, heterogeneous dose distributions, sharp dose gradients, and use of multiple isocenters—it is important to commission the TPS across a comprehensive range of doses and delivery techniques. This may include arc therapy using circular collimators, regular and irregular shaped conformal beams, dynamic

conformal arcs, IMRT, as well as combinations of these distributed among multiple isocenters. Absolute dose ranging to 20 Gy or higher should be measured using a calibrated or cross-calibrated microionization chamber, whereas dose distributions are typically verified using film or an array detector. The process has been described recently for two newer radiosurgery units.[64,93] Figure 7-13 show examples of film measurements in solid water phantoms, with calculations from the treatment planning system superimposed, for a small field IMRT (top) and multiple isocenter (bottom) delivery. Dosimetric commissioning should also be performed using an end-to-end approach.[70] This can be facilitated using a simple phantom fixed in a stereotactic frame or using an anthropomorphic phantom in combination with image guidance, as illustrated in Figure 7-14. Use of the Radiological Physics Center (RPC) SRS, thorax-lung, spine, and head and neck IMRT phantoms

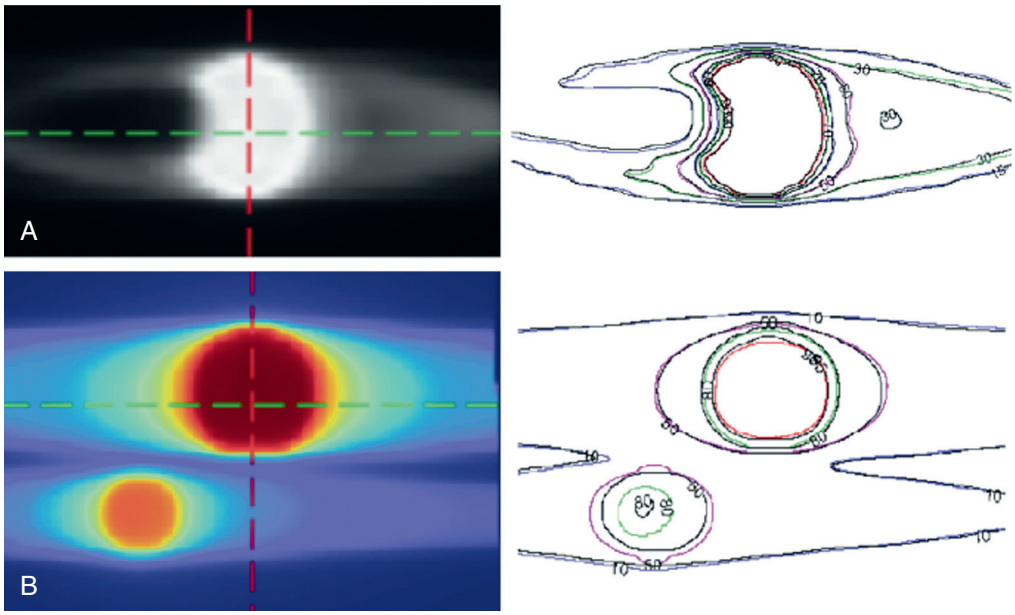

Figure 7-13 Film measurements in solid water phantoms *(left)*, superimposed on calculations from the treatment planning system *(right)*, for a small IMRT field *(top)*, and multiple isocenters *(bottom)*.

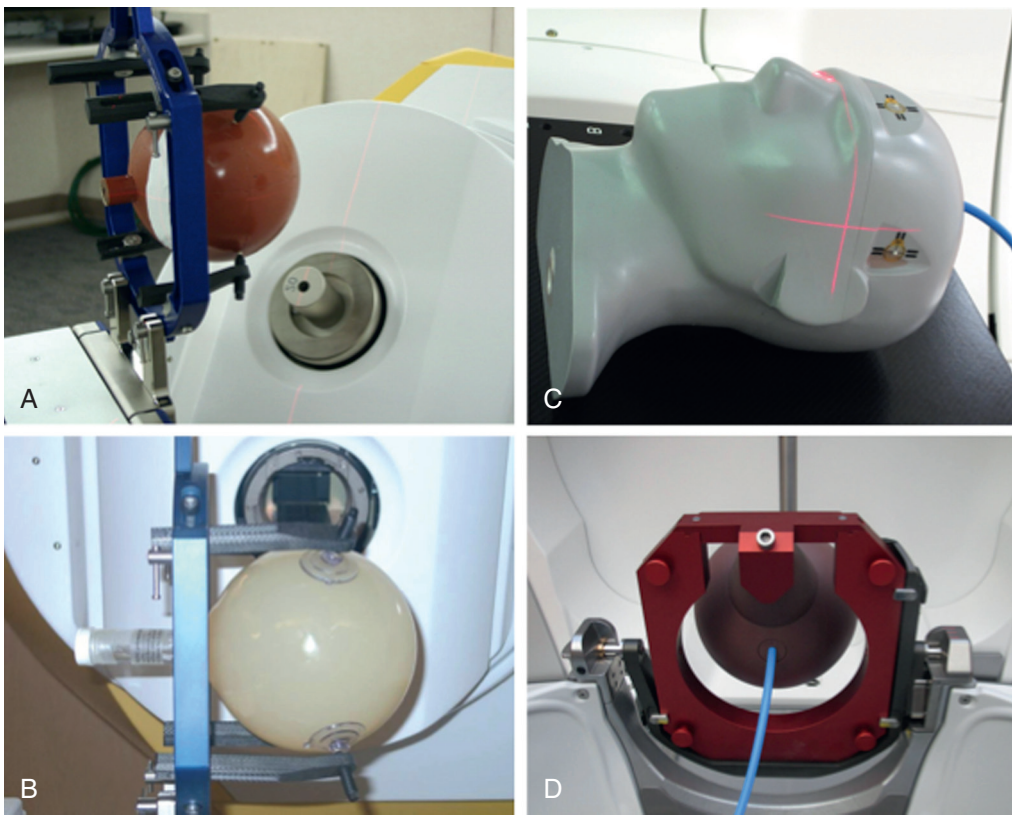

Figure 7-14 End-to-end dosimetric verification on **(A)** a linac system using a solid water phantom, **(B)** a linac system using a BANG-gel phantom, **(C)** a linac system using an anthropomorphic head phantom, and **(D)** a Perfexion system using a solid water phantom.

as an independent means of verification is also highly recommended.[66] Finally, TPS commissioning should always be performed through a record-and-verify system to help detect potential systematic errors that may propagate through the electronic record.

CONCLUSIONS

SRS has become a standard of care in the management of cranial disease and stimulated application in extracranial disease sites. The clinical success of SRS and SBRT has been facilitated in large part through technological development and depends on fundamental understanding of nonequilibrium physics and dosimetry and diligent attention to commissioning and quality assurance.

CHAPTER 8

Surgical Principles

Y. Nancy You and John H. Donohue

Surgery remains the central treatment for most cancers. Survival for the majority of patients with solid malignancies is still most dependent on the stage of the tumor and on the physician's ability to resect all of the known tumor. Surgeons help in the diagnosis, staging, curative and palliative therapy, and follow-up of patients with cancer. The surgical oncologist does not act in isolation; instead, interaction with colleagues from other specialties is routine. Because many of the common solid tumors are treated with a combination of therapies, the surgeon usually provides treatment in collaboration with medical and radiation oncologists. This interaction among specialists provides the best chance for patient cure and effective palliation.

Preoperatively, an accurate patient history is obtained and a physical examination plus routine laboratory tests and, when indicated, more specialized evaluations are performed to assess the tumor extent and the patient's ability to tolerate the proposed treatment. The goals of surgical intervention in patients with cancer include providing a histologic diagnosis, disease staging, and disease treatment, either with potential cure or symptom palliation. The role of surgical treatment in the relief of patient suffering is particularly beneficial for visceral obstruction, hemorrhage, perforation, and pain caused by tumor involvement. High-quality radiologic imaging studies such as ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) plus three-dimensional reconstructions are instrumental in planning the appropriate operative procedure. A preoperative biopsy of a lesion that appears to be malignant is not necessary for diagnosis but is indicated for a patient receiving preoperative (neoadjuvant) or nonoperative therapy.

The role of the surgical oncologist in the multidisciplinary management of the cancer patient will be highlighted in this chapter. The surgeon's role in multimodality therapies for malignant diseases will be illustrated by the management of cancers of the breast, pancreas, rectum, and retroperitoneum.

HISTOLOGIC DIAGNOSIS

A pathologic diagnosis should be secured before the definitive surgical procedure in some patients. The goal of the diagnostic biopsy is to obtain sufficient tissue for complete analysis with minimal risk for complication. Either cytologic or histologic samples are adequate for most cancers, but a histologic diagnosis is usually preferable. A false-negative cytologic result occurs in 10% to 20% of cancer patients, and false-positive cytologic diagnoses can rarely occur. Biopsies that sample a tumor may underestimate the aggressiveness of a lesion (e.g., atypia or carcinoma in situ instead of invasive cancer) because of sampling error. A diagnostic tissue specimen may be obtained by aspiration cytology, core-needle biopsy, incisional biopsy, or excisional biopsy. A separate biopsy procedure is unnecessary unless it affects preoperative treatment planning. Endoscopically or laparoscopically directed biopsies both allow more accurate staging of intraabdominal malignancies than noninvasive procedures plus provide tissue for diagnosis.

Fine-needle aspiration cytology (FNAC) is widely used to evaluate solitary thyroid nodules. Using a 21-gauge needle and syringe, an aspirate of cellular material or fluid is obtained, differentiating between solid and cystic masses. If a cyst does not completely disappear with aspiration, FNAC examination of any residual solid component is necessary. The success of FNAC depends on the experience of the clinician performing the aspiration and on the interpretation of a skilled cytologist. FNAC of the thyroid enables the pathologist to differentiate most benign from malignant tumors. Papillary, medullary, and anaplastic carcinomas have typical cytologic appearances. Cytology cannot differentiate benign from malignant follicular and Hürthle cell neoplasms. A definitive diagnosis for these thyroid neoplasms depends on histologic examination of the entire excised tumor. The introduction of routine FNAC has dramatically reduced the number of diagnostic surgical operations for benign thyroid masses.

Percutaneous radiograph-directed FNAC has gained great popularity over the past 25 years.[1] Ultrasonography or CT scanning is routinely used to obtain hepatic, renal, pancreatic, and retroperitoneal biopsies. Percutaneous biopsy techniques are particularly useful to confirm the presence of metastases in a patient with a history of malignancy. Adrenal FNAC should be avoided if a pheochromocytoma has not been excluded. If potentially curable metastases (e.g., limited hepatic metastases from colorectal cancer) are present, this diagnostic test is unwarranted and potentially dangerous because of rare tumor seeding. If unresectable cancer is present at exploratory laparotomy, a confirmatory biopsy should be obtained.

The choice of ultrasonographic or CT guidance depends on several factors. In general, ultrasonography is used for superficial lesions. Ultrasonography possesses other advantages, including real-time imaging, which allows constant monitoring of the needle position, and lower costs compared with CT scanning. Ultrasonographic examination is limited by overlying bone and gas. CT guidance is more beneficial for deeper tumors, particularly in the retroperitoneum. Advantages of CT-guided biopsy include better spatial resolution and lack of interference from air or bone. Intravenous contrast provides an estimate of tumor vascularity.

Core-needle biopsy can be performed by hand if the mass is easily palpable and can be stabilized by the operator. Radiographically directed core biopsies, particularly of solid breast masses, are commonly performed preoperatively. Unlike an FNAC, a core biopsy provides sufficient tissue for histologic

analysis. Using local anesthesia, a small (3-mm) incision is made in the skin through which a coring biopsy needle is directed into the center of the lesion. Typically, a 1- × 10- to 20-mm tissue sample is obtained. Core-needle biopsy may also be performed with stereotactic imaging or ultrasonography for nonpalpable breast lesions.

Core-needle biopsies of intraabdominal and thoracic tumors offer the advantages of a histologic diagnosis and greater accuracy than the FNAC. Larger-bore needles can cause complications, most commonly hemorrhage. Some tumors, including many adjacent to major blood vessels, are not safely accessible percutaneously. Core-needle biopsy should not be used for potentially resectable malignancies because of a higher risk of needle track seeding than with FNAC. Intraoperative diagnostic core biopsies are preferable to incisional biopsies when a diagnosis is needed for an unresectable tumor. The decision to resect or not, as in a pancreaticoduodenectomy for painless jaundice, should be based on the clinical and operative findings; a histologic diagnosis is not mandatory before resection.

Incisional biopsy excises more of a tumor mass than needle biopsy. A full-thickness biopsy using a scalpel or punch biopsy tool of a larger skin tumor is a commonly performed incisional biopsy. A full-thickness sampling of the thickest portion of the lesion should be removed to allow accurate tumor staging. Sometimes an incisional biopsy of a sarcoma is performed to provide the diagnosis before proceeding with definitive treatment (e.g., amputation, preoperative chemotherapy, or radiation), but core-needle biopsies are another option. An incisional biopsy of an extremity tumor is preferably obtained through a longitudinal rather than a transverse incision because the longitudinal incision can be more readily incorporated with a wide local excision.[2] Intraoperative incisional biopsies during thoracotomy and laparotomy are rarely indicated; tumor spillage is more likely than with FNAC or core-needle biopsies.

Excisional biopsy of a breast mass illustrates the key principles of a diagnostic surgical biopsy. This procedure can be used for small, palpable lesions amenable to easy complete excision. A diagnostic excisional breast biopsy is now rarely performed. Almost all breast cancers are diagnosed with FNAC or core biopsy preoperatively. If possible, the skin incision should be circumareolar or situated within the elliptical incision that would be used for a mastectomy (Figure 8-1). If the breast mass is believed to be malignant, it should be excised with a 1-cm margin of normal tissue, centering the suspicious lesion in the specimen (Figure 8-2, *A*). The biopsy specimen should be oriented to permit the pathologist to specify which of the resection margins, if any, are histologically involved by tumor. Specimen orientation can be denoted with two sutures (Figure 8-2, *B*) or by painting the specimen with multiple-colored stains. If frozen-section evaluation of the resection margins is available, reexcisions can be performed immediately when necessary. When frozen-section evaluation is unavailable, separate, individually labeled margins may be sent in addition to the primary tumor specimen. Selective reexcision can be performed at a later date if the main specimen has been appropriately oriented with sutures, clips, multicolored inks, or separate margins. Surgical clips left at the base of the biopsy cavity facilitate accurate

partial breast or boost-field radiation therapy after breast-conservation surgery. Small titanium clips provide accurate localization for the radiation oncologist with minimal interference on future images, including MRI.

STAGING

The stage of a malignant tumor usually determines the goal of intervention. Symptoms or physical signs frequently alert the clinician to metastatic disease, but diagnostic studies are usually required to confirm distant disease spread. Accurate preoperative staging results in the best treatment because the extent of tumor spread remains the single-most important determinant of patient prognosis.

Clinical and pathologic stages of disease for most cancers have been standardized in the American Joint Committee for Cancer (AJCC) TNM system.[3] In this nomenclature, T refers to the primary tumor, N indicates the status of regional lymph nodes, and M denotes the presence or absence of metastatic disease. For most cancers, the size (e.g., in lung, liver, or breast cancers) or the degree of invasion (e.g., in melanoma or stomach or colorectal cancers) of the primary tumor correlates with the probability of metastases.

Clinical tumor staging is normally determined using combined data from physical examination, a variety of radiologic tests (including plain radiographs, ultrasonography, CT, and MRI), and endoscopic examination. Positron emission tomography (PET)-CT imaging provides more sensitive staging compared with other imaging studies in a number of disease sites. PET-CT can be especially helpful in the diagnosis of unsuspected metastatic disease (e.g., esophageal cancer; melanoma) and in evaluating patients with possible recurrent cancer (e.g., locally recurrent rectal cancer). In symptomatic patients, skeletal metastases can also be diagnosed with a radioisotope bone scan or correlative plain radiographs.

Role of Laparoscopy

The introduction of laparoscopy in general surgical practice has led to more precise staging of many intraabdominal malignancies, particularly gastric,[4] pancreatic,[5] and hepatobiliary cancers.[6,7] Thoracoscopy allows inspection and biopsy of the pleural cavity to assess for intrathoracic tumor spread. When used for diagnosis, laparoscopy allows visualization of peritoneal surfaces; histologic evaluation of peritoneal, omental, or hepatic tumor masses; biopsy of lymph nodes; and collection of ascites or peritoneal washings for cytologic examination. Laparoscopic ultrasonography further improves the staging of pancreatic and hepatobiliary malignancies.[8-10] If the laparoscopic findings confirm metastatic malignancy, the attendant morbidity from tumor resection by traditional or minimally invasive techniques can be avoided. Laparoscopic techniques can be used for cancer therapy to palliate patients with advanced malignancy and curatively resect others.[11]

Staging of Pancreatic Malignancy

Laparoscopy is frequently used to stage pancreatic and periampullary carcinomas because hepatic or peritoneal metastases undetectable by radiographic means occur in up to 30% of patients with tumors believed to be resectable preoperatively.[5,12,13] Recent data[14] show an extended, complete laparoscopic inspection of the abdominal cavity should be undertaken using a 10-mm port at the umbilicus (Figure 8-3). Additional cannulae allow for retraction of the liver to allow observation of all surfaces, plus the lesser sac, omentum, and loops of intestine. Laparoscopic inspection should also include a Kocher maneuver to visualize the paraduodenal retroperitoneum. Inspection of the upper abdomen, looking for small hepatic metastases or drop metastases on the parietal and visceral peritoneum or the greater omentum, is readily accomplished. Any suspicious lesions should be sampled using a biopsy forceps or core-needle biopsy tool. The remainder of the abdomen can be examined, including the peritoneal surfaces, for seeding and dependent areas for ascites. Evidence of direct spread of a pancreatic carcinoma into the transverse mesocolon and small bowel mesentery should be assessed.

With the patient in the reverse Trendelenburg position, limited visualization of the anterior surface of the pancreas may be obtained with a supragastric approach after division of the lesser omentum (Figure 8-4, *A*) or an infragastric approach, entering the lesser sac through the gastrocolic omentum (Figure 8-4, *B*). Biopsy of peritoneal implants within the lesser sac should be obtained. Laparoscopic ultrasonography provides a more accurate assessment of visceral vascular involvement and deep hepatic metastases,[10] although

endoscopic ultrasonography (EUS) provides highly accurate staging in these sites.

GOALS OF SURGICAL INTERVENTION

The primary intent of surgical intervention is curative resection. The surgeon must be familiar with the cancer biology, including modes of spread (i.e., hematogenous, lymphatic, intracavitary, or direct extension). En bloc excision of the tumor is performed for the highest probability of cure (complete resection or R0 resection = no residual tumor). Complete extirpation of the primary tumor with a margin of normal tissue plus a regional lymph node dissection typifies this type of resection. For cancers such as colon carcinomas or retroperitoneal sarcomas, normal adjacent structures directly invaded or adherent to the malignancy should also be resected. Lysis of adhesions between a primary cancer and an adjacent structure can result in residual cancer and tumor spillage. When the local extent of a nonmetastatic malignancy prevents a gross total resection with negative margins, the surgeon should facilitate postoperative irradiation planning by leaving titanium clips at the site of residual microscopic disease (R1 resection = microscopic residual cancer).

Certain intraabdominal malignancies are appropriately treated by surgical debulking (R2 resection = gross residual disease) plus perioperative therapy. Examples include ovarian carcinomas and rare low-grade mucinous adenocarcinomas, known traditionally as pseudomyxoma peritonei, that are usually of appendiceal origin. The goal of operative therapy is to remove as much macroscopic intraabdominal disease as is feasible because patient outcome is improved.

For patients with known metastatic disease who have symptoms or are at risk for complications from locally advanced disease, surgical palliation (R1 or R2 resection) should be considered. Operative procedures should be reserved for well-defined problems amenable to surgical treatment in patients with reasonable performance status and life expectancy. Intestinal obstruction can be corrected by a resection, bypass, or proximal diversion (i.e., ostomy formation). When technically feasible, laparoscopic, laparoscopically assisted (i.e., mobilization using laparoscopic technique and a portion of the procedure performed through a limited celiotomy), and endoscopic stenting techniques are suitable and preferable to a formal laparotomy. Diffuse peritoneal implantation often prevents successful palliation and increases the risk of postoperative complications, including infection and intestinal fistula formation. The surgeon may prevent life-threatening hemorrhage or improve pain by resection of some cancers. Pain can also be alleviated by nerve transection or blockade, such as celiac plexus block for pancreatic carcinoma.

PERIOPERATIVE CARE OF THE ONCOLOGY PATIENT

The cancer patient may develop unique perioperative problems. The surgeon must strive to avoid such problems and must monitor the patient for their occurrence to minimize morbidity and minimize delays in adjuvant therapy. Patients with malignancy have a higher prevalence of postoperative complications because of their neoplastic disease, coincidental comorbidities in older patients, the major surgical procedures patients have undergone, and perioperative and adjuvant therapy-induced immunosuppression. Patients with gastrointestinal malignancies with or without obstruction frequently suffer from substantial weight loss, malnutrition, and resultant immunodeficiency. The hematologic, gastrointestinal, pulmonary, and cardiac toxicities associated with chemotherapy pose additional risks for the patient postoperatively. Before adjuvant therapy is started, sufficient time must be allowed to pass for wound healing and resolution of infectious complications to occur.

The extent and type of operative management must take into account the patient's preexisting and malignancy-induced comorbidities. Cancer cachexia resulting from anorexia is common and results in significant lean tissue loss and immunodeficiency. Because malnutrition significantly increases the risk for perioperative morbidity, the surgeon must carefully assess the degree of preoperative malnutrition. Although retrospective studies evaluating preoperative nutritional support show a reduction in postoperative complications for patients with severe malnutrition,[14] a meta-analysis did not support routine preoperative nutrition for oncologic patients.[15] Total parenteral nutrition should be reserved for patients unable to tolerate enteral nutrition, those unable to take sufficient calories by oral or enteric routes during therapy, and those felt to be unsuitable for operative or combined-modality therapy until their nutritional status improves. Enteral rather than parenteral nutrition should be used whenever possible. Postoperative nutritional support should always be considered, especially in patients with upper gastrointestinal malignancies such as esophageal, gastric, and pancreatic cancers. A feeding jejunostomy catheter placed intraoperatively facilitates delivery of postoperative nutrition.

The oncologic patient has a higher risk for postoperative infection. Immune compromise in patients with cancer occurs as a result of older age, surgical stress, malnutrition, and impaired host defense mechanisms. Neutropenia combined with defective cell-mediated immune responses render malnourished patients especially prone to postoperative complications and impair the patient's response to sepsis. Appropriate perioperative antibiotics and vigilant postoperative observation for infection are critical in reducing the morbidity of postoperative infections.

Older age, the presence of a malignancy, and undergoing operative procedures all increase the incidence of thromboembolic complications. A hypercoagulable state is especially common in patients with pancreatic, prostate, lung, breast, and gastric cancers. Increased factors I, V, VIII, IX, and XI;

decreased proteins C and S; and reduced antithrombin III levels have all been implicated in higher rates of thromboembolic events in patients with cancer. Perioperative subcutaneous heparin (both low-molecular-weight and unfractionated heparin are appropriate treatments), thromboembolic stockings, and sequential compression devices should be used for all patients undergoing oncologic surgery. Patients at high long-term risk for thromboembolic complications (e.g., prior history of deep venous thrombosis/pulmonary embolism [DVT/PE], inherited hypercoagulable trait, debilitated, or those with residual cancer) need to be considered for extended anticoagulation therapy.

Patients with malignancy are often anemic. Blood transfusions result in immunosuppression, including depression of specific cellular immunity, and nonspecific immune responses, including natural killer cell activity and macrophage phagocytosis. Some retrospective studies have shown higher cancer relapse rates in cancer patients receiving blood transfusions, but controlled trials have not demonstrated a poorer disease-specific survival (DSS) rate specifically related to perioperative transfusions.[16,17] Blood transfusion must be administered as appropriate in oncologic patients.

RADIATION THERAPY AND WOUND HEALING

Tissues exposed to radiation therapy develop acute inflammatory changes in proportion to the total dose. Higher-dose fractions may cause more significant changes. Acute radiation injury is manifested by vasodilation (erythema) and tissue edema. Following moderate-dose preoperative radiation (45 to 50 Gy in 1.8- to 2.0-Gy fractions), a 3- to 6-week preoperative recovery period is generally allowed for partial resolution of acute radiation changes.[18] Late radiation changes include atrophy and fibrosis, which result from decreased tissue vascularity.

Wound healing is impaired in irradiated tissue by several factors, including diminished blood supply, impaired collagen formation, and the increased risk of infection resulting in part from decreased leukocyte function. After high-dose irradiation, slow and nonhealing wounds are commonplace. In this situation, nonirradiated tissues, such as vascularized myocutaneous flaps, may need to be transferred into the radiation field to allow proper wound healing.[19] This is preferably done at the time of tumor resection rather than after a nonhealing postoperative wound develops. If partial resection of an irradiated hollow organ (e.g., bowel, bile duct, trachea) is necessary, one side of the anastomosis should be nonirradiated tissue whenever possible. This precaution provides a better blood supply for healing of the anastomosis. This policy will reduce the incidence of early postoperative leak and fistula formation and late anastomotic strictures.

SURGICAL TREATMENT OF BREAST CANCER

The treatment of patients with breast cancer should occur in a multidisciplinary setting. Ideally, patients are evaluated in a breast clinic with treatment specialists, including a surgeon, radiation oncologist, medical oncologist, nurse, and medical geneticist providing preoperative consultation. There should be a focus on patient education regarding the treatment options currently available for both operative and nonsurgical adjuvant therapies.

Most women with breast cancer can now choose breast conservation. Data from multiple mature, controlled trials have demonstrated no significant difference in disease control or survival between patients who elect breast-conservation therapy and those who choose mastectomy.[20-22] Mastectomy is a suitable option if the woman chooses this form of treatment. Mastectomy is preferable for the management of multicentric disease and most large primary tumors (neoadjuvant chemotherapy may allow breast conservation in patients with a sufficient response) and in patients unable to receive postoperative radiation therapy. The majority of patients undergoing mastectomy can have immediate breast reconstruction, if desired. Consultation with a plastic surgeon should be obtained preoperatively to allow the patient to assess the immediate reconstruction options. The timing of breast reconstruction depends partly on patient preference. In addition, if chest wall irradiation is indicated by the breast cancer stage, the immediate reconstruction results are often cosmetically affected.

Early Breast Cancer

Most women with early-stage breast cancer (i.e., stage 0, I, or II breast cancers) are suitable candidates for breast-conservation surgery. The goals of breast-conservation surgery are optimal locoregional control of the breast cancer and preservation of the natural appearance of the breast. All known breast cancers must be excised from the breast and axilla. (It is not necessary to pathologically stage the axilla for most ductal carcinomas in situ.) Radiation therapy must be administered following breast-conservation surgery to reduce the risk of local tumor recurrence, given the high incidence of residual microscopic disease, even with pathologically clear margins. Because radiation therapy is an integral component of breast conservation, patients who are unsuitable for radiotherapy should not undergo this form of surgery. Contraindications to breast-conservation surgery include a history of certain collagen vascular diseases (e.g., scleroderma, polymyositis), the presence of diffuse indeterminate or suspicious calcifications on mammography, a history of therapeutic irradiation to the breast, and positive margins of resection despite wide excision.

Breast-conserving surgery is performed through an incision as close to the primary tumor as possible, whether the lesion is a palpable mass or a mammographic abnormality that has been localized. It is best to remove the entire abnormality with a 1-cm margin of grossly normal tissue to improve the probability of microscopically clear margins. A curvilinear incision in Langer's lines optimizes the cosmetic result in most locations, whereas a radial incision may be preferable in the lower quadrants. Incisions should be positioned to allow them to be included in a standard mastectomy incision wherever possible. After specimen excision, markers (e.g., sutures, clips, dyes) should be placed on the tissue to provide orientation. If frozen-section pathologic analysis is available, evaluation of margins can be obtained intraoperatively. If margin evaluation is performed later, correct specimen orientation will result in less tissue reexcision when the original specimen has tumor involvement of one or more margins. Titanium clips are placed at the base of the biopsy cavity to help target postoperative irradiation. The breast wound is usually closed without approximation of the breast parenchyma. Oncoplastic closures with mobilization of flaps can provide better cosmesis, especially with larger tumor excisions.

Sentinel lymph node biopsy or axillary lymph node dissection is best performed through a separate incision. The axillary incision should be placed between the axillary folds and not cross the lateral border of the pectoralis major muscle (Figure 8-5). Axillary staging aids patient management in determining prognosis and systemic adjuvant treatment. Patients with positive axillary nodes are almost routinely advised to receive systemic treatment, usually combination

chemotherapy. Postoperative therapy commences after sufficient wound healing has occurred, usually within 4 weeks.

Sentinel Lymph Node Biopsy

Axillary lymph node dissection was once routinely performed in women with invasive carcinoma of the breast. The rationale for axillary lymphadenectomy has shifted from increasing the rate of cure and improved regional disease control to improved staging and appropriate selection of systemic therapy. With the widespread acceptance of the sentinel node biopsy procedure, formal axillary nodal dissection for early breast cancer is limited to patients with pathologic nodal metastasis. Regional metastases are the single-most important prognostic variable for patients who have breast cancer without distant metastases. Because nodal involvement cannot be accurately predicted except with microscopic tissue evaluation, axillary node examination is a necessity.

Minor complications, including seroma development, wound infection, and sensory nerve transection, occur after axillary lymphadenectomy. Although these problems are generally minor, severe and permanent disability from an axillary lymph node dissection may occur. Most commonly this results from upper extremity lymphedema and occasionally from sensory neuropathy. A sentinel lymph node biopsy with limited sampling of the nodes provides an accurate assessment of regional metastasis, with a low prevalence of significant complications. Sentinel lymph node biopsy allows selective completion lymphadenectomy in patients who have documented nodal metastasis.

A sentinel lymph node biopsy identifies and excises the first draining regional node(s). First popularized in the management of cutaneous malignant melanoma, in 1994 Giuliano et al[23] reported their adaptation of the sentinel node technique for patients with breast cancer. Using isosulfan blue to isolate the sentinel lymph node, they identified a sentinel node in 93% of patients with high accuracy for detecting axillary metastases. Given their success with sentinel node biopsy to identify nodal metastases, Giuliano et al[23,24] stopped performing axillary lymphadenectomy for patients with a negative sentinel node biopsy.

To successfully predict nodal metastasis requires an orderly spread of tumor cells in the lymphatics, not a random distribution. The initial draining node or sentinel lymph node is the site of first metastasis. After several confirmatory reports, sentinel lymph node biopsy became standard practice for patients with breast cancer who had no clinical evidence of axillary metastasis.[25-27] The sentinel lymph nodes can be localized with a dye (usually isosulfan blue or methylene blue), a radiolabeled colloid (usually sulfur colloid or human serum albumin), or with both dye and colloid. Through a small axillary incision (2 to 3 cm), the blue-stained lymphatics are frequently located at the lateral border of the pectoralis major muscle and followed to the blue-stained sentinel node. Alternately, a handheld gamma probe allows localization of the radioactive lymph nodes. All nodes stained with dye, those with high radioactivity counts, and those with both staining and high counts are excised and evaluated histologically. Any hard lymph node should also be removed and examined by the pathologist because a tumor-replaced node has no lymphatic flow. Tumor-involved nodes found on frozen-section evaluation allow immediate completion of the axillary dissection. The prognostic importance of minimal tumor involvement of a sentinel node, such as that detected only by immunohistochemical staining (i.e., N0[i+]) and micrometastases (i.e., a tumor deposits less than 2 mm in diameter; i.e., N1mi), remains controversial. Recommendations for complete axillary lymph node dissection and adjuvant treatment based on these limited metastases are still evolving.[28]

MULTIMODALITY THERAPY FOR PANCREATIC ADENOCARCINOMA

Ductal adenocarcinoma of the pancreas is a highly lethal disease with approximately the same number of new cases and deaths each year in the United States. The postoperative mortality rate after major pancreatic resection with curative intent has fallen significantly in major centers over the last three decades. With improved cross-sectional body imaging and endoscopic ultrasonography, preoperative disease staging has dramatically improved. This and new methods of nonsurgical palliation limit surgical intervention in patients with advanced disease that is not curable. Early diagnosis of pancreatic cancer is required to improve the probability of patient survival, but because the symptoms of pancreatic carcinoma are nonspecific and metastases occur early, the diagnosis commonly occurs when the cancer cannot be controlled with local treatments. Specific symptoms do not occur until there is invasion of adjacent structures. Most adenocarcinomas arise in the pancreatic head, with obstructive jaundice being a common presentation. Constant mid-back pain is an indicator of locally advanced cancer with tumor involvement of the splanchnic plexus and the central retroperitoneum. Duodenal obstruction resulting in nausea and vomiting can occur with local progression of the cancer.

Preoperative staging of pancreatic carcinoma should determine if a curative operation is possible. High-quality, thin-cut, spiral CT scanning with oral and intravenous contrast media delineates the primary pancreatic mass, local vascular invasion, and liver metastasis in most patients. EUS and laparoscopy with or without ultrasonography provide more sensitive evaluation of limited metastatic disease.[8-14] With EUS, a high-frequency transducer within the gastric and duodenal lumen is positioned near the pancreas. This technique can detect small pancreatic masses (<1 cm), identify enlarged regional lymph nodes (and allow fine-needle aspiration biopsy of both), and better define the presence and extent of visceral vascular involvement. Laparoscopy for staging pancreatic carcinoma is the best means to detect peritoneal or liver metastases not detected with preoperative imaging.

Only 10% to 20% of patients with carcinoma of the pancreas can be completely resected (R0 resection). Palliation of symptoms to improve quality of life becomes the therapeutic goal for most patients with pancreatic cancer. Obstructive jaundice can be palliated surgically or nonoperatively. Several prospective, randomized studies showed nonoperative biliary

stenting to be as effective in the relief of jaundice as surgical biliary bypass.[29,30] Pain from posterior tumor invasion is effectively treated with a combination of oral analgesics and a celiac plexus block. Operative (laparoscopic or open) gastrojejunostomy or expanding metal endoluminal stents are both reasonable options for the management of duodenal obstruction caused by tumor invasion. Stenting is generally less durable than surgical bypass, requiring multiple procedures when patient survival is lengthy.

The operative results and long-term survival rates after pancreaticoduodenectomy have improved most significantly in medical centers with larger patient experiences. Operative management includes a full abdominal exploration, focusing on inspection of the liver, peritoneum, and omentum for distant metastases. The regional lymph nodes are also palpated to assess for tumor involvement. Periaortic, porta hepatis, small bowel mesentery, or celiac lymph node metastases indicate tumor spread beyond the limits of standard resection. Japanese surgeons have advocated radical lymphadenectomy to improve patient outcome,[31] but randomized trials of extended lymph node dissection have not resulted in improved patient survival rates.[32,33]

Local tumor factors that usually prevent curative resection include retroperitoneal extension to involve the inferior vena cava or aorta or direct involvement or encasement of the superior mesenteric artery or celiac axis. Several centers have shown that en bloc resection of the involved superior mesenteric or portal vein results in patient survival comparable to those of standard pancreaticoduodenectomy.[34,35] After excluding unresectable tumors, the surgeon can proceed with pancreaticoduodenectomy. The classic Whipple procedure, which resects the gastric antrum, or the pylorus-preserving modification provides similar results. Recently laparoscopic and robotic minimally invasive pancreaticoduodenectomy have become reasonable options at select centers with skilled surgeons.

Unfortunately, no more than 25% of patients who have a curative resection for ductal adenocarcinoma of the pancreas will survive for 5 years. Optimal long-term survival is seen with complete resection (R0), no lymph node metastases, small tumor size (<2 cm), and lack of perineural or duodenal invasion. Because survival after curative resection is modest, many nonsurgical therapies have been investigated.

Because approximately 50% of patients have locoregional recurrence after curative resection, adjuvant irradiation could have beneficial effects on patient survival rates.[36] The Gastrointestinal Tumor Study Group[37] first reported encouraging results from a prospective, randomized trial in 1985. The efficacy of adjuvant postoperative irradiation and chemotherapy for adenocarcinoma of the head of the pancreas was evaluated. Forty-three patients were randomized to receive adjuvant therapy with irradiation and 5-fluorouracil (5-FU) or no adjuvant therapy. The median survival time for the 21 patients who received adjuvant therapy was 20 months, and 3 (14%) survived more than 5 years. Among the 22 patients who did not receive adjuvant therapy, the median survival time was 11 months, and only 1 patient (4.5%) survived 5 years.[37] Similar results were noted in a collaborative study from Johns Hopkins Hospital and the Mayo Clinic[38] favoring adjuvant postoperative chemoradiation therapy over surgery alone. A European Study Group for Pancreatic Cancer (ESPAC-1)[39] trial showed benefit for adjuvant chemotherapy, with a deleterious impact of concurrent chemotherapy and irradiation. Major flaws in the ESPAC-1 trial are discussed in Chapter 48, Pancreatic Cancer, in this textbook.

Adjuvant chemotherapy and irradiation are still used in most major treatment centers in the United States for patients with resectable and locally advanced, unresectable pancreatic tumors. Despite improved local control of disease with adjuvant chemoradiation, most patients with pancreatic cancer will succumb to liver or other distant metastases. Pancreatic cancer appears to be a systemic disease at diagnosis in the majority of patients, and death commonly occurs despite clinical presentation with localized disease.

For locally advanced, unresectable pancreatic carcinomas, the use of external beam irradiation (EBRT) plus chemotherapy has been reported to result in a doubling of median survival compared with surgical bypass or biliary stenting. The 2-year survival range increases from 0% to 5% up to 10% to 20% with palliative chemoirradiation. Five-year survivors are rare, and nonprogression of the primary tumor is uncommon. The addition of intraoperative irradiation therapy (IORT) to EBRT with or without 5-FU improves local control, as shown by physicians at the Mayo Clinic and Massachusetts General Hospital.[40-42] This benefit did not translate into an improved patient survival because of liver and peritoneal metastatic progression.

If the full course of adjuvant chemoradiation is delivered preoperatively for patients with locally unresectable or borderline resectable pancreas cancer, this sequence allows restaging 2 to 3 months after treatment initiation.[42,43] The 2-year overall survival appears to be improved with this sequence of treatment followed by IORT. Improvement may result from altered patient selection, however, because the incidence of liver plus peritoneal failure is still excessive.[42,43] Until better systemic therapy is developed, the improved local control of locally unresectable pancreatic adenocarcinoma observed with IORT will not translate into improved survival for patients with locally advanced disease.

THERAPY FOR ADENOCARCINOMA OF THE RECTUM

Despite significant evolution in the multimodality therapy of rectal adenocarcinoma over the past decades, surgical resection continues to be the primary curative modality in these patients. The goal of surgery is to resect all known malignant tissue from the pelvis, thereby optimizing survival and minimizing local failure, while preserving normal bowel, bladder, and sexual function whenever possible. Several patient- and tumor-related factors influence not only the choice of the operation but also the coordination of surgical and nonsurgical treatment modalities. Preoperative clinical tumor staging should assess the level of the tumor from the anal verge, the extent of circumferential involvement, the depth of tumor invasion (T category), and the presence of locoregional adenopathy (N category), and of metastatic disease (M category).[3] Important patient-related factors may include body habitus, preoperative bowel and sphincter function, and the medical conditions that may contraindicate surgical resections due to high operative risk. Additional factors such as performance status, blindness, severe arthritis, or mental incapacity should also be considered before an operation that might result in an ostomy.

Accurate preoperative staging of rectal carcinoma is of central importance for selection of surgical strategy and for determining the need for preoperative therapy. Distant metastatic disease can be detected by CT scanning with 75% to 87% sensitivity. For patients without metastatic disease, preoperative pelvic irradiation with concomitant 5-FU–based chemotherapy remains the current standard of care in the United States for patients clinically staged to have T3-4 or node-positive disease.

Local clinical staging for rectal cancer can be accomplished by either transrectal EUS or by high-resolution pelvic MRI. At present, T and N category are most commonly assessed by

transrectal EUS in the United States. EUS may be preferred to pelvic MRI for tumors of earlier T categories, given the ability for direct inspection of each layer of the rectal wall and perirectal structures. Fine-needle aspiration of suspicious perirectal nodes or extramural lesions can be performed. The reported stage-specific sensitivities and specificities of EUS are T1 (88% and 98%), T2 (81% and 96%), T3 (96% and 91%), and T4 (95% and 98%); corresponding sensitivity and specificity for nodal staging are 73% (95% CI, 71% to 76%) and 76% (95% CI, 74% to 78%), respectively.[44,45] EUS is operator dependent and is of limited value when severe luminal stenosis is present or when EUS is performed in the postirradiation setting because inflammatory changes of the soft tissues reduce the accuracy of EUS.[46] Although nodal staging by CT scanning carries a lower sensitivity (45% to 73%), visible perirectal adenopathy should be suspected as malignant.

High resolution MRI has recently emerged as a preferred method for clinical staging, especially in England and Europe, particularly when the assessment of the circumferential resection margin (CRM) or adjacent organ involvement might be critical. CRM refers to the degree of tumor infiltration of the mesorectal fascia.[47] Preoperative recognition of a threatened CRM where malignant infiltration is present within 1 to 2 mm of the mesorectal fascia allows surgical planning for a resection plane that will result in a negative CRM.[48] In the multicenter Magnetic Resonance Imaging and Rectal Cancer European Equivalence Study (MERCURY),[49] high-resolution MRI accurately predicted the involvement of the mesorectal margin to within 1 mm and extratumoral extension with a specificity of 92%. Using surgical resection specimens as the gold standard, 94% of the patients did have a negative CRM.[50,51] Long-term data after 62 months of follow-up showed high-resolution MRI preoperative assessment of CRM status is excellent for assessing local recurrence risk and disease-free survival.[52] For patients with locally advanced primary cancer or locally recurrent rectal tumor, pelvic MRI or CT are best for assessing tumor involvement or fixation to adjacent pelvic organs, helping the surgeon plan en bloc resection of involved organs for a microscopically negative margin.[48,51] The need for urologic, orthopedic, and plastic surgical assistance can be anticipated preoperatively with pelvic MRI or CT staging.

Surgical resection of curative intent removes the primary tumor, draining lymphatic tissue, and any involved pelvic structures in an en bloc fashion. Proximal, distal, and radial/circumferential resection margins are all key determinant of outcome after standard rectal resection.

The need for adequate distal resection margin is a key contributor to whether the patient is a candidate for sphincter preservation. Sphincter-preserving procedures include low anterior resection (LAR) and proctectomy with coloanal anastomosis, whereas an abdominoperineal resection (APR) results in a permanent colostomy. The choice of the procedure is mainly dictated by whether there is adequate distance remaining between the tumor and the anal verge. The exact location of the tumor is measured in reference to the anal verge or to the top of the anal sphincter complex (i.e., anorectal ring) by digital rectal examination and proctosigmoidoscopy. The adequacy of the distal margin is then assessed to determine the feasibility of sphincter preservation. The operative surgeon should ideally perform this evaluation before the patient receives preoperative adjuvant treatment. Previous studies have shown that tumor deposits in nodal tissue are rarely seen more than 2 to 4 cm distal to the tumor. Thus for tumors in the upper and mid rectum, the ideal adequate distal margin is 5 cm. For tumors located in the very distal rectum where the mesorectal tissue is very thin and has tapered significantly, a 2-cm distal margin is considered adequate because it resulted in no difference in overall survival or local failure rates when compared with a greater distal margin.[53,54] In all rectal operations, proximal ligation of the inferior mesenteric and superior hemorrhoidal vessels and full mobilization of the rectum either to a level well below the gross tumor or to the level of the levator ani muscles are performed. If sphincter preservation is possible, the rectum is transected, usually with a cutting linear stapler. An end-to-end colorectal anastomosis is then created using either a hand-sewn or stapling technique. When the line of rectal transaction is at the level of the anal sphincter, the rectal division may be accomplished transanally. A hand-sewn coloanal anastomosis using interrupted sutures placed transanally is then performed. Although intersphincteric dissection followed by hand-sewn anastomosis has been reported, its role remains highly limited.[55] When sphincter preservation is not possible, an APR is performed. Recently, a "cylindrical" approach to APR has been advocated, with an extended perineal dissection including the origin of the levator ani muscle from the lateral pelvic sidewall. This en bloc resection of the levator muscles results in a more cylindrical specimen and had been associated with less CRM positivity and intraoperative specimen perforation.[56]

When counseling patients for sphincter-preserving procedures, the risk of anastomotic leakage and long-term altered bowel function must be discussed. In an analysis of 5187 patients undergoing LAR in five randomized control trials, the symptomatic anastomotic leakage rate was 9.7%.[57] Leakage was associated with reduced overall survival. A diverting stoma lessened the symptoms of the leakage. Construction of a diverting stoma is prudent with a low rectal anastomosis or in patients who received neoadjuvant chemoradiation or will have adjuvant chemoradiation, or both.[58,59] Sphincter-preservation procedures are also accompanied by altered bowel function, most commonly stool frequency, urgency, and incontinence. Reconstructive techniques, including the colonic J pouch, transverse coloplasty, or side-to-end anastomosis, have been developed. A recent Cochrane review showed that functional outcomes were better with the colonic J pouch than with a straight rectal anastomosis in the short term (18 months). There was insufficient evidence for any long-term benefit.[60] These reconstructive options may not be feasible in patients with a bulky mesentery or narrow pelvis. Therefore, sphincter preservation must be considered in the context of (a) adequate oncologic margin, (b) risk of anastomotic leakage, and (c) altered bowel function.

For tumors confined within the mesorectum, total mesorectal excision (TME) is the optimal technique to minimize the risk of an involved CRM.[61] Popularized by Heald and associates,[62] TME involves sharp dissection of the avascular plane between the visceral covering of the mesorectum and the parietal fascia of the pelvis. The surgical planes between the integral visceral mesentery of the hindgut and the surrounding tissues provide a unique opportunity for defining a surgically achievable "tumor package," and, serendipitously, the field of spread of rectal cancer is commonly limited within this package, or mesorectum.[63,64] TME encompasses virtually every tumor satellite except those in patients in whom the tumor is widely disseminated. The excised specimen includes the entire posterior, distal, and lateral mesorectum to the plane of the inferior hypogastric nerve plexus, which is carefully preserved whenever possible. Anteriorly, the specimen includes the intact Denonvilliers fascia and the peritoneal reflection. The characteristic smooth, bilobed, encapsulated appearance posteriorly and distally reflects the contours of the pelvic floor and the midline anococcygeal raphe. In contrast to the local recurrence rates of 20% to 45% reported with traditional resections, rates between 4% and 7% and 5-year disease-free survival approaching 80% have been reported with TME alone.[63,64]

Several less-invasive surgical approaches for patients with rectal cancer have gained attention in recent years. Transanal local excision, either conventionally or via transanal endoscopic microsurgery, may be an option in select patients with well-differentiated T1 tumors located within 8 cm of the anal verge, less than 3 cm in diameter, occupying less than 30% of the luminal circumference, and without suspicious perirectal adenopathy.[65] Excised specimens should be full-thickness, nonpiecemeal specimens with an adequate margin of resection for pathologic examination. Patients treated in this fashion enjoy minimal morbidity but face increased risks for local failure and, perhaps, decreased overall survival.[66-68] Although laparoscopic-assisted operations for rectal cancer are technically feasible, long-term data demonstrating oncologic equivalence to open procedures are just emerging. Particular concerns of the laparoscopic approach include inadvertent spillage of luminal contents, handling of the tumor specimen, implantation of tumor cells in the pelvis, and the potential for port-site relapse. In the short term, patients have reduced analgesia requirements, ambulate more readily, and appear to have less paralytic ileus.[69] The United Kingdom Medical Research Council trial of conventional versus laparoscopic-assisted surgery in colorectal cancer (UK MRC CLASSIC trial) included a subgroup of 381 patients with rectal cancer who were randomized to open versus laparoscopic procedures.[70] After accounting for a 34% conversion rate, 189 and 87 patients were treated in each arm, respectively. No statistically significant difference was seen in the rates of positive proximal, distal, or circumferential margins; 3-year local recurrence; or overall survival. However, in the subgroup of patients who underwent laparoscopic versus open LAR, the CRM was positive in 12% versus 6% of the open LAR patients (p = 0.19).[70] Finally, robotic surgery for rectal cancer has emerged, and offers the advantages of three-dimensional vision and fine articulation for pelvic dissection.[71] In the United States, the ACOSOG Z6051 trial compared open to minimally invasive surgery for resection of locally advanced rectal cancer, and allowed several minimally invasive techniques in the experimental arm including hand-, laparoscopic-, and robotic-assisted techniques. The initial results of this trial are expected to become available in 2014. Currently available evidence appears to suggest that the number of resected lymph nodes and surgical margins were similar and laparoscopic and open TME had similar effects on five-year disease-free survival.[69]

Despite surgical resection of rectal cancer with curative intent, approximately 20% of the patients develop disease relapse, usually during the first 3 postoperative years. Local pelvic recurrences can be highly morbid, causing pain, bowel obstruction, hemorrhage, and malignant fistulization. The risk of relapse correlates with the T and N category of the tumor, as well as completeness of surgical excision[72] (Table 8-1). Local failure is also more common with a positive CRM.[47,73] Consequently, adjuvant therapy has evolved with the goals of preventing local tumor recurrence, eliminating distant metastases, and increasing both disease-free and overall survival.[74] Both preoperative and postoperative regimens of irradiation or chemoradiation have been developed. Although early trials mainly involved postoperative irradiation, the potential for tumor down-staging, less tissue hypoxia, and less exposure to small bowel in the radiation field has shifted the focus toward preoperative treatment. Two meta-analyzes showed that when compared with surgery alone, the addition of preoperative irradiation to surgery decreased the local failure rate (odds ratio [OR] 0.49; 95% CI 0.38 to 0.62; p<0.001)[75] and that the yearly local failure rate was 46% lower with preoperative irradiation (p<0.001) and 37% lower with postoperative irradiation (p=0.002).[76] In the era of TME surgery, the German Rectal Cancer Study Group trial demonstrated the added benefit of preoperative combination chemoradiation: the local recurrence rate was 6% with preoperative treatments versus 13% with postoperative treatments (p=0.006), although no difference was seen in overall survival.[77] Although a second trial of similar design, NSABP R-03, did not meet its accrual goal, a superior 5-year disease-free survival was observed in the preoperative versus postoperative arm (65% vs. 53%; p=0.011).[78] A 5-year local recurrence rate of 10.7% was reported for both treatment arms. Although preoperative combination chemoradiation has been widely adopted in the United States for nearly all T3-4 and patients with node-positive rectal cancer, its use is more selective in Europe. A recent trial from the Medical Research Council (MRC CR07) compared short-course preoperative irradiation with TME surgery and selective postoperative chemoradiation and demonstrated that preoperative treatment still led to a 6% lower 3-year local recurrence rate, although no difference was seen in overall survival.[79] Finally, based on pooled data from five phase III North American rectal adjuvant trials, selected patients with intermediate-risk rectal cancers (T1-2N1 and T3N0) might not need radiation therapy as a component of adjuvant treatment.[72] An ongoing trial ALLIANCE N1048 is investigating the feasibility of omitting pelvic radiation in select intermediate risk upper rectal cancers (treatment arms of preoperative chemotherapy versus preoperative chemoradiation).[80] Ongoing research continues to focus on finding the optimal treatment regimen that provides oncologic benefit but spares potential toxicities.

MANAGEMENT OF RETROPERITONEAL SOFT-TISSUE SARCOMA

Soft-tissue sarcomas constitute less than 1% of all malignant tumors in the United States. Approximately 15% of sarcomas arise in the retroperitoneum.[81] Retroperitoneal sarcomas provide a challenge for the surgical oncologist. Most patients with retroperitoneal sarcoma eventually die of their disease, despite never developing disease outside the abdomen. The locally invasive growth pattern, the lack of anatomic boundaries in the retroperitoneum, and the large size of most sarcomas at presentation make complete R0 resection difficult. The rate of complete gross tumor resection (R0 and R1), which was

TABLE 8-1 Rectal Cancer: Overall Survival and Risk of Relapse by TN Category

Risk for Relapse	TN Category	5-Year Local Recurrence (%)	5-Year Distant Metastasis (%)	5-Year Overall Survival (%)
Low	T1-2N0	≤5	10	90
Intermediate	T3N0, T1-2N1	7-9	15-20	65-73
Moderately high	T4N0, T3N1,T1-2N2	8-12	28-37	48-58
High	T4N1, T3-4N2	14-23	39-53	30-36

approximately 50% in major centers,[81] has increased to 67% to 75%.[82,83] The local recurrence rate at 5 years after complete surgical resection ranges from 40% to 50%.[82-85] Among patients who are disease free at 5 years, 40% will experience a relapse by 10 years after their operation.[86] Uncontrollable local recurrence is the most common cause of death from retroperitoneal sarcoma. Retrospective analysis of more than 1000 patients with retroperitoneal sarcoma found primary tumor size; tumor fixation to nerve, vessels, or bone; regional lymph node involvement (rare); presence of metastatic disease; and tumor grade predictive of survival.[87]

The most common presentation for retroperitoneal sarcoma is an abdominal mass or pain, or both. An abdominal CT scan establishes the extent of tumor, the relationship of the sarcoma to normal organs, the presence or absence of tumor necrosis, and the presence of liver metastases. CT scanning of the chest is performed to rule out pulmonary metastases. Diagnosis of a retroperitoneal sarcoma can be made by a needle or rarely incisional biopsy if preoperative treatment is planned. A limited biopsy to exclude metastatic testicular cancer or lymphoma is indicated before primary surgical resection when the diagnosis is in doubt.

The surgical treatment of retroperitoneal sarcomas consists of en bloc resection of the tumor plus adjacent organs invaded by or adherent to the sarcoma. Recent reports recommend removal of any adjacent organs regardless of apparent tumor involvement.[88,89] This is feasible for some sarcomas but not for others.[90] This policy has not been shown to give better results in a controlled study.[87] Most retroperitoneal sarcomas involve left- or right-sided retroperitoneal structures, with few arising in the midline. Because of their large dimensions, en bloc resection often requires ipsilateral nephrectomy and colectomy, partial small bowel resection, distal pancreatectomy, and splenectomy. Less frequently, a partial gastrectomy, pancreaticoduodenectomy, major hepatectomy, or vascular resection may be indicated. Any adherence of the sarcoma to an adjacent structure must be assumed to be malignant in nature. These structures should be excised en bloc whenever feasible. If extensive venous collaterals are present from vena caval occlusion, the inferior vena cava may be resected without reconstruction; a prosthetic graft reconstruction is indicated in other patients. An aortic resection and prosthetic reconstruction should be considered for a sarcoma encasing the aorta when the sarcoma can be completely excised. When a retroperitoneal sarcoma has an extensive volume of necrotic tissue, care must be used during mobilization to avoid tumor rupture.

Resection of a large retroperitoneal sarcoma en bloc is presented in Figures 8-6 and 8-7. This patient reported pain and had an abdominal mass. A preoperative CT scan image appears in Figure 8-6. The sarcoma filled the left upper quadrant, displacing the spleen and distal pancreas anteriorly. On abdominal exploration through a midline incision, the tumor was found to be limited to the left retroperitoneum. The stomach was not involved by tumor. After opening the lesser sac, the stomach was reflected cephalad. The splenic flexure of the colon was also uninvolved. It was retracted caudad, providing excellent exposure of the distal pancreas, spleen, left kidney, and anterior surface of the sarcoma (Figure 8-7, *A*). The neck of the pancreas was divided, allowing ligation of the splenic artery and vein (Figure 8-7, *B*). To minimize intraoperative bleeding, the vascular supply along the medial aspect of the sarcoma was ligated before the sarcoma was mobilized and en bloc resection was performed. The left renal artery and vein were then exposed and ligated (Figure 8-7, *C*). The resected retroperitoneal sarcoma with the distal pancreas, spleen, and left kidney are shown in Figure 8-7, *D*.

Because local tumor recurrence is the most common pattern of treatment failure, radiation therapy should theoretically improve results. Some retrospective series have suggested an improvement in the local control and survival of retroperitoneal sarcoma patients with adjuvant irradiation.[91,92] The large-field radiotherapy needed to treat the resection bed following retroperitoneal sarcoma excision can cause significant complications. IORT plus EBRT has been considered a better alternative to full-dose EBRT because of less toxicity to normal tissues. A prospective, randomized clinical trial performed at the National Cancer Institute compared IORT plus postoperative low-dose EBRT with postoperative high-dose EBRT alone. This study showed no statistically significant difference in survival rates between patient groups, but the pattern of disease failure differed between the two groups. Patients receiving IORT plus EBRT had significantly better local disease control within irradiation fields and a significantly lower prevalence of small bowel toxicity.[93] A trial sponsored by the American College of Surgeons Oncology Group to study whether adjuvant EBRT improved local control and survival rates compared with resection alone for patients with retroperitoneal sarcoma closed prematurely because of poor patient accrual. Currently, there is no proven survival benefit for the use of either adjuvant radiation therapy or chemotherapy for retroperitoneal sarcomas.

SUMMARY

Surgery is still the single-best treatment for most solid tumors in adults. The surgical oncologist must understand the biology of the particular malignancy. Accurate preoperative tumor staging is crucial in treatment decisions. The goal of surgical intervention may be potential cure or palliation. Adjuvant radiotherapy and chemotherapy should be used whenever evidence-based data show that they confer additional survival time or palliative benefit. The physiologic status of the patient must be established and maximized preoperatively to minimize surgical morbidity or mortality. The principles of surgical oncology, including complete en bloc tumor resection, should be followed whenever possible. Adequate postoperative healing must occur before adjuvant therapy starts. The survival of patients with most surgically treated cancers will likely improve as the result of improved nonsurgical treatments rather than more radical surgical procedures.

CHAPTER

9 Principles of Chemotherapy

Benjamin Izar, David P. Ryan, and Bruce A. Chabner

A BRIEF HISTORY

In the history of medicine, cancer was initially regarded as a localized disease, and engaged the primary attention of surgeons and radiation oncologists. Metastatic disease was regarded as untreatable. With the arrival of cancer chemotherapy in the form of alkylating agents, in the post–World War II era, it became possible for the first time to entertain the use of drugs to improve local control of cancer, to prevent distant recurrence after surgery, and even to cure systemic disease, as in childhood acute leukemia and choriocarcinoma. With the introduction of adjuvant therapy of breast cancer in the late 1960s the concept of even apparently localized cancer as a potentially systemic disease, which demands systemic therapy, was integrated into the thinking of cancer management in its earliest stages. However, progress in drug discovery was slow. At the time of the publication of the first trials of melphalan for adjuvant therapy of breast cancer in 1971, only a handful of agents were available for treatment of cancer and were primarily drugs developed for the treatment of leukemia. The addition of anthracylines, taxanes, and platinum analogs, and most recently targeted agents, has since that time vastly expanded the effectiveness and the range of uses of chemotherapy.

The history of cancer drug development begins with the initial trials of *alkylating agents* at Yale University, as first reported in 1946.[1] The Yale experiments proved that a systemically administered agent could cause regression of murine leukemia and ultimately a human tumor—in this case a mediastinal mass in a patient with Hodgkin disease. The conceptual basis for clinical studies of nitrogen mustard was the observation that mustard gases used in military campaigns produced lymph node depletion and bone marrow aplasia. Although it was known at the time that these compounds were highly reactive with proteins, nucleic acids, and other electron-rich molecules, the specific intracellular targets on nucleic acids were not identified until more than a decade later, and we are only now beginning to understand the reasons for the somewhat selective action of alkylating agents on tumor cells.

This early experience with alkylating agents led a number of bold investigators to undertake an alternative approach and search for compounds (antimetabolites) that would act as fraudulent counterparts of natural metabolites known to stimulate cancer cell growth. Among these metabolic targets, folic acid and nucleic acid bases proved most vulnerable (Figure 9-1). In the late 1940s, scientists from American Cyanamid synthesized analogs of folic acid, a vitamin known to stimulate the proliferation of cancer cells in culture and in humans. Sidney Farber, a pathologist, found striking but short-lived responses to the first antifolate, aminopterin, and its closely related analog, methotrexate, in children with acute lymphoblastic leukemia (ALL). Prospects for the treatment of leukemia with drugs escalated in the following decade, as new antimetabolites were discovered. Hitchings and Elion at Burroughs Wellcome successfully developed purine analogs, 6-thioguanine and 6-mercaptopurine. Soon afterward, corticosteroids, first used as antiinflammatory agents, were found to kill malignant lymphocytes in children with ALL and in adults and children with lymphoma. In response to the success of combination chemotherapy in childhood ALL, large-scale screening systems for anticancer drugs were initiated at the National Cancer Institute in 1955. These initial attempts at drug discovery tested random chemical libraries and natural product extracts against transplantable murine leukemias and later murine solid tumors, leading to the isolation of new cytotoxic compounds. The newly discovered compounds fell into four primary classes: agents that formed adducts with DNA, agents that blocked mitosis, agents that blocked the function of topoisomerases (DNA unwinding drugs), and antimetabolites.

Combinations of these drugs successfully overcome resistance to single agents and were able to cure childhood ALL and lymphomas. Solid tumor chemotherapy advanced more slowly. Through the discovery of 5-fluorouracil (5-FU), an analog of thymine and a highly potent inhibitor of thymidylate synthase, breast and colon cancer proved modestly responsive. Platinum analogs with potent DNA damaging activity were discovered to have antitumor activity in the early 1970s and, in combination, led to the cure of testicular cancer and to effective combination therapy of ovarian and colon cancer. In addition 5-FU and the platinum drugs were found to be radiosensitizers and improved local control in many tumors of the aero-digestive tracts.

Equally rewarding efforts in the field of natural product chemistry yielded valuable new anticancer drugs with unique mechanisms of action. Scientists at Eli Lilly discovered the antimitotic and antitumor properties of the vinca alkaloids. Shortly thereafter, analysis of fermentation broths led to the discovery of DNA damaging drugs such as mitomycin C, a novel alkylating agent; bleomycin, a DNA-cleaving peptide; and inhibitors of topoisomerase (anthracyclines, and camptothecins); and from natural product screening, even more potent antimitotic agents (paclitaxel and eribulin). Various drug combinations have become standard therapies for most metastatic tumors, and when combined with radiation treatment and surgery as adjuvant therapy, improved the 5-year survival of patients with cancer from 30% in 1950 to more than 60% in the year 2000.

The beginning of the 21st century has witnessed a major breakthrough for cancer treatment with the arrival of targeted therapies (Table 9-1).[2] The development of highly efficient technology for gene sequencing led to the identification of molecular alterations that cause malignancy and shifted the field of drug discovery from cytotoxics to therapies that selectively target oncogenic driver alterations. These driver mutations produce gene products that transform otherwise normal cells and create a tumor dependent for its survival on the specific activated pathway, a conditioned termed *oncogene addiction*. Inhibitors that shut down the target and its pathway lead to death of the cancer cell.

The goal of targeted therapy is not to induce DNA damage but is rather to inhibit specific signaling pathways that control proliferation, cell survival, invasion, metastases, or angiogenesis. A growing number of these agents are available and run the gamut from highly potent small molecules that inhibit

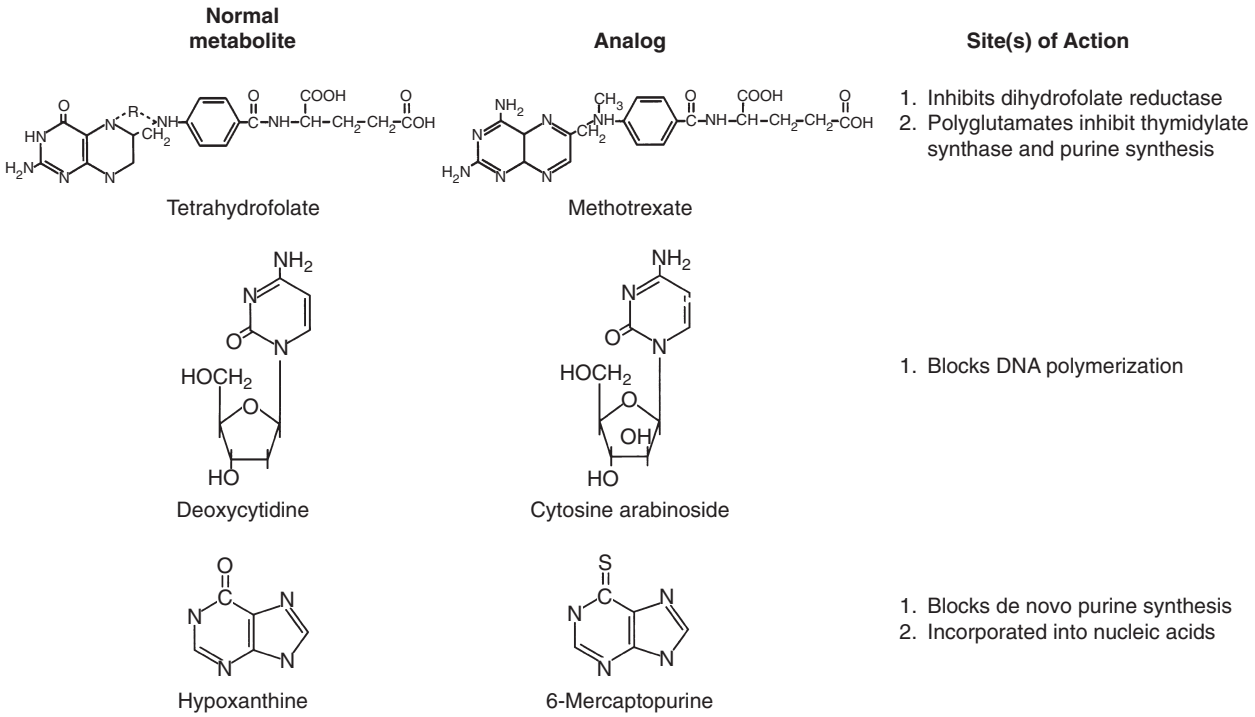

Figure 9-1 Examples of chemotherapy drugs that are analogs of natural metabolites.

TABLE 9-1 FDA-Approved Targeted Cancer Therapies

Drug	Class	Target	Application
Imatinib (Gleevec)	Benzamide	BCR-ABL, C-KIT	CML, GIST
Dasatinib (Sprycel)	Carboxamide	BCR-ABL, SRC, C-KIT, PDGFRβ	CML, Ph + ALL
Nilotinib (Tasigna)	Benzamide	BCR-ABL, PDGFR, C-KIT	CML
Ponatinib (Iclusig)	Benzamide	BCR-ABL (including T151I), PDGFR, C-KIT, SRC, RET	CML, Ph+ ALL
Bosutinib (Bosulf)	Quinolinecarbonitrile	BCR-ABL, SRC, LYN, HCK	CML
Omacetaxine mepesuccinate (Synribo)	Cephalotaxine	Unclear	CML
Gefitinib (Iressa)	Quinazolinamine	EGFR-TKI	NSCLC
Erlotinib (Tarceva)	Quinazolinamine	EGFR-TKI	Colorectal, NSCLC
Afatinib (Gilotrif)	Butenamide	EGFR, HER2, HER4	NSCLC
Crizotinib (Xalkori)	Pyridin-2-amine	ALK, ROS1, MET	NSCLC
Dabrafenib (Tafinlar)	Sulfonamide	BRAF, CRAF	Melanoma
Trametinib (Mekinist)	Acetamide	MEK1 and MEK2	Melanoma
Vemurafenib (Zelboraf)	Carboxamide	BRAF	Melanoma
Ipilimumab (Yervoy)	Recombinant human monoclonal antibody	CTLA4	Melanoma
Cetuximab (Erbitux)	Chimeric monoclonal antibody	EGFR extracellular domain	Colorectal, ENT
Panitumumab (Vectibix)	Human monoclonal antibody	EGFR extracellular domain	Colorectal
Regorafenib (Stivagra)	Carboxamide	RET, VEGF receptor 1-3, PDGFR, FGFR, and others	Colorectal
Bevacizumab (Avastin)	Humanized monoclonal antibody	VEGF	Colorectal, NSCLC, breast, glioblastoma
Ziv-Afilbercept (Zaltrap)	Fusion protein (VEGF-binding portion of VEGF receptors 1 and 2 fused to human IgG1)	VEGF1 and 2	Colorectal
Trastuzumab (Herceptin)	Humanized monoclonal antibody	HER2 extracellular domain	Breast
Lapatinib (Tykerb)	Quinazolamine	HER2 and EGFR-TKI	Breast
Pertuzumab (Perjeta)	Humanized monoclonal antibody	HER2	Breast
Rituximab (Rituxan)	Chimeric monoclonal antibody	CD20	Lymphoma
Tositumomab (Bexxar)	131I murine monoclonal antibody	CD20	Lymphoma

TABLE 9-1 FDA-Approved Targeted Cancer Therapies—cont'd

Drug	Class	Target	Application
Ibritumomab (Zevalin)	111In murine monoclonal antibody	CD20	Lymphoma
Brentuximab (Adcetris)	Antibody-drug conjugate (IgG1, MMAE and a linker)	CD30	Lymphoma
Ibrutinib (Imbruvica)		BTK	Lymphoma
Vorinostat (Zolinza)	Phenyloctanediamide	HDAC	Lymphoma
Romidepsin (Istodax)	Bicyclic depsipeptide	HDAC	Lymphoma
Dentileukin Difitox (Ontak)	Recombinant fusion of diphtheria toxin and IL-2	IL2-receptor(s)	Lymphoma
Bortezomib (Velcade)	Modified boronic acid	26S proteasome	Myeloma
Carfilzomib (Kyprolis)	Carboxamide	26S proteasome	Myeloma
Obinutuzumab (Gazyva)	Humanized monoclonal antibody	CD20	CLL
Ofatumumab (Arzerra)	Human monoclonal antibody	CD20	CLL
Alemtuzumab (Campath)	Humanized monoclonal antibody	CD52	B-CLL
Gemtuzumab (Mylotarg)	Calicheamicin linked to human monoclonal antibody	CD33	AML (CD33+)
Sunitinib (Sutent)	Butanedioic acid	VEGFR, C-KIT, PDGFR, RET, FLT3	Renal, GIST
Sorafenib (Nexavar)	Carboxamide	BRAF, FLT3, C-KIT, VEGFR, RET, PDGFRβ	Hepatocellular, renal
Everolimus (Afinitor)	Rapamycin derivative	mTOR	Renal
Temsirolimus (Torisel)	Macrolide	mTOR	Renal
Axitinb (Inlyta)	Benzamide	VEGF receptor 1-3	Renal
Pazopanib (Votrient)	Methylbenzenesulfonamide	VEGF receptor 1-3, PDGFR, FGFR1, C-KIT	Renal, sarcoma
Vandetanib (Vandetanib)	Quinazolin-4-amine	EGFR and VEGF	Thyroid
Vismodegib (Erivedge)	Benzamide	Smoothened (Hedgehog pathway)	Basal cell
Capozantinib (Cometriq)	Carboxamide	RET, MET, PDGFR, FGFR	Thyroid

AML, *Acute myelocytic leukemia;* B-CLL, *B-cell chronic lymphocytic leukemia;* CML, *chronic myelogenous leukemia;* GIST, *gastrointestinal stromal tumor;* NSCLC, *non–small cell lung cancer.*

specific targets such as receptor tyrosine kinases (RTKs), to monoclonal antibodies that block the same receptors, initiate immune responses against tumor antigens, carry cytotoxic payloads, or block tumor blood vessel formation. Monoclonal antibodies such as trastuzumab, cetuximab, and bevacizumab also enhance the effectiveness of chemotherapy, and cetuximab, an inhibitor of the epidermal growth factor receptor (EGFR), synergizes with irradiation (see Chapters 4 and 5). The role of targeted drugs in the overall management of cancers is continuously evolving. Targeted drugs used in sequence with or in conjunction with irradiation and chemotherapy are under active investigation in most solid tumors, lymphomas, and leukemia.

THE BASIS OF CHEMOTHERAPY: CANCER CELL BIOLOGY

Every phase of chemotherapeutic research, from discovery to clinical application, is based on our improved understanding of cancer cell biology (see Chapter 2). Cancer cells have unique properties that distinguish them from their normal counterparts and that form the basis for treatment. Among these properties are continuous and excessive proliferation, defective repair of DNA leading to high mutation rates and great population diversity, reduced rates of apoptosis (i.e., programmed cell death), altered metabolism to enhance lipids and nucleic acid synthesis, induction of nutrient vessels, ability to escape immune surveillance, and ability to invade neighboring tissues and to metastasize.[2] Many of these properties have been the starting point for successful drug discovery efforts.

Most cancer cells display defects in DNA repair that allow the rapid generation of a diversity of subclones, thus increasing their adaptation to adverse environments (low pH, poor nutrients), and increasing the probability of drug resistance. With a few notable exceptions, the successful cytotoxic drugs have attacked only the first of these properties, proliferation. The new generation of targeted agents is expanding the horizon for cancer treatment by addressing the full circle of biological changes in human tumors.

MODELS FOR CHEMOTHERAPY

In parallel with the discoveries of new drugs in the period from 1946 to 1970, Skipper and colleagues[3] at the Southern Research Institute and at the National Cancer Institute developed and characterized transplantable murine leukemias, notably L1210 and P388, as well as murine solid tumors such as sarcoma 180 and B16 melanoma. Their model systems allowed reproducible, quantitative experiments with chemotherapy and radiation therapy in mice. They established a rational basis for understanding the kinetics of cell kill, evaluating efficacy of drug combinations, and studying mechanisms of drug resistance. From their experiments emerged the theoretical basis for combination chemotherapy:

1. *Fractional cell kill.* Each dose of chemotherapy kills a constant fraction of the tumor cell population. Pharmacokinetic parameters correlate with cell killing. For example cell kill by alkylating agents increases linearly with dose and

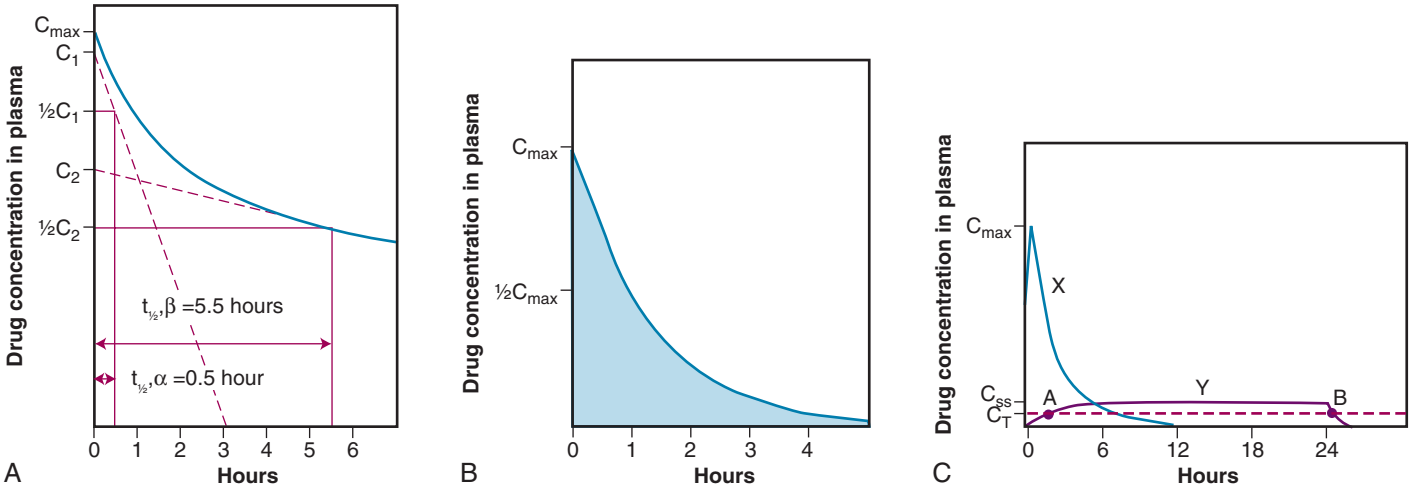

Figure 9-2 Drug elimination from plasma. **A,** The *solid blue curve* illustrates a semilogarithmic plot of drug concentration versus time after a rapid intravenous injection. The *dashed red line* intercepting the *y*-axis at C_2 represents an extrapolation of the log-linear terminal phase. The *dashed red line* that intersects the *y*-axis at C_1 is obtained by subtracting the extrapolated values of the log-linear terminal phase from the observed drug concentrations. Maximum drug concentration in plasma (C_{max}) = $C_1 + C_2$. The initial (α) phase half-life ($t_{1/2,\alpha}$) is the time for C_1 to decay to $\frac{1}{2}C_1$. The terminal (β) phase half-life ($t_{1/2,\beta}$) is the time for C_2 to decay to $\frac{1}{2}C_2$. This biphasic behavior results from distribution of the drug among rapidly and slowly perfused regions of the body, as well as its elimination. **B,** Drug concentration in plasma versus time is plotted on linear axes. The *blue shaded area* is the area under the curve (AUC); it represents the integral of drug concentration over time. The AUC is a measure of total systemic exposure to the drug. **C,** Linear plots of drug concentration versus time are illustrated for a rapid intravenous injection *(X)* and a 24-hour continuous infusion *(Y)* of the same total dose of drug (the AUCs are equivalent). Notice that the duration of drug concentrations above the threshold for cytotoxicity (C_T) is much longer with the continuous infusion (represented as B-A) than with the bolus administration. Conversely, the maximum plasma concentration achieved by bolus administration (C_{max}) is much larger than that of the continuous infusion (C_{SS}).

peak drug concentration, whereas for most other drugs, kill depends on the area under the curve describing drug concentration over time (or $C \times T$) (Figure 9-2). For other drugs, such as paclitaxel and for most of the targeted therapies, the *time of exposure above a threshold concentration* determines the cytotoxicity for tumor and for normal target tissues. For drugs that depend on continuous inhibition of the target, such as the receptor tyrosine kinase inhibitors, it is important to maintain a constant receptor-inhibiting drug concentration in plasma.

2. *Importance of dose intensity (dose per unit time).* During the time period between cycles of treatment, tumor cells resume proliferation. Short rest periods between treatment cycles, and higher doses of drug produce the best results.
3. *Drug resistance.* Exposure of tumors to single-agent chemotherapy rapidly results in outgrowth of drug-resistant cells. Biochemical studies of these drug-resistant cells disclosed a number of changes, including decreased drug uptake (methotrexate), increased drug export (anthracyclines and taxanes), enhanced DNA repair (alkylating agents and platinum analogs), mutations or amplification in the drug target (methotrexate and 5-FU), or loss of intracellular pathways required for drug activation (many nucleoside and base analogs such as 5-FU and fludarabine require phosphorylation). Combinations of drugs with different mechanisms of action and different mechanisms of resistance were able to cure lymphomas and leukemia that readily become resistant to single agents.
4. *Cell cycle dependency of cell kill.* Most anticancer drugs, particularly the antimetabolites, have their greatest effect on actively proliferating cells. Drugs that act on DNA synthesis damage cells during periods of DNA synthesis (S phase), whereas mitotic inhibitors produce cell kill through exposure of cells during mitosis (M phase) (Figure 9-3). The rate of cell proliferation slows and the number of nonproliferating cells increases with expansion of the tumor mass. Other factors such as poor perfusion and increased oncotic pressure discourage nutrient and drug entry into large, poorly vascularized tumor masses. Chemotherapy is most effective when the tumor burden is lowest and cell proliferation is most active, as in the adjuvant setting.

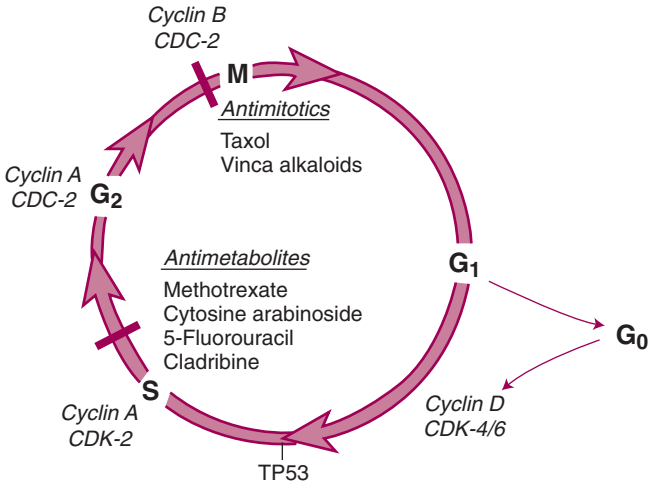

Figure 9-3 The cell cycle, its controls and checkpoints, and the site of action of cell cycle phase-specific drugs. The cell cycle phases are G_0 (nondividing cells), G_1 (resting phase), S (DNA synthesis), G_2 (gap between S and M), and M (mitosis). Transitions between phases are controlled by the appearance of specific cyclin proteins that complex with and activate cyclin-dependent kinases. The G_1/S transition is also controlled at a checkpoint by proteins such as TP53, which monitor DNA integrity. Other proteins monitor the G_2/M checkpoint.

These principles expounded in mouse models profoundly influenced all aspects of clinical chemotherapy, including regimen design, the use of drugs in combination, adjuvant

chemotherapy, and high-dose chemotherapy. Relying on these principles, the cure of ALL was accomplished through development of effective combination therapy. However, other measures were required to prevent relapse: the institution of intrathecal methotrexate and neuro-axis irradiation to eliminate central nervous system (CNS) leukemia, refinement of drug dosage and schedule to maximize drug efficacy, the implementation of maintenance methotrexate and 6 mercaptopurine,[4] and supportive care with platelets and antibiotics. Each of these insights, further refined by the use of new antinausea medications and bone marrow colony-stimulating factors, has become a basic component of modern chemotherapy.

SOLID TUMOR CHEMOTHERAPY

The principles enumerated have been applied with greatest success to the treatment of aggressive and rapidly proliferating tumors such as leukemias and lymphomas. The development of drug therapy for the more common solid tumors has taken a slower and more tortuous course. Drugs identified in mouse leukemia screening systems have been less effective against most solid tumors, notable exceptions being choriocarcinoma and testicular cancer, which can be cured with repeated cycles of intensive chemotherapy. However, new chemotherapies have improved survival of metastatic cancer: 5-FU, beginning in the 1950s, doxorubicin and cisplatin in the early 1970s, etoposide and paclitaxel in the late 1980s, the antimetabolites pemetrexed and gemcitabine in 1990s, and since 2000, a new antimitotic, eribulin[5]; a unique alkylator, bendamustine[6]; and an albumin encased taxane, abraxane.[7]

An important breakthrough in solid tumor chemotherapy was the proposal to employ drugs in the adjuvant setting after removal of the primary tumor in patients at high risk for relapse. Drugs that produced only partial responses in advanced disease could prevent disease recurrence in a significant fraction of women with Stage II (node positive) localized breast cancer. The conceptual basis for this strategy derived from experimental chemotherapy models that revealed that tumors are most susceptible to chemotherapy when the tumor burden is small and cells are actively proliferating. Cytotoxic drugs now have a firmly established role in the adjuvant treatment of lung, breast, and colorectal cancers either before or after surgery (see Chapter 4).

Newer concepts aimed at improving local control of otherwise inoperable tumors have led to so-called neoadjuvant, or induction, therapy.[8] In this strategy, drugs are used alone or in combination with radiation therapy, before surgery, in the initial treatment of locally advanced tumors of the breast, head and neck, bladder, rectum, and lung (see Chapter 4, Tables 4-2 to 4-7). This preoperative therapy reduces the size of otherwise unresectable tumors to a point where total surgical removal is feasible, less morbid and organ preserving, or, in some cases, such as anal cancer, even unnecessary. A new paradigm for drug approval has been established with the Food and Drug Administration's (FDA's) accelerated approval of the monoclonal antibody, pertuzumab, for neoadjuvant therapy of HER2+ breast cancer, based on improvements in the pathological complete remission rate at the time of surgery.[9]

Advances in bone marrow stem cell harvesting from peripheral blood, their storage, and reinfusion after high-dose chemotherapy has allowed escalating drug dosage and increasing dose intensity. In this setting, high-dose chemotherapy followed by marrow stem cell infusion is remarkably safe and reliably cures a significant minority of patients with relapsed lymphomas and relapsed or high-risk leukemia and a fraction of patients with relapsed testicular cancer. As they become safer to use, high-dose regimens may be employed in earlier stages of disease to enhance the cure rate of otherwise incurable cancers in patients, although the value of this approach for most solid tumors is unproven

DRUG INTERACTIONS WITH IRRADIATION

Because most patients with cancer now require multimodality therapy, even for early-stage tumors, it is important to understand the potential benefits and risks of drug interaction with irradiation.[10] The biological basis for these interactions and the rationale for current regimens are presented in Chapters 4 and 5. To be effective, irradiation requires the presence of oxygen to produce toxic oxygen radicals and is countered by the cell's attempts to scavenge the radicals and repair DNA damage. Radiosensitizers can act by increasing oxygenation, creating new DNA breaks, depleting scavengers of oxygen free radicals, or blocking repair of DNA breaks. Each of these properties has been the subject of intensive clinical investigation. The most favorable of these interactions identified thus far stem from the radiosensitizing properties of three drugs, often used in combination with irradiation: 5-FU, a drug that inhibits thymidylate synthase and thereby blocks DNA synthesis; platinum analogs, which form adducts with DNA, create DNA breaks, and deplete free radical scavengers such as sulfhydrils and glutathione; and mitomycin C, which forms free radicals and DNA adducts in hypoxic environments. Other drugs, particularly gemcitabine, doxorubicin, and bleomycin, are extremely potent radiation sensitizers, and generally should not be used simultaneously with irradiation for fear of serious toxicity to heart, lungs, and other normal tissues. The potential value of combining irradiation with antivascular endothelial growth factor (anti-VEGF) therapies, which normalize tumor blood vessels and improve oxygenation and drug deliver, is reviewed in Chapter 5 and is again intriguing, but unproven.

Most recently, inhibitors of DNA repair have entered clinical trial. Oliparib blocks the function of polyadenosyl ribose polymerase (PARP), a central component of base repair; it has antitumor activity in patients harboring breast cancer or serous ovarian cancer with defects in homologous DNA repair due to BRCA 1 or BRCA 2 mutations, and has interesting, but unproven potential for enhancing radiation damage to DNA in tumors with DNA repair defects such as BRCA 1 or 2 mutations (see Chapter 4).

Drugs and irradiation may share common mechanisms of tumor cell resistance. Increased proficiency of repair of double strand breaks may impair the response to both irradiation and to several classes of antitumor drugs, including alkylating agents, platinum analogs, and topoisomerase inhibitors (see Chapter 4). Cells with defects in apoptosis and checkpoint function (TP53 mutation) fail to initiate apoptosis in radiation resistant tumors. Stem cells, both cancer related and normal varieties, are inherently resistant to reactive oxygen damage and overexpress the multidrug resistance (MDR) transporter.[11] Tumor stem cells are quiescent regarding cell cycle progression and may reside in hypoxic niches within tumors. The epidermal-to-mesenchymal phenotypic transition (EMT), with distinctive cell surface markers[2] and a drug-resistant profile similar to that seen in stem cells, appears to be a common event in drug- and radiation-resistant tumors. New drugs designed to reactivate apoptotic pathways (BCL2 inhibitors) and cell checkpoint function (HMD2 inhibitors), and inhibitors of the PI3 kinase cell survival pathway are of particular interest in reversing EMT changes.

Because drugs have become an integral part of the initial therapy of many patients with cancer, it is essential that the medical oncologist, surgeon, and radiation oncologist understand the principles of chemotherapy and the specific features of the commonly used agents.

THE CYTOTOXIC DRUGS: TARGETING DNA SYNTHESIS AND MITOSIS

The cytotoxic drugs in current clinical use act directly on the synthesis or integrity of DNA. These drugs may inhibit synthesis of DNA or its precursors, block cell division, inhibit necessary changes in DNA topology, or covalently bind to DNA, causing strand breaks or miscoding. All such drugs affect the integrity of DNA, and in the presence of the normal machinery (TP53) for monitoring DNA integrity, they induce apoptosis. Unfortunately, they are also cytotoxic toward normal cells. The reasons for their somewhat selective toxicity for malignant versus normal cells, as is apparent in the cure of lymphomas and leukemias, are poorly understood. The process of malignant transformation may enhance sensitivity to DNA damage by virtue of defects in DNA repair, although at the same time these same defects expand tumor cell diversity and encourage drug resistance. Many of the defective genes responsible for inherited cancer syndromes, such as *BRCA1* and *BRCA2* genes, mismatch repair genes, *TP53*, and nucleotide excision repair defects, create sensitivity to irradiation and to agents that inhibit aspects of DNA repair.

In designing clinical regimens, the relationship of drug action to the cell cycle is of particular importance because this knowledge serves as the basis for combining drugs and sequences in clinical practice and influences their use in combination with radiation therapy. The cell cycle and its primary controls are shown in Figure 9-3. Antimetabolites such as methotrexate, 5-FU, cytosine arabinoside, gemcitabine, and the purine antagonists kill cells that are actively synthesizing DNA; therefore, they are cell cycle dependent. Nucleoside analogs, including cytosine arabinoside, fludarabine phosphate, and cladribine, must be incorporated into newly synthesized DNA to be cytotoxic. Alternately, other agents such as the camptothecins, etoposide, and doxorubicin produce DNA strand breaks at any stage of the cell cycle, and are less dependent on cell cycle events for cytotoxicity, although these breaks may become lethal only as the cell crosses a checkpoint and enters DNA synthesis. Antimitotic agents, constituting a separate class of drugs, block the formation of the mitotic spindle and thereby prevent separation of chromosomes to the daughter cells. Drugs of this class are therefore effective against cells during the mitotic phase of the cell cycle. Still others, such as alkylating agents and platinum compounds, bind covalently to DNA and produce strand cross-links and strand breaks. Their toxicity seems less dependent on cell cycle stage.

Once it has been damaged through its encounter with a cytotoxic drug, the cancer cell has several options, and its eventual viability depends on which pathway it takes. If the normal monitors for genomic integrity (including most prominently the product of the *TP53* gene) are intact, the cell may halt further progression in the cell cycle while its DNA is repaired. If the damage is sufficiently extensive, TP53 may initiate apoptosis. If, however, TP53 function is absent, cell cycle progression may continue past the G1-S checkpoint despite drug-induced DNA damage, and the cell may prove viable. In most experimental settings, lack of wild-type TP53 is associated with drug and irradiation resistance. Paradoxically, some DNA repair defects, as found in mismatch repair (colon cancer), are associated with resistance to thio-purine analogs, platinum analogs, and alkylating agents, perhaps as a result of a failure to respond to DNA adducts and to initiate apoptosis.

From a theoretical viewpoint, it is understandable that rapidly dividing tumor cells, such as those found in acute leukemia, high-grade lymphoma, and choriocarcinoma, may be exquisitely sensitive to antimetabolites and cell cycle–specific drugs. How do these drugs kill the more slowly dividing solid tumors? Many of these tumors have long cell cycles (4 to 5 days). Many cells are in the G0 phase (nondividing state), and at any moment, only 1% to 3% of cells are in S phase. Cell kinetic factors diminish the effectiveness of chemotherapy, and the disordered vascularization of tumors may also contribute by limiting drug entry into areas of slow blood flow. Despite these disadvantages, solid tumor chemotherapy produces meaningful responses. Several factors, including pharmacologic, pharmacokinetic, and tumor cell-specific factors likely contribute to solid tumor killing by cycle specific or cycle sensitive drugs:

1. Drugs such as paclitaxel and doxorubicin clear slowly from the blood stream and the extracellular space. Alternative regimens, such as prolonged drug infusion, seem to increase the activity of 5-FU and paclitaxel, compared with the results of bolus administration.
2. Other drugs, such as methotrexate, which forms an intracellular polyglutamated species, and gemcitabine, which forms a long-lived intracellular triphosphate, persist inside the cell long after their disappearance from plasma.
3. As mentioned, tumor cells may be less able to repair DNA and more susceptible to cell death induced by DNA damage than their normal counterparts. For example, transformed mouse embryo fibroblasts have a heightened sensitivity to cancer drugs compared with their nontransformed parent, provided they have wild-type *TP53* genes.[12]
4. Underlying the tumor proliferation rate is a significant death rate that results from a number of factors, such as hypoxia, nutrient deprivation, disordered DNA synthesis, and mitosis, and, in general, a high-background rate of mutation that affects genes essential for cell integrity and survival. A small shift in the balance between cell proliferation and cell death may lead to regression of a tumor, despite its low growth fraction

DRUGS THAT INDUCE DIFFERENTIATION

Although differentiation inducers have long attracted interest for cancer drug development, only a small number of compounds have reached clinical evaluation. 5-aza-cytidine and its close congener, 5-aza-2′deoxycytidine are both approved for treatment of myelodysplastic syndrome. They induce differentiation by irreversibly inhibiting DNA methyl transferase. They are modestly myelosuppressive but induce the production of both myeloid and erythroid lineages and reduce transfusion dependence in MDS.[13]

A more compelling example of differentiation induction is provided by all trans-retinoic acid (ATRA), which binds to the mutated retinoic acid receptor created by the RAR-PML translocation in acute promyelocytic leukemia (APL), thereby inducing differentiation and remission. Its primary toxicity is a syndrome of pulmonary failure resulting from clogging of small vessels by the mature leukemic granulocytes. Arsenic trioxide is a second agent capable of induction of differentiation in APL. It promotes degradation of the translocated fusion protein, produces free radicals, and has antiangiogenic properties as well. Its toxicities include the pulmonary failure syndrome seen with ATRA, prolongation of the PR interval, arrhythmias that are accentuated by potassium (K+) and magnesium (Mg+) depletion, and hyperglycemia.

IMMUNOTHERAPY

Immunotherapies have been the object of much research attention, but only in the past decade have drugs of this kind proved useful. Monoclonal antibodies have clearly won a place in the standard regimens for treatment of lymphoma

(brentuximab for Hodgkin disease and rituximab for B-cell lymphomas), breast cancer (traztuzumab, pertuzumab, and TDM1 for Her-2 positive tumors), and cetuximab and panitumumab for colorectal cancer. Their mechanisms of action may simply be engagement and inhibition of a receptor necessary for survival, but auxiliary actions such as antibody dependent cellular cytotoxicity may play a role. The newest additions to immunotherapy include anti CTLA-4 and anti-PD1 and antiPDL-1 antibodies, which release autoimmune antitumor responses; these have shown remarkable long-term responses in melanoma, kidney cancers, and adenocarcinoma of the lung.[14-17] Even more impressive are the massive antitumor effects of chimeric antigen receptor T cells in which T-cell receptors are engineered to recognize the CD-19 auto-antigen antigen and destroy all B cells, physiological and malignant, including B-cell lymphomas and leukemias.[18]

TARGETED THERAPIES: SIGNAL TRANSDUCTION INHIBITORS

Expanding knowledge of the biology of cancer cell growth and death and the processes that regulate differentiation has provided a new set of targets for cancer treatment. Excessive proliferation of tumor cells has many causes; observations of tumor biology in model systems and in well-studied human cancers have shown that the proliferative drive may result from mutations that stimulate cell division as, for example, mutated growth factor receptors, whereas other mutations free the cancer cell from normal cell cycle controls through loss of suppressor functions such as mutations in the cell cycle checkpoint, TP53, or mutations in the retinoblastoma pathway. Still other mutations promote cell survival as occurs with activating mutations in the PI3-kinase pathway and activation of antiapoptotic proteins such as BCL-2 (see Chapter 2).

Drug discovery efforts have targeted specific activated pathways and mutations that promote proliferation and cell survival (see Table 9-1).[19] Inhibiting the function of a dominant gene product is a classic problem in cancer drug discovery. In the late 1980s, the first efforts at targeted inhibition led to development of inhibitors of the K-RAS protein, a signal transducer that links growth factor receptors to the MEK-ERK downstream cascade. K-RAS is mutated in 80% to 90% of pancreatic cancers and provides the proliferative drive in subsets of patients with non–small cell lung cancer (NSCLC), acute myelogenous leukemia, and colorectal cancers. The K-RAS protein is activated by an enzymatic step that attaches a lipid tail (a farnesyl group) to its near-terminal cysteine. Although inhibitors of farnesylation caused regression of experimental K-RAS-driven tumors, these drugs failed in clinical trials because the inhibitors lacked specificity for farnesylation of K-RAS, and alternative pathways for lipid modification of K-RAS circumvented the inhibition. New K-RAS strategies now focus on blocking a unique binding pocket in the G12C mutation, or downstream inhibition of the MEK-ERK pathway activated by mutant K-RAS.[20]

The first successful targeted small molecule emerged from studies of the BCR-ABL kinase in chronic myeloid leukemia (CML). In 1998, Druker introduced imatinib, an adeno triphosphate (ATP) competitive inhibitor that produced molecular remissions in a high percentage of patients who had progressed on standard chemotherapy. Imatinib produces long-term disease control, with normalization of both blood counts and cytogenetics in more than 90% of previously untreated patients in the chronic phases of the disease. Newer inhibitors, nilotinib, busotinib, and dasatinib, kill CML cells with mutations that confer resistance to imatinib. The newest and most potent BCR-ABL inhibitor, ponatinib, has sustained activity against virtually all resistant cell lines, including T315I, and was approved for the treatment of resistant CML and Philadelphia chromosome positive ALL.[19]

The success of imatinib has spawned an ever-increasing number of successful targeted agents (see Table 9-1). A parallel development in chronic lymphocytic leukemia (CLL) has led to the success of ibrutinib, an inhibitor of the Bruton tyrosine kinase, a key mediator of B-cell receptor signaling and early B-cell proliferation. The drug is approved for second line CLL and mantle cell lymphoma.[21] Its toxicities are limited to diarrhea, rash, and mild hepatic enzyme elevations. It does not produce profound immunodeficiency, as compared to the highly immunosuppressive anti-CD20 antibody, rituximab.

Imatinib also inhibits the KIT (CD117) receptor and proved to be the first targeted small molecule effective in the management of a solid tumor, in this case metastatic gastrointestinal stromal tumor (GIST). The presence of specific activating mutations within the *KIT* gene predicts for response in patients with GIST (see Table 9-1). The multitargeted tyrosine kinase inhibitor, sunitinib, has demonstrated benefit in patients with imatinib-refractory GIST, even in those with *KIT* mutations that are typically resistant to imatinib.[19]

Downstream of RTKs, other phosphorylation steps, when constitutively activated by mutation, may lead to malignancy and may be successfully targeted by small molecules. A striking example is presented by B-RAF inhibitors for melanoma. More than 50% of advanced stage melanomas carry a mutation of *B-RAF*, most commonly resulting from V600E or V600K mutations (BRAFV600E or BRAFV600K), which are transforming alterations that produce constitutive activation of the downstream MEK/ERK pathway and cancer cell proliferation. Vemurafenib, a selective inhibitor of the mutated BRAF protein, with limited inhibition of the wild type enzyme, produced an unparalleled 80% antitumor response rate in patients with advanced melanomas. A subsequent study showed that the combination of another BRAF inhibitor, dabrafenib, with a MEK inhibitor, trametinib, was superior to monotherapy with dabrafenib. The response rate in the cohort receiving combination therapy was 76% and a progression-free survival of 9.8 months compared with 5.8 months in the monotherapy groups, leading to approval of both new drugs in 2013.[22] It is noteworthy that the same mutation in *B-RAF*, V600E, found in melanoma also occurs in subsets of colorectal cancer, thyroid cancer, and NSCLC. Although lung and thyroid cancers with B-RAF mutations do show sensitivity to B-RAF inhibition, colorectal cancers of this type are unresponsive, indicating that the tissue context of the mutation may be important in determining response.[19]

RECEPTOR TYROSINE KINASES AS TARGETS

Mutations or translocations in genes coding for RTKs cause epithelial cancers arising in subsets of patients with lung, colon, thyroid, and breast tumors. These RTK mutations constitutively activate the kinase function of EGFR, EML4-ALK, and ROS-1 in NSCLC, C-KIT in melanoma and gastrointestinal stromal tumors, and RET in medullary thyroid cancer. The net effect is to create a cell under constant proliferative stimulus. Cells with these mutations become addicted to the aberrant signal and die when the signal is interrupted. Most clinically effective kinase inhibitors target the ATP binding pocket of the RTK.

EGFR inhibitors have proved useful in NSCLC. EGFR is overexpressed in many solid tumors and plays a critical role in activating downstream molecules that control cell cycle

progression, proliferation, angiogenesis, and survival. Subsequent trials have revealed that this new class of drugs is highly effective for the 10% of patients with NSCLC with tumors that harbor *activating mutations* in EGFR, but there is no clear benefit in the 40% to 80% of NSCLCs that overexpress *nonmutated* EGFR. Activating mutations caused by deletions or base substitutions clustered around the ATP-binding pocket of the tyrosine kinase domain of EGFR. Seventy percent of EGFR-mutated tumors respond initially to erlotinib. The median duration of response is 10 months, exceeding the results of chemotherapy by 3 to 4 months. The benefits of erlotinib and gefitinib are offset by important toxicities, including acneform rash and diarrhea. Resistance arises through further mutations in the ATP-binding pocket of the receptor, or by activation of the c-MET pathway. A second-generation EGFR inhibitor, afatinib, with greater potency of binding, produced a highly significant improvement in response rate and progression-free survival, compared to conventional chemotherapy for relapsed patients. Third-generation inhibitors from Astra-Zeneca and Clovis, which irreversibly bind to mutant EGFR and specifically block the mutant receptor, remain active against EGFR-resistance mutations such as T790M, have much reduced toxicity to bowel and skin, and produce clinical responses in patients resistant to erlotinib, according to early clinical experience.

Cetuximab, a chimeric IgG1 monoclonal antibody targeting the extracellular portion of the EGFR, is not active against lung adenocarcinoma with wild type or mutated EGFR, but is approved for the treatment of chemotherapy-refractory colorectal cancer. The addition of cetuximab to irinotecan results in nearly doubled response rates, as compared to irinotecan alone.[19] Panitumumab, another monoclonal antibody targeting the EGFR, improved progression-free survival rates compared with placebo in patients with chemotherapy refractory. Responses are more frequent in patients who develop the typical acneform rash associated with these agents. More importantly, patients who have activating mutations of K-RAS or BRAF derive no benefit from these EGFR antibodies. Cetuximab enhances local disease control with irradiation in squamous cell carcinoma of the head and neck.[23]

Other subsets of NSCLC contain unique RTK translocations that have been successfully targeted. The *EML4-ALK* translocation activates the anaplastic large-cell kinase RTK in 4% of patients with NSCLC. In a phase I/II trial of the MET/ALK inhibitor, crizotinib, patients possessing the ALK fusion protein exhibited a 53% clinical response rate, with an additional 20% of patients having stable disease for prolonged periods, findings confirmed in a phase II trial. This agent also has activity against other *ALK* driven tumors, including anaplastic large cell lymphoma and inflammatory myeofibroblastic sarcomas.[19] Resistance to crizotinib develops in the form of mutations in the ATP-binding site of the fusion kinase. A series of second-generation inhibitors, insensitive to these crizotinib-resistance mutations, have strikingly high response rates in *EML4-ALK* mutated tumors and will likely displace crizotinib as primary therapy (Shaw, A. New Engl J Med, in press). Crizotinib is also active against kinases associated with an activating translocation of the ROS-1 RTK,[24] found in 1% of NSCLC.

HER2-DIRECTED THERAPY

HER2 (EGFR 2 or ERB B-2), is a RTK activated by heregulin. It lacks the ability to signal downstream but promotes proliferation and survival through dimerization with one of the other EGFR receptor family members, preferentially HER3. As a dimer, it signals through both the MAP kinase and PI3K/AKT pathways. About 25% of breast cancers demonstrate amplification of the *HER2* gene, resulting in ligand-independent cancer cell proliferation and survival. *HER2* amplification is associated with a more aggressive phenotype and worse clinical outcomes. Trastuzumab, a monoclonal antibody against HER2, is approved for the treatment of metastatic HER2-positive breast cancer. Although monotherapy with traztuzumab shows modest efficacy, its combination with taxanes or other chemotherapies in HER+ breast cancer results in improved response rate, disease-free survival, and overall survival and decreased recurrence in adjuvant therapy, as compared with chemotherapy alone.[25] Trastuzumab also shows efficacy with chemotherapy for *HER2* amplified gastric adenocarcinomas.[26]

A newer antibody, pertuzumab, blocks HER2 dimerization with HER 3 and prevents signaling through HER3. In combination with trastuzumab and docetaxel, pertuzumab improved progression-free survival (18.5 months versus 12.4 months) and overall survival in metastatic disease[27] and yielded an improved pathological complete response rate in presurgical treatment of breast cancer (neoadjuvant therapy). A growing number of targeted therapies are being tested, with the aim of gaining accelerated approval by demonstrating improvements in pathological CR rates in neoadjuvant trials of early breast cancers.

Small molecules that compete with ATP are also effective in blocking HER2 signaling. Lapatinib, a selective HER2 and EGFR inhibitor, proved effective with capecitabine in the treatment of HER2-positive breast cancer, after progression on traztuzumab.[19] In combination with traztuzumab and a taxane, lapatinib enhances time to progression in first-line therapy.[25]

Trastuzumab has also been used as a carrier of a highly toxic maytansine derivative, emtansine. Trastuzumab-DM-1 (TDM-1), approved in 2013 for the treatment of HER2-positive breast cancer after progression on trastuzumab, produced superior progression-free survival (9.6 months versus 6.4 months) and overall survival (30.9 months versus 25.1 months), as compared with lapatinib plus capecitabine.[9]

PI3 KINASE AS A TARGET FOR CANCER THERAPY

Intracellular regulatory pathways have attracted the interest of drug discovery programs. The phosphatidylinositol-3-kinase (PI3K) pathway (Figure 9-4) receives signals from a number of RTKs; these signals activate proliferation and exert prosurvival effects through down-regulation of the intrinsic pathway of apoptosis. Multiple components of this pathway, especially the PI3K alpha (breast, endometrial, lung, and colon cancer) and delta (lymphomas) iso-enzymes, display amplification or mutations in human cancer. The PTEN phosphorylase, a suppressor of the pathway, is frequently inactive or deleted in breast cancer and other tumors. Inhibitors of sequential components of this pathway, including PI3CA inhibitors for metastatic breast cancer and the PI3K delta inhibitor idelalisib, used with rituximab for chronic lymphocytic leukemia,[28] have shown promising activity in early trials.

mTOR occupies a central position in the downstream signaling pathway for PI3K. It forms multiprotein complexes that signal for proliferation, survival, and angiogenesis and modulate intermediary metabolism. mTOR inhibitors specific for the TORC1 complex have been approved for cancer indications, including the immunosuppressive rapalogs, temsirolimus for patients with high-risk renal cell carcinoma, and everolimus for the same disease refractory to immunotherapies. Everolimus is also approved for mantle cell lymphoma and for carcinoid and peripheral neuro-ectodermal tumors, and in combination with examestane for hormone refractory breast cancer. The mTOR inhibitors cause interstitial lung

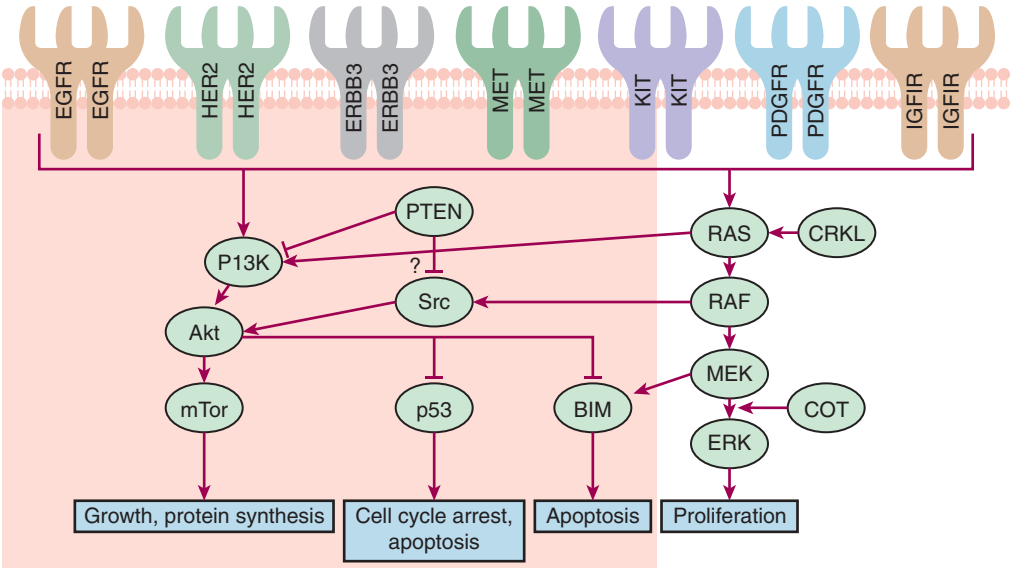

Figure 9-4 Physiology of major transmembrane tyrosine-kinase receptors and associated intracellular pathways. Receptors are displayed as homodimers. Note that most of these receptors may form heterodimers to activate the same intracellular pathways. The blue background highlights intracellular tyrosine kinases of the PI3K/AKT pathway; the yellow background highlights the RAS/RAF/ERK pathway. There is crosstalk between both pathways on multiple levels, three of which are displayed, including RAF-dependent Src-activation, MEK-dependent BIM-activation and RAS-dependent PI3K activation.

disease as a major complications, along with rash, diarrhea, and hepatic toxicity and may augment myelosuppression as a result of chemotherapy.[19] Newer mTOR inhibitors block both TORC-1 and TORC-2 complexes, as well as upstream kinases, and may show improved therapeutic effects.

PROTEASOME INHIBITION

In 2003, the FDA approved bortezomib, a proteasome inhibitor, for patients who have progressed while receiving prior therapy for multiple myeloma. It blocks the chymotryptic activity of proteasome degradation of key proteins and thereby blocks activation of nuclear factor kappa B (NFκB), a potent survival factor for cancer cells. It is currently approved for first-line therapy for multiple myeloma in combination with dexamethasone, and second-line therapy of mantle cell lymphoma. A more potent successor molecular, carfilzomib, also a proteasome inhibitor, has impressive antimyeloma activity and less neurotoxicity in second-line treatment.[19] Their other toxicities are occasional myelosuppression and diarrhea.

ANGIOGENESIS ANTAGONISTS

Although most drug discovery efforts are aimed at pathways and targets that govern the balance of cell proliferation and cell death, other unique aspects of cancer biology have attracted notice, particularly tumor blood vessel formation, Angiogenesis has been traced to tumor cell secretion of factors such as basic fibroblast growth factor, angiopoeitins, and VEGF. Specific inhibitors of this process, such as anti-VEGF antibody (bevacizumab) (see Table 9-1) and anti-VEGFR small molecules (sunitinib, pozatinib, vandetanib, and sorafenib), are now approved for multiple clinical indications.[19]

In 2004, the humanized monoclonal antibody bevacizumab was approved for the first-line treatment of metastatic colorectal cancer in combination with chemotherapy and subsequently with chemotherapy for first-line treatment of ovarian and lung cancer and for recurrent glioblastoma multiforme after first-line therapy. Compared with chemotherapy alone, the addition of bevacizumab to chemotherapy in metastatic colorectal cancer and metastatic cervical cancer improved the response rate, progression-free survival rate, and overall survival rate.[29,30] Bevacizumab also extends progression-free survival as a single agent in renal cell carcinoma, and in combination with temozolamide and radiation therapy in glioblastoma multiforme but does not extend overall survival for those indications. Bevacizumab has multiple effects on tumor perfusion and drug access. A study of neoadjuvant 5-FU combined with radiation therapy for T3 rectal cancer demonstrated a decrease in tumor perfusion, vascular volume, microvascular density, and interstitial fluid pressure after administration of bevacizumab.[31] As a class effect, the antiangiogenic drugs reduce interstitial pressure and improve oxygenation to enhance irradiation effects, and improve delivery of cytotoxic chemotherapy to the tumor, enhancing the radio- and chemosensitizing properties of the drug.

Other antibodies target EGFR by using a decoy receptor. Ziv-afilbercept, a recombinant fusion protein of IgG and VEGFR, binds circulating VEGF. Added to FOLFIRI, it doubled the response rate and marginally improved survival in refractory metastatic colorectal cancer, as compared to FOLFIRI alone.[19]

Small molecules effectively inhibit VEGFR by competing with ATP for the intracellular kinase site on the receptor molecule. Many of these compounds inhibit other tyrosine kinases. Sunitinib inhibits VEGFR2, c-KIT, and platelet-derived growth factor receptor (PDGFR). In a phase III trial comparing sunitinib with interferon-alfa in patients with metastatic renal cell carcinoma, sunitinib produced a superior response rate and progression-free survival. Sunitinib improved time to tumor progression in patients with GIST resistant to imatinib therapy and lengthened survival in patients with unresectable or metastatic peripheral neuro-ectodermal tumors. It received approval for these three indications.[19]

Other antiangiogenic compounds have been approved for clinical use. Sorafenib, an inhibitor of B-RAF kinase and VEGFR2, is approved for unresectable hepatocellular carcinoma on the basis of an improvement in overall survival.

Sorafenib also improved survival rates when compared with placebo in patients with metastatic clear cell carcinoma of the kidney. Axitinib produced longer progression-free survival than did sorafenib as second-line therapy for renal cell carcinomas.[32] Pazopanib has also won approval for renal cancers and soft-tissue sarcomas.[19]

It is notable that the antiangiogenic drugs produce significant toxicity: hypertension with occasional congestive heart failure, proteinuria, rare episodes of intestinal perforation (usually in patients who have undergone abdominal surgery), thrombosis, and hemorrhage, and for the oral compounds, diarrhea, fatigue, and hepatic enzyme elevations.[19]

Thalidomide and its analogs, also called immunomodulatory derivatives (IMIDs) have defied categorization with respect to their mechanism of antitumor activity. Originally used as a sedative and then as a the treatment for erythema nodosum leprosum, thalidomide and its IMID analogs have antiangiogenic and anticytokine properties, suppressing TNFα, IL-12, IL-6, and NFκB. Analogs are known to destabilize cyclin D complexes and promote ubiquitination of key lymphocyte transcription factors, IKZF1 and IKZF.[33] More potent and less sedating derivatives, lenalidomide and pomalidomide, are highly active in multiple myeloma and mantle cell lymphoma, and have notable activity in other lymphomas and chronic leukemias. Lenalidomide produces hematologic remissions in the 5q-forms of myelodysplasia. The side effects of the IMIDS include peripheral neuropathy, diarrhea or constipation, and venous thrombosis, especially when used in combination with dexamethasone, and lenalidamide is associated with an increased rate of second malignancies when used with melphalan.[34]

EPIGENETIC MODIFIERS

Epigenetics is a rapidly expanding area of research that examines the control of gene expression by histones and by DNA methylation. Histones couple with DNA and, in their unmodified state, block access by polymerases and transcription factors. Methylation, acetylation, or phosphorylation of histones decompacts chromatin, increases gene expression, and can induce differentiation and apoptosis in tumor cells. Histone deacetylase inhibitors (HDACs) are a new class of antitumor drugs that can induce cell cycle arrest and differentiation. They may cause hyperacetylation of nonhistone proteins as well, including TP53, HSP90, RAF, AKT, HER2, and BCR-ABL. Through their effects on acetylation of histones and key oncoproteins, they exert valuable antitumor activity in cutaneous and peripheral T-cell lymphomas. They may also serve as radiation sensitizers.[35] Two agents of this class, vorinostat and romidepsin, are FDA approved for patients with cutaneous T-cell lymphoma. Their most common side effects are diarrhea, fatigue, nausea, and loss of appetite, but they may also prolong the cardiac QT interval and may induce arrhythmias. They are currently being studied in combination therapy of multiple solid tumors.

OPTIMIZING CLINICAL CHEMOTHERAPY: PHARMACOKINETICS AND PHARMACODYNAMICS

In the treatment of patients with cancer, the ultimate effectiveness of drug therapy is determined by three factors[1]: the inherent sensitivity of the tumor,[2] the ability to deliver drug to its site of action in therapeutic concentrations, and the limitations of host toxicity.[3] It is generally not possible to measure drug concentrations in tumor, although new imaging techniques such as positron emission tomography (PET) and nuclear magnetic resonance imaging (MRI) do allow noninvasive tracking of the distribution and transformation of some drugs in humans in experimental settings.[36] The pharmacokinetic profile of drug in plasma, or change in drug concentration over time, represents the closest correlate of tumor exposure accessible to measurement in the usual clinical setting. In the initial clinical trials of new agents, pharmacokinetic studies are critical for determining whether cytotoxic drug concentrations are achieved and for adjusting the route and schedule of drug administration to achieve an optimal profile, as suggested by preclinical models. In phase II and III trials, pharmacokinetics can yield important additional information on the effects of age, gender, drug interactions, and organ dysfunction on drug clearance.

Anticancer drugs are cleared from the body by one mechanism or a combination of several mechanisms, including renal excretion, hepatic metabolism, chemical decomposition, or metabolic alteration at extrahepatic sites (Table 9-2). Considerable variation is often found among individuals in their ability to clear anticancer drugs, which may necessitate dose adjustment for patients with renal or hepatic dysfunction. Other factors, such as gender, age, serum albumin concentration, lean body mass, nutritional status, and performance status, can influence the pharmacokinetic behavior and pharmacologic effect of a drug, but their quantitative impact on drug disposition is difficult to predict in individual patients. Inherited defects (polymorphisms) in metabolic capability may lead to severe unexpected toxicity for drugs such as 5-FU (i.e., dihydropyrimidine dehydrogenase deficiency) and 6-mercaptopurine (i.e., thiopurine methyltransferase deficiency).[37] Genetic variation in the UDP*-glucuronosyltransferase 1A1 gene (UGT1A1 gene), which is associated with Gilbert syndrome, results in severe toxicity, primarily neutropenia, in patients receiving irinotecan because of the inability to conjugate and clear the active compound, SN-38.

Virtually all targeted small molecules and natural products (taxanes, vincas, and anthracyclines) are cleared through metabolism by hepatic microsomes and require dose reduction in the presence of abnormal liver function. A smaller number of cytotoxic drugs, including methotrexate, pemetrexed, fludarabine, hydroxyurea, and bleomycin, are excreted unchanged in the urine (see Table 9-2) and depend primarily on renal function. Adjustments in dose are required in the presence of renal dysfunction.

Correlations between pharmacokinetic and pharmacodynamic endpoints, such as organ toxicity and therapeutic outcome, are more difficult to establish, but some important insights into these relationships have been identified for several anticancer drugs (Table 9-3). For antimetabolites, most natural product drugs, and platinum compounds, pharmacodynamic endpoints such as antitumor effects and toxicity to bone marrow and intestinal epithelium correlate best with the area under the plasma concentration time curve (see Figure 9-2). For other drugs, such as paclitaxel, the duration of time above a threshold plasma concentration (0.05 to 0.1 μM) correlates best with toxicity to marrow, and there is preliminary evidence that duration above a threshold level also correlates with antitumor effectiveness (Figure 9-2).[49] For alkylating agents, which display a relatively simple relationship between peak plasma concentration and toxicity, dose rather than drug concentration over time correlates best with toxicity and tumor cell killing.

Pharmacokinetic studies can also reveal the existence of drug interactions, which are common for drugs that depend on hepatic microsomal clearance. Inducers of metabolism such as phenylhydantoin, or inhibitors such as imidazole antifungal drugs, can alter clearance, leading to toxicity or ineffective therapy (Table 9-4).

TABLE 9-2 Clearance Mechanisms of Anticancer Drugs

Primary Clearance Mechanism	Drug	Dose Modification for Organ Dysfunction
Hepatic metabolism	Busulfan, taxanes, vinca alkaloids, irinotecan, anthracyclines, imatinib, nilotinib, bosutinib, dabrafenib, pazopanib, axitinib, lapatinib, vandentanib, bortezomib	Y
	Chlorambucil, cyclophosphamide,* ifosfamide,* thiotepa, ponatinib, dasatinib, erlotinib, gefitinib, crizotinib, sorafenib, sunitinib, ibrutinib, regorafenib, cabozantinib, vismodegib, carfilzomib, romidepsin	N
Reduction	Mitomycin C*	N
Deacetylation	Trametinib	N
Conjugation	Etoposide, vorinostat	N
	6-Mercaptopurine	Y†
Soluble enzymes	Ara-C, gemcitabine, omacetaxine mepesuccinate, cyclophosphamide metabolites, ifosfamide metabolites	N
	5-Fluorouracil	Y‡
Nonenzymatic hydrolysis	Camptothecins, BCNU,* mechlorethamine, melphalan	N
Renal excretion	Bleomycin, carboplatin, deoxycoformycin, etoposide, fludarabine, hydroxyurea, methotrexate, topotecan, imatinib, vandetanib	Y

Y, *Yes;* N, *No.*
**Enzymatic and spontaneous chemical reactions required for drug activation, aldehyde dehydrogenase inactivates.*
†Methyltransferase deficiency.
‡Dihydropyrimidine dehydrogenase deficiency.

TABLE 9-3 Pharmacodynamic Relationships of Chemotherapeutic Agents in Cancer Patients

Drug	Clinical Effect	Pharmacokinetic correlate	References
Busulfan	Hepatotoxicity	AUC	38
Carboplatin	Thrombocytopenia	AUC	39
Cisplatin	Nephrotoxicity	C_{max} (unchanged drug)	40
Doxorubicin	Cardiotoxicity	C_{max}	41
Etoposide phosphate	Myelosuppression	AUC (etoposide)	42
Fludarabine phosphate	Leukopenia	AUC	43
5-Fluorouracil	Risk of toxicity	AUC	44
Methotrexate	Response Bone marrow suppression	$C_{max,}$ C × T: (C over 10 μM)	45,46
Paclitaxel	Neutropenia	Time above threshold C_p	47
Topotecan	Neutropenia	AUC (total drug)	48

AUC, *Area under the plasma concentration–time profile;* C_{max}, *maximum plasma concentration;* C_p, *plasma concentration;* GSH, *glutathione.*

TABLE 9-4 Examples of Pharmacokinetic Drug Interactions Involving Anticancer Agents

Chemotherapeutic Agent	Interacting Drugs	Effect on Anticancer Drug Clearance	Probable Mechanism	References
Cyclophosphamide	Phenobarbital	↑	CYP450 enzyme induction	50,51
Doxorubicin	Cyclosporine	↓	Inhibit P-glycoprotein–mediated biliary excretion	52,53
Methotrexate	Aspirin, penicillins	↓	Inhibit tubular secretion	54-56
	Cephalosporins	↑	Inhibit tubular resorption	
Paclitaxel	Verapamil	↓	Inhibit CYP450 metabolism or biliary excretion, block MDR pump	57
Vinblastine	Erythromycin, imidazole antifungal drugs	↓	Inhibit CYP450 metabolism	58

CLINICAL SCHEDULES OF DRUG ADMINISTRATION

Cancer drugs are given in repetitive cycles of administration interrupted by rest periods that facilitate the recovery of normal tissues, particularly bone marrow and gastrointestinal mucosa. With the availability of myeloid stimulatory factors such as granulocyte colony-stimulating factor, it is possible to shorten the period between cycles from the traditional 4-week interval to 2 weeks. The ability to provide such dose-dense therapy with the aid of growth colony-stimulating factor may result in improved outcome without an increase

in toxicity.[59] The theoretical basis for cyclic chemotherapy was established by animal models, which showed that for any given drug schedule and dose, a specific fraction of tumor cells is killed. Repeated cycles of treatment are therefore required for curative therapy. Whether it is necessary to eliminate the last tumor cell to cure the disease is still in doubt. Molecular markers for residual disease may be present for years after remission induction in children with acute leukemia.

Although peak drug plasma concentration, area under the curve (AUC), and time over a threshold level have been correlated with response and toxicity for selected chemotherapeutic agents, clinical investigators lack pharmacokinetic data and further, lack correlations of pharmacokinetics with pharmacodynamic effects for most combination therapy regimens. A greater effort has been made to develop such correlations for targeted drugs, but the information is usually imprecise. The practical endpoint in combination clinical studies is typically to maximize dose intensity (drug administered per unit time) of the individual agents. For cytotoxic drugs, clinical data support a strong relationship between dose intensity and response in the treatment of lymphomas, breast, ovarian, and colon tumors.[60] Taken to its extreme, high-dose chemotherapy with bone marrow stem cell replacement yields the highest dose intensity and the highest response rates in patients who have otherwise refractory tumors, but at a high dollar cost and at the risk of fatal toxicity. In clinical practice, most oncologists administer full doses of drug, aiming at achieving reversible and readily tolerated toxicity as their clinical endpoint.

In designing a combination chemotherapy regimen, the clinical investigator must choose from a range of options regarding route, schedule, and sequence of drug administration. A number of factors determine the final choice of schedule of administration.

1. *Pharmacokinetics of the individual agents in humans.* Specific factors, such as peak drug concentration and clearance from plasma, desired AUC, and duration of drug concentration above a threshold, are central considerations for individual agents (see Figure 9-2). In general, clinical investigators attempt to reproduce a profile of drug concentration and duration of exposure that mimics optimal conditions in experimental systems.
2. *Cell cycle kinetics and cell cycle phase specificity of the agent.* If the agent in question exerts its effects only against cells in a specific phase of the cell cycle, the schedule must be planned to ensure a maximum duration of drug concentration above the threshold. In practice, the best example is the prolonged infusion of antimetabolites (i.e., 5-FU or cytosine arabinoside given by continuous infusion). Most dividing cells in a tumor that is growing relatively rapidly, such as acute myelocytic leukemia, are exposed to drug during their DNA synthetic phase if the infusion of cytosine arabinoside lasts for 7 days.
3. *Drug interactions.* Interactions that alter pharmacokinetic behavior or enhance or inhibit cytotoxicity (Table 9-4) may dictate the use of a specific schedule or sequence of drug administration.
4. *Drug interactions with irradiation.* The growing interest in combined-modality treatment for solid tumors stems from the expectation that many cancer drugs act as radiosensitizers. In most instances, the maximum radiosensitization is realized if the drug is present during the exposure of tumor to irradiation. Continuous drug infusion or daily administration is favored, although rigorous proof that one schedule is better than another is often lacking.
5. *Toxicity.* Most chemotherapy regimens are developed to allow rapid and complete recovery of normal tissues between cycles of treatment. Ultimately, toxicity limits the dose of drug employed and the duration of administration. If drugs are used in combination with other treatment modalities, further limitations of schedule and dose may be imposed. For example, the radiosensitizing effect of 5-FU or cisplatin-based chemotherapy on mucosa or bone marrow may limit the dose of radiation therapy and chemotherapy if the two modalities are given concurrently and particularly if the field of irradiation includes the marrow, gut, or other epithelial surfaces.
6. *Convenience and cost.* Oral drug administration is the easiest and least expensive way to give drugs. However, because of variable and often limited oral bioavailability of cancer drugs, few cytotoxic drugs are given by this route. Intravenous administration guarantees entry of the full dose into the bloodstream. Intermittent bolus schedules are usually favored, although pharmacokinetic or cell cycle kinetic considerations can pose strong arguments for prolonged infusion schedules. An example of such a cell cycle phase-specific drug is the antimetabolite 5-FU. An improved response rate and less toxicity result when 5-FU is administered as a continuous infusion for 48 hours, rather than the daily times five schedule.[61] Oral therapies represent a further advance in terms of convenience and cost, provided they are equally effective. Capecitabine, an oral prodrug of 5-FU, appears to be equally active as infusional 5-FU when combined with oxaliplatin in patients with metastatic colorectal cancer.[62]
7. *Targeted drugs* are usually administered on a schedule that ensures long-term, continuous exposure to the agent. Monoclonal antibodies administered every 3 to 4 weeks provide prolonged exposure because of their very long plasma half-life (2 to 3 weeks), whereas the daily oral dosing of targeted drugs is required to produce trough levels of drug in plasma above the minimum inhibitory concentration.

The Special Problem of Drug Sanctuaries

Although drug distribution from the bloodstream into most tissue compartments occurs with relative ease, certain "sanctuary" sites present special barriers to penetration. In general, tumor blood vessels proliferate in response to the needs imposed by rapid tissue proliferation, but the resulting vessels tend to be unusually permeable, allowing permeation of protein into the extracellular space and resulting in an increased interstitial pressure, sluggish flow, and poor drug penetration. These changes are corrected by antiangiogenic therapies such as bevacizumab and small-molecule VEGFR inhibitors (see later discussion) and may allow better penetration of oxygen and small molecules.

Other tissue sites tend to exclude many drugs. Most chemotherapy agents achieve low concentrations in the testes, vitreous humor of the eye, and the brain when administered systemically. The brain is protected by blood-brain barrier, a compact alignment of microvascular endothelium, which limits the passage of large molecules and hydrophilic drugs. In addition, there are active MDR export pumps in the vascular endothelium of the brain.[63] Disruption in the barrier by tumor vessels associated with metastases or primary brain tumors allows for greater penetration of drugs into the CNS, but the barrier seems to be maintained at the infiltrating edge of tumor. Although radiation therapy is the most effective means of treating many types of brain metastases, systemic chemotherapy or immunotherapy may benefit patients with CNS tumors. Temozolomide, a highly lipophilic alkylating agent, extends the survival time of patients with malignant glioma when it is used in conjunction with irradiation. Other drugs clearly reach intracranial tumors.[64]

EGFR inhibitors and second-generation ALK inhibitors have demonstrated activity against brain metastases resulting from NSCLC.[19] High-dose methotrexate is the preferred mode of treatment for primary CNS lymphomas, although the ratio of cerebrospinal fluid (CSF) to blood concentration of drug is less than 0.1.[65,66] Even antibodies, such as ipilimumab may be effective against intracranial tumors. The VEGF inhibitor bevacizumab depletes a systemically circulating growth factor. It is approved for second-line treatment for patients with glioblastoma multiforme with tumor progression after temozolomide and radiotherapy.[67]

PREDICTING TUMOR RESPONSE

Pharmacogenomics may enable the clinician to determine which drugs will be poorly tolerated by an individual and may allow more rational selection of a particular antineoplastic agent in the individual patient. For example, a high level of thymidylate synthase, in some tumors, the result of a polymorphism in tandem repeats in the gene's promoter region, predicts for resistance to 5-FU in patients with colorectal cancer.[68] Genomic polymorphisms in the DNA repair genes *ERCC1* (formerly designated *XPD*) and *XRCC1* may be prognostic factors in patients with NSCLC treated with cisplatin.

Transcriptional silencing may alter gene expression and affect the outcome of chemotherapy. O-6-methylguanine-DNA methyltransferase (MGMT) is an enzyme responsible for DNA repair following alkylating agent chemotherapy. The gene may be silenced in tumors by methylation of its promoter, creating vulnerability of the tumor cell to DNA damage. MGMT gene silencing occurs in about 20% of glioblastomas and is associated with a high response rate to the alkylating agent temozolomide in patients with glioblastoma and neuroendocrine tumors.[69]

As discussed previously, it is now possible to predict which patients with NSCLC, melanoma, or colorectal cancer are more likely to benefit from a particular targeted therapy. In the case of NSCLC, those patients whose tumors possess an activating mutation in the ATP-binding pocket of the RTK are more likely to benefit from the use of an EGFR-TKI or an inhibitor of the ALK receptor tyrosine kinase. Similarly, patients with colorectal cancer whose tumors possess a mutation in either KRAS or BRAF, resulting in their constitutive activation, are unlikely to benefit from a monoclonal antibody inhibiting EGFR.

DRUG RESISTANCE

The fractional cell kill hypothesis must be modified to incorporate concepts of drug resistance. In practice, the response to an initial cycle of chemotherapy may be much greater than to subsequent doses, and in many solid tumors, such as breast cancer and lung cancer, tumors may again grow rapidly after an initial response. The explanation for this finding lies in the problem of drug resistance and the ability of cancer drugs to select for drug-resistant cells. Mechanisms of resistance may affect any of the steps necessary for drug action: entry of drug into tumor cells by means of active transporters, enzymatic drug activation, action at a molecular target within cells, and even the processes in the cell that trigger cell death. Although many examples of drug resistance have been characterized in model systems, the understanding of resistance in clinical practice remains incomplete. Some of the more common mechanisms in model systems, and evidence for the same mechanism in the treatment of human tumors are given in Table 9-5.

TABLE 9-5 Drug Resistance Mechanisms in Cancer Therapies

Molecular Mechanism	Example	Drugs Affected
Decrease in cellular uptake	Deletion of folate transporter Deletion of nucleoside transporter	Methotrexate, pemetrexed Ara-C, gemcitabine
Increase in cellular efflux	Increased multidrug resistance (CD116) expression or gene amplification	Vinca alkaloids, anthracyclines, taxanesl, etoposide, topotecan
Alteration of target protein	Mutant dihydrofolate reductase Mutant topoisomerase I Mutant tubulin BCR-ABL mutations or amplification EGFR mutations EML4-ALK mutations BRAF splicing variants or BRAF amplification KIT mutation, KIT amplification, or PDGFR alterations	Methotrexate Topotecan Vinca alkaloids, paclitaxel Imatinib, dasatinib, nilotinib Gefitinb, erlotinib, cetuximab, crizotinib Crizotinib Vemurafenib Imatinib
Alternative pathway activation	Multiple mechanisms (see reference 19 for details)	Gefitinib, erlotinib, crizotinib, cetuximab, panitumumab, imatinib (GIST), vemurafenib, bevacizumab, trastuzumab
Deletion of target protein	Deletion of topoisomerase I Deletion of topoisomerase II	Topotecan Anthracyclines, etoposide
Decreased activation of drug in tumor	Deoxycytidine kinase deficiency Decreased folylpolyglutamate synthetase	Ara-C, fludarabine, cladribine Methotrexate, pemetrexed
Increased detoxification	Increased glutathione or glutathione transferase	Alkylating agents, platinum analogs
Enhanced DNA repair	Increased nucleotide excision repair Increased O-6-alkyl-guanine alkyl transferase	Platinum compounds, alkylating agents, Procarbazine, temozolamide Nitrosoureas
Defective recognition of DNA adducts	Mismatch repair defect	Platinum compounds, 6-mercaptopurine, nitrosoureas
Alteration of apoptosis pathways	Mutant TP53, BCL2	Alkylating agents, antimetabolites, EGFR inhibitors, RAS/RAF/MEK pathway inhibitors

With few exceptions, single-agent treatment of cancer produces only temporary responses. This rule applies as well to the targeted agents, where resistance to agents such as EGFR inhibitors develops through mutation in the binding site of the target protein or through activation of an alternative proliferation pathway (C-MET). Resistance likely antedates exposure to the drugs but is a spontaneous product of the underlying genetic instability of tumors. Although the sensitive fraction of cells is killed with each dose of drug, drug-resistant mutants proliferate and replace their sensitive counterparts under the selective pressure of drug. Based on the experience of antibiotic treatment of bacterial infections, it was logical to combine drugs that had different mechanisms of resistance. If the frequency of mutation to resistance is 1 cell of 10^{-6}, the chances of any cell being simultaneously resistant to two drugs would be the product of these probabilities, or 10^{-12}. Goldie et al have argued convincingly that the best strategy for chemotherapy is to employ as many non–cross-resistant agents as early as possible in the treatment regimen.[70] In addition, the use of radiosensitizing chemotherapy with irradiation can have major benefits for local control of tumor and for reducing local morbidity related to surgery in tumors of the aerodigestive tract and have the added potential of synergistic DNA damage.[71-74]

In using drug combinations, certain qualifying considerations have to be kept in mind:

1. Drug resistance mechanisms, such as the overexpression of the MDR transport system, may confer resistance to multiple drugs, as may defects in cell death pathways, enhanced DNA repair, poor tumor blood flow, or other biological factors[2]
2. Simultaneous administration of multiple agents may lead to overwhelming toxicity, unfavorable drug interactions at the molecular target, or unwanted pharmacokinetic interactions. Because of negative interactions, multiple agents may be given sequentially rather than simultaneously, with more favorable outcome.

COMBINATION CHEMOTHERAPY

With few exceptions, multiagent therapy has proved more effective than single-agent therapy in the treatment of most human cancers. In general, the choice of drugs for combination therapy is made on the basis of mechanistic, pharmacokinetic, and toxicologic considerations. The most important criteria for including drugs in a combination regimen are the following:

1. single-agent activity in the disease to be treated;
2. nonoverlapping toxicities, allowing full doses of each drug to be used;
3. different mechanisms of action; and
4. nonoverlapping mechanisms of resistance.

These are not hard and fast rules. There are numerous examples of clinical regimens that use multiple alkylating agents, multiple natural products (despite their shared cross-resistance), or combinations of myelotoxic drugs. Often, these choices are dictated by impressive single-agent activity in the tumor being treated and the uncertainty of knowledge about clinical mechanisms of drug resistance. For example, individual alkylating agents differ in their mechanisms of activation, transport, and adduct formation. Their DNA adducts are repaired by a variety of enzymatic pathways. It is not clear which of these factors contributes to clinical drug resistance (see Table 9-5). Although these agents belong to the same class of drugs, in the absence of more complete knowledge about resistance, it is possible to construct a reasonable argument for combining different alkylating agents.

The development of targeted drugs has greatly expanded opportunities to address resistance to cytotoxic chemotherapy. Drugs such as bevacizumab and trastuzumab have significantly enhanced the effectiveness of cytotoxic chemotherapy of colon and breast cancers, respectively. Trastuzumab blocks signaling through the MEK-ERK and PI3K pathways that promotes proliferation and survival, whereas bevacizumab normalizes tumor vasculature and improves access of cytotoxics to poorly perfused tumor cells. The further development of targeted drugs in combination may allow successful inactivation of multiple resistance pathways, as exemplified by the joint use of B-RAF and MEK inhibitors in melanoma, a strategy that holds great promise for cancer treatment. To implement this strategy, it is necessary to perform molecular profiling of tumor samples on a routine basis, a capability not widely available in current practice, and one must be able to combine drugs without experiencing excessive toxicity.

SUMMARY

The potential for cancer chemotherapy to cure of metastatic cancer has been fully realized in only a few clinical circumstances, primarily those in which a rapidly proliferating hematologic cancer has been treated aggressively with a multiagent regimen. Solid tumor chemotherapy with curative intent must be given early in the course of disease, carefully interdigitated with irradiation and surgery, and administered in maximal doses. Because of the likelihood of serious side effects and drug–irradiation interactions, such regimens are difficult to design and implement. Thus far, the key drugs for such combinations have been 5-FU and cisplatin or carboplatin. The development of optimal chemoradiotherapy regimens must take into account the advantages and disadvantages of sequential versus concurrent combined-modality approaches. To maximize therapeutic synergy and minimize toxicity, protocol planning must pay careful attention to potential drug–irradiation interactions, drug pharmacokinetics, and drug–drug interactions. The patient population being treated (often, elderly patients with associated conditions such as heart disease or hypertension and other evidence of organ dysfunction) may have limited ability to tolerate the rigors of combined-modality treatment. Advances in cancer biology, particularly in the areas of angiogenesis and metastasis, will lead to newer, more tumor-specific, less-toxic approaches to cancer control. Recent strides in molecular profiling of an individual's tumor may lead to a more rational, tailored design of a patient's treatment, and ultimately beneficial therapy, while sparing the unnecessary toxicity and expense of treating with an ineffective drug.

CHAPTER

10 Imaging in Oncology

Ersan Altun, Valerie S. Jewells, and Julia R. Fielding

Computed tomography (CT) has been the mainstay radiologic modality for detection of primary malignant disease and metastatic disease for many years. Advantages of CT include the speed, patient comfort, and high spatial resolution. The technology of CT scanners has improved dramatically for the last 15 years. The present generation of scanners can obtain a larger volumetric data during each turn of gantry by using single tube (single source) or double tubes (dual source). The state-of-the-art single source scanners can obtain 320 to 640 slices and dual-source scanners can obtain 256 slices per gantry rotation allowing image acquisition of the whole body in seconds. These sophisticated scanners enable the reconstruction of multiplanar reformatted (MPR) images including, but not limited to, the coronal and sagittal planes; MPR maximum and minimum intensity projection images as well as three-dimensional (3D) images including volume rendering (VR), surface shaded display (SSD), or fused 3D-MPR images of any desired organ or structure. These scanners are also capable of performing dynamic time-resolved or four-dimensional (4D) angiography and perfusion imaging, which can demonstrate the entire circulation and perfusion of the desired vessels, structures, or organs in seconds. Additionally, fluoroscopic and kinematic images of the desired organs and structures can be acquired. CT is the best technique for the evaluation of lungs and vessels. CT is also successful for the evaluation for the neck, mediastinum, abdomen, and pelvis.

Disadvantages of CT include exposure to ionizing radiation. The average effective dose for the chest is 7 to 15 mSv, abdomen 8 mSv, and pelvis 6 mSv. Patients must also often drink barium or iodine-based contrast material.

Visceral organ and vascular assessment require the intravenous injection of relatively large volumes (50 to 100 mL) of iodine-based intravenous contrast agent.[1] Contrast agents increase the conspicuity of tumors and enable the visualization of vessels allowing for accurate surgical, interventional, and therapeutic planning. In rare cases contrast injection results in allergic-like reactions, ranging from urticaria to shock.[2-9] The overall incidence of allergic-like reaction is 0.2% and the incidence of serious acute allergic-like reactions is 0.04%.[2,3] The mortality rate is 0.9/100,000 to 2.1/1,000,000 injections.[2,5,6] These rates are lower than those for the administration of the antibiotic penicillin. Active asthma or a history of multiple allergies to food, drugs, or the environment increase the risk of an allergic reaction to iodine-based intravenous contrast minimally.[9] However, the history of a prior reaction is the best indicator of a future adverse event. The likelihood of a recurrent reaction is in the range of 8% to 25%.[9] These patients can be premedicated with steroids to decrease the risk.[9]

Another possible adverse outcome is that of contrast media–induced nephropathy. This is an important consideration because renal impairment is present in a significant proportion of oncology patients. In general, patients with serum creatinine levels of less than 1.5 mg/dL can undergo intravenous contrast-enhanced CT without significant risk of nephropathy.[10] For those patients with elevated serum creatinine levels, vigorous oral and intravenous hydration for several hours before and after the examination can significantly decrease the risk of renal damage.[9]

The now widespread use of F-18 fluorodeoxyglucose (FDG)–enhanced fused positron emission tomography/computed tomography (PET/CT) images allows for localization of metabolically active sites of disease accurately with the help of fused CT images. The most important advantage of PET/CT examination is the capability of whole body imaging enabling metabolic and anatomic information. It is particularly helpful in primary lung and esophageal cancers and lymphoma. Although FDG is the most commonly used agent, new specific agents may be used routinely in the near future.

Magnetic resonance imaging (MRI) has become the preeminent tool for the evaluation of the central nervous system and musculoskeletal system since its introduction into routine clinical practice. It has been also used extensively for head and neck imaging. Over the past 15 years, MRI has also been widely used for body imaging including the thorax, abdomen, and pelvis. Thus, MRI has become important in staging cancers in every part of the body because of its higher soft-tissue contrast resolution and improved identification of normal anatomy. MRI is the most accurate and sophisticated technique for the evaluation of central nervous system, musculoskeletal system, and head and neck tumors. MRI has also become the most accurate technique for the evaluation of mediastinum, diaphragm, chest wall, and pelvis. However, the motion artifacts, which are the most important drawback of MRI, may especially limit interpretation of chest and abdomen studies and the visualization of gastrointestinal tract. Despite these limitations, with the use of proper techniques and motion-resistant protocols, MRI has been proven to be a successful method for evaluation of the solid organs of the abdomen.

The lack of available protons in the air-filled lungs makes MRI of limited value in the detection of pulmonary nodules, airways, and lung cancer. MRI is the most accurate and safe method for the evaluation of primary and secondary tumors involving the heart chambers, pericardium, and great vessels. MRI is also successful for the evaluation of large and medium sized arteries and veins. However, because of its lower spatial resolution compared to CT, evaluation of small vessels is not as successful. CT remains the test of choice for the evaluation of patients with trauma and in intensive care because it provides comprehensive information in seconds without any motion artifacts.

Most oncology studies done on MRI use an intravenous contrast material composed of a gadolinium chelate. The incidence of acute adverse events is 0.08% and the vast majority of them are mild.[11,12] The incidence of anaphylaxis is 0.001% to 0.01% and the overall death rate according to Food and Drug Administration is less than one case per million injections.[12,13] In healthy patients, the risk of nephrotoxicity is virtually nonexistent. However, in 2006, a new disease entity called

nephrogenic systemic fibrosis (NSF) was associated with the use of gadolinium-based contrast agents in patients with acute renal failure and stage 4 and 5 chronic renal insufficiency with an estimated glomerular filtration rate <30 mg/dL/1.73 m^2.[14] NSF is a systemic fibrosing disorder, which may be fatal, and no effective treatment has been identified.[14] NSF has been particularly associated with the use of specific type of gadolinium chelates having low stability including gadodiamide, gadopentate dimeglumine, and gadoversetamide.[14-17] These agents are now contraindicated in patients with acute renal failure and stage 4 and 5 chronic renal insufficiency.[14] Cautious use of all gadolinium agents in patients with renal insufficiency, including the implementation of lower dose policy and preferential use of more stable agents, decreased the incidence of NSF significantly in the last 5 years.[14,18]

Intravenous contrast volumes used in MRI are in the range of 1 to 20 mL in adults and pediatric patients depending primarily on the weight of the patient. Patients must be cooperative and be able to lie supine for 10 to 20 minutes. The presence of ferromagnetic implants, including cardiac pacemakers, ocular implants, and aneurysm clips prohibits performance of MRI.[19] Surgical clips, artificial joints, and heart valves can be safely imaged.

MR-PET systems, which have the ability to combine the morphologic imaging features of MRI with metabolic imaging data of PET, have recently begun to be used in clinical practice. Although the clinical role of this imaging modality has not been established, the combination of functional and anatomic imaging may play an important role in the evaluation of treatment response.

In the following sections, the imaging appearances of common primary and metastatic cancers in the head, neck, chest, abdomen, and pelvis will be demonstrated using CT, MRI, and, in some cases, PET/CT images obtained with standard imaging protocols. Imaging of primary breast cancer is omitted because it is generally performed using mammography and ultrasound.

MRI of the head and neck including central nervous system, spine, abdomen, and pelvis usually consists of T1-weighted (black fluid), T2-weighted (bright fluid), and contrast-enhanced images obtained sequentially using T1-weighted images in multiple planes. In addition to the body coil, surface coils are available for each part of the body, increasing both signal to noise and spatial resolution. Most tumors have increased T2 signal compared with adjacent normal tissue and demonstrate characteristic enhancement patterns. Bone imaging often requires fat saturation to demonstrate marrow changes as well as comparison with plain radiographs.

Picture archiving and communications systems (PACS) allow the images to be viewed at multiple sites simultaneously by radiologists and clinicians.

IMAGING OF THE BRAIN

The goal of imaging is to stage tumor extent and assess for tumor type. Therefore, all patients with brain tumors will need imaging for extent of disease, to aid surgical and radiation therapy planning, and determine tumor type/prognosis.[20] Evaluation of primary and metastatic brain tumors is best performed with postcontrast MRI because postcontrast CT is less sensitive for lesion conspicuity and assessment of disease extent.[21] In addition to conventional MR techniques, multiple nonconventional MRI techniques have proven to be useful for assessment of tumor type and grade as well as therapeutic response. These include diffusion weighted imaging (DWI), perfusion imaging (PI), and MR spectroscopy (MRS) and have shown promise particularly when combined for separation of tumor grades II and III at least with oligodendrogliomas.[22]

Using conventional MRI, malignant potential is related to lesion size, extent of T2/FLAIR abnormality, enhancement, and necrosis. The T2/FLAIR abnormality needs to be assessed because in many tumors it reveals more about tumor extent than contrast enhancement as the tumor infiltrates beyond the mass lesion into the brain structures and often also even beyond the extent of the T2/FLAIR abnormality. On conventional MRI, necrosis and enhancement are features that are consistent with higher grade of primary brain tumors based on the World Health Organization (WHO) grading criteria. However, be aware that conventional MRI simply assesses morphologic criteria.[23] By WHO criteria, those tumors that are lower grade (i.e., grades I and II, do not necrose, and are less likely to enhance). One tumor that does not appear to follow these rules is the pediatric pilocytic astrocytoma (grade I), which often presents in the posterior fossa and enhances with cystic areas that can be misinterpreted as necrosis.

Brain tumors in adults are divided into intraaxial and extraaxial tumors. Extraaxial tumors are typically dural meningiomas (grade I) or less commonly atypical meningiomas (grades II to III) that are more commonly in patients older than 65 in nonskull base regions, are the second-most common intracranial tumor, and are most commonly seen at the cerebellopontine angle regions and vertex. Higher grade, extraaxial tumors such as angiosarcomas and malignant meningiomas usually cannot be definitively differentiated by conventional imaging before surgery, although obvious infiltration portends a poorer prognosis (Figure 10-1, *A*). However, apparent diffusion coefficients have recently shown some promise in differentiating lower and higher-grade meningiomas.[24] Other dural-based disease processes in the differential include metastases, leukemia, lymphoma, sarcoidosis, Wegener's, tuberculosis, and meningitis.

Intraaxial adult brain tumors are most frequently derived from astrocytes or oligodendrocytes and are most commonly high grade (i.e., glioblastoma multiforme; Figure 10-1, *B*) and gliomatosis cerebri (WHO grades III and IV). In order of descending frequency are astrocytomas (grades I to II), oligodendrogliomas (WHO grades II to III), lymphomas and gliomatosis cerebri (WHO grades III to IV). Factors that result in reduced enhancement and therefore an incorrect assumption of lower grade or better tumor response include steroid administration[25] and antiangiogenesis chemotherapies.[26]

Also impacting on appropriate diagnosis are similar appearance patterns with different tumor types. For example, GBM and lymphoma both have a tendency to cross the corpus callosum and enhance/necrose, which makes differentiation difficult. Generally, lymphoma is found in patients who are HIV+, has a significantly better prognosis, and different assessment needs for pathologic diagnosis. MRI features that may help distinguish between GBM and lymphoma are dark T2 signal and restricted diffusion on DWI (Figure 10-1, *C-E*) as a result of dense cellularity.

An additional method of nonconventional tumor assessment is MRS, which can assist determination of tumor grade and differentiation of a single metastasis from a primary brain tumor. Because primary brain tumors are infiltrative in nature, their edges will be less well defined with regard to changes in metabolites unlike metastatic disease (Figure 10-1, *F-G*).[27] MRS measures 1 cm cubes or voxels which, when performed together as many voxels adjacent to each other as multivoxel MRS, can assess metabolite concentrations over the entire tumor and adjacent regions.

Other discriminating factors for a metastatic lesion include typical peripheral location at the gray-white matter junctions, significant surrounding edema, and multiplicity. Using MRS, higher-grade tumors will have lower N-acetyl-acetate (NAA) levels in correlation with the number of neurons and axons in

the voxel being destroyed (Figure 10-1, *H-J*). Higher-grade tumors will demonstrate higher choline (Cho) levels secondary to rapid cell turnover. Typically, values of NAA and Cho are assessed with regard to creatinine (Cr) concentrations, as NAA/Cr and NAA/Cho ratios as Cr levels typically remain stable. However, a more accurate method of absolute metabolite quantification can be performed with programs such as the LC model.[28] Other MRS markers of higher-grade malignancy are lactate and lipid, commonly seen in GBMs and consistent with anaerobic metabolism and myelin destruction respectively.[29] Occasionally, MRS will assist in the differentiation of GBM and tumefactive multiple sclerosis (MS) by assessing other regions of the brain for lipid levels. Also, for differentiation of tumefactive MS, one looks for a broken ring of enhancement[30] and assesses other regions for T2/FLAIR lesions in typical locations for MS including the corpus callosum (radiating outward as Dawson fingers) or in other typical locations including the periventricular white matter and subcortical regions. If still uncertain and MS is suspected, follow-up imaging to identify new lesions over time may avert unnecessary biopsies. Also within the differential are infectious lesions/abscesses. In general, abscesses will show restricted diffusion unlike primary brain tumors and they may also exhibit the presence of "daughter" or secondary lesions that are adjacent to the larger "mother" lesion. Another type of metastatic disease that the clinician needs to be aware of is leptomeningeal metastases (Figure 10-2, *A*-C) that can coat the brain surfaces and because of free cerebrospinal fluid (CSF)

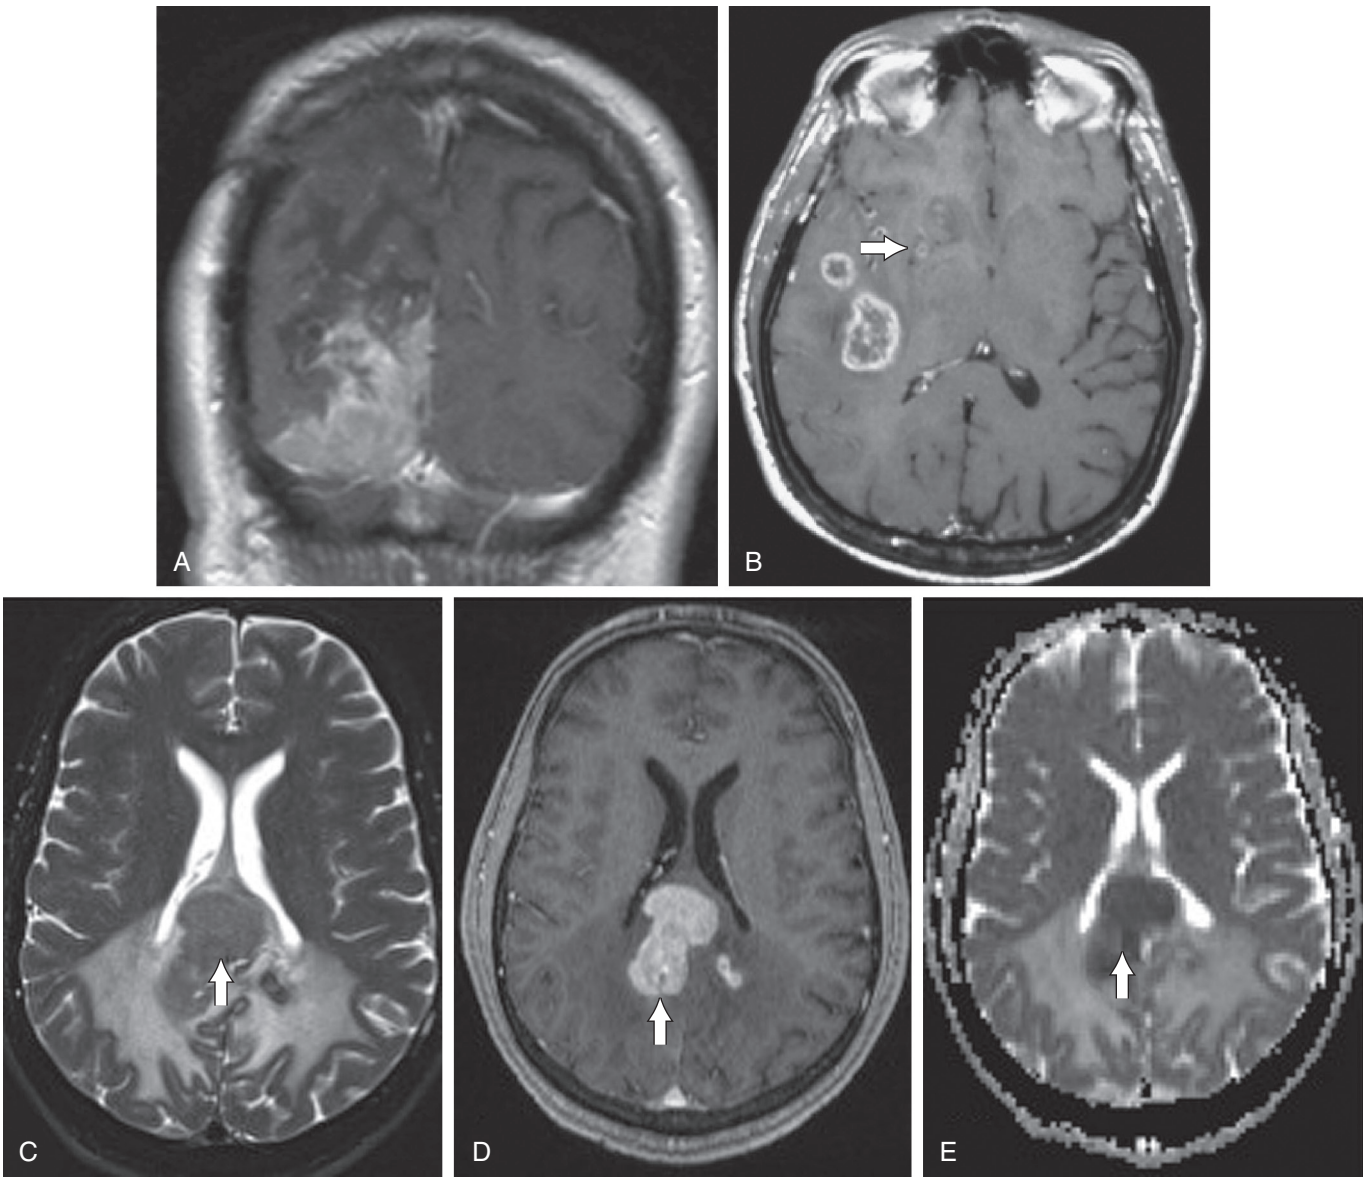

Figure 10-1 **A,** Meningiomas are extraaxial tumors whose margins are usually well defined. This meningioma is atypical and has poorly defined margins that can mean higher grade and more difficult resection **B,** This glioblastoma multiforme GBM demonstrates typical necrosis and enhancement and is centered in the white matter not at the gray-white matter junction as is typically seen with metastases. **C-E,** This case reveals perivascular spread *(arrow, b)* a poor prognostic indicator. Lymphoma can be difficult to differentiate from GBM because both tumors will exhibit increased T2/FLAIR signal **(C),** enhancement **(D),** and be in a butterfly distribution across the corpus callosum. Also commonly seen is low T2 signal (**C,** *arrow*) and low signal on the apparent diffusion coefficient (ADC) map consistent with restricted diffusion (**E,** *arrow*) in lymphoma.

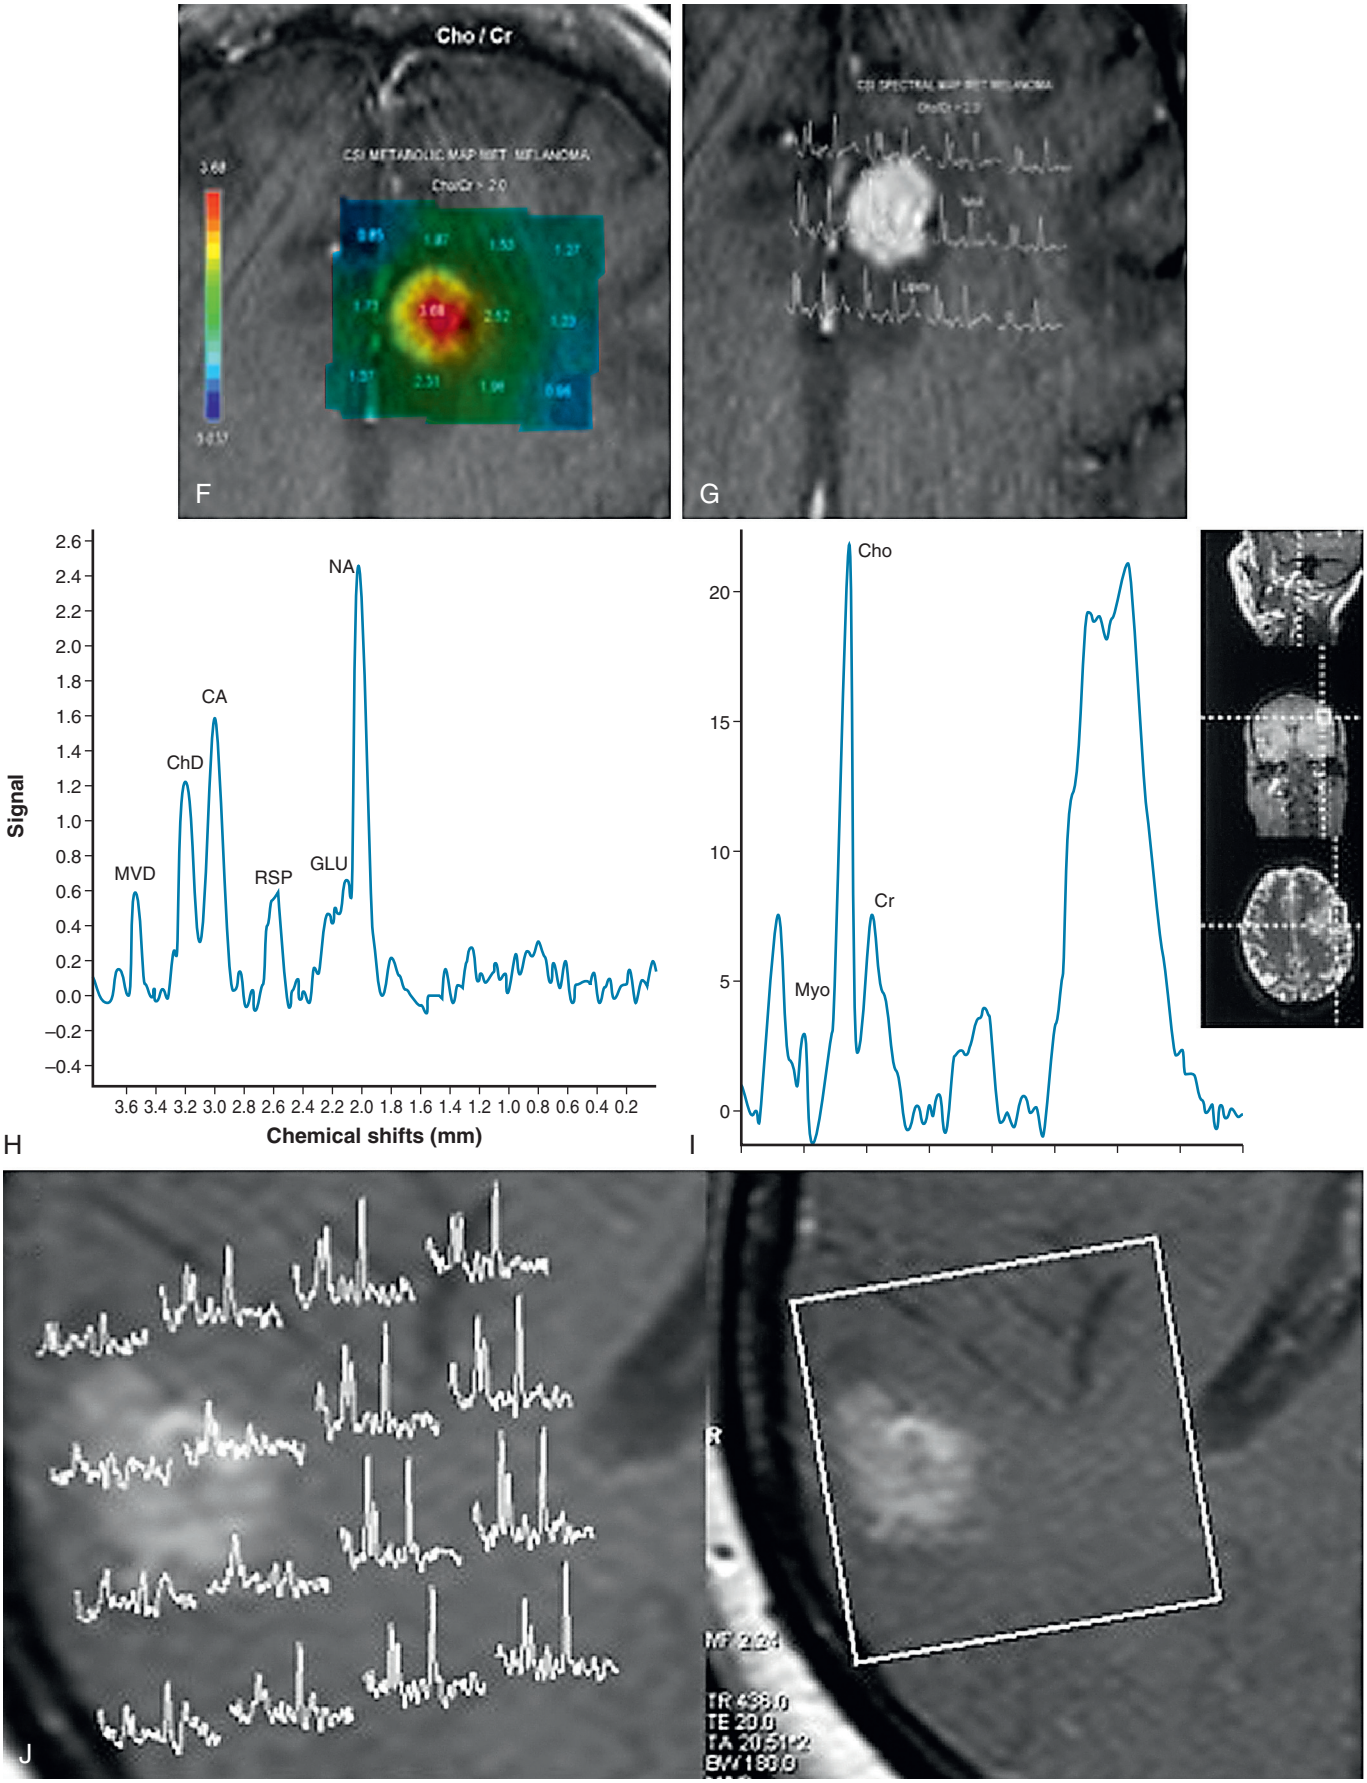

Figure 10-1, cont'd **F-J,** The above gray-white matter junction metastatic melanoma lesion demonstrated an abrupt cut off in of MR spectroscopy. A normal spectrographic pattern **(H)** while versus a typical tumor pattern **(I)** of elevated choline (*Cho*) from increased cell division, depressed N-acetylaspartate (NAA) from neuronal loss, and elevated lipids in a GBM.

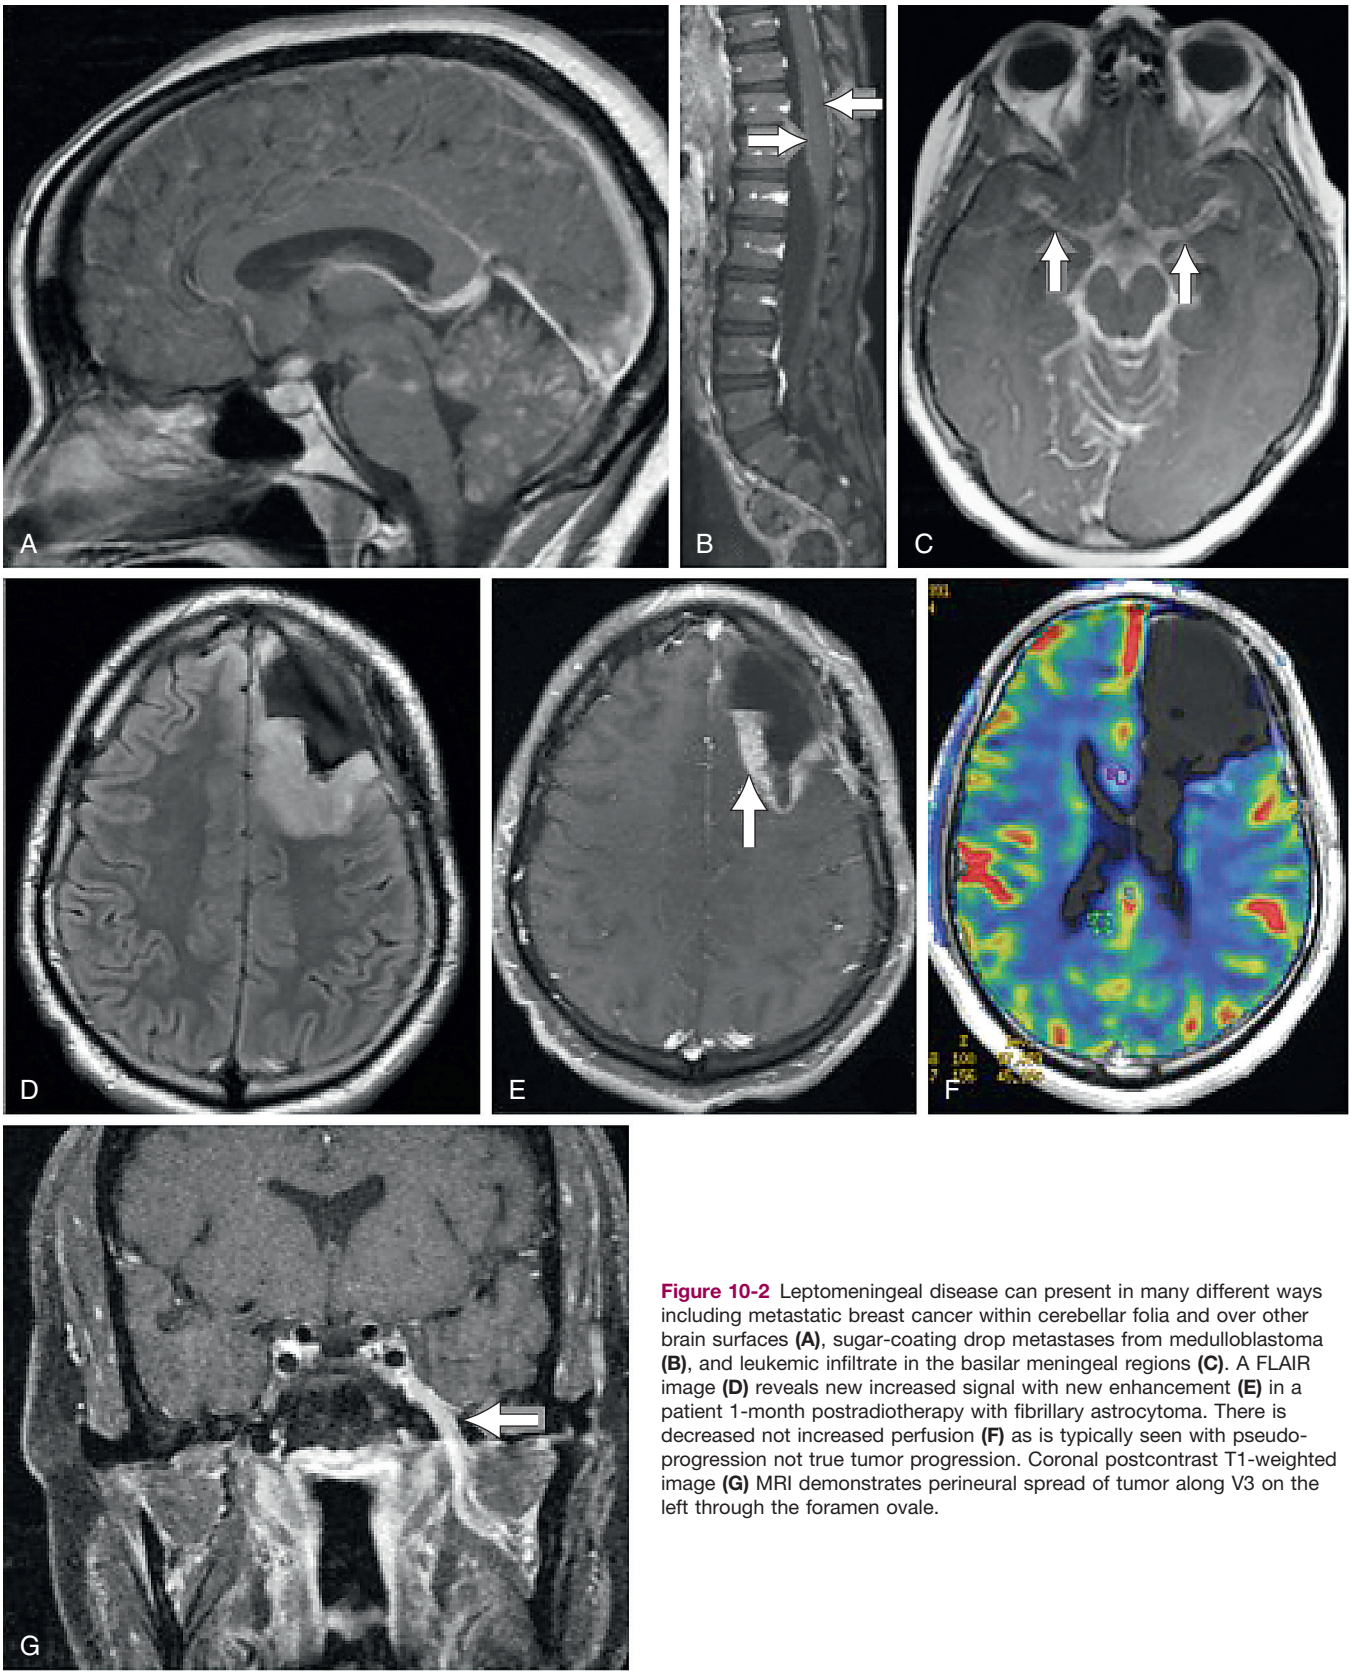

Figure 10-2 Leptomeningeal disease can present in many different ways including metastatic breast cancer within cerebellar folia and over other brain surfaces **(A)**, sugar-coating drop metastases from medulloblastoma **(B)**, and leukemic infiltrate in the basilar meningeal regions **(C)**. A FLAIR image **(D)** reveals new increased signal with new enhancement **(E)** in a patient 1-month postradiotherapy with fibrillary astrocytoma. There is decreased not increased perfusion **(F)** as is typically seen with pseudo-progression not true tumor progression. Coronal postcontrast T1-weighted image **(G)** MRI demonstrates perineural spread of tumor along V3 on the left through the foramen ovale.

flow tumor cells can also be deposited on the surface of the spinal cord (Figure 10-2, *C*).

PI, another nonconventional MRI technique determines tumor grade using time to peak (TTP), mean transit time (MTT), cerebral blood flow (CBF), and cerebral blood volume (CBV), which correlate with tumor grade and angiogenesis properties seen in higher-grade tumors.[31] However, the greatest use of PI is for the exclusion of residual or recurrent disease compared to pseudo-progression. Posttreatment brain tumors can be difficult to assess because of a process called pseudo-progression. In pseudo-progression there is mass-like enhancement or necrosis mimicking an active or recurrent tumor that is actually a result of tumor necrosis. Therefore, there will not be increased perfusion as occurs in recurrent or residual tumor[32] (Figure 10-2, *D-F*). MRS has also been useful for determination of pseudo-progression.[33]

IMAGING OF THE HEAD AND NECK

Typically, patients with head and neck cancers are initially imaged with CT. CT is more convenient for patients with large neck masses who may have respiratory compromise. However, the use of MRI is often advocated in children to reduce radiation dose. In performing neck CT, we use 75 mL of contrast with a 45-second delay for axial scanning and then reconstruct the coronal and sagittal planes for assessment of tumor extent. The contrast delay is needed for optimal tumor and mucosal enhancement. Also, employment of butterfly images through the oral cavity will help avoid dental artifact. In general, CT is preferred over MRI to identify the primary head and neck tumor extent if imaging in the oropharngeal, laryngeal, and hypopharyngeal regions is performed in all three planes, because of swallowing and respiratory artifact.[34]

However, MRI is better for perineural spread along cranial nerves (CNs) V (Figure 10-2, *G*) and VII as well as for tumor localization in patients who cannot receive contrast.[35] MRI is also helpful for assessment of dural involvement with intracranial extension and has accuracy rates of 84% for determination of dural involvement.[36] MRI also demonstrates better definition of the skull base structures including the pharyngobasilar fascia, sinus of Morgagni, cartilaginous Eustachian tube, and levator veli palatine muscles. Therefore, for nasopharyngeal carcinoma including sino-nasal undifferentiated carcinoma (SNUC) and esthesioneuroblastoma, or cases of malignant parotid masses, MRI is the preferred study. Our standard protocol for skull base assessment includes axial 4 mm T1/T2/3D MPD rage postcontrast axial and coronal images through the entire brain as well as 0.7 mm isotropic T2 weighted CISS in the axial plane through the region of the skull base.

For assessment of cartilaginous involvement of the larynx, MRI and CT are equally accurate.[37] With regard to nodal assessment CT is slightly superior to MRI,[38] unless SPIO particles are added to the neck MRI protocol.[39] Abnormal nodes will not uptake SPIO particles and will not be dark on T2. Therefore, with SPIO, MRI will surpass CT and likely also PET for assessment of nodal involvement, but it is not approved by the Food and Drug Administration for use in the United States. Ultrasound (US) with color Doppler can also be used to assess benign and malignant nodes and be used for biopsy guidance of suspicious nodes and is equal to CT for malignant nodal detection.[40] US is the preferred method of guidance for thyroid biopsy. PET/CT for head and neck cancers staging is most cost effective in cases of unknown primary, T3/T4 stage and multiple bilateral neck nodes because distant metastases are more likely. It is also useful for the N0 neck to forgo neck dissection and to help with the decision-making process in cases in which surgical resection would be extensive and the patient may be best treated with chemotherapy and radiation therapy. PET/CT is further discussed in Chapter 11.

IMAGING OF THE SPINE

If a primary or metastatic tumor is suspected in the spine, imaging is best performed with pre- and postcontrast MRI in axial and sagittal planes. In general, primary tumors of the cord (i.e., intramedullary) include astrocytomas (40%), ependymomas (50% to 60%), and hemangioblastomas. Because ependymomas arise from ependymal cells lining the central canal, they are typically central in location and are more common in the cervical than thoracic regions followed by the filum. Filar ependymomas are usually myxopapillary type, can seed the subarachnoid space, and are more likely to recur than other types of ependymomas,[41] suggesting that long-term follow-up is necessary. Eighty-four percent of ependymomas exhibit cyst formation and a hemosiderin cap from hemorrhage is seen in nearly half of the cases. Spread can be retroperitoneal as well as inferiorly into the sacro-coccygeal region.

Astrocytomas occur in children as well as adults in the third to fifth decades and are more common in males than females (1.3:1). Astrocytomas are more common in the thoracic than cervical regions, are more infiltrative, associated with a syrinx, eccentric in location, and up to 30% may not demonstrate enhancement.[42] Therefore, astrocytomas are in the differential diagnosis of nonenhancing cord lesions. Hemangioblastomas another primary spinal cord tumor are low grade, capillary rich, and seen in young women sporadically or males with Von-Hippel Lindau syndrome. Although typically in the thoracic, cervical, lumbar, sacral regions; respectively, hemangiomblastoma are also often within the cerebellum. These lesions typically have a cystic component with a mural enhancing nodule. Extramedullary tumors include meningiomas, schwannomas/neurofibromas, and metastases, often leptomeningeal (Figure 10-2, *B*) and often drop metastases from brain tumors, or directly extending from bone metastases. Metastases to the cord are uncommon. We have found the use of diffusion tensor imaging for determination of tumor resectability to be useful, and this is a technique you may wish to add to your preoperative assessment.[43-45]

IMAGING OF THE CHEST

Primary Tumors of the Lung

Lung cancer is the leading cause of cancer-related death in the United States and the world. Malignant neoplasms of the pulmonary parenchyma and bronchi mainly consist of two histologic types: (1) non–small cell type (80% to 85%) and (2) small cell type (15% to 20%).[46-49] Non–small cell cancer includes three different subtypes: (1) squamous cell, (2) large cell, and (3) adenocarcinoma.[46-49] Treatment strategies mainly differ depending on the non–small cell and small cell type. The three subtypes of non–small cell group have similar treatment options and a better prognosis compared to small cell type when the disease is localized.

Imaging Strategies

Radiologic studies are used for the diagnosis, staging, and evaluation of treatment response.

Lung cancer is most frequently discovered on chest radiographs. When there is a suspicion of lung cancer either clinically or on a chest radiograph, contrast-enhanced CT scanning is the technique of choice for the detection and characterization of a primary mass. Contrast-enhanced CT enables limited local staging with the identification of additional nodules, assessment of size and location of lymphadenopathy, and

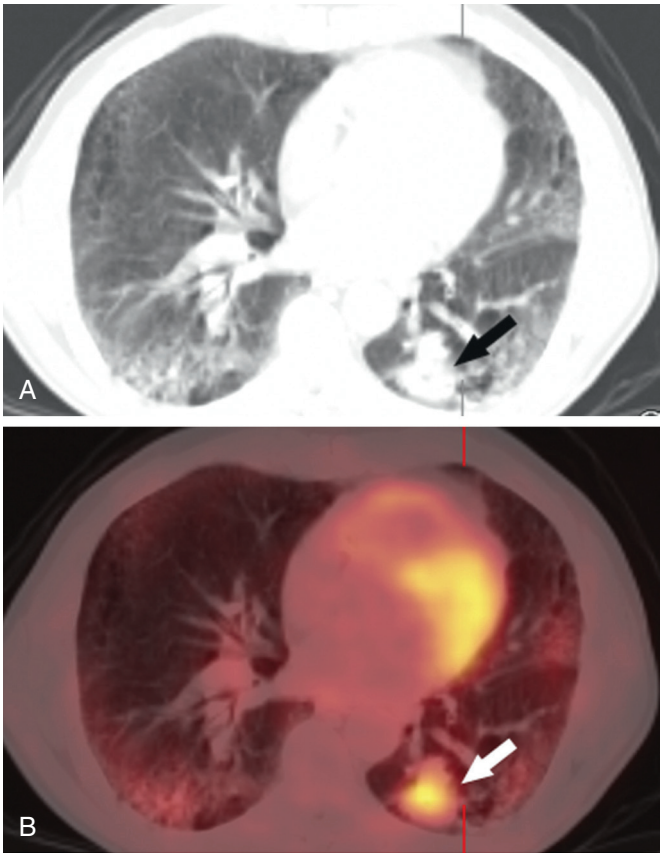

Figure 10-3 Male, age 56 years, with treated lung cancer. Axial CT scan **(A)** demonstrates a residual mass within the left lower lobe *(arrow)*. Corresponding fused PET/CT image **(B)** reveals increased avidity for FDG, similar to the heart, and indicative of residual disease *(arrow)*. PET imaging should be performed approximately 8 weeks following radiation therapy to minimize false-positive results because of inflammation of the targeted tissues.

detection of lung, adrenal, or soft-tissue metastases. Lymph nodes larger than 1 cm in the short-axis are considered pathologic on CT.[48,49] However, the sensitivity and specificity of this criterion is low. PET/CT examination allows for the addition of metabolic information to anatomic or morphologic information and is generally used as the next step in the workup including identification of involved lymph nodes and metastases to the whole body including the adrenal glands, bones, and liver.[48,49] MRI can also be used as a problem-solving technique in certain situations such as the evaluation of chest wall, mediastinum, and major vessel or brachial plexus invasion.[48,49] In most cases, CT or PET/CT is used to follow response to chemo- or radiotherapy and surgery and to diagnose their complications (Figure 10-3).[48-50]

Tumors may be visible as central or peripheral masses on imaging studies. Central tumors may be obscured by associated atelectasis or postobstructive pneumonitis. The distribution of parenchymal findings depends on the tumor location and may range from a subsegmental atelectasis to collapse of an entire lobe or lung. A solitary pulmonary nodule may be a finding of lung cancer and certain characteristics including size, calcification, shape, edge characteristics, cavitation, contrast enhancement, and growth rate may help differentiate between a benign and malignant lesion. Certain types of calcifications including lamellated or central calcifications in granulomas; the popcorn pattern in hamartomas are highly specific for benignity. Dystrophic calcifications may rarely be seen in primary and secondary tumors. A smooth peripheral margin is more frequently associated with benign lesions whereas lobulation, spiculation, and the presence of a pleural tag are worrisome findings. Cavitation may be seen in malignant lesions and thick-walled lesions and irregular internal margins are more frequently associated with malignancy.

The absence of growth over a 2-year period is the most reliable indicator of benignity because the doubling time varies between 30 and 490 days (mean value 120 days).[51] Intrathoracic involvement is not limited solely to mediastinal and hilar lymph nodes. The pleura, chest wall, heart, great vessels, diaphragm, and phrenic and recurrent laryngeal nerve are additional structures that can be involved secondarily. Pleural involvement may be seen as a pleural effusion with or without an associated mass.

Local extension and resectability may also be evaluated with imaging. Although the extension and invasion of tumor can be visualized in the chest wall and mediastinum, subtle invasion may be difficult to detect. Less than 3 cm contact with the chest wall and mediastinum, less than 90 degrees contact with the aorta and presence of fat between the mass and normal structures suggest technically feasible resectability, although the opposite findings are not reliable for either invasion or unresectability.[48] The most frequent distant metastases are bone, brain, contralateral lung, liver, adrenals, soft tissue, and skin.[48,49]

Non–small Cell Cancers

Adenocarcinoma accounts for 30% to 40% of lung cancers.[47] These tumors are typically small, round, smoothly marginated, and peripherally located. However, central location does not exclude the diagnosis of adenocarcinoma. When the primary mass is located peripherally, hilar and mediastinal lymph node metastases are present at diagnosis in 18% and 2% of cases, respectively. When the primary mass is located more centrally, hilar and mediastinal lymphadenopathy is present in 40% and 27% of cases, respectively.[52] Calcifications are rarely present in primary lung adenocarcinomas.

Broncheoalveolar carcinoma (BAC) is considered a subtype of adenocarcinoma. Approximately 60% of BACs presents as a solitary peripheral pulmonary nodule.[53] Other common presentations include multiple nodules (15%) and alveolar filling pattern mimicking pneumonia (10%).[54] These opacities may present a diagnostic challenge because they can remain unchanged in size for several years and are generally not hypermetabolic on PET/CT imaging. Mediastinal lymphadenopathy is present at diagnosis in 18% of patients.[54]

Approximately 10% of lung cancers are large cell carcinomas.[47] These typically present as large, peripherally located masses. Cavitation and calcification are uncommon findings. Hilar and mediastinal lymphadenopathy is found in 30% and 10% of cases, respectively.[53] Large cell carcinomas are characterized by a rapid growth pattern with early lymphatic and hematogenous metastases.[54,55] Large cell carcinomas can be histologically difficult to differentiate from poorly differentiated adenocarcinomas and squamous cell carcinomas.[47]

Squamous cell carcinomas (SCCs) make up 30% to 40% of lung cancers.[47] Although SCC often presents as a centrally located mass, it is peripherally located in a third of cases and may occur as an endobronchial mass that is associated with bronchial obstruction.[53] Cavitation of the primary mass occurs in 10% to 20% of patients. Most apical tumors, or Pancoast tumors, are SCC.[54] Pancoast tumors may extend superiorly and invade the subclavian artery and brachial plexus. Radiologic findings may include apical mass, prominent apical cap, bone destruction, and clinical findings may include arm pain and Horner syndrome as a result of involvement of brachial

plexus and stellate ganglion, respectively. Brachial plexus involvement, apical chest wall, vertebral bodies, and neural foramina are best examined with MRI.

Small Cell Cancers

Approximately 90% of small-cell carcinomas are located centrally and tend to spread longitudinally along submucosal and intramural portions of the bronchial walls and in the supporting tissues and lymphatics. They often have extensive mediastinal or hilar lymphadenopathy and may encase mediastinal structures. This histologic subtype is composed of neoplasms arising from neuroendocrine cells. Distant metastases occur early.[53]

Staging of Lung Cancer

The distinction between T1 and T2 is generally easy as it depends on size criteria; however, the diagnosis of chest wall, diaphragm, pleural, or mediastinal invasion may be difficult. MRI may be helpful in these situations.[48,49] Assessing the mediastinum for nodal metastases is important for staging. Unfortunately, morphologic criteria on MRI and CT are not effective in characterizing lymph nodes. Using the 1-cm short-axis criteria, CT has been reported to be 41% to 67% sensitive and 79% to 86% specific for detection of nodal metastases.[46] Oftentimes, enlarged nodes are hyperplastic because of infection or inflammation, particularly in the setting of postobstructive pneumonia. PET/CT is useful in differentiating benign from malignant lymphadenopathy in patients without superimposed infection. If an enlarged node discovered by CT does not show 18-Fluoro deoxyglucose (FDG) avidity, it will be free of metastases with nearly 100% certainty.[56,57] PET/CT has a high negative predictive value for small (T1), peripheral tumors with low FDG uptake and no significant activity in the hilar lymph nodes.[48,49] Problems remain with detection of lung nodules less than 5 mm in diameter and superimposed or concurrent infection, which also shows increased uptake. PET/CT examination is also effective for the detection of distant metastases and in the absence of symptoms the negative predictive value is usually 90% to 95% for liver, brain, adrenal gland, and bone. However, small liver metastases may not be detected on PET/CT and benign adrenal nodules may be FDG avid.

Follow-up of Lung Cancer

CT and PET/CT are used for the evaluation of treatment response; however, there are no commonly accepted follow-up criteria.[48] Metabolic imaging is helpful for the evaluation metabolic activity in tumors that do not show any change in size or show increased necrosis despite increase in size.

Screening for Lung Cancer

The National Lung Cancer Trial (NLST) in 2011 found a mortality benefit of at least 15% in long-term smokers who underwent annual screening with low-dose CT screening. Although, based on this finding, the U.S. Preventive Services Task Force issued a draft recommendation in favor of CT lung cancer screening, the debate over cost continues.[58]

Lymphoma

Lymphoma is a malignant disease of hematopoietic cells of specific lineage including T and B cells and histiocytes. The lymphocytes located in the lymph nodes, organs, and bone marrow may develop into lymphomas, which may involve any part of the body. Lymphoma is mainly composed of two groups: Hodgkin disease (HD) and non-Hodgkin lymphoma (NHL). More than 80% of patients with HD have intrathoracic involvement at presentation consisting of enlarged anterior mediastinal and paratracheal lymph nodes.[59] NHL is a more heterogeneous group of diseases, and thoracic lymph node involvement is present in 45% of cases.[60] The prognosis and treatment vary according to the type of NHL. The paratracheal and anterior mediastinal lymph nodes are the most commonly involved sites. Large mediastinal lymphadenopathy (>10 cm) is associated with an increased risk of relapse and usually requires aggressive combination therapy.[61] Lung nodules are uncommon in both HD and NHL.

NHL and HD may also be seen in patients with posttransplant lymphoproliferative disorder (PTLD).[62] PTLD may involve various sites in the body and present most commonly as a pulmonary mass or nodules in the lungs.[63,64] PTLD may be divided into two groups according to its pathogenesis including Epstein-Barr virus–dependent type and Epstein-Barr virus–independent type, in which the underlying etiology is unclear.

In addition to CT and MRI, PET/CT (Figure 10-4) provides metabolic information, which is especially critical for the early evaluation of viable tumor in patients undergoing chemo- or radiotherapy without significant change in the size of the lesions.

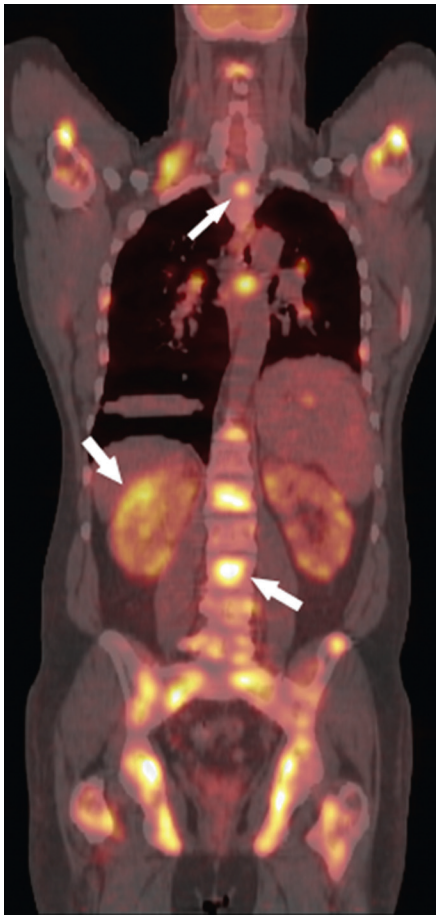

Figure 10-4 Male, age 44 years, with known lymphoma. Coronal fused PET/CT image shows multiple regions of increased uptake, including the kidneys, bones, and thyroid gland *(top arrow)*.

Metastatic Disease to the Chest

CT scan is the test of choice for identification of metastatic disease and response to therapy. Many cancers secondarily

involving the lungs will present with multiple nodules. In the case of SCC and adenocarcinomas, nodules may be cavitary. Response to therapy is often determined based on an increase or decrease in the size and number of nodules. It is prudent to compare the current scan with the most recent prior scan and the most remote scan to avoid overlooking slow-growing disease. Other manifestations of metastatic disease include enlarged mediastinal, hilar, or axillary lymph nodes, nodular pleural thickening, pleural effusion, and, particularly in the case of lung or breast cancer, chest wall invasion. Osteolytic or osteoblastic bone metastases can be identified. Three-dimensional reconstructions can be of particular value in identifying central lung nodules abutting vessels, chest wall masses, and rib or spine lesions. Maximum intensity projection (MIP) reconstructions are especially helpful for the detection of small pulmonary nodules.

CANCERS OF THE ABDOMEN AND PELVIS

Primary Tumors of the Gastrointestinal Tract

Primary Esophageal Tumors

Esophageal carcinoma is the thir-most common gastrointestinal tract malignancy. Surgical resection after preoperative radiation therapy and chemotherapy is currently the best curative treatment for patients without distant metastases. Accurate preoperative staging and evaluation of response to neoadjuvant therapy is critical for the therapeutic approach. The diagnosis is generally made with endoscopy.[65,66] The tumor may spread via direct extension, lymphatic, or hematogenous routes. SCCs predominately affect the proximal two thirds of the esophagus and the majority of adenocarcinomas affect the distal third and together constitute more than 90% of the tumors.[65,67] Because the esophageal mucosa lacks a serosa, which may behave like a barrier to the spread of disease, the tumor easily spreads to adjacent structures in the neck and mediastinum.

The esophagus has an extensive lymphatic drainage and therefore mediastinal, perigastric, and celiac lymph nodes can be involved. Additionally, lymphatic spread may result in discrete mucosal implants. Hematogenous metastases most commonly involve the liver, lungs, and bones.[65] Initial screening includes the use of three modalities: CT, endoscopic US, and PET/CT.[65-67] Endoscopic US is the most accurate technique for the differentiation of T stage and has overall 75% to 95% accuracy for these stages.[65,67] The exclusion of T4 disease is the most important role of CT. Staging accuracy using combined endoscopic ultrasound and contrast-enhanced CT reaches 85% to 90%.[68] PET/CT is the most accurate technique for the evaluation of lymph node involvement (Figure 10-5) and is helpful for the detection of distant metastases. PET/CT is sometimes used to follow therapy and more commonly used to determine late recurrences.[68,69]

Primary Stomach Tumors

Gastric adenocarcinoma is the second-most common gastrointestinal tract malignancy and usually identified at an advanced stage.[70] Endoscopy is the gold standard for the diagnosis of gastric adenocarcinoma. Endoscopic US is used to assess the depth of invasion into the gastric wall and has higher accuracy (78% to 93%) compared to cross-sectional imaging techniques for the determination of T staging.[70] Cross-sectional imaging is used for staging of lymph nodes and distant metastases.[70-73] PET/CT is particularly important for the demonstration of involvement of small morphologically normal appearing lymph nodes in FDG avid tumors.[70] CT and MRI are superior in the identification of lymph nodes increased in size and number and distant disease including parenchymal metastases or peritoneal involvement.[74,75] MRI has higher accuracy for the detection of small metastases, especially in solid organs. The combination of cross-sectional techniques is used for the evaluation of treatment response.

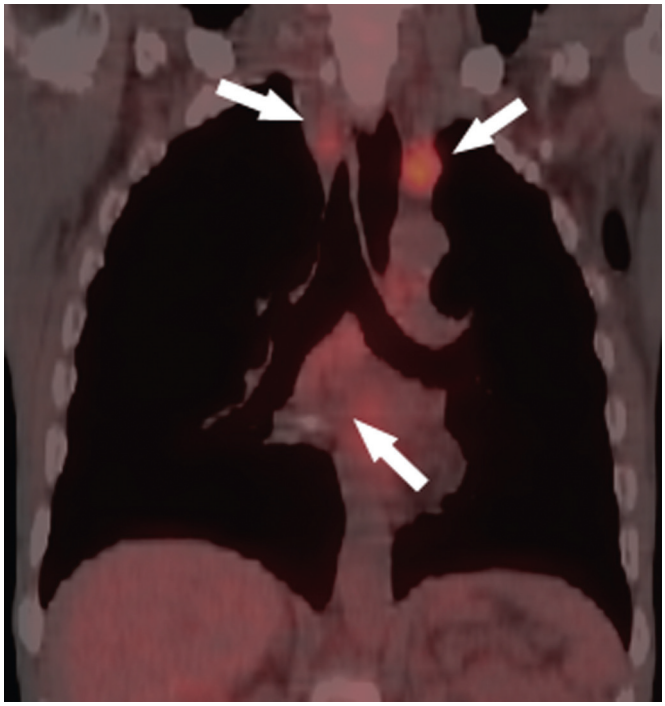

Figure 10-5 Male, age 67 years, with known esophageal cancer. On CT scan, multiple enlarged nodes involving nearly all mediastinal sites were identified. Coronal fused PET/CT image shows increased avidity in the paratracheal and subcarinal lymph nodes *(arrows)*, indicative of carcinoma.

The most common finding of adenocarcinoma is the gastric wall thickening, which may be focal or diffuse. Ulceration is common. Differential diagnosis includes gastrointestinal stromal tumor (benign or malignant), metastatic disease, and lymphoma. For tumors located in the gastric cardia or fundus, lymph node involvement patterns are similar to those of distal esophageal tumors and include the gastrohepatic ligament and periaortic spaces.[70-73] Distal cancers often drain along the lesser curvature of the stomach.[70-73] Reformated images are usually helpful for the detection of small asymmetrical wall thickening and lymph nodes.[76]

Primary Small Bowel Tumors

Small bowel tumors constitute less than 5% of all gastrointestinal tumors.[77] Tumors are more common in the duodenum compared to the jejunum or ileum. Tumors may manifest as nodules, annular lesions, excavating masses, or stricturing lesions. The most common malignant neoplasms include adenocarcinoma (40%), carcinoid (20% to 25%), lymphoma (10% to 15%), and gastrointestinal stromal tumors (GIST) (10%). Adenocarcinoma occurs most commonly at the duodenum near the ampulla, whereas carcinoid tumors originate most often in the ileum. Adenocarcinomas present as soft-tissue mass causing annular or eccentric luminal narrowing and obstruction. Carcinoid tumors may vary from small submucosal lesions to large ulcerating lesions with a prominent desmoplastic reaction and homogeneous enhancement. Lymphomas

usually present as circumferential or cavitary mass. CT is the most commonly used and available technique for diagnosis.[78] The use of conventional small bowel imaging with barium under fluoroscopy has dramatically decreased after the evolution of CT and MR enterography or enteroclysis techniques.[77-83] CT and MR enterography/enteroclysis techniques have similar accuracy and have increased the accuracy of detection of small bowel tumors compared to CT or MRI alone.[77-83] Metastastases to the small bowel are uncommon. Staging is performed with CT or MR, which often demonstrates extension to mesenteric lymph nodes, the liver, and peritoneum.[82,83]

Primary Tumors of the Colon and Rectum

Primary colorectal tumors are usually discovered during colonoscopy. Occasionally, an obstructing colonic cancer will be identified on a CT scan of the abdomen. Wall thickening is the most common presentation and may be associated with colonic obstruction and advanced disease.[84] The primary use of cross-sectional imaging is for identification of locoregional and distant metastatic disease. Patterns of spread are primarily lymphatic and hematogenous. Direct extension occurs when a tumor perforates the serosa and invades adjacent tissue. Lymphatic spread may occur into the ischiorectal fossa and perianal space (rectum/anus) or along the mesenteric vessels (left and right colon). A common final pathway for many tumors is the nodal region adjacent to the origin of the inferior mesenteric artery. Enlarged nodes may also be seen in the porta hepatis. Lymph nodes greater than 1 cm in short-axis diameter are considered suspicious for metastatic disease. Unfortunately, size is not a good indicator of tumor involvement. Lymph nodes greater than 1 cm in size harbor cancer in only 65% of cases.[85] Hematogenous spread yields liver or lung metastases. MRI is the best technique for the evaluation of the liver and staging of rectal cancer.[86,87] Advanced disease may consist of pulmonary nodules, widespread lymphadenopathy, and solid tumor masses within the mesentery and pelvis because of direct extension of disease. PET/CT has high accuracy for intraabdominal and extraabdominal staging ranging between 92% and 99%, respectively.[86]

Metastatic Disease to the Gastrointestinal Tract

Metastases most commonly affect the serosa and develop secondary to direct extension or peritoneal dissemination. Gynecologic malignant neoplasms (ovarian) and gastrointestinal malignant neoplasms (colon, gastric, and pancreatic) are the most common tumors. Most serosal metastatic implants distort and narrow the small and large bowel, sometimes leading to obstruction. Rarely, hematogenous or lymphatic metastases to the bowel wall may occur. Cross-sectional imaging including CT and MRI can be used for the diagnosis although CT is more commonly used and especially helpful for the evaluation of bowel obstruction.

Primary Tumors of the Liver

Hepatocellular carcinoma (HCC) is the most common primary malignancy of the liver and occurs most commonly in patients with cirrhosis and chronic liver disease.[88,89] The nodular regeneration and fibrotic network of chronic liver diseases make detection of HCCs difficult. Excluding HCCs, three focal nodular lesions are specifically seen in patients with chronic liver disease: regenerative nodules, low-grade and high-grade dysplastic nodules.[88,89] Regenerative nodules and low-grade dysplastic nodules are benign lesions.[88,89] High-grade dysplastic nodules may be premalignant.[88,89] HCCs may develop de novo or may develop in high-grade dysplastic nodules.

MRI is the most accurate imaging technique for the detection and characterization of focal liver lesions including hepatocellular carcinoma.[88,89] The use of dynamic postgadolinium imaging, including hepatic arterial dominant, hepatic venous, and interstitial phases, are critical. Although high-grade dysplastic nodules demonstrate arterial enhancement with fading, HCCs show arterial enhancement with wash out and capsular enhancement on later phases.[88,89] HCCs show variable signal intensities on T1- and T2-weighted sequences.[90,91] HCCs may have fat content or contain hemorrhage. Subcapsular lesions may cause subcapsular or intraperitoneal hemorrhage. HCCs are usually focal lesions; however, diffuse infiltrative HCCs are uncommonly seen and generally associated with portal or hepatic venous tumor thrombosis (Figure 10-6).[88,89]

Metastatic Disease to the Liver

MRI is the most accurate technique for the detection and characterization of metastases in the liver.[92,93] Metastases may be hyper- or hypovascular. Adenocarcinoma metastases are the most common cell type and vary in vascularity depending on the primary site. The most common hypovascular adenocarcinoma metastasis is secondary to colon adenocarcinoma (Figure 10-7), and the most common hypervascular adenocarcinoma metastasis results from breast cancer (Figure 10-7). Typical hypovascular adenocarcinoma metastases appear as lobulated masses with intensely enhancing borders and minimal central enhancement on CT and MRI. Typical hypervascular adenocarcinoma metastases appear as oval lesions showing thick ring enhancement or homogeneous enhancement. Adenocarcinoma metastases are of increased signal intensity on T2-weighted images but are less bright than cysts or hemangiomas. Another common and typical pattern of metastatic disease is rapid, complete enhancement with later washout, which is a characteristic feature of hypervascular metastases including carcinoid or neuroendocrine tumors. Hemorrhagic or melanin containing metastases (malignant melanoma) demonstrate high signal on T1-weighted images (Figure 10-7). Cystic metastases may be seen with epithelial ovarian cancers. Using MRI, it is usually possible to identify benign lesions with confidence when they exceed 10 mm in diameter.

Primary Tumors of the Retroperitoneal Organs

Primary Pancreatic Tumors

The most common pancreatic malignancy, adenocarcinoma, usually occurs in the head of the pancreas (Figure 10-8) and may occlude the pancreatic duct, common bile duct, or both.[94,95] This can lead to the classic (although rare) presentation of painless jaundice with a distended, palpable gallbladder. MRI combined with Magnetic resonance cholangiopancreatography is the most accurate technique for the evaluation of pancreatic adenocarcinoma when the tumor is confined to the pancreas. CT is advantageous in evaluation of vascular encasement of the superior mesenteric artery, a sign of unresectable disease.[94] Endoscopic US has been reported to be comparable to MRI for local staging.[94] Although endoscopic US is limited because of its invasive nature, the ability to do biopsy under ultrasound is an important advantage. Diagnostic accuracy is high, ranging from 88% to 94%.[96,97]

Staging is best done using the combination of MRI-MRCP and PET/CT.[94] Dynamic MR imaging including hepatic arterial and venous phases depicts vascular encasement and invasion with a high degree of accuracy and plays a critical role not only for the determination of resectability but also

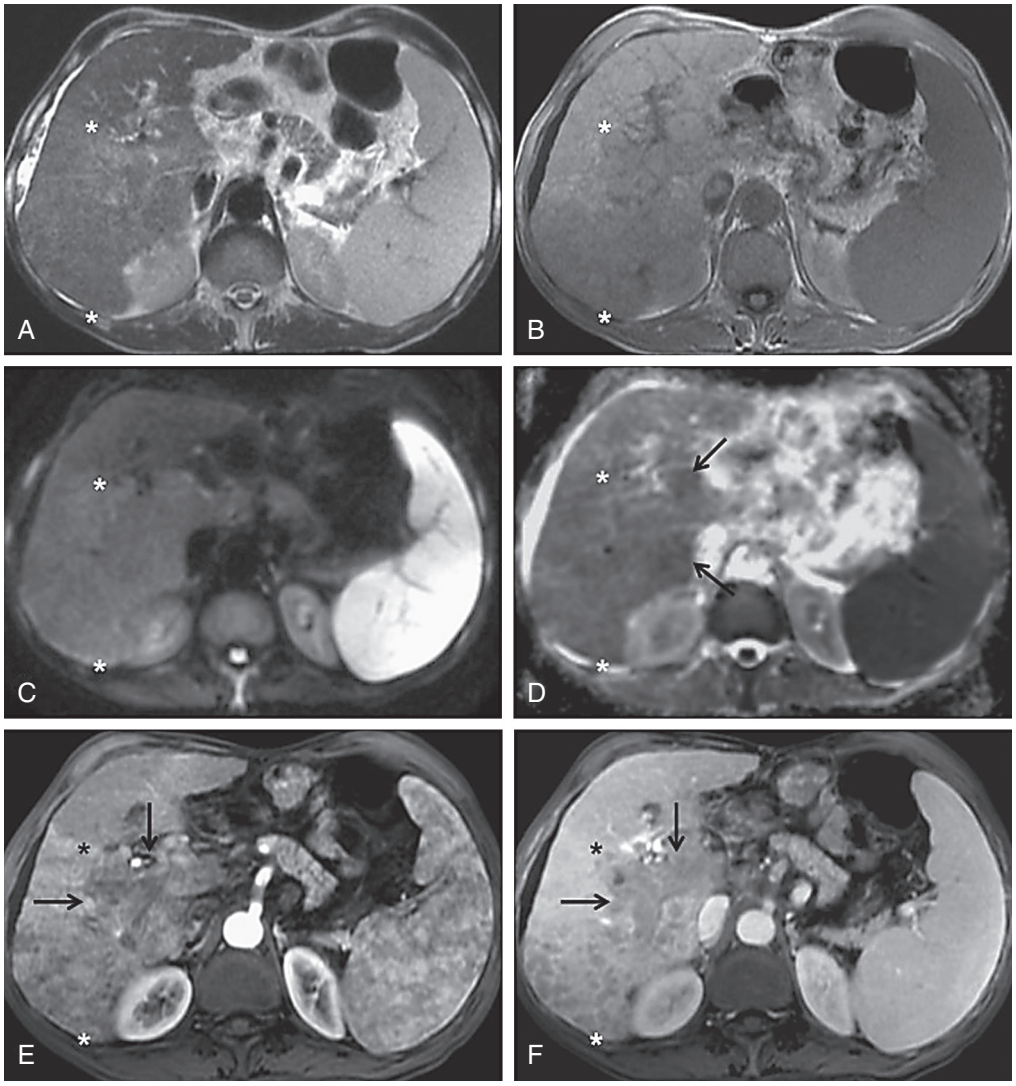

Figure 10-6 Male, age 60 years old with chronic liver disease secondary to Hepatitis C infection presents with very high alpha fetoprotein (AFP) levels and jaundice. A diffuse hepatocellular carcinoma (anterior and posterior borders are marked with asterisk on images) replacing the right lobe of the liver and part of the left lobe shows is shown with mild to moderate high signal on transverse T2-weighted SS-ETSE **(A)** and diffusion weighted **(C)** images. The lesion shows partially low signal on T1-weighted 2D-GE image **(B)**. The lesion shows areas of diffuse restriction *(arrows)* adjacent to the thrombosed portal vein on apparent diffusion coefficient (ADC) map **(D)**. Please note that the portal vein could not be differentiated on precontrast images. The lesion and associated tumor thrombosis *(arrows)* demonstrates early heterogeneous enhancement **(E)** with later heterogeneous washout **(F)** on postgadolinium images.

for treatment planning.[94] Local lymph node enlargement and liver metastases are accurately identified. MRI is more accurate compared to CT in the detection of small tumors, small liver metastases, and peritoneal metastases.[94] MRI is slightly more accurate or comparable in the determination of local invasion. MRI can detect pancreatic lesions at 1 cm range although CT can detect the lesions at 2 cm range. Unfortunately, identification of very small (<1 cm) pancreatic cancers remains difficult. Pancreatic ductal dilation with abrupt cutoff may be a sign of small neoplasms.[94] The second most common solid malignant neoplasms of the pancreas are hypervascular tumors including neuroendocrine tumors (Figure 10-8).

Primary Tumors of the Kidney

Renal cell carcinoma is most often identified serendipitously, usually on a CT scan or ultrasound study performed for symptoms unrelated to the genitourinary tract. Once a solid, vascular mass is identified, treatment is surgical removal or ablation, barring significant medical comorbidities. Staging may be performed with contrast-enhanced CT or MRI, which have similar high accuracy, although contrast-enhanced CT is more commonly used (Figure 10-9).[98,99] MRI may be preferred in patients with severe allergy to iodinated contrast media, whereas CT may be preferred because of the concerns of nephrogenic systemic fibrosis. PET/CT is usually not used for the initial staging. Tumor size, location, and vascular supply are critical in determining whether the patient is a candidate for laparoscopic or partial nephrectomy.[100] Multiplanar imaging or reformatted images fully depict the vascular and urinary tract anatomy.[101] Extension into the renal vein, the presence of enlarged perihilar lymph nodes, involvement of the ipsilateral adrenal gland, and invasion of adjacent organs can also be assessed.[98]

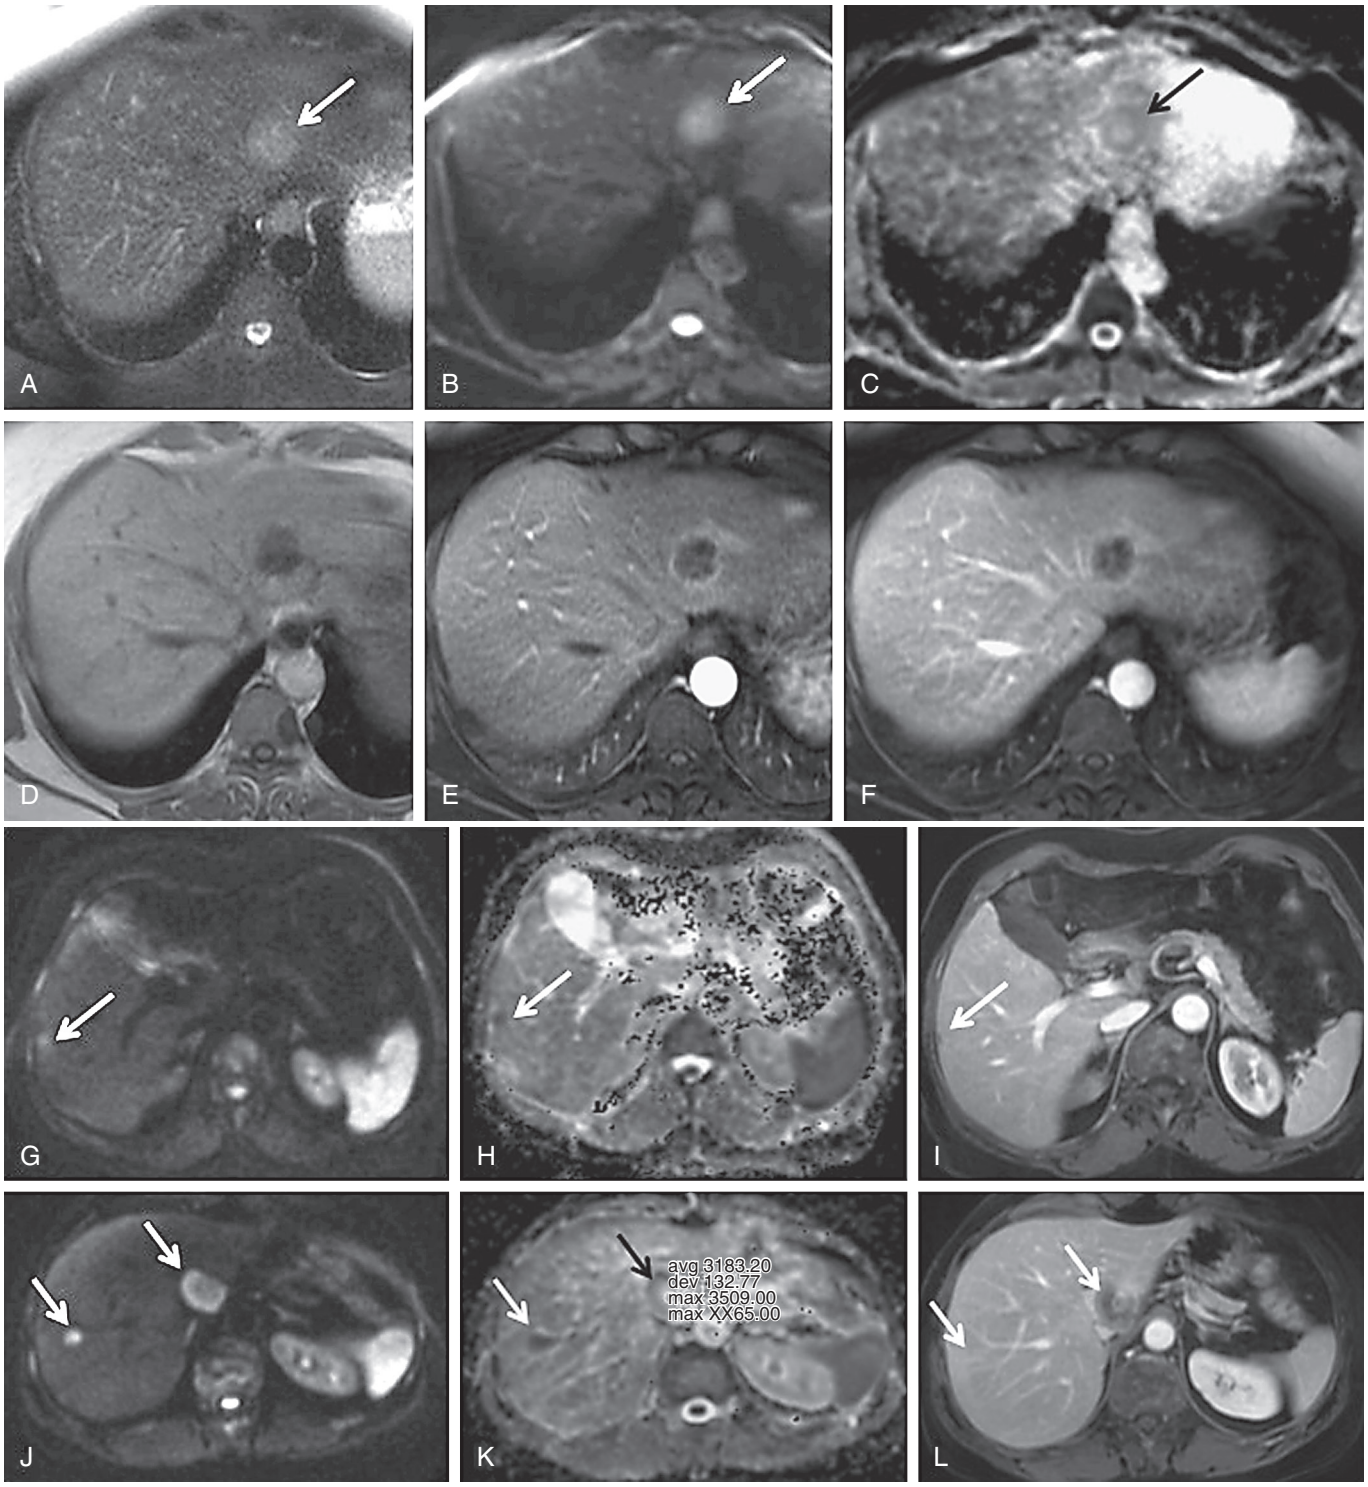

Figure 10-7 Male, age 51 years old with a solitary liver metastasis secondary to colon cancer. The lesion *(arrows;* **A-C***)* is located in the left lobe of the liver and shows mildly high T2 signal on T2-weighted transverse SS-ETSE image **(A),** mildly high signal on diffusion weighted (DW) image **(B)** and peripheral low signal on apparent diffusion coefficient (ADC) map **(C),** which represents peripheral diffusion restriction. The central high signal on ADC map represents central necrosis. The lesion shows typical mildly lobulated appearance on T1-weighted in-phase image **(D)** and predominant peripheral enhancement on contrast-enhanced images **(E** and **F)**. Female, 55 years old with liver metastases secondary to invasive ductal carcinoma of the breast. A small lesion *(arrow)* with high signal on DW image **(G)** shows low signal representing diffusion restriction on ADC map **(H)**. It is difficult to visualize the lesion *(arrow)* on postgadolinium image **(I)** because of its similar enhancement due to background liver. Female, 48 years old with liver metastases secondary to invasive ductal carcinoma of the breast. Two lesions *(arrows)* with high signal on DW image **(J)** are noted. The smaller lesion *(white arrow)* shows low signal representing diffusion restriction on ADC map **(K)** while the larger lesion *(black arrow)* with indicated measurements on ADC map **(K)** demonstrate peripheral low signal suggesting peripheral diffusion restriction. The smaller lesion shows similar enhancement compared to the background liver and is difficult to visualize on postgadolinium image **(L)** whereas the larger lesion shows predominantly peripheral enhancement **(L)**.

Continued

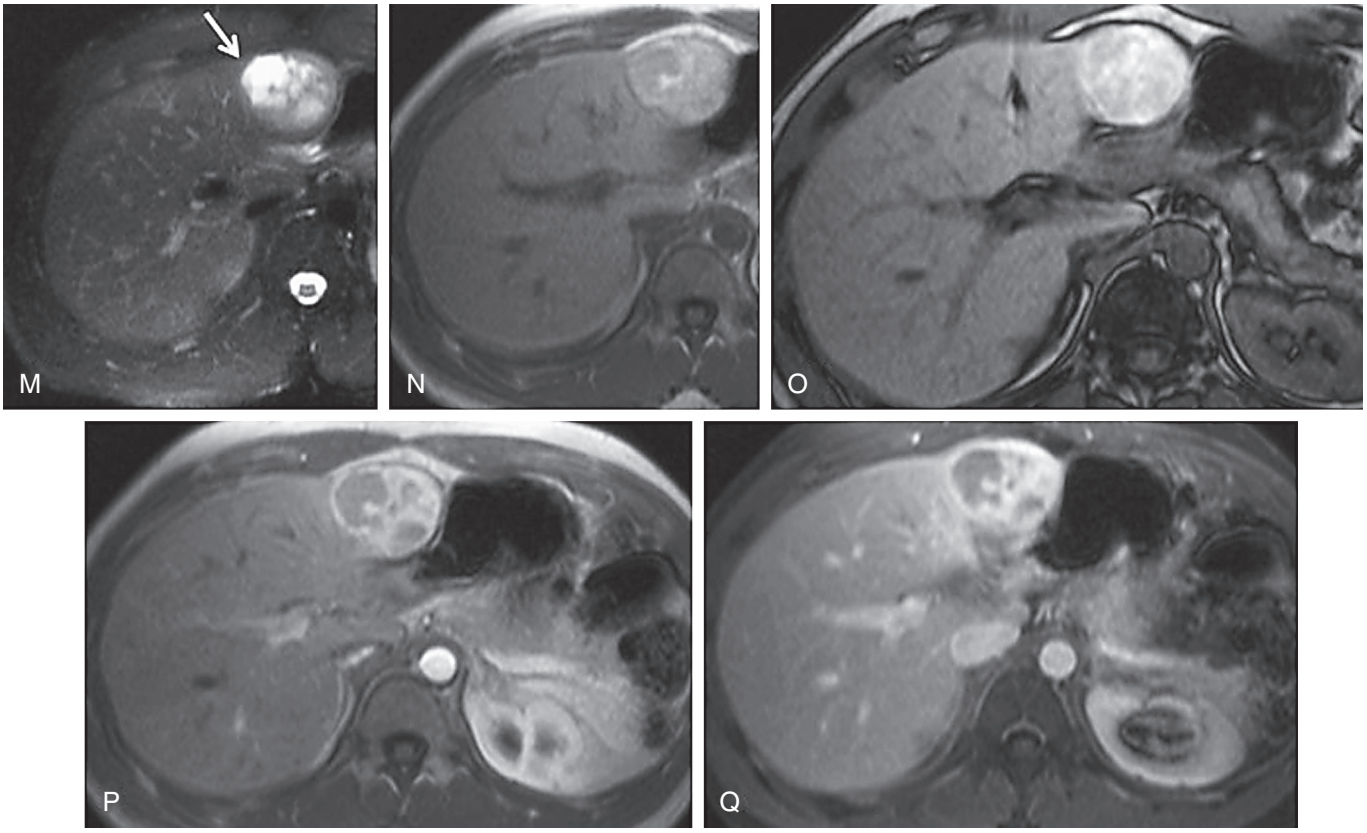

Figure 10-7, cont'd DW imaging may be particularly helpful for the better demonstration of small liver metastases, especially if they are located peripherally or treated with chemotherapy. Male, 35 years old with liver metastasis secondary to malignant melanoma. A metastasis *(arrow)* with heterogeneous high signal on transverse T2-weighted SS-ETSE image **(M)**, high signal on both in-phase and out-of-phase T1-weighted 2D-GE images **(N** and **O)** and heterogenous enhancement on postgadolinium images **(P** and **Q)** is seen in the left lobe of the liver. High T1 signal is typical for malignant melanoma metastasis because melanin shows high signal on T1-weighted images.

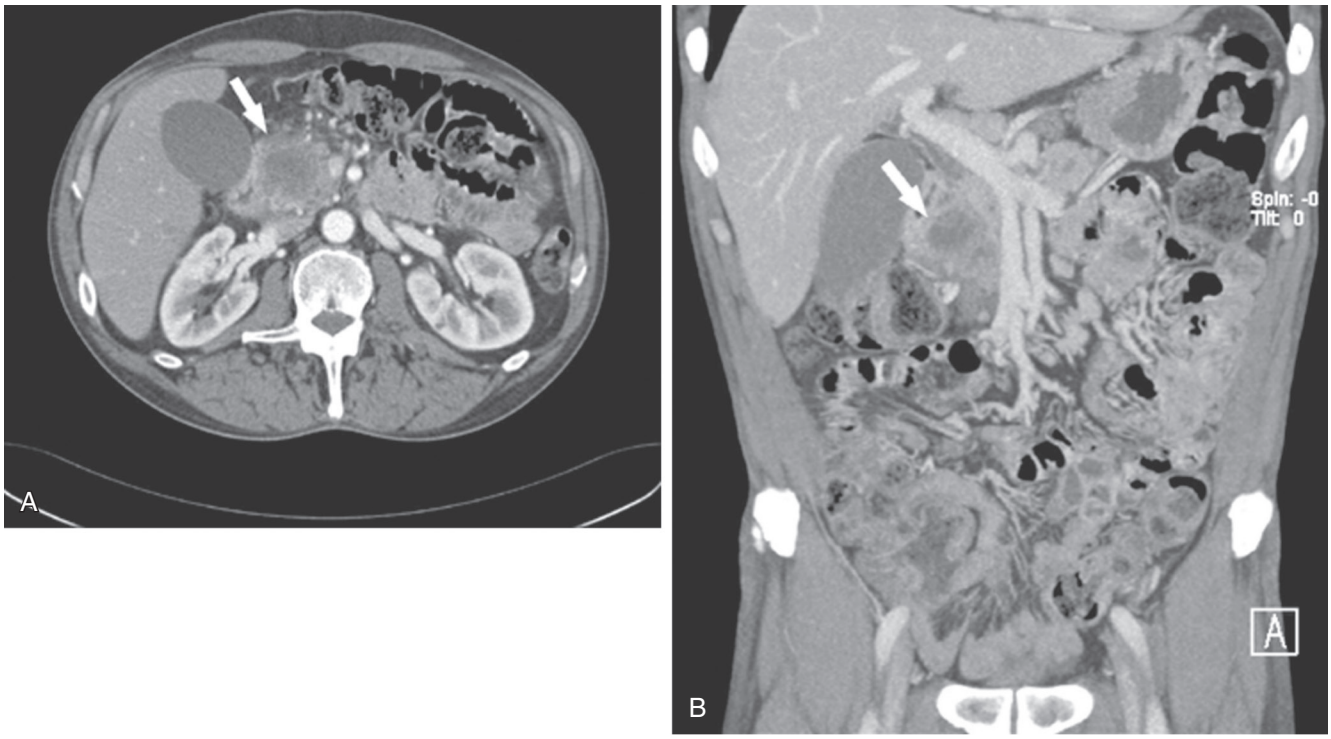

Figure 10-8 Female, age 67 years, with pancreatic cancer. Axial contrast-enhanced CT image **(A)** shows low-density mass arising from pancreatic head and encasing the superior mesenteric vein. Coronal reformatted image derived from the axial CT data **(B)** shows the relationship of the tumor *(arrow)* to the adjacent vasculature and gallbladder. No liver metastases or enlarged local lymph nodes were identified. Male, 45 years old with pancreatic neuroendocrine tumor and liver metastases.

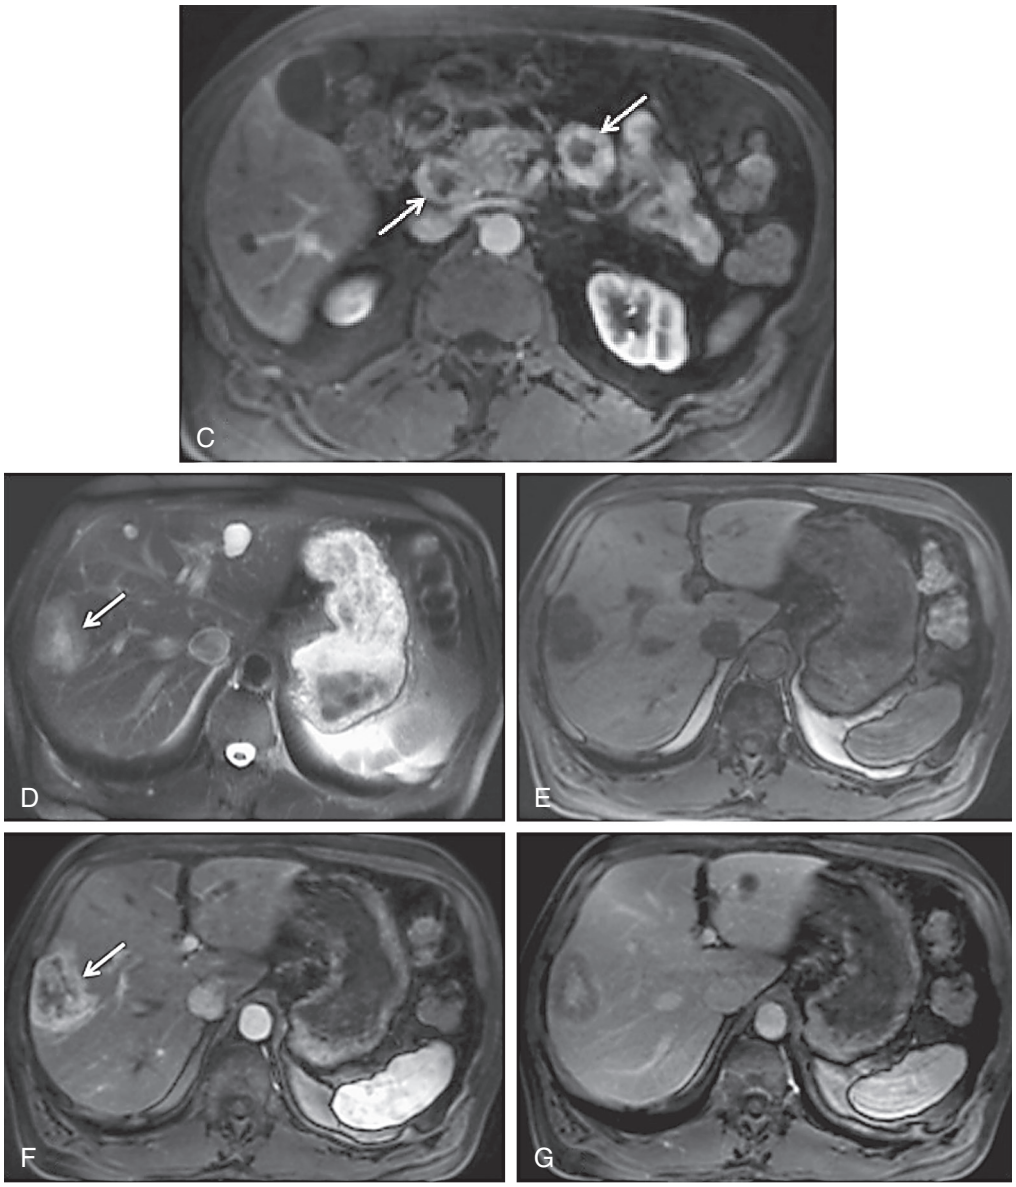

Figure 10-8, cont'd Two peripherally enhancing hypervascular lesions *(arrows)* are detected in the pancreatic head and body of the pancreas on the hepatic arterial dominant phase on postgadolinium 3D-GE image **(C)**. A hypervascular metastasis *(arrows)* is noted in the right lobe of liver demonstrating mildly high signal on transverse T2-weighted SS-ETSE image **(D)** and low signal on T1-weighted 3D-GE image **(E)**. The metastasis shows intense peripherally dominant heterogeneous enhancement on the hepatic arterial dominant phase **(F)** and later peripheral wash-out with central wash-in on the hepatic venous phase **(G)**. Please note that additional hypervascular small metastases and small cysts are also seen in the liver.

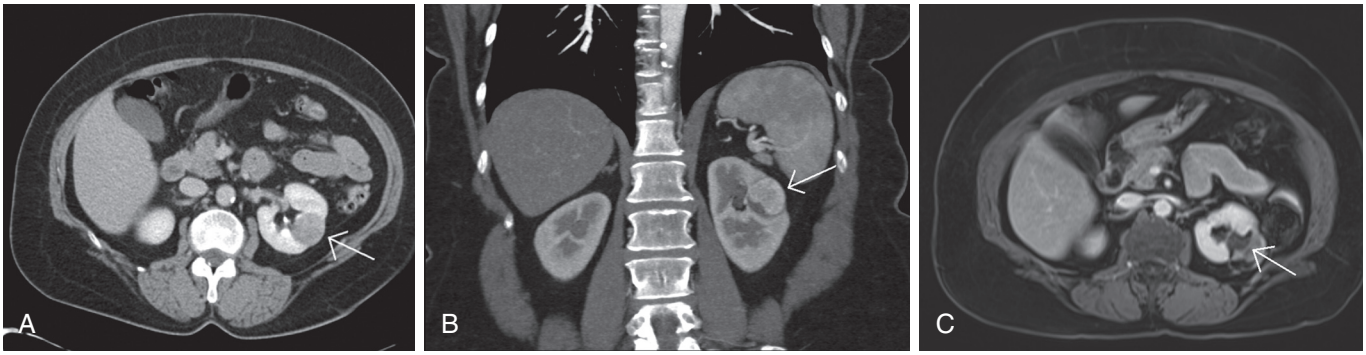

Figure 10-9 Female, age 65 years, with renal cell carcinoma. Axial contrast-enhanced CT image **(A)** and coronal reformatted contrast-enhanced CT image **(B)** demonstrate an enhancing mass involving the left kidney *(arrows)*. The patient subsequently underwent percutaneous radiofrequency ablation (RFA). Axial contrast-enhanced MRI image **(C)** demonstrates no suspicious enhancement *(arrow)* following RFA, and surrounding hematoma at the RFA site.

Urothelial carcinoma is staged primarily using CT urography, in which delayed multiplanar images are reconstructed to visualize the urinary tract with high resolution. Three-dimensional delayed images can also be acquired with this approach similar to an intravenous urogram.[101,102] A synchronous bladder or upper tract lesion can be staged with CT urography, eliminating the need for an additional test. Alternatively, MR urography can be used in younger patients to evaluate the urinary tract, without the radiation exposure of CT scanning.

Primary Tumors of Other Retroperitoneal Organs

Large masses of the retroperitoneum are often sarcomas. They may arise from the inferior vena cava (IVC), renal capsule, muscle, or fat. MRI and CT can successfully be used for the diagnosis and staging although CT is more commonly used.[103,104] MRI may be more advantageous for the evaluation of vascular invasion or superficial organ or body wall invasion, whereas CT may be more advantageous for bowel involvement. MRI can also better evaluate the internal structure of the tumor including fat content, necrosis, or hemorrhage. Liposarcomas are the most common type of retroperitoneal sarcomas, and CT and MRI demonstrate the fat content successfully. Retroperitoneal sarcomas most commonly metastasize to the lungs and liver.

Primary and Secondary Adrenal Tumors

Nonfunctioning adenomas are the most common adrenal lesions, whereas metastastases are the most common malignancy. It is critical to definitely identify adenomas to avoid overstaging of a primary neoplasm, particularly lung cancer. When an adrenal lesion measures less than 10 HU on an unenhanced CT scan, it contains intracytoplasmic lipid and is reliably benign. Unenhanced CT with a cutoff value of 10 HU has 71% sensitivity and 98% specificity for the differentiation of benign lesions from metastatic lesions.[105-107] Lipid poor benign lesions cannot be reliably identified with unenhanced CT. The measurement of washout on contrast enhanced CT can be employed because benign lesions demonstrate increased washout of contrast material on delayed images acquired at 15 minutes, compared to metastatic lesions.[105-107] An absolute percentage washout of 60% or higher has reported sensitivity of 86% to 88% and specificity of 92% to 96% for the diagnosis of adenoma.[105] Chemical shift imaging (CSI) MRI is based on the detection of signal loss on T1-weighted images determined with slightly different parameters. The decrease in signal intensity arises from the different precession frequencies of fat and water protons and is indicative of a benign adenoma.[105,107,108] CSI-MRI has 81% to 100% sensitivity and 94% to 100% specificity for the differentiation of adenomas from metastases.[105] PET/CT is a reliable technique for the identification of hypermetabolic metastases to the adrenal gland that are more than 1 cm in size. PET/CT has 100% sensitivity and 98% specificity for the differentiation of adenomas from metastases.[105]

Adrenal cortical carcinomas and pheochromocytomas are other rare retroperitoneal tumors that can be diagnosed with CT and MRI. Pheochromocytoma is usually a clinical diagnosis based on physical findings and increased urinary excretion of vanillymandelic acid. MRI is used to locate the source of the tumor.

Primary Tumors of the Pelvic Organs

Primary Testicular Tumors

Testicular tumors are diagnosed with US with high accuracy.[109] MRI has high accuracy for the diagnosis and differentiation of testicular and extratesticular tumors and is used for the diagnosis in equivocal cases.[109,110]

Following the standard treatment of orchiectomy, contrast-enhanced CT scans of the abdomen and pelvis are performed to search for nodal involvement and metastatic disease.[111] The lymphatic drainage of the testicles follows the gonadal veins.[111-113] Therefore, for right-sided testicular tumors, the sentinel nodes are those in the aortacaval and pre- or paracaval lymph nodes at the level of L2; whereas on the left paraaortic and preaortic lymph nodes just below the left renal vein are of greatest importance.[112,113] Right-to-left crossover of lymphatic involvement may be seen following the normal drainage to the cisterna chyli and thoracic duct. Left-to-right crossover may be seen more frequently (20% of cases).[112,113] The involvement of contralateral nodal metastases is rare (less than 2% of cases) without the involvement of ipsilateral nodes.[112,113] The iliac chain lymph nodes may be involved because of the spread from the sentinel nodes if the tumor burden is high.[112,113] The pelvic and inguinal lymph nodes may also be involved if the normal lymphatic drainage pathways are disrupted due to previous pelvic or scrotal surgery or orchiectomy.[112,113]

Involved lymph nodes are of soft-tissue density with moderate to prominent enhancement. Enlarged lymph nodes from nonseminomatous germ cell tumors including teratoma may contain cystic areas. Unfortunately, node density does not correlate with the degree of cell kill following chemotherapy. Residual nodes often undergo surgical resection to maximize potential for cure. On follow-up scans, all nodes greater than 5 mm are considered suspicious for metastasis. Enlarged nodes may encase the renal vessels and compress and occasionally invade the inferior vena cava (IVC). MRI has similar accuracy for the diagnosis of lymph node involvement and it may be preferred not only because of the concerns of allergic reaction to iodinated contrast, but also because of the concern of radiation because testicular cancer is most common in young men. PET/CT is also successful for the evaluation of metabolic activity of large residual solid lymph nodes, which do not decrease in size following therapy.

Primary Tumors of the Prostate Gland

Transrectal image–guided biopsy is still the gold standard for the diagnosis of prostate cancer. MRI has been increasingly used for prostate imaging over the last 10 years. MR imaging is usually performed with endorectal and surface phased array coils using a high field strength 1.5 T magnet. Endorectal coils may not be necessary using a 3.0 T magnet because of its higher signal-to-noise ratio. Small field-of-view high-resolution T2-weighted MRI imaging is the standard mainframe for prostate imaging. On T2-weighted images, prostate cancer usually appears as a region of low to intermediate signal.[114-118] Direct extension of disease through the low T2-signal capsule is indicative of extracapsular extension and seminal vesicle or neurovascular bundle invasion and enlarged lymph nodes can be detected.[114-118]

Multiparametric MR imaging including T2-weighted imaging, diffusion-weighted imaging, dynamic contrast-enhanced imaging, and MRS detect tumors in approximately 70% to 75% of cases. (Figure 10-10).[114-118] Diffusion weighted imaging may be particularly helpful for the differentiation of fibrosis and benign prostatic hypertrophy from adenocarcinoma.[117] This is especially helpful in detection of cancer in the central and transitional zones. Combined diffusion weighted and T2-weighted imaging has better sensitivity and specificity (70% and 83%) compared to T2-weighted imaging alone.[117] Additionally, multiparametric MR imaging has a sensitivity of 93%, positive predictive value of 57%, and an overall accuracy of 92% in patients with low prostate-specific antigen (PSA)

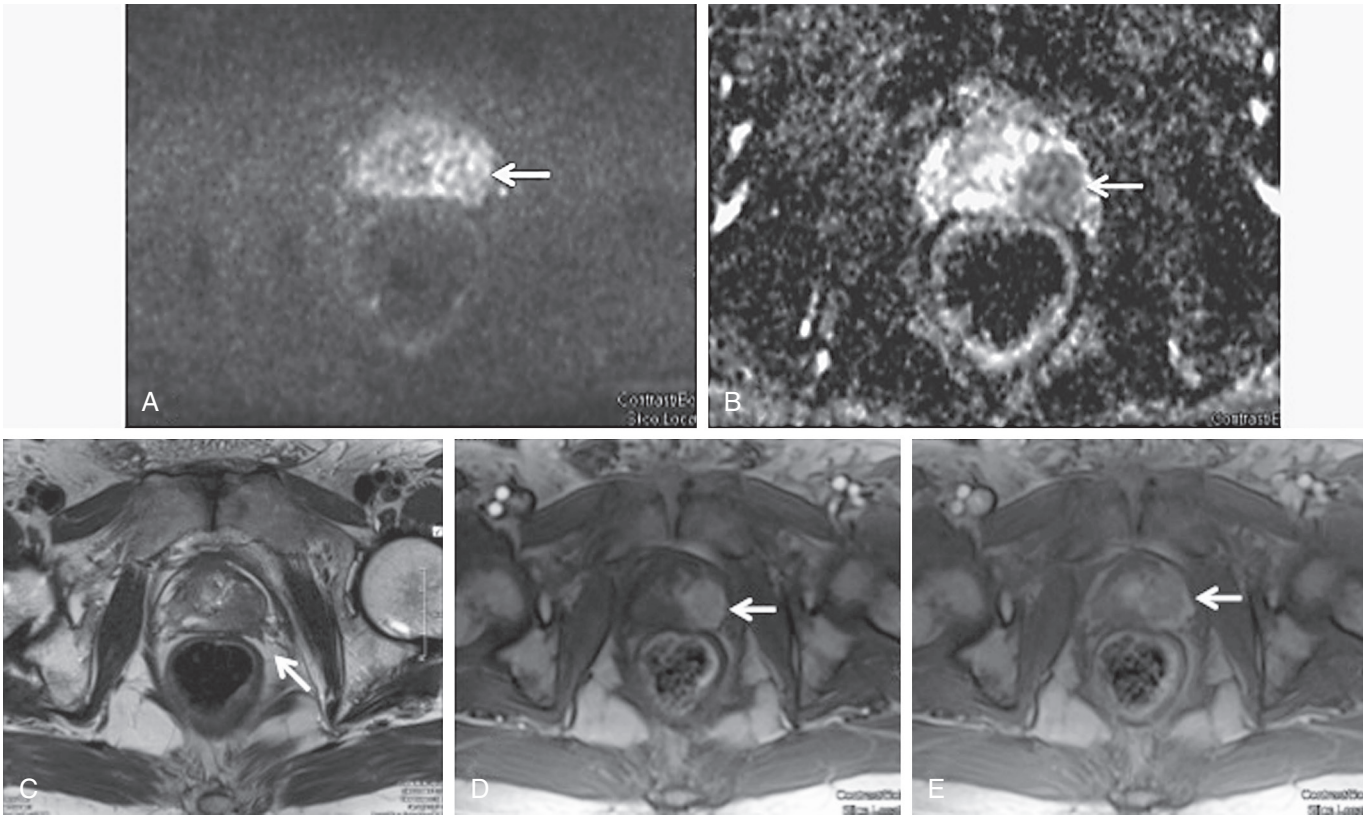

Figure 10-10 Male, age 63 years old man with prostate adenocarcinoma. The lesion *(arrows)* shows high signal on diffusion weighted (DW) image **(A)** and low signal on apparent diffusion coefficient (ADC) map **(B)** representing diffusion restriction. The capsular invasion and extracapsular extension (*arrow*, **C**) is detected on high-resolution T2-weighted turbo spin echo (TSE) image **(C).** On raw postgadolinium perfusion images **(D** and **E)** of prostate gland, the lesion (arrows) shows early increased enhancement **(D)** and late washout **(E)**.

levels and Gleason scores who are undergoing active surveillance.[119]

In most institutions, no pelvic imaging is performed before radical prostatectomy. CT or MR scans of the abdomen and pelvis are ordered before the onset of radiation therapy to identify soft tissue and bony landmarks for planning. In advanced disease (PSA > 20 ng/mL), in patients with high-risk histopathology and in patients with biochemical recurrence, CT or MRI can be used to image the pelvis to identify enlarged pelvic and retroperitoneal lymph nodes. These images are fused with projected radiation fields to optimize dose to the tumor. PET/CT and bone scans are also helpful for the detection of distant organ metastases and bone metastases, respectively. Finally, although US remains the standard, MRI has begun to be used for the evaluation of rising PSA levels in patients with negative US-guided biopsy results, for targeted biopsies, and radiation seed placement in the treatment of prostate cancer.

Primary Bladder Tumors

About 90% of bladder tumors arise from urothelial cells and are primarily transitional cell carcinomas.[120] SCC accounts for 6% to 8% of bladder cancers.[120] Adenocarcinomas typically arise from the urachus. Urothelial tumors are classified as invasive or noninvasive based on extension into and through the muscle.[120] Initial evaluation for painless hematuria, which is the clinical presentation in 80% to 90% of patients with urothelial tumors, includes CT urography and cystoscopy. Cystoscopic staging is the essential part of pretreatment planning and biopsy of the lesions is performed to assess the pathology, grade, and depth of invasion.

CT urography has a more than 90% sensitivity and specificity for the diagnosis of bladder cancer.[120] However, the accuracy for T staging is low (40% to 60%), and CT is especially important for the detection of disease involving the perivesical fat.[120,121] MRI has comparable accuracy for the diagnosis of bladder cancer and may be more accurate especially for the diagnosis of invasion of adjacent organs and T staging (75% to 92%).[120,122,123] It has been reported that MRI may be more accurate for the identification of T2 disease because the detrusor muscle is better visualized with high-resolution T2-weighted sequences, and differential enhancement of tumors and bladder wall is better appreciated with MRI (Figure 10-11).[120,122] Because urothelial carcinoma is often multifocal, CT or MRI should be performed to evaluate the entirety of the urothelial tract for the detection of additional masses, although CT urography is more commonly used for the evaluation of ureters and renal collecting systems with the help of multiplanar and 3D imaging. MR urography is performed with coronal heavily T2-weighted and postgadolinium 3D-GE T1-weighted sequences. Urine appears bright, with or without the use of gadolinium-based contrast agents. CT and MRI have similar accuracy of 70% to 90% for lymph node staging.[120] However, disease involving small lymph nodes less than 10 mm cannot be detected and enlarged lymph nodes may be reactive. Therefore, specificity is limited. Obturator lymph

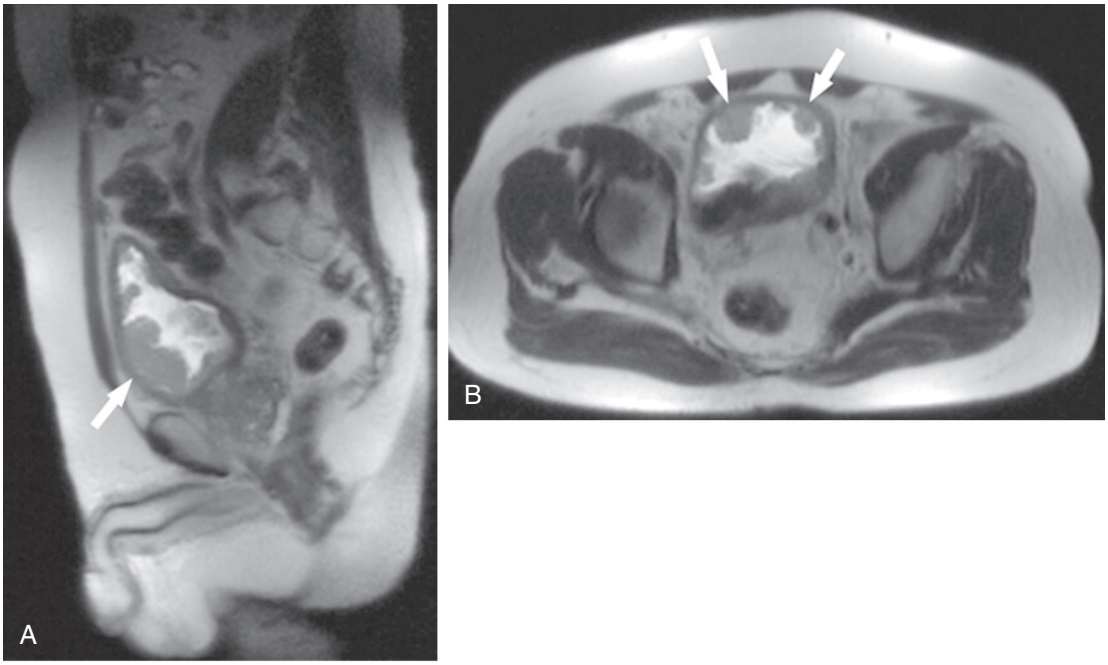

Figure 10-11 Male, age 82 years, with transitional cell carcinoma of the bladder. Sagittal **(A)** and axial **(B)** T2-weighted MRI images show multiple nodules *(arrows)* arising from the bladder wall surrounded by high-signal urine. There is no evidence of invasion of the low-signal muscular wall.

nodes, iliac, and retroperitoneal lymph nodes are the most commonly involved. In general, patients with enlarged lymph nodes are treated with chemotherapy before surgery.

Primary Gynecologic Tumors

Using either CT or MRI imaging, it is best to approach gynecologic cancers in a systematic way. The goals of abdominal and pelvic imaging are to identify the source of the mass whenever possible, locate findings indicative of extension such as peritoneal implants and ascites, assess lymph nodes for increased size and number, and determine whether there is renal compromise. Hydronephrosis will often need to be treated before chemotherapy can begin.

Primary Cervical Tumors

Cervical carcinoma is the third-most common gynecologic malignancy in the United States and the most-common gynecologic malignancy worldwide. The revised FIGO staging system recommends CT or MRI when available. CT has lower accuracy compared to MRI for local staging although CT is able to depict extensive disease, enlarged lymph nodes, hydronephrosis, a fistula into the bladder or rectum, and distant metastases.[124] MRI has higher accuracy than CT for the identification of important prognostic factors including tumor size, parametrial involvement, pelvic wall invasion, and bladder or rectal invasion. MRI has 93% accuracy for determination of tumor size.[125,126] MRI has similar accuracy for the detection of lymph nodes and can also depict ureteral involvement and hydronephrosis.[125,126] Tumor size less than 4 cm, with preservation of low signal intensity cervical stromal ring excludes parametrial invasion with a negative predictive value of 94% to 100%, MRI has 88% to 97% accuracy for the detection of parametrial invasion, which is a contraindication for surgery.[125,126] Dynamic contrast-enhanced imaging and diffusion weighted imaging may be helpful for the detection of small tumors or involvement of adjacent structures.[125]

MR imaging is used for the local staging of tumors at stage IB or higher. MRI can exclude local invasion into the adjacent organs with a negative predictive value of 100% and has 71% to 100% sensitivity and 88% to 91% specificity for bladder or rectal invasion.[125]

The presence of pelvic lymph node metastases does not change the FIGO staging but is a sign of poor prognosis. MR and CT have similar accuracies (85% to 90%) for lymph node detection and are both limited by size criteria.[125] PET/CT is especially helpful for the evaluation of lymph nodes and distant metastases and for the demonstration of posttreatment response. In western countries it has become the test of choice before surgery. MR-PET using the morphologic information from MRI and metabolic information from PET is a promising technique for the diagnosis and follow-up of cervical carcinoma.

Primary Uterine Tumors

Endometrial carcinoma is the fourth-most common malignancy in females and the most common gynecologic malignancy in the United States.[125-128] Adenocarcinomas comprise 90% and sarcomas 2% to 6% of endometrial neoplasms.[125-128] Adenocarcinoma with squamous cell differentiation and adenosquamous carcinoma form the remaining histologic types.[125-128]

On US examination of a postmenopausal woman, the thickness of the endometrium should not exceed 4 to 5 mm. Women with thickened endometrial linings on ultrasound examination may merit biopsy. However, even in the presence of vaginal bleeding, endometrial thickness of less than 4 to 5 mm usually excludes endometrial cancer. MRI has higher accuracy for the diagnosis and staging of endometrial carcinoma compared to CT. MRI plays significant role for the determination of prognostic factors including depth of myometrial or serosal invasion; involvement of cervix, vagina, adnexa, pelvic side wall, bladder, and rectum; and lymph node involvement.[125-128]

Surgical staging of endometrial cancer is done according to FIGO system.[128]

MRI is especially helpful for the evaluation of large tumors, and small tumors of intermediate and high risk. High-resolution T2-weighted images including the sagittal plane are essential for the evaluation of endometrial cancer. Diffusion weighted imaging may be helpful. Dynamic contrast-enhanced images including early and late phases are helpful for the determination of invasion of the tumor because the tumors show early increased enhancement compared to endometrium and myometrium and are prominently hypointense compared to myometrium on the late phases.[125-128]

MR and CT have similar accuracies (85% to 90%) for lymph node detection and are both limited by size criteria.[125,128] In cases in which pelvic lymphatic pathways are blocked by tumor, extension via the processus vaginalis to the inguinal nodes may occur. PET/CT may be especially helpful for the evaluation of lymph nodes and distant metastases and for the demonstration of posttreatment response.

Primary Ovarian Tumors

Ovarian cancer is the leading cause of death from gynecologic cancers in the United States and the majority of cases have advanced disease at the time of diagnosis with a 5-year-survival rate of 30% to 73%.[129] These lesions not infrequently are detected incidentally.[130] The risk of undergoing surgery for incidentally found adnexal masses is 5% to 10%.[129] Benign adnexal lesions are common even in the postmenopausal period.[129,130] Because the imaging features of benign and malignant ovarian neoplasms often overlap, the purpose of imaging is to differentiate benign lesions from indeterminate and malignant lesions and to stage malignant lesions.[129,130] Surgery, despite its risks, is the preferred diagnostic and therapeutic approach for indeterminate lesions rather than follow-up.

US and CT are usually the first modalities used for the evaluation of adnexal masses.[130,131] US has variable sensitivity (85% to 100%) and specificity (52% to 100%) levels for the detection of ovarian malignancies.[129,130] The sensitivity and specificity of CT for the diagnosis for indeterminate masses detected on US is 81% and 87%, respectively.[129,131] CT can successfully diagnose advanced ovarian cancers and may be used for presurgical or pretreatment evaluation and staging (Figure 10-12). PET/CT is not recommended for primary detection or diagnosis because of low sensitivity (52% to 58%) and specificity (76% to 78%) because borderline tumors and low-grade or small tumors may result in false-positive results, whereas inflammatory conditions including hydrosalpinx, endometriosis, and physiologic hypermetabolic uptake in premenopausal women may cause false-positive results.[129,132] However, PET/CT is successfully used for follow-up.[132] Although MRI has high sensitivity and specificity in the diagnosis of ovarian malignancy and staging of ovarian malignancies, it is not as commonly used as CT, primarily because of the time required to acquire and review images.[129,133]

Epithelial ovarian neoplasms constitute 90% of ovarian cancers and arise from the surface epithelium. These tumors, including serous, mucinous, clear cell, endometrioid, and Brenner tumors, are classified as benign, borderline malignant, or malignant. Epithelial malignant tumors typically present as cystic lesions with solid components, mural nodules, thick walls, and septae. Ascites, hydronephrosis, and omental and peritoneal implants are common accompaniments. Enlarged lymph nodes are less common but do occur. Borderline tumors usually present without ascites, peritoneal implants, or involvement of lymph nodes. Fat and fibrous tissue are present in benign ovarian tumors including dermoid tumors and fibromas, respectively.[129,133]

Metastatic Disease to the Pelvis

MRI and CT may both be used to identify tumors within the pelvis. With either technique it can be difficult to separate enhancement caused by inflammation or fibrosis from irradiation or surgical therapy from recurrent disease. Although the presence of a mass lesion abutting the peritoneal surface is indicative of a metastasis (Figure 10-13), the follow-up is important for the detection of small metastases. Enlarged lymph nodes are also usually an ominous sign. PET/CT is especially helpful for the evaluation of response to therapy and the detection of small metastases or metastatic lymph nodes during the follow-up and is usually used in combination with MRI. MR/PET may also be more helpful for the detection of early small volume disease.

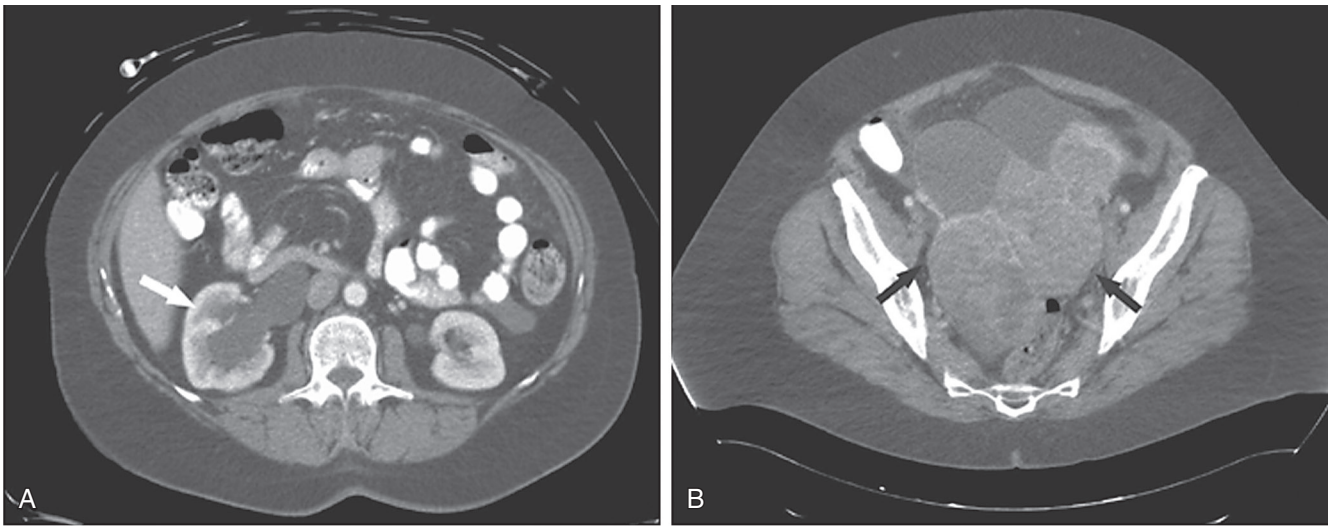

Figure 10-12 Female, age 57 years, with a pelvic mass. Axial contrast-enhanced images at the level of the kidneys **(A)** and pelvis **(B)** show an obstructed right kidney *(white arrow)* and bilateral pelvic masses with cystic and solid components *(black arrows)*. Upon resection this mass was found to consist of bilateral ovarian cystadenocarcinomas.

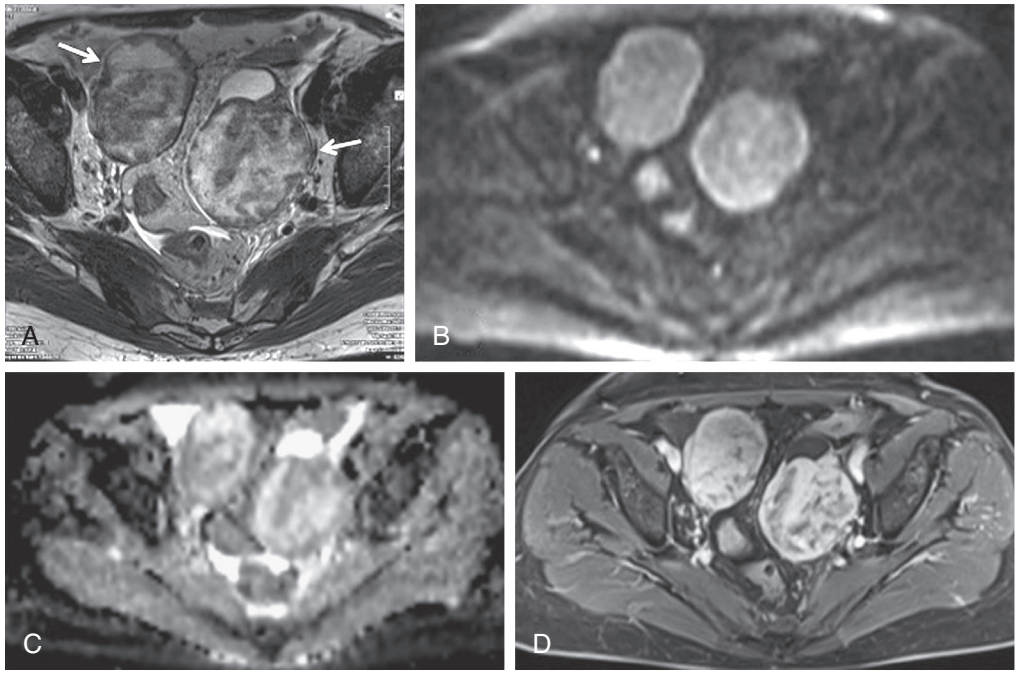

Figure 10-13 Female, age 40 years old with gastric adenocarcinoma with bilateral ovarian metastases (Krukenberg tumor). Both enlarged ovaries *(arrows)* with heterogeneous signal are seen on transverse high-resolution T2-weighted turbo spine echo (TSE) image **(A)**. The enlarged metastatic ovaries show increased signal on diffusion weighted (DW) image **(B)**, partially low signal on apparent diffusion coefficient (ADC) map **(C)** representing restricted diffusion and heterogeneous increased enhancement on postgadolinium image **(D).**

CHAPTER

11 Nuclear Medicine

Terence Z. Wong, Amir H. Khandani, and Arif Sheikh

Molecular imaging techniques such as nuclear medicine are playing an increasingly important role in oncology. In particular, hybrid imaging modalities such as positron emission tomography/computed tomography (PET/CT) and single photo emission computed tomography/computed tomography (SPECT/CT) frequently provide more accurate initial staging and follow-up in oncology patients. Moreover, metabolic changes to therapy almost always precede anatomic changes, and functional imaging can be useful to assess early response to therapy.

Because CT is used routinely for radiation treatment planning, adding the metabolic information provided by PET or SPECT tracers provides a natural opportunity for selectively targeting tumor subpopulations. Adaptive treatment plans based on PET imaging are currently being investigated.

POSITRON EMISSION TOMOGRAPHY (PET)

Despite the exquisite spatial resolution of CT and magnetic resonance imaging (MRI), the physiologic aspects of disease processes are generally not revealed by these anatomically based modalities. Anatomic modalities also have shortcomings in assessing the early response to treatment and in distinguishing responders from nonresponders.

Over the past half-century, a variety of nuclear medicine probes have been used to evaluate disease processes at the cellular level. Nuclear medicine is the only clinical discipline using intracellular contrast agents in imaging, and it is therefore more sensitive than anatomic modalities in detecting disease processes. The concentration of tracer needed (picomolar levels) for PET imaging is many orders of magnitude less than needed to measure enhancement using MR or CT contrast agents (millimolar levels). On the other hand, nuclear medicine imaging techniques have generally suffered from low specificity and low spatial resolution, the latter being associated with the physics of single-photon-emitting radiotracers. Hybrid imaging (SPECT/CT, PET/CT, PET/MRI) affords the opportunity to combine the strengths of both anatomic and functional imaging.

PET is a nuclear medicine modality that uses positron emitters such as ^{18}F, ^{15}O, ^{13}N, and ^{11}C. The fact that these nuclides are components of common biologic molecules makes PET particularly suitable for visually capturing a wide range of biologic pathways. With the exception of ^{18}F these radionuclides have a relatively short half-life and generally require an on-site cyclotron for availability. The longer half-life (110 min) of ^{18}F has enabled ^{18}F PET tracers to be produced commercially at centralized cyclotron facilities and distributed widely for PET imaging.

Currently, the most widely used PET tracer is the glucose analog 2-deoxy-2-[^{18}F]fluoro-D-glucose (fluorodeoxyglucose [FDG]). FDG-PET has proven applications in staging and restaging a variety of malignancies. Currently, clinical investigations are under way using FDG-PET to evaluate early response to therapy, and some trials are incorporating adaptive treatment strategies based on the metabolic response. Although there is keen interest in developing additional PET tracers, FDG has proven to be a versatile general-purpose radiopharmaceutical and will likely remain a "workhorse" oncology tracer in the foreseeable future.

BASIC PHYSICS OF POSITRON EMISSION TOMOGRAPHY

The radioisotope portion of the molecule used in PET imaging emits a positron (i.e., positively charged electron), which travels a distance of a few millimeters in tissue before it collides with a negatively charged electron. This collision annihilates the entire mass of the positron and electron, generating two photons with energy of 511 KeV each. These two photons travel at the speed of light in exactly opposite directions (i.e., 180 degrees apart). Coincident detection of these two photons by two oppositely positioned detectors in the PET scanner results in images with a much higher resolution compared with the conventional, single-photon nuclear medicine studies.

PET/CT allows metabolic information from PET to be combined with the anatomic information from CT. PET/CT increases the diagnostic accuracy compared with stand-alone PET. In PET/CT, the patient undergoes a CT scan, followed by a PET scan, without changing the patient's position. PET for most oncologic indications is acquired from the base of the skull through the upper thighs. In some instances, such as in melanoma patients, PET is acquired from the vertex of the skull through the toes. The CT portion of PET/CT is acquired within seconds, whereas the PET acquisition time for each bed position (about 15 cm) is several minutes; the total PET acquisition time in newer machines is 15 to 25 minutes.

In addition to delivering anatomic information, the CT portion of PET/CT is used to measure the attenuation of the x-ray photons traveling through the patient to produce the so-called attenuation map and correct the PET data for tissue attenuation. During PET acquisition, photons from structures deep in the abdomen or pelvis are more strongly attenuated than those from superficial structures and the chest. The intensity of uptake in deeper structures is underestimated on nonattenuation-corrected PET images; the intensity of uptake in the deeper structures is normalized to the intensity of uptake in the superficial structures on the attenuation-corrected PET images (Figure 11-1). Attenuation correction of the PET data is also a prerequisite for quantification of radiotracer uptake in PET/CT scans.

Spatial alignment between the PET and CT scans is crucial both for correct anatomic localization and for accurate quantification. Misalignment may be caused by the changed position of a body part (e.g., neck, legs) or physiologic changes in the position of an organ (e.g., respiratory movement) between the CT scan and PET scan. The most commonly encountered problem occurs at the lung bases because CT is obtained over a short time interval and PET images are acquired with the patient quietly breathing. This respiratory misregistration can be minimized by acquiring the CT scan with respiration suspended in quiet end-expiration. Because the degree of misalignment and resulting mislocalization can be significant, the

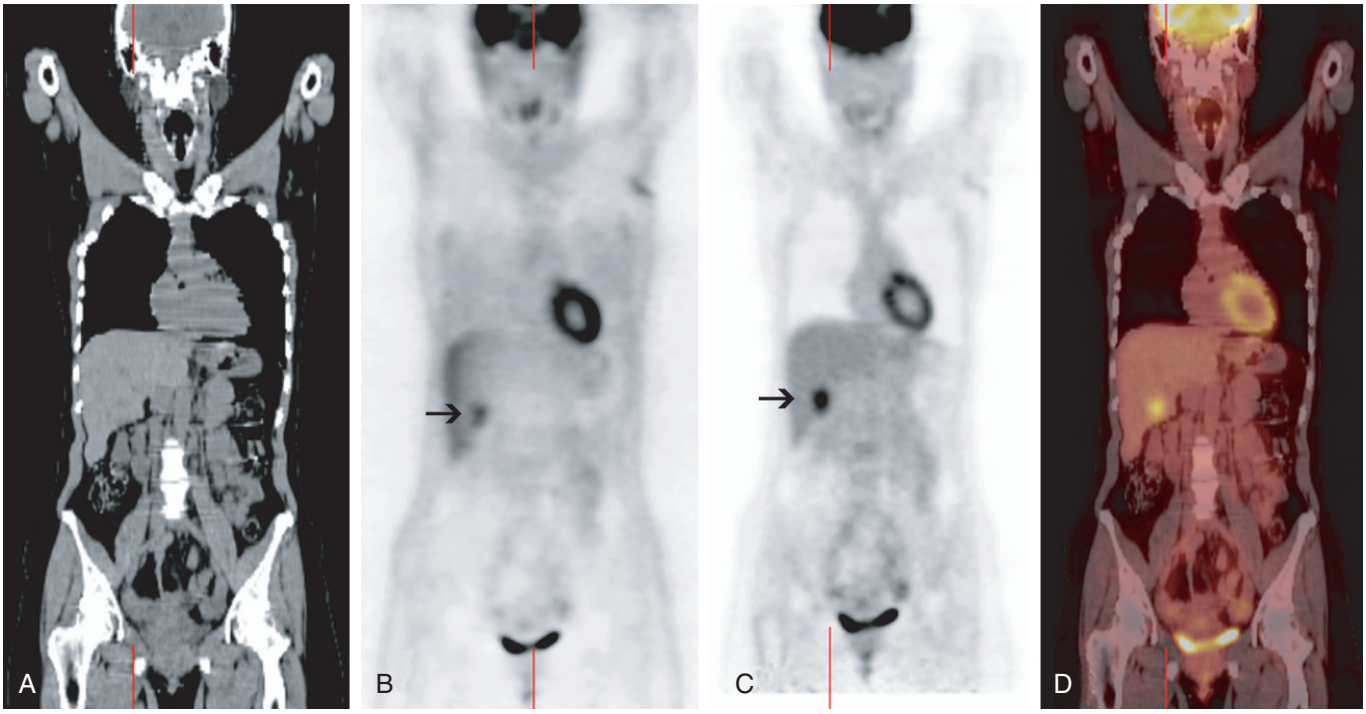

Figure 11-1 CT **(A)** provides diagnostic information (morphology), anatomic localization **(D)**, and photon attenuation data to equalize the intensity of uptake between deeper and superficial structures on the PET scans. In this example, the metastatic liver lesion *(arrow)* is better appreciated on the attenuation-corrected PET image **(C)** than on the nonattenuation-corrected PET image **(B)**.

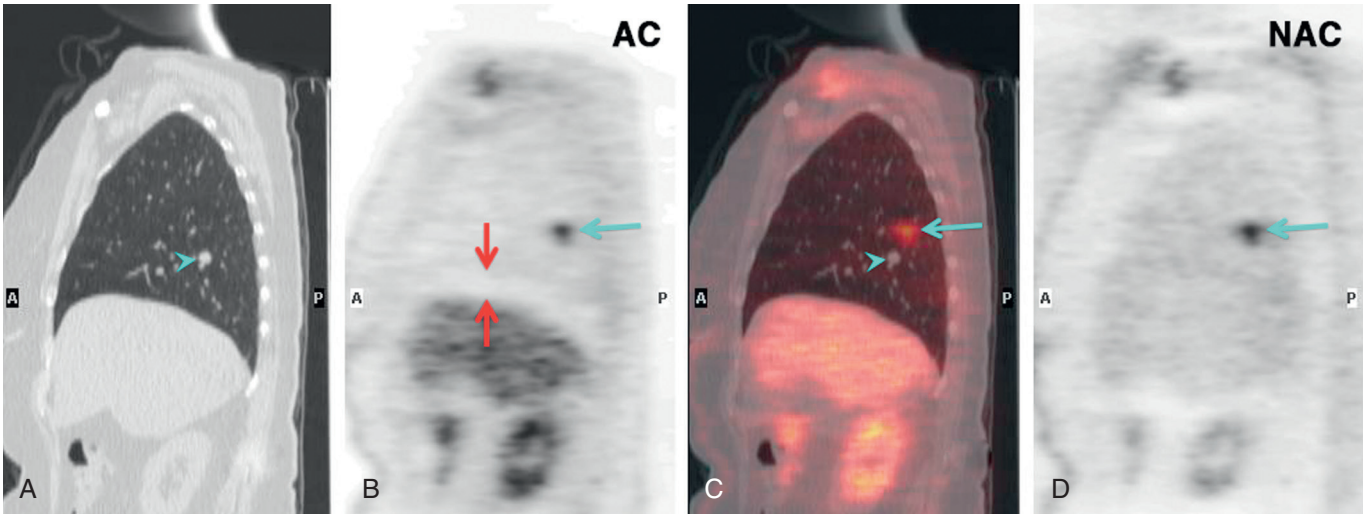

Figure 11-2 Respiratory misregistration. Patient took a full inspiratory breath during the CT scan **(A)**, while FDG-PET imaging (NAC = without attenuation correction) was obtained with the patient quietly breathing **(D)**. Consequently, the lung nodule on CT *(blue arrowhead)* does not correlate with the hypermetabolic focus *(blue arrow)* on PET, as illustrated on the fused PET/CT image **(C)**. On the attenuation-corrected (AC) PET images **(B),** a photopenic rim is noted at the lung base reflecting diaphragmatic misregistration *(red arrows)*. Because the CT scan is used for attenuation correction of the PET images, standardized uptake value (SUV) measurements made on misregistered lesions may not be accurate.

radiologist must be cautious when interpreting or quantifying the attenuation-corrected PET/CT images or using PET/CT images for radiation therapy planning. The magnitude of this misalignment can be assessed by using the fusion display of the nonattenuation-corrected PET images with CT. In case of significant misalignment, the nonattenuation-corrected PET images should be reviewed without fusion with CT, and the metabolic findings on PET should be correlated side by side with the anatomic findings on CT (Figure 11-2).

Current PET/CT scanners are equipped with multidetector CT (MDCT) and have full diagnostic CT capabilities that are equivalent to stand-alone CT scanners. This enables comprehensive PET/CT examinations to be performed that combine PET with fully diagnostic contrast-enhanced CT.[1] MDCT allows reconstruction to be performed using isotropic voxels, enabling multiplanar display of CT images with full spatial resolution. This provides optimal definition of target lesions as well as morphologic characterization and therefore can maximize the diagnostic capabilities of combined PET/CT imaging.

PET-MR has been introduced clinically relatively recently, which offers the ability of obtaining PET images with MRI,

and fusion of that information. MRI provides superior soft-tissue contrast compared to CT. In addition, advanced imaging sequences such as diffusion-weighted imaging (DWI) and dynamic contrast enhancement (DCE-MRI) permit quantitative physiologic information to complement the PET radiotracer information. MRI is also used to calculate attenuation correction for the PET images. Because MRI is limited in its ability to visualize bone and does not use photons, quantification of uptake on PET images may be less accurate compared to PET/CT. However, MRI has diagnostic advantages over CT in evaluating the brain, head and neck, and pelvis, and clinical applications for PET/MRI are currently being developed. Another advantage of MRI is that there is no associated ionizing radiation, so PET/MRI may have additional applications in the pediatric population.

GENERAL ASPECTS OF TUMOR VISUALIZATION ON FDG-PET

FDG is currently the most commonly used radiotracer in clinical PET imaging. Tumor imaging with FDG is based on the principle of increased glucose metabolism of cancer cells, which are more dependent on anaerobic glycolysis (Warburg effect). Like glucose, FDG is taken up by the cancer cells through facilitative glucose transporters (GLUTs). Once in the cell, glucose or FDG is phosphorylated by hexokinase to glucose-6-phospate or FDG-6-phosphate, respectively. Expression of GLUTs and hexokinase, as well as the affinity of hexokinase for phosphorylation of glucose or FDG, is generally higher in cancer cells than in normal cells. Glucose-6-phosphate travels farther down the glycolytic or oxidative pathways to be metabolized, in contrast to FDG-6-phosphate, which cannot be metabolized. In normal cells, glucose-6-phosphate or FDG-6-phosphate can be dephosphorylated and exit the cells. In cancer cells, however, expression of glucose-6-phosphatase is usually significantly decreased, and glucose-6-phosphate or FDG-6-phosphate therefore can become only minimally dephosphorylated and remains in large part within the cell. Because FDG-6-phosphate cannot be metabolized, it is trapped in the cancer cell as a polar metabolite, and it constitutes the basis for tumor visualization on FDG-PET scans.

The intensity of a malignant tumor on PET is dependent on the histology and number of malignant cells in the tumor mass. Hodgkin lymphoma and melanoma are markedly intense on FDG-PET, whereas other tumors such as bronchioloalveolar lung cancer, mucinous adenocarcinomas, or mucosal-associated lymphoid tissue (MALT) lymphomas may have only modest FDG activity. In addition, FDG is also taken up in benign processes such as infection and inflammation because white blood cells and fibroblasts are highly avid for FDG. The major causes for false positive and false-negative FDG-PET activity are summarized in Box 11-1.

Radiation therapy can elicit a chronic accumulation of metabolically active macrophages that are avid on FDG-PET scans. The time course is variable and is dependent on the tumor site, but FDG activity may persist for months in the radiation treatment field. An example of evolving postradiation therapy changes in lung cancer is shown in Figure 11-3. Interestingly, FDG-PET may be obtained during chemoradiation therapy to evaluate early response in patients with non–small-cell lung cancer, suggesting that this inflammatory activity may be delayed until some time after therapy.[2,3] In contrast, radiation therapy may result in false-positive FDG activity when evaluating early response to neoadjuvant therapy in esophageal cancer, and FDG-PET is typically used to evaluate early response to the chemotherapy alone prior to adding radiation therapy.

BOX 11-1 Potential Pitfalls in Oncologic Imaging with FDG-PET

I. FALSE-POSITIVE UPTAKE

1. Variant physiologic activity
   a. Cardiac
   b. Thyroid
   c. Gastrointestinal tract
   d. Genitourinary tract
   e. Brown fat, muscle
2. Nonmalignant conditions
   a. Inflammation, particularly chronic
   b. Atypical infection, including fungal
   c. Granulomatous diseases, sarcoidosis
   d. Pneumoconioses
   e. Benign neoplasms (adenomas)
   f. Reactive lymph nodes
3. Posttreatment changes
   a. Prior radiation therapy
   b. Talc pleurodesis
   c. Postsurgical

II. FALSE-NEGATIVE UPTAKE

1. Variable FDG metabolism
   a. Prostate adenocarcinoma
   b. Renal cell carcinoma
   c. Neuroendocrine tumors, carcinoid
   d. Adenocarcinoma in situ (bronchoalveolar)
   e. Lobular breast cancer
   f. Mucinous neoplasms
   g. Mucosa-associated lymphoid tissue lymphoma (MALT)
   h. Hepatocellular carcinoma
   i. Sclerotic osseous metastases
   j. Necrotic tumors and nodes
   k. Small or superficial lesions
   l. Sentinel lymph nodes
2. High adjacent FDG background activity
   a. Cerebral cortex
   b. Gastrointestinal tract
   c. Genitourinary tract
   d. Cardiac

PATIENT PREPARATION FOR FDG-PET

To minimize FDG uptake in the muscle while maximizing its uptake in tumor, patients are instructed to fast for at least 4 hours and avoid excessive physical activity for 24 hours before the PET appointment. Glucose-containing drinks and intravenous glucose should be avoided at least 4 hours before FDG injection. The fasting state lowers the serum level of glucose so that FDG has less competition for uptake by the tumor, whereas muscle uptake is minimized by fasting (by lowering the serum insulin level) and by avoiding excessive physical activity; low FDG uptake in the muscles improves the tumor-to-background ratio and the image quality.

High glucose levels in diabetic patients can decrease the image quality. Although a normal glucose level in diabetic patients before FDG injection is desirable, it often cannot be achieved. Most institutions perform PET for diabetics after one or two attempts to reduce the serum glucose level below an empirically set level of 200 to 250 mg/dL. Although the positive predictive value of the findings on such a scan remains high, the negative predictive value may be reduced. In patients with diabetes, the image quality (i.e., muscle and soft-tissue uptake) should be assessed before interpretation and mentioned in the report.

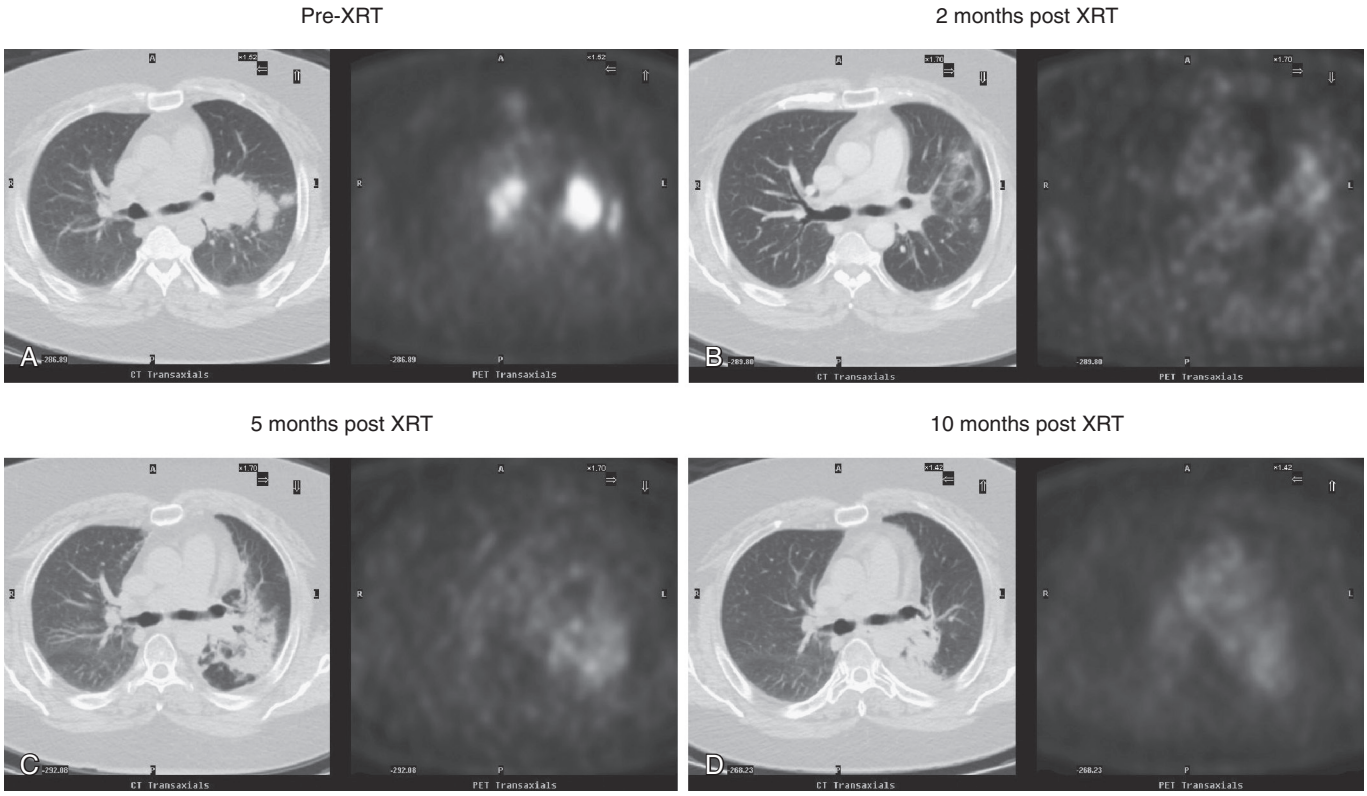

Figure 11-3 Evolution of posttreatment changes in the lung following radiation therapy. Pretherapy PET/CT scan **(A)** demonstrates bilateral hilar masses, predominantly on the left. PET/CT at 2, 5, and 10 months following radiation therapy **(B-D)** include evolving atelectasis and bronchiectasis on CT, with associated mild homogeneous FDG accumulation. The geographic distribution and absence of focal FDG accumulation are characteristic of expected postradiation changes.

FDG uptake in the brown fat in the neck and supraclavicular regions may obscure pathologic findings in these areas. FDG uptake in brown fat is even more extensive in pediatric patients, and it can be seen in the mediastinum, paraspinal region, and upper abdomen. Diazepam administration can reduce the FDG uptake in brown fat.

PET QUANTIFICATION

As previously mentioned, one of the advantages of PET imaging with attenuation correction is the ability to measure activity within target lesions. The standardized uptake value (SUV) is a semiquantitative measure of the tracer uptake in a region of interest that normalizes the lesion activity to the injected activity and a measure of the volume of distribution (usually total body weight or lean body mass). For FDG-PET, it is generally accepted that SUV alone is not reliable to differentiate malignant from benign processes and that other factors, including lesion location, size, CT morphology, pattern of contrast enhancement, and symmetry contribute to this evaluation. In addition, there are many technical and biological factors that can influence the observed SUV, such as the patient's serum glucose, the time between tracer injection and image acquisition, the detector technology of the PET scanner, attenuation-correction map, imaging field of view, and the image reconstruction parameters.[4] Nonetheless, SUV may be useful as a measure to follow the metabolic activity of a tumor over time within the same patient and to compare different subjects within a research study under defined conditions. For FDG-PET, the magnitude of early response to therapy varies with tumor histology. Most malignancies responding to therapy exhibit a 20% to 35% reduction in SUV early in the course of therapy, and these changes have prognostic significance.[5] On the other hand, Hodgkin lymphoma and gastrointestinal stromal tumors (GIST) have a dramatic response on FDG-PET soon after initiation of therapy, which can be assessed visually. Several clinical trials are investigating the ability of PET to direct therapy based on metabolic response early in the course of therapy. Currently, SUV measurements are not sufficiently standardized between PET/CT scanners, and the baseline and follow-up scans should be performed on the same PET/CT scanner for reliable assessment of early response to therapy.

MOST COMMON INDICATIONS FOR FDG-PET/CT IN ONCOLOGY

Lung Cancer

FDG-PET/CT (referred to hereafter as PET) has an overall sensitivity higher than 90% and specificity of about 85% for diagnosing malignancy in primary and metastatic lung lesions; the sensitivity and specificity of PET for small cell lung cancer are similar. The sensitivity of PET for bronchioloalveolar lung cancer and carcinoid of the lung is about 60%, and the specificity of PET for lung cancer is lower in areas with a high prevalence of granulomatous lung disease. PET is particularly useful in patients with a low (5% to 20%) or intermediate (20% to 70%) risk of lung cancer, as determined by an evaluation of symptoms, risk factors, and radiographic appearance. In these cases, PET is helpful in moving the patient to the very-low-risk (<5%) or high-risk (>70%) category.[6] It is expected that the use of PET for diagnosing malignancy in indeterminate lung nodules will continue to grow as more patients are diagnosed

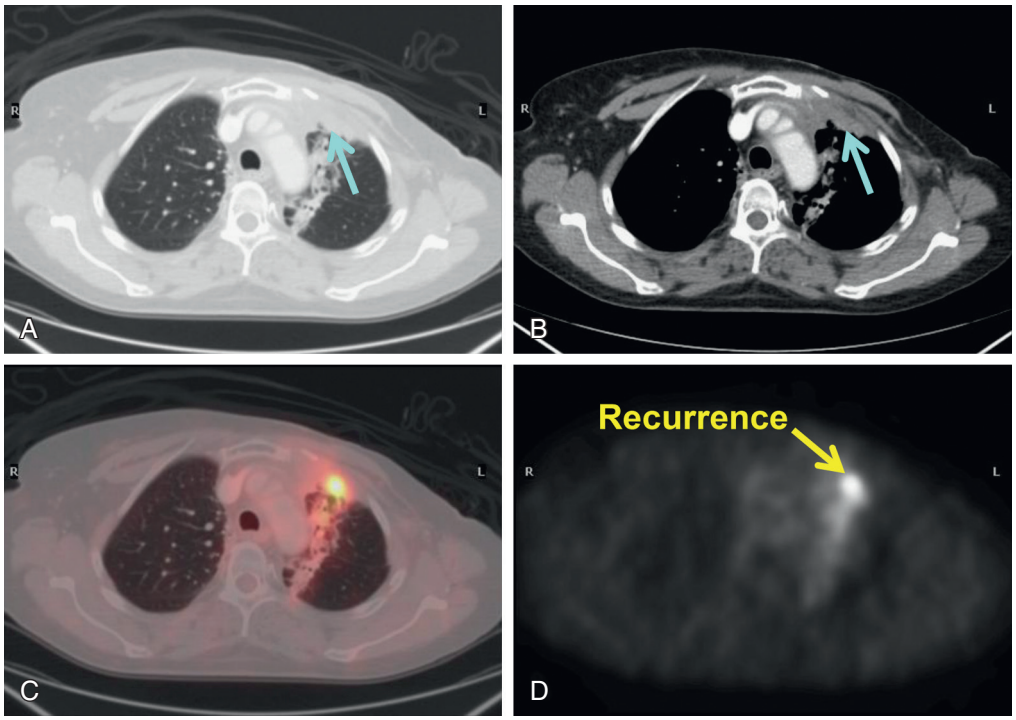

Figure 11-4 Recurrence following radiation therapy. Contrast-enhanced CT (with lung **(A)** and soft-tissue **(B)** windows) demonstrates opacity in the left upper lung in a geographic distribution consistent with postradiation therapy changes. Fused PET/CT **(C)** and PET **(D)** images reveals expected mild activity within the radiation treatment field, but superimposed focal activity *(arrow)* on FDG-PET corresponding to a focal area of nodular pleural thickening on CT *(light blue arrows)* which was subsequently shown to represent recurrent tumor.

with nodules on CT performed for other indications or as a screening test. Most of the current PET scanners are capable of detecting lung lesions as small as 4 to 5 mm.

In mediastinal staging of non–small cell lung cancer (NSCLC), patients with clinical stage I and II disease have by definition a radiographically negative mediastinum. However, in patients with central tumors, adenocarcinoma, or N1 lymph node enlargement, the false-negative rate of CT for mediastinal involvement is 20% to 25%. It is unclear whether PET should be used instead of mediastinoscopy in staging the disease of these patients. In mediastinal staging of clinical stage III tumors, positive results of PET need to be confirmed by tissue diagnosis because of a relatively high false-positive rate (15% to 20%). The false-negative rate of PET and mediastinoscopy in assessing enlarged mediastinal lymph nodes is 5% to 10%, and some authorities therefore do not pursue biopsy in the case of a negative PET result for disease in the mediastinum, whereas others argue that mediastinoscopy can detect "microscopic" metastases, and they are not comfortable accepting a negative PET result.[7] Practically, in larger centers, patients with stage III tumors undergo both PET to assess for distant metastases, and mediastinoscopy, but a strong argument for staging of the mediastinum with PET can be made in communities without an experienced mediastinoscopy service. In any case, it should be noted that the term *microscopic* is not well defined, and that routine pathologic tissue processing may be a limiting factor in detecting microscopic disease.

For patients with clinical stage I peripheral tumors, most authorities do not request mediastinoscopy before surgery because the rate of mediastinal or systemic involvement is very low (about 5%). Among patients with clinical stage II tumors, the rate of metastatic disease is higher, and there is a debate about whether PET is warranted in these patients to assess for systemic disease. For stage III tumors, the false-negative rate of clinical evaluation for systemic disease is about 15% to 30%, and PET therefore is justified instead of a battery of other tests (e.g., bone scan, CT, MRI) to assess for distant metastases.[7] According to the most recent recommendations of the American College of Chest Physicians, in patients with a normal clinical evaluation and no suspicious extrathoracic abnormalities on chest CT who are being considered for curative-intent treatment, PET is recommended to evaluate for metastases.[8] PET is more sensitive (90% versus 80%) and more specific (90% versus 70%) than bone scan in detecting bone metastases from NSCLC; PET has a sensitivity and specificity of greater than 90% in detecting adrenal metastases from NSCLC. Brain CT or MRI is still needed because PET cannot reliably detect brain metastases because of physiologically intense brain uptake of FDG. For patients with stage IV tumors, PET can potentially indicate the best accessible site for biopsy.

PET is also useful in restaging NSCLC. In particular, PET appears to be more sensitive than CT in differentiating postirradiation change from local recurrence, although differentiating these two entities remains a challenge. The postirradiation change in the chest can remain intense on PET for up to several years. In differentiating local recurrence from postirradiation change, the intensity of uptake and its shape should be taken into account (Figures 11-3 and 11-4).

Head and Neck Cancers

Most patients with head and neck cancers present for PET with a known diagnosis. However, cervical lymph node metastases from an unknown primary constitute about 5% of newly diagnosed head and neck cancer cases; CT and MRI can identify up to 50% of the primary tumors in patients with no findings on physical examination. The overall PET detection

rate in patients with negative results of physical examination, CT or MRI, and endoscopy is about 25%. However, this number is probably higher if PET is performed before endoscopy. In one prospective study, patients underwent PET prior to endoscopy but the results were first not revealed to surgeons performing the procedure under anesthesia. The surgeons were able to find the primary site of the disease in only 5 out of 20 patients. When PET information was revealed to the surgeons during the procedure, they were able to find the primary site of the disease in another 6 patients, which improved the detection rate to a total of 11 out of 20 patients.[9] It should be noted that knowledge of the variable benign and physiologic uptake patterns in the head and neck region is essential to minimize false-positive interpretations.

In initial staging of head and neck tumors, PET has a sensitivity and specificity of about 90% for nodal staging, and PET therefore is more sensitive and specific than CT or MRI. A weakness of PET is its low sensitivity (30%) for nodal disease in patients with clinically N0 necks. Given the high specificity of PET in nodal staging, it appears reasonable to perform neck dissection in patients with a positive PET result, whereas those with a negative PET result may be able to undergo sentinel node localization and biopsy.[10] In addition to local staging, PET can detect synchronous malignancies and distant metastases. In initial staging of head and neck malignancies, a PET scan is overall most helpful in patients with locally advanced disease because these patients have a risk of 10% or greater for distant disease. Furthermore, PET has been playing an increasingly important role in planning of radiation treatment in patients with head and neck cancers because it helps to better delineate the primary tumor from surrounding tissue and differentiate between metastatic and benign lymph nodes.

For restaging of head and neck tumors after radiation therapy, PET is highly sensitive but should be performed at least 3 months after irradiation to avoid false-positive findings. Patients with a negative scan at 3 months after irradiation can be followed without intervention (i.e., high negative predictive value), but those with a positive scan need to undergo further evaluation and probably biopsy.[10] For follow-up of the patients with a negative FDG-PET 3 months after completion of radiation therapy, there are currently no definitive data to indicate the time interval and total duration of the follow-up, and this should depend on the patient's individual risk factors.

Lymphoma

Hodgkin disease and high-grade non-Hodgkin lymphoma are mostly markedly avid for FDG and almost always visible on PET, whereas low-grade non-Hodgkin lymphoma may be only mildly intense and, in rare cases, completely invisible on PET. FDG-PET is superior to CT in staging of lymphoma and is recommended by the International Harmonization Project (IHP) for staging of Hodgkin lymphoma and aggressive non-Hodgkin lymphoma because of their consistent FDG avidity and potential curability. Furthermore, it is reasonable to use FDG-PET in all lymphomas except chronic lymphocytic leukemia (CLL)/small lymphocytic lymphoma (SLL), marginal zone lymphoma (MZL), and some peripheral T-cell lymphoma (PTCL)[11]; however, there is no definite evidence that PET changes the initial management in a significant number of patients with lymphoma. Other controversial issues related to the initial stating of lymphomas with PET include the sequence of imaging tests to avoid redundant testing and the routine use of contrasted CT after PET/CT. Contrasted CT is definitely helpful to better delineate intraabdominal disease and for reliable measurement of lymph node size.[11]

The normal spleen shows mild uptake, whereas the uptake of the normal bone marrow can be variably intense. Intense spleen uptake (i.e., more intense than the liver) before chemotherapy is a reliable indicator of its involvement, but spleen involvement by lymphoma cannot be excluded with normal uptake. PET can be used to identify areas of bone marrow involvement although the impact of this on the overall staging is unclear because most patients with clearly visible marrow involvement on PET have other sign of stage IV disease. The relevance of PET in this setting remains controversial. Activation of hematopoiesis after chemotherapy or by bone marrow stimulating factors can cause intense uptake in the bone marrow, spleen, or thymus, which can persist for a while after the termination of the chemotherapy or stimulating factors.

The most promising role of PET in lymphoma management appears to be in therapy monitoring: early prediction of response to chemotherapy (i.e., interim or midway PET) and evaluation of a residual mass for active lymphoma at the completion of chemotherapy (i.e., end-of-treatment PET). The decrease of uptake associated with effective chemotherapy seen on interim PET precedes the anatomic changes seen on CT by weeks to months. At the completion of chemotherapy, CT demonstrates a residual mass at the initial site of disease in as many as 50% of patients. On the end-of-treatment PET, these patients demonstrate increased FDG uptake in the area of residual lymphoma in contrast to those without active lymphoma. The positive predictive value of residual uptake at the completion of chemotherapy is more than 90%. The negative predictive value is likely lower and associated with microscopic remnant disease. Generally, patients with non-Hodgkin lymphoma and stages III and IV Hodgkin disease and negative PET results at the completion of chemotherapy should undergo repeat PET at least once at about 6 weeks after the last cycle of chemotherapy.

In follow-up of patients in remission, PET is more sensitive than CT in detecting recurrent disease. However, there are no guidelines as how often follow-up PET scans should be performed. Follow-up PET scans are often performed, depending on the individual risk factors, as frequently as every 3 months.

Colorectal Cancer

PET plays no role in the screening or diagnosing of colorectal cancer, and neither the depth of the tumor nor the local lymph nodes status can be assessed by PET. However, PET is highly sensitive in detecting distant hepatic and extrahepatic metastases. A meta-analysis of the literature on detection of hepatic metastases from colorectal, gastric, and esophageal cancers by ultrasound, CT, MRI, and PET found that in studies with a specificity higher than 85%, the mean weighted sensitivity was 55% for ultrasound, 72% for CT, 76% for MRI, and 90% for PET. Results of pairwise comparison between imaging modalities demonstrated a greater sensitivity of PET than ultrasound ($p = 0.001$), CT ($p = 0.017$), and MRI ($p = 0.055$). The conclusion was that at equivalent specificity, PET is the most sensitive noninvasive imaging modality for the diagnosis of hepatic metastases from colorectal, gastric, and esophageal cancers.[12] Considering the higher sensitivity of PET in detecting distant metastases and the introduction of intravenous contrast to the CT portion of fused PET/CT, it is conceivable to use PET/CT in preoperative staging of colorectal cancer; the contrast-enhanced CT portion of PET/CT can be used instead of conventional CT or MRI for evaluation of anatomic resectability of liver metastases. PET plays an important role in restaging of colorectal cancer. PET can visualize the site of the local and distant disease when recurrence is suspected based on the clinical findings, findings on other imaging modalities, or an increasing carcinoembryonic antigen level with sensitivity and specificity higher than 90% (Figure 11-5).

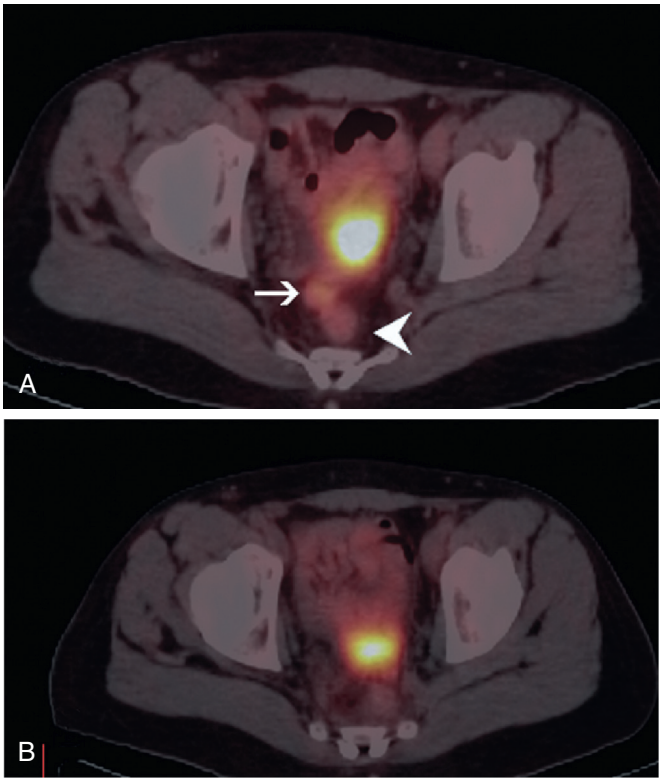

Figure 11-5 PET/CT for differentiating local recurrent from scar in a patient with colon cancer, status after low anterior resection. Recurrent disease was suspected based on increasing carcinoembryonic antigen (CEA) level. CT is not able to differentiate between scar and local recurrence. **A,** FDG-PET indicated an intense focus *(arrow)* suspicious for malignancy. A second mild focus was interpreted as scar *(arrowhead)*. **B,** The diagnosis was confirmed surgically and the recurrent tumor was removed.

Breast Cancer

PET can increase the detectability of small primary breast cancers and may be useful especially in evaluating patients with dense breasts. In evaluating the axillary lymph nodes, PET does not play any role because of its low sensitivity (60%) despite relatively high specificity (80%).[13] In contrast, PET is relatively sensitive (85%) and specific (90%), and it is superior to CT (sensitivity of 54%, specificity of 85%) in evaluation of the internal mammary chain lymph node for metastases. The main role of PET in breast cancer lies in the investigation of distant metastases and response monitoring. Compared with CT, PET has a higher sensitivity (90% versus 40%) but lower specificity (80% versus 95%) in detecting metastatic disease. Overall, PET has the same sensitivity as bone scan in detecting bone metastases (both about 90%), but PET appears to be somewhat more sensitive than bone scan for osteolytic lesions and somewhat less sensitive than bone scan for osteoblastic lesions. PET has a higher specificity than bone scan in detecting bone metastases (95% versus 80%). This may be explained by the fact that PET captures the metabolic activity of the tumor cells independently of changes in the bone, whereas bone remodeling seen on bone scan can result from metastatic disease and benign causes. Overall, priority should be given to FDG-PET over ^{99m}Tc bone scan for staging purposes not only because FDG-PET can detect both bone and soft-tissue metastases.

In patients with advanced breast cancer undergoing neoadjuvant chemotherapy, PET differentiates responders from nonresponders as early as after the first cycle of therapy. This may help improve patient management by avoiding ineffective chemotherapy and supporting the decision to continue dose-intensive preoperative chemotherapy in responding patients although universal criteria for assessing response have not been established. PET has great efficacy in cases of suspected recurrence and surpasses conventional imaging (including bone scan) for whole body evaluation.

FDG-PET/CT Applications in Other Malignancies

In esophageal and gastric cancer, PET is useful to assess for distant disease. In esophageal cancer, PET has the potential to be used for monitoring the effect of neoadjuvant therapy. In ovarian, uterine, and cervical cancer, PET is used to assess for recurrent disease. In cases of cervical cancer, because of its greater sensitivity than CT and MRI for detecting paraaortic nodes, PET plays an important role in nodal staging and radiotherapy planning. In malignant melanoma, PET is used to evaluate the presence of distant metastases at the time of initial diagnosis and to assess for recurrent disease after initial treatment in high-risk patients. In sarcoma, the most intense areas on PET have usually the highest grade and should be considered for biopsy.

Targeted Imaging in Nuclear Medicine

From its inception, nuclear medicine has used specific physiologic and biophysical targets for imaging and therapy.

Because nuclear imaging techniques have had high sensitivities with known lower specificities, agents with greater specificity are being developed. Even though there may be some trade-off in sensitivity compared with other nuclear modalities, they have proved to be better than general radiologic modalities for many indications, and in some cases, they can be used for targeted radionuclide therapies. Newer imaging technologies have been developed that greatly enhance molecular imaging.

Traditionally, nuclear imaging involves planar imaging using single photon emitters, such as technetium-99m (^{99m}Tc), indium-111 (^{111}In), iodine-123 (^{123}I), among many others. However, it is also possible to do tomographic—or SPECT—imaging of radiotracers, providing overall greater accuracy of lesion diagnosis and detection. Compared to PET imaging, SPECT imaging has lower resolution, and can be further limited in large patients because of inherent attenuation. In the last few years, however, there have been substantial advances using concurrent CT imaging—as in PET/CT—for both attenuation correction as well as anatomic localization. The result has been the development of SPECT/CT that has provided a great leap forward in disease evaluation and the continued development of molecular imaging independent of PET/CT.

In the realm of radiopharmaceutical development, some agents rely on targeting using antibodies or their fragments, peptides, or are receptor or even gene specific. Although established procedures like FDG-PET imaging are clearly superior to most of these newer methods at the present time, they remain clinically important in sites where PET may not be available. Nevertheless, radiopharmaceutical development in both the PET and SPECT side show promise in the evaluation of disease, and the evolution of molecular imaging.

Bone Scanning

Bone scanning is the most basic oncologic imaging procedure in nuclear medicine. Its utility has long been proven in multiple diseases in both detection of osseous metastases and in follow-up. Traditionally, the study is done using planar whole

body studies using ^{99m}Tc-labeled bisphosphonates, most commonly methyl diphosphonate (MDP) and hydroxyethylene diphosphonate (HDP). Multiple additional limited planar or SPECT views can also be obtained by focusing in on the body part of interest. The procedure allows a rapid skeletal survey and an overall assessment of disease.

There are drawbacks to this modality. MDP and HDP accumulation is related to the osteoblastic phase of bone remodeling, so planar bone scintigraphy is relatively insensitive for the detection of lytic lesions. In addition, bone remodeling occurs in many conditions, including arthritis, inflammation, trauma, benign and malignant neoplasms, and metastatic disease, reducing the specificity of the study. SPECT and SPECT/CT imaging can improve both the sensitivity and specificity of the study; however, a single SPECT acquisition can take 15 to 30 minutes and only covers a selected area of the body. Some have advocated whole-body SPECT studies, which could take more than 90 minutes of scan time.

^{18}F-sodium fluoride (NaF) was one of the first radiopharmaceuticals used for skeletal scintigraphy, but it fell out of favor with the development of ^{99m}Tc tracers and improved gamma camera technology. However, there is now renewed interest in bone imaging with NaF utilizing PET/CT technology.[14] Additional advantages of NaF-PET/CT compared to ^{99m}Tc bone scans include shorter uptake time (1 hour versus 2 to 4 hours) and the ability to obtain diagnostic contrast-enhanced CT scans along with the NaF-PET images. Although NaF is FDA approved, NaF PET scanning is currently being evaluated by CMS at the time of writing this manuscript for potential reimbursement as a routine clinical procedure.

Antibody-Based Imaging Agents

One of the more successful antibody-based agents is ProstaScint (capromab pendetide), an antibody against prostate membrane surface antigen, a type II membrane glycoprotein strongly associated with prostate cancer. The usual indication is a rising prostate-specific antigen (PSA) level in a patient who has had a prostatectomy but who has no obvious location for a metastatic focus as determined by CT or MRI. These modalities have sensitivities of disease detection of only 5% to 20%, although they have much higher specificities. The accuracies for capromab imaging are about 70%, although it is much less sensitive than bone scan for skeletal metastases. Absence of extrapelvic disease on capromab and other studies may allow for radiotherapy to the pelvis.

Carcinoembryonic antigen scans use a labeled murine antibody fragment (^{99m}Tc-arcitumomab) to detect recurrent colorectal and breast cancer. OncoScint (^{111}In-satumomab pendetide) is another antibody also used for detection of recurrent colorectal and ovarian carcinomas. The sensitivity of extrahepatic disease recurrence detection for satumomab is 97%, whereas for CT scan it is 72% for colorectal malignancy. For liver metastases CT is better, but when the two modalities are combined, the sensitivity is approximately 90%.[15] Although FDG-PET outperforms these modalities and is the scan of choice, the antibodies may be of clinical value if FDG-PET is not available.

Clear cell renal cell carcinomas can constitute up to ~55% to 60% of histologies of incidentally discovered renal masses, and methods to identify this aggressive malignancy early and preoperatively could be useful. A recently developed agent—^{124}I-cG250 (Girentuximab)—a radiolabeled chimeric antibody against the carbonic anhydrase IX (CA IX), is reactive in >95% in immunohistochemical assays on fresh frozen tissues and can be used with PET/CT imaging. A phase I trial for this agent showed more than 90% accuracy for the detection of primary clear cell renal carcinoma, although the accuracy for metastatic disease detection was not studied.[16] This agent is still undergoing review for clinical approval as an imaging agent.

Cellular Imaging

Various agents being developed build on the newer understanding of cellular physiology, including angiogenesis, apoptosis, and other ideas. Some are routinely used clinically, but others show potential for future development and may revolutionize the way cancer is approached.

^{18}F-fluorothymidine (^{18}F-FLT) is a thymidine analog and a PET tracer, which is phosphorylated by thymidine kinase-1 (TK1) to FLT-monophosphate. FLT uptake correlates with TK1 activity and cellular proliferation. FLT may be more suitable than FDG to monitor the effect of chemotherapy and radiation therapy. Another important area of current PET tracer research concerns cell-cell and cell-matrix interaction. Tracers such as ^{18}F-galacto-GRD (glycosylated Arg-Gly-Asp) enable the noninvasive determination of integrin $\alpha_v\beta_3$ expression and are being evaluated for use in assessing angiogenesis and metastatic potential of tumors.

Annexin-V shows great promise for evaluating apoptosis, and it is available as a single-photon and PET agent. Highly apoptotic areas in tumors may be more likely to be sensitive to irradiation or chemotherapy, and there is the potential for evaluating therapy response or overall disease prognosis with such agents. Similarly, the field of tumor hypoxia is central to the understanding of tumor response to irradiation. PET agents such as ^{18}F-fluoromisonidazole (^{18}F-MISO) and Cu-labeled diacetyl-bis (*N*(4)-methylthiosemicarbazone (Cu-ATSM) can be used to detect intratumoral hypoxia. Although still in the evaluation phase, these agents could potentially be used to evaluate areas of hypoxia for targeting radiation delivery.[17]

Recently, ^{11}C-choline has obtained clinical approval in the United States for imaging prostate cancer. Tumor cells produce abundant quantities of choline because it is a precursor of phosphatidylcholine, a major constituent of membrane lipids, which along with proteins, are synthesized during cell proliferation. Choline kinase is upregulated in malignancy, which leads to incorporation and trapping of choline into lecithin. The limitation for this tracer is that its use requires proximity to a cyclotron given its short half-life. A recent study showed an accuracy of 99% when ^{11}C-choline PET is used in a hybrid PET-MRI scanner.[18] ^{18}F-fluorocholine (FCh)[19] and ^{18}F-FACBC (1-amino-3-fluorine 18-fluorocyclobutane-1-carboxylic acid)[20] are also being evaluated for evaluating prostate cancer, and will also likely benefit from the combination of PET/MRI.

Neuroendocrine Tumor Imaging

^{111}In-octreotide is a peptide that is routinely indicated for neuroendocrine tumors, including carcinoids, tumors associated with the multiple endocrine neoplasias, meningiomas, and lymphomas (i.e., Hodgkin disease and non-Hodgkin lymphoma). Increased activity can be seen in benign disease such as sarcoidosis and other inflammatory processes. ^{111}In-octreotide has the highest affinity for somatostatin receptor (SSTR) subtypes 2 and 5, with weaker affinities for others. This agent is still relevant in the era of PET because many of the well-differentiated lesions will not take up FDG. Even so, many diseases do not have appropriate receptor expression and therefore have limited detection on such scans. A similar agent, ^{99m}Tc-depreotide, has greater affinities for SSTR 2, 3, and 5 and therefore has the potential for greater sensitivities for tumors with various SSTR expressions and uptake in a broader number of malignancies, including lung cancers.

Routine imaging of neuroblastoma and pheochromocytomas involves metaiodobenzylguanidine (MIBG), a

norepinephrine analog taken up by the uptake 1 mechanism in receptors. It has uptake in many of the same malignancies as octreotide, although not with the same frequency. For imaging, MIBG may be labeled with ^{131}I, ^{123}I, or ^{124}I, a positron emitter. The sensitivity for lesion detection can exceed 90%, and specificity approaches almost 100% for single photon imaging.[21] Nevertheless, as tumors de-differentiate or metastasize to other sites, specifically the bones, MIBG becomes less sensitive in detecting disease, in which case a bone scan is useful. With the advent of ^{124}I-MIBG used in PET/CT, it is unknown whether the increased resolution will allow better detection of disease, obviating the need for bone scans.

There is growing interest in being able to use newer tracers such as 3,4-dihydroxy-6-^{18}F-fluoro-phenylalanine (^{18}F-FDOPA) and PET in neuroendocrine imaging, which use neurohumoral pathways of uptake, and trapping similar in concept to that of FDG to concentrate in relevant areas. Many studies show that this tracer has far greater accuracy for disease detection than either octreotide analogs or MIBG.[22] Unlike the SPECT counterparts, the PET imaging can be done within an hour after injection, with PET quality images. Still, ^{18}F-FDOPA is most useful in the well-moderately differentiated tumors, with FDG being superior for the more poorly differentiated ones. Additionally, octreotide based positron tracers labeled with ^{68}Ga—such as [1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid]-1-Nal3-octreotide (^{68}Ga-DOTANOC), and others—are undergoing review, with at least one of these forms expected to be approved in the near future for imaging.[23]

Other Modalities

Breast-specific gamma imaging (BSGI) is gaining interest in breast imaging. The limitations and controversies surrounding mammography are well known. Single photon gamma devices have now been developed for specifically imaging breast. These use ^{99m}Tc-Hexakis (2-methoxy-2-methylpropylisonitrile), also known as sestamibi, a tracer which has been used for imaging in malignancies before the rise of FDG PET or where PET was not readily available. The modality may be particularly useful in denser breasts where traditional mammographic evaluation is more limited. Recent publications have shown good ability to evaluate lesions, with an overall accuracy of about 91%.[24]

Positron emission mammography (PEM) similarly uses breast-specific PET imaging technology with FDG. Again, this holds promise in mammography, demonstrating significant improvement in diagnostic accuracy. Studies have demonstrated a similar performance as compared to breast MRI, providing complementary information in the evaluation of breast cancer. Still, even combining these modalities show some limitations in the initial surgical management of disease.[25]

TARGETED RADIONUCLIDE THERAPY

Imaging agents are valued more for their sensitivity, but for targeted therapy, it is the specificity that is essential. Many imaging agents are specific enough for therapeutic purposes. Treatment of well-differentiated thyroid cancer, radioimmunotherapy, and bone metastases pain palliation are discussed elsewhere in this text. The following sections provide examples of selected therapies used in other clinical settings that show promise for development in the near future.

Thyroid Diseases

Thyroid diseases are the most successful clinically relevant application of targeted therapy. The thyroid's unique ability to metabolize elemental iodine to synthesize thyroid hormones is fortuitous because it is a highly specific but easily targeted process with radioactive iodine. Treatment is effective, is virtually definitive, and has minimal side effects. There are practically no long-term sequelae from appropriate radioactive iodine administration for benign thyroid disease. Generally, radioactive iodine treatment in benign disease is reserved for hyperthyroid conditions, such as Graves disease or toxic and multinodular goiters. Radioactive iodine is used when the disease cannot be controlled medically, and it is often a first-line option in clinically hyperthyroid patients. Surgery is reserved for instances in which radioactive iodine may be contraindicated (e.g., pregnancy, marrow suppression, etc.) or when there may be compressive findings of the enlarged thyroid on critical structures, such as the trachea.

Patients with thyroid cancer have traditionally undergone 4 to 6 weeks of L-thyroxine withdrawal before radioiodine scanning and treatment to stimulate tumors to take up iodine. The introduction of recombinant human thyroid stimulating hormone (rhTSH) has revolutionized thyroid malignancy evaluation. rhTSH is injected intramuscularly to stimulate residual thyroid cells to take up radioiodine. This avoids the prolonged hypothyroid state that patients traditionally had to go through, and can be used in those who would otherwise be unable to tolerate hormone withdrawal. When used before therapeutic radioiodine in post-surgical remnant thyroid ablation for low-risk disease groups, prospective studies show equivalent efficacy in short-term outcomes.[26] Retrospective studies show similar efficacy between hormone withdrawal and rhTSH in longer-term outcomes in even moderate-higher risk patients.[27]

Octreotide Derivatives in Neuroendocrine Malignancies

A novel application is to use octreotide in targeted radionuclide therapy. ^{111}In-octreotide has been used in clinical trials and initial results were encouraging, although objective response rates were a meager 0% to 8%, with 42% to 81% with stable disease and 12% to 38% showing disease progression. The octreotide molecule has subsequently been modified to increase its specificity for tumor targeting, decrease its affinity for nontargeting areas in other organs, and in an effort to improve its toxicity profile. ^{111}In-octreotide has been altered to create [^{90}Y-DOTA^{0}]- Tyr^{3}-octreotide (DOTATOC) and [^{177}Lu-DOTA^{0}]-Tyr^{3}-otreotate (DOTATATE), with some improvement in their target to nontarget ratios. The DOTATOC trials showed improved objective responses ranging from 7% to 33%, stable disease in 52% to 81%, and disease progression in 9% to 19%. Trials with DOTATATE also showed similar objective response rates. Aside from marrow toxicity and myelodysplasia, nephrotoxicity was the other most significant long-term sequela, which could be decreased with infusion of amino acids before therapy. As in most targeted therapies for solid tumors, hematotoxicity was seen in these patients.[28]

The success of DOTATOC and DOTATATE likely results from their better targeting of tumor compared with octreotide. The radiobiology of the beta emitters ^{90}Y and ^{177}Lu appears to be superior to the Auger emitter ^{111}In. The newer trifunctional, somatostatin-based derivatives have prolonged cell retention, and they are internalized into the cell nucleus, making them optimal for Auger therapy, such as ^{111}In.[29] Future trials with such compounds are of great interest in developing targeted radionuclide modalities.

Metaiodobenzylguanidine Therapy in Neuroendocrine Malignancies

MIBG has been used therapeutically as ^{131}I-MIBG in neuroblastomas in children and pheochromocytomas. Objective

responses have ranged from 47% to 80% as a single agent in neuroblastoma. The main toxicity was hematologic, and subsequent trials are being conducted with autologous stem cell reconstitution. Studies have also been conducted combining MIBG with chemoradiotherapy.[30]

Other Targeted Radionuclide Therapies

Polycythemia vera was frequently treated with ^{32}P-phosphorous in the past, but with the advent of modern chemotherapy, this has become uncommon. Although the median survival was improved, there was an increase in the incidence of secondary blood dyscrasias. This therapy is used in patients who cannot tolerate hydroxyurea and other treatments, or who have symptoms that do not respond to other therapeutic maneuvers.

Radiocolloids such as ^{198}Au-gold colloid or chromic phosphates labeled with ^{32}P or ^{90}Y have been used as palliative regimens in malignant ascites in ovarian carcinoma, pleurodesis for pleural effusions, intracavitary injections for cystic brain tumors, and even for radiosynovectomies in benign inflammatory arthritic diseases. Other therapies have included using ^{35}S-thiouracil for ocular melanoma. Despite being effective treatments, they have been replaced by modern medical management, although they are still rarely used when other therapies fail. Interest in radiosynovectomy is growing as an alternate to surgical management, or delaying surgery when medical management is no longer adequate.

Some newer therapies involve using microspheres embedded with ^{90}Y for palliation in hepatocellular carcinoma, as well as other malignancies such as colorectal carcinoma and neuroendocrine malignancies that have metastasized to the liver. Following arterial access by an interventional radiologist, the ^{90}Y microspheres are injected selectively into the hepatic artery to the site of diseased liver, where they will reside in the vascular space, delivering lethal radiation doses locally. Because the product is not systemically delivered, side effects are well tolerated and less severe than other therapeutic options. Palliative benefits are clear, and some initial evidence suggests promising survival time compared to systemic options.[31,32] Its role compared to bland embolization or chemoembolization is not well defined. Similarly, ^{131}I-Lipiodol is also emerging as a candidate for similar indications, and has undergone trials with cisplatin showing a well tolerated toxicity profile.[33] In the future, newer therapies may use liposomes to deliver therapeutic radionuclides to micrometastases in various other malignancies to complement antibody mediated therapies.[34]

Therapy-Enhancing Strategies

Therapy enhancement basically relies on trying to boost radionuclide uptake and prolong its cellular retention for improving efficacy, or improving tumor sensitivity to make them more susceptible to the effects of targeted radiation. In thyroid cancer, lithium has been shown to have a modest increase in free iodine retention and raising the dose delivery to tissue.[35] There is some evidence to suggest that medications like rosiglitazone, SAHA and others may improve radioiodine uptake in tumors with decreasing ability to take it up, but no clear clinical benefit has yet been demonstrated.[36] Whereas newer agents—such as sorafenib and sunitinib—have demonstrated some activity against tumors independent of radioiodine, no studies have been done to see whether combined modality therapies are any more effective in the treatment of advanced thyroid cancer.

Conversely, the addition of gemcitabine to an yttrium-90 radiolabeled antibody—^{90}Y-hPAM4—has shown some promise in pancreatic cancer in improving therapeutic efficacy of targeted therapy, presumably by acting as a radiosensitizer.[37] Currently, a Phase III trial is under way in evaluating this combination as a potential future clinical therapy.

Some of the newer antibody therapies use genetically engineered antibodies or altered pharmaceuticals and attach radionuclides with more favorable characteristics to improve tumor-specific targeting and possibly therapeutic efficacy. Other methods employ multistep targeting, all of which are experimental, but they hold promise. Such results have prompted their use in conjunction with external beam therapy and chemotherapy. This could help to bring targeted radionuclide therapy into general clinical practice.

Health Services Research in Radiation Oncology: Toward Achieving the Achievable for Patients with Cancer

William J. Mackillop, Timothy Paul Hanna, and Michael D. Brundage

WHAT IS HEALTH SERVICES RESEARCH?

Medical research may be considered as a continuum of four overlapping domains: basic or biomedical research, clinical research, health services research (HSR), and population health research. HSR aims to create the knowledge required to improve population health by improving the delivery of health services. Although there is some overlap between the domains of clinical research and HSR, their purposes are distinct. *Clinical research* describes the natural history of diseases, it investigates their pathophysiology, and it seeks to discover more effective treatments. *HSR* describes how health systems work, it investigates how they go wrong, and it seeks to discover better ways to deliver health services. The results of clinical research are primarily intended to guide physicians' decisions about the care of individual patients, whereas the results of HSR are intended to guide the decisions of managers and policy makers about the design and implementation of healthcare programs.

Need for Health Services Research in Radiation Oncology

Clinical radiation oncology is a mature science. It has a sound theoretical basis, in both biology and physics. We have a universal language for describing the diseases treated, the treatments used, and the outcomes achieved. Much is now known about the factors that influence outcomes in the individual case. There is a well-established process for evaluating the efficacy of treatment, and a large body of empirical information now permits evidence-based decisions about the use of radiotherapy (RT) in the majority of cases.

In contrast, the science of HSR in radiation oncology is at a much earlier stage of development. There is no comparable universal language for describing the performance of RT programs. There is only limited information available about the factors that influence the performance of RT programs in the population at large. There is no well-established process for measuring the effectiveness of RT programs at the population level. In the absence of empirical evidence, most decisions about the design and management of RT services are guided only by theory and expert opinion, and their consequences are unpredictable. Given that we would no longer tolerate this unscientific approach to decision making in the care of individual patients, it is anomalous that it should still be used in making decisions about health systems that may affect tens of thousands of patients.

The challenges for the HSR community in radiation oncology are to create the knowledge required for evidence-based management of RT programs and to promote the use of evidence in the design and management of RT programs.

How Can Health Services Research Help to Improve the Outcomes of Cancer?

At any point in time, the state of scientific knowledge and technological development sets an upper limit on what is *achievable* for patients with cancer. What is achievable in any particular society is also limited by how much that society is able and willing to spend on cancer care. However, what is actually *achieved* depends not only on what would be achievable if we made optimal use of the available knowledge, technology, and resources, but also on how close we get to attaining the achievable, which is a quantity we have termed the *attainment factor*.

$$\text{Attainment Factor} = \text{Achieved outcome} / \text{Achievable outcome}$$

The achieved and the achievable outcomes are measured in units that correspond to the outcome of interest. Attainment can have any value between 0 and 1 or may be multiplied by 100 and expressed as a percentage. The equation may be rewritten as

$$\text{Achieved outcome} = \text{Achievable outcome} \times \text{Attainment factor}$$

Cancer outcomes can be improved by increasing the *achievable* or by increasing the *attainment factor*. Biomedical and clinical research aim to improve outcomes by increasing the *achievable*. HSR aims to improve outcomes by increasing the *attainment* of what is already potentially achievable within the limits of existing knowledge, technology, and resources.

What Is the Scope of Health Services Research?

Health system performance has three dimensions: accessibility, quality, and efficiency. Together these determine the extent to which we attain the achievable in health care. *Accessibility* describes the extent to which patients are able to get the care they need, when they need it. *Quality* describes the extent to which the right care is delivered in the right way. *Efficiency* describes the extent to which accessibility and effectiveness are optimized in relation to the resources expended. HSR is concerned with measuring these quantities, understanding the factors that influence them, and discovering and evaluating ways of enhancing them.

The scope of HSR in oncology covers the entire continuum of cancer care. In a systematic cross-sectional study of 1,113 HSR publications from 2009, the majority of HSR focused on active treatment (32%), with fewer studies addressing survivorship (19%) or screening (16%), and even fewer than that focused on diagnosis/assessment (10%), palliation (8%), or

Hours of operation
Transportation services
Lodges/hostels

AFFORDABILITY

Prices in relation to patients' ability and willingness to pay
Indirect costs

AWARENESS

Physicians' awareness of patients' needs and of potentially useful services
Patients' awareness of needs and services

prevention (4%)[1] Across this continuum, the focus of HSR was most commonly on quality of care (56%), with fewer studies focused on accessibility (25%), efficiency (5%), or general well-being of subjects (14%).[1]

Figure 12-1 shows a general framework for a program of HSR aimed at improving some specific aspect of health system performance. The first step is to select, define, and validate appropriate indicators of the aspect of performance that has been targeted for investigation. The next two steps are to: (1) develop methods of measuring system performance in terms of the chosen indicator(s) and (2) prescribe standards or targets for system performance in terms of the chosen indicators. These two steps, which often involve the use of different methods, can sometimes be undertaken in parallel. Once standards have been set and methods for measuring performance have been established and validated, it becomes possible to evaluate the performance of the system against the standards. This in turn permits further explanatory studies aimed at identifying factors that are associated with better or worse performance. This information can be used to design interventions aimed at improving performance. The interventions may then be implemented and systematically evaluated. Interventions may be refined through further cycles of improvement before they are suitable for dissemination and incorporation into routine practice.

STUDIES OF THE ACCESSIBILITY OF RADIOTHERAPY

Concept of Healthcare Accessibility

The term *accessibility* was originally used narrowly to describe the ability of patients to obtain entry into the health system.[2] It is now used more broadly to represent the overall "degree of fit between the clients and the system."[2,3] Accessibility can be seen as having a number of dimensions that determine that overall degree of fit (Box 12-1). *Availability* describes the total volume of the service available in relation to the total number of clients that would benefit from it. Availability depends on the adequacy of supply of healthcare workers and on the adequacy of facilities and equipment. For any given level of resources, availability also depends on the degree of efficiency in production of services. *Spatial accessibility* describes the geographic relationships between the places where services are provided and the places where potential clients reside. The term *accommodation* describes the extent to which the system is designed and operated to facilitate clients' access to service, for example, by operating at convenient hours or by providing transportation for patients who may need it. *Affordability* describes the relationship between the cost of health services and clients' ability and willingness to pay. It depends not only on the direct cost of services, but also indirect costs, for example, loss of earnings during a protracted course of treatment. *Awareness* describes the extent to which those who need the service know that it is available and that they might benefit from it. In the context of a specialized service such as RT, patients' awareness of the potential benefits of RT depends largely on their attending physician's awareness of the indications for RT.

Need for Studies of Access to Radiotherapy

There are compelling reasons for doing research aimed at optimizing the accessibility of RT. In To achieve optimal cancer outcomes at the population level, it is necessary to make effective treatments accessible to every patient who needs them. RT is known to be effective in many clinical situations and the World Health Organization (WHO) recognizes RT as a key component of any overall program of cancer control. In its 2005 declaration on Cancer Control, the WHO states that "recognizing that the technology for treatment of cancer is mature and that many cases of cancer can be cured …, all nations should improve access to appropriate technologies."[4] Many nations aspire to providing adequate and equitable access to health care for all of their citizens, but there is remarkably little information available about how successful they are in achieving this laudable goal with respect to RT. In reality, the widespread reports of waiting lists for RT in the medical literature and news media and the limited supply of radiotherapy equipment and personnel in many developed and developing countries suggest that access to RT remains suboptimal in many parts of the world.

Waiting Lists for Radiotherapy

Long waiting times for RT were first identified as a cause for concern in the medical literature in a report from Norway more than 20 years ago.[5] Waiting lists for RT have since been

reported in many other countries including Australia,[6] the United Kingdom,[7] Canada,[8] New Zealand,[9] Denmark,[10] Germany,[11] Spain,[12] and Italy.[13] In countries affected by waiting lists of RT, they have been a major concern for both patients and the providers. The problem of waiting lists for RT is an ongoing challenge for health services researchers in radiation oncology; but the first step in dealing with the problem is to learn how to measure waiting times for RT.

Measuring Waiting Times for Radiotherapy

Different methods are available for quantifying waiting times and waiting lists for RT, including mail surveys, retrospective reviews of preexisting administrative data, and prospective collection of information about delays as patients pass through the system.

Mail and e-mail surveys can provide a lot of information about waiting times from multiple institutions and can also be used to compare waiting times between different centers within one country or compare waiting times between different countries. In the 1990s, a survey of heads of radiation oncology at comprehensive cancer centers in the United States and Canada showed that waiting lists for RT were widespread throughout Canada but revealed no evidence of similar problems anywhere in the United States. Median waiting times for a range of indications for RT were two to three times longer in Canada than in the United States.[14] Figure 12-2 shows, for example, that at almost every Canadian center, patients with laryngeal cancer waited longer for RT than they did at almost any U.S. center. However, the validity of such surveys may be questioned because they rely on the veracity of self-reports and because the primary information on which each report is based may differ from center to center.

Retrospective analysis of data that have been gathered for other purposes can provide more objective information about waiting times for RT. This may be an important first step in addressing this type of problem. At the beginning of the 1990s, reports of long waiting lists for RT in Ontario were frequently in Canadian news media. Health system managers felt that these reports were unduly alarmist and at first denied that there was any systemic problem.[8] To clarify the situation, we undertook an analysis of waiting times for RT based on computerized electronic records of all visits to the province's radiotherapy centers over the preceding decade. Once these administrative records had been linked to the province's cancer registry, we were able to describe waiting times for RT for various specific conditions.[8] For example, Figure 12-3, *A* shows that waiting times from diagnosis to start of radical RT

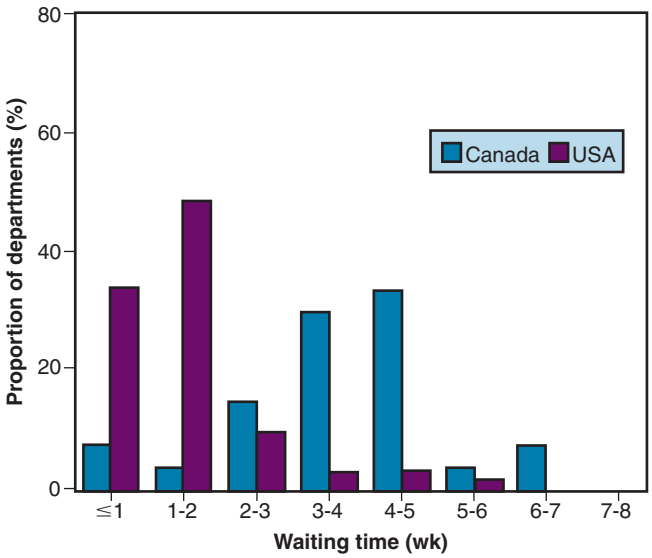

Figure 12-2 Waiting times for RT for carcinoma of the larynx in Canada and the United States. The frequency distributions illustrate the time from referral to initiation of RT for a T2N0M0 carcinoma of the larynx in Canada and the United States based on the results of a mail survey. *(Adapted from Mackillop WJ, Zhou Y, Quirt CF: A comparison of delays in the treatment of cancer with radiation in Canada and the United States. Int J Radiat Oncol Biol Phys 32:531–539, 1995.)*

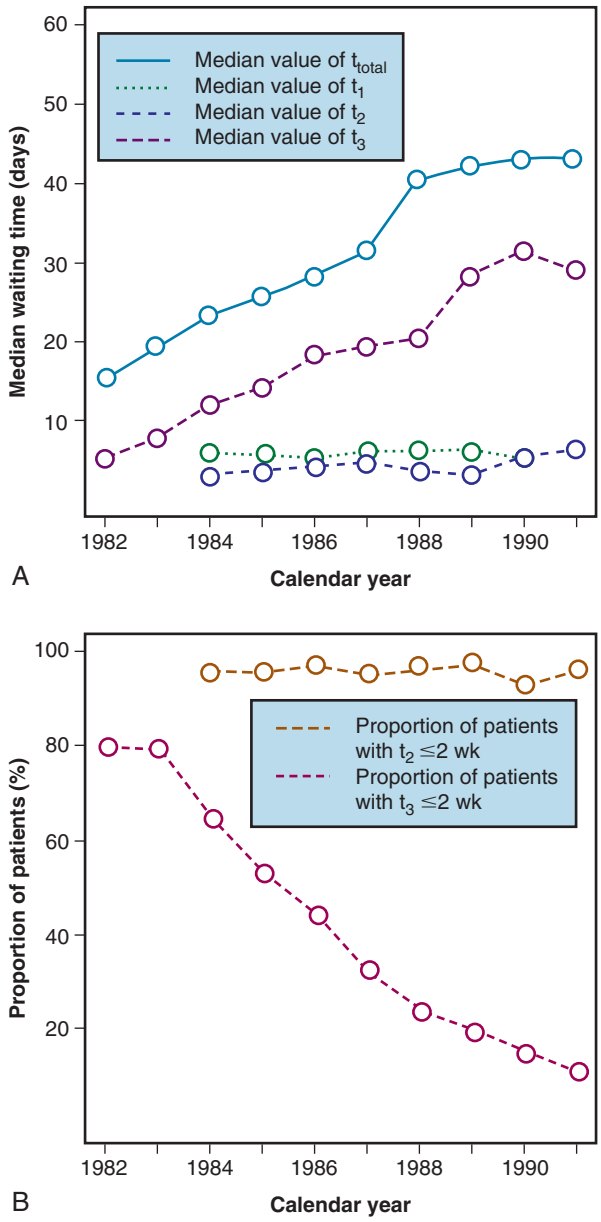

Figure 12-3 Waiting times for RT for carcinoma of the larynx in Ontario. **A,** Temporal trends in median waiting time for RT in Ontario, for which t_{total} is the interval between diagnosis and start of RT, t_1 is the interval between diagnosis and referral to RT, t_2 is the interval between referral and consultation, and t_3 is consultation and start of RT. Data needed to measure t_1 and t_2 were available only from 1984. **B,** The proportion of patients meeting the standards of the Canadian Association of Radiation Oncologists, which states that patients are to be seen in consultation within 2 weeks of referral (i.e., $t_2 < 2$ weeks) and started on RT within 2 weeks of consultation (i.e., $t_3 < 2$ weeks). *(Adapted from Mackillop WJ, Fu H, Quirt CF, et al: Waiting for radiotherapy in Ontario. Int J Radiat Oncol Biol Phys 30:221–228, 1994.)*

for laryngeal cancer increased dramatically through the late 1980s and early 1990s. Similar large increases in waiting times were found in many other clinical situations. Further, as shown in Figure 12-3, *A*, the observed increases in overall waiting time between diagnosis and treatment were entirely the result of increases in the waiting time between the first visit to a radiation oncologist and the start of RT. There was no increase in the interval between diagnosis and referral to radiation oncology or between referral and consultation. These findings pointed to rate-limiting problems in access to planning or treatment machines. It is useful, whenever possible, to report observed waiting times in relation to standards or guidelines. At the time of this first report, the Canadian Association of Radiation Oncology (CARO) had already set standards for acceptable waiting times for RT: the maximum acceptable delay between referral to, and consultation by, a radiation oncologist was deemed to be 2 weeks, and the maximum acceptable delay between consultation and the start of RT was deemed to be 2 weeks.[8] Although these standards were based only on expert opinion, they provided a useful framework for comparison. Figure 12-3, *B* shows trends in compliance with these standards over time. Most patients met the CARO standard for prompt consultation throughout the study period, but the proportion of patients meeting the CARO standard for prompt start of RT fell from 90% to 10%. This simple study, which merely quantified the magnitude of the problem in the community, was useful because it led to public recognition of the seriousness of the problem.[8] This proved to be an important first step in promoting the reinvestment in the infrastructure of the provincial RT system.

There are limitations to the retrospective analysis of waiting times. First, this approach is blind to patients who dropped off the waiting list before they were treated because it starts by identifying patients treated with RT and then follows them backward to measure waiting times from date of diagnosis or some other milestone. Secondly, it is unlikely that any database created for other purposes will provide all the information necessary to identify the rate-limiting step in the RT process. The date of the decision to treat with RT, for example, is an important milestone that signals the transition from pretreatment assessment to planning, and this is collected only in systems designed specifically to monitor flow through the RT process. Administrative databases may also lack information about other elements of the patient's care that are necessary to interpret waiting times for RT. For example, planned deferral of the start of postoperative RT because of delayed wound healing is indistinguishable from unscheduled delay unless the date when the patient is ready to be treated is recorded prospectively. Finally, the retrospective approach does not provide the real-time information needed to fine-tune the performance of an RT program. Prospective collection of the pertinent information is the preferred approach for tracking patients through the system. This approach has now been adopted by the Ontario RT system (see "A Canadian Case Study" in this chapter).

Causes of Waiting Lists for Radiotherapy

Kinetics of Waiting Lists

When demand for RT exceeds supply, waiting times inevitably increase and a waiting list for RT starts to grow. In theory the waiting list will then continue to grow for as long as demand continues to exceed supply. In reality, waiting lists for RT do not grow indefinitely. When waiting times for RT become longer than the referring physicians believe is acceptable, they may begin to offer their patients alternative treatments in circumstances in which RT would normally have been their first choice. For example, when long waiting lists for RT developed in Ontario in the early 1990s, there was a significant decline in the use of primary RT in the management of head and neck cancers, followed by a rebound when waiting lists decreased after a major reinvestment in facilities.[15,16] It has also been shown that there is a significant negative association between the prevailing waiting time for RT and the proportion of patients receiving postoperative RT following a partial mastectomy for breast cancer.[17] Furthermore, tumor progression or deterioration in patients' general condition during the delay may render them ineligible for RT that would initially have been appropriate, and these cases drop off the list. Decreasing referrals and increasing drop-offs from the waiting list serve to reduce demand for RT. As demand declines, the balance between supply and demand is eventually restored; the waiting list then ceases to grow, waiting times stabilize at a higher level, and RT utilization rates stabilize at a lower level. This phenomenon has been referred to as *implicit rationing* because it limits utilization without explicitly limiting access to care.[18]

Even when average supply is equal to average demand for RT, random fluctuations in referral rates may produce transient peaks in demand that exceed supply, and this may be sufficient to cause a substantial waiting list.[19] This risk can be reduced by forward planning that provides a buffer of reserve capacity or by building flexibility of capacity into the system. The smaller the functional unit, the greater is the impact of random fluctuations, and the more reserve capacity is required to avoid a waiting list.[19]

Even in the absence of any shortfall in supply, quite long delays may develop in a complex process such as RT planning, simply because of the many serial steps involved. Process mapping and redesign can be useful in streamlining health systems and can reduce delays in some situations. For example, a French proton therapy center applied such an approach to reduce average wait times by 4 or more weeks and to increase the annual number of treatment sessions from 4000 in 2007 to 4500 in 2009.[20] Investigators at the University of Michigan examined streamlining the referral to treatment process for patients requiring palliative radiation for bone and brain metastases. They standardized processes and cut the number of individual steps to begin treatment from 27 to 16. The proportion of patients receiving consultation, simulation, and treatment within the same day was increased from 43% to nearly 95%.[21] However, no amount of fine-tuning will have any impact on waiting times for RT if total demand exceeds total supply.

Consequences of Waiting Lists for Radiotherapy

Delays in starting RT are a source of great concern both to the patients and to those involved in their care. Box 12-2 summarizes the potential adverse effects of waiting list for RT. Delays have both direct and indirect effects on the well-being of patients, and waiting lists also have broader economic and social consequences. It is useful to classify the direct effects of delay on the well-being of individual patients as *nonstochastic* or *stochastic*.[22] We use these terms as they have been used in the field of radiation protection, in which they provide a useful distinction between the effects of radiation that depend on chance and those that do not. The nonstochastic effects of delay include the psychological distress resulting from the delay and the physical symptoms as a result of the untreated cancer. They occur in most cases and often increase in intensity with time, although they may not occur at all before some initial threshold period has been exceeded. The stochastic effects of treatment delay include the development of metastases and failure to achieve local control with radiation. These are all-or-nothing phenomena. Their probability increases as a function of time, but their severity is independent of time,

BOX 12-2 The Effects of Waiting Lists for Radiotherapy

DIRECT EFFECTS OF DELAY IN RT ON THE WELL-BEING OF PATIENTS

- 1.0 Nonstochastic effects
  - 1.1 Persistence or worsening of symptoms while waiting for treatment
  - 1.2 Psychological distress
- 2.0 Stochastic effects
  - 2.1 Decreased probability of local control
  - 2.2 Increased probability of spread beyond the irradiated field
  - 2.3 Decreased probability of cure because of 2.1 and 2.2
  - 2.4 Increased probability of complications due to compensatory increases in dose and/or volume

INDIRECT EFFECTS OF WAITING LISTS FOR RT ON THE WELL-BEING OF PATIENTS

- 3.0 Decreased probability of being referred for RT when it is appropriate
  - 3.1 Omission of necessary RT
  - 3.2 Exposure to less effective or more toxic alternatives to RT
- 4.0 Re-referral to a distant center for RT with loss of continuity of care
- 5.0 Decreased quality of practice of radiation oncology
  - 5.1 Risk of cutting corners to treat more patients (e.g., hypofractionation)
  - 5.2 Decreased quality of personal care because of the imperative to maximize technical productivity
  - 5.3 Decreased scope for innovation

ECONOMIC EFFECTS OF WAITING LISTS

- 6.0 Decreased efficiency of RT programs
  - 6.1 Decreased net benefits of RT (see 1.0 and 2.0)
  - 6.2 Increased costs associated with care for patients during delay
- 7.0 Decreased overall efficiency of cancer treatment programs
  - 7.1 Decreased benefits of RT because of treatment delayed or denied
  - 7.2 Increased costs because of the requirement for additional care during delay or use of more expensive alternatives to RT

OTHER SOCIETAL EFFECTS OF WAITING LISTS

- 8.0 Legal liability of providers for failure to provide adequate access to care
- 9.0 Decreased public confidence in the healthcare system

and there is no lower limit of waiting time below which they will not occur. Waiting lists may also have indirect adverse effects on patient care, mediated by changes in medical practice. In addition to their effects on health outcomes, waiting lists have important economic and societal implications.[22]

Measuring the Direct Effects of Delays in Radiotherapy

Some of the direct effects of delays in RT are self-evident. Delays in cancer treatment cause psychological distress and patients who are symptomatic wait longer for relief. There are also good reasons to believe that delays may adversely affect the long-term outcomes of RT. Delays provide an opportunity for tumor progression. There is abundant evidence that the probability of local control decreases as tumor volume increases and that the risk of metastasis increases over time.[23] These arguments are probably sufficient to persuade most radiation oncologists that unnecessary delays in RT should be avoided. However, in a publicly funded health system, in which waiting lists are endemic and widespread, many different specialties may each use their own waiting list problems to try to lever additional funding from a limited overall pool. In this context, direct evidence that delays in RT have an adverse effect on clinical outcomes is necessary to ensure that the needs of the RT sector are given appropriate priority.

Given the scant direct evidence that was available about the impact of delay on outcomes in the early 1990s, we initially used a mathematical modeling approach to estimate the risks of treatment delay.[22] The model was based on radiobiological principles that had been validated in experimental systems, and it incorporated the best available clinical information about tumor doubling times and the relationship between tumor volume and local control in the context of cancer of the tonsil.[22] The model predicted a decrease in local control rates of between approximately 10% per month of delay in the start of RT. Others have since made similar predictions.[24,25] However, although this approach was credible to radiation oncologists, it was not readily understood by those outside the field and had no impact on public policy. To make the case for increased resources, we therefore needed to provide direct clinical evidence of the adverse effects of delay.

Measuring the magnitude of the stochastic effects of treatment delay is not straightforward. It is inherently difficult to measure the risk of treatment failure as a result of delay because local failures caused by delay are absolutely indistinguishable from treatment failures resulting from other causes. The problem is analogous to that of defining the risk of carcinogenesis associated with low-dose radiation. One cannot simply count the cancers resulting from radiation because they are usually indistinguishable from the many other cancers that may occur because of causes other than radiation. Rates of failure must, therefore, be compared in groups of patients who have been exposed to longer and shorter delays, and the challenge is to ensure that those groups are comparable with respect to all other relevant prognostic factors. A randomized trial would be the best way of creating truly comparable groups, but it would be unethical to randomize patients to timely RT versus delayed RT, because there is no conceivable benefit in delay. Comparisons of the outcomes of RT in nonrandomized groups of patients who have waited longer or shorter periods of time are subject to all the biases that may affect any retrospective observational study. However, in this context, such studies are important because they represent the best available direct source of information.[25,26]

Recent systematic reviews have identified a growing number of observational studies that have investigated the association between treatment delay and the outcome of radiotherapy in certain clinical situations.[27] Figure 12-4 summarizes the results of the 20 high-quality studies included in a recent published meta-analysis.[27] Most of these studies had been done in the context of head and neck cancers and breast cancer. In these two disease groups, meta-analysis have showed a significant increase in the risk of local recurrence in patients who waited longer for RT.[27] A large population-based outcomes study, not included in this meta-analysis, recently confirmed that delay was associated with a higher risk of local failure following postlumpectomy RT for breast cancer.[28] We found no evidence of a threshold below which delay was free of risk. Moreover, although there was less evidence of an association between delay and local control in sites other than breast and head and neck, there was insufficient data available to conclude that delay in RT is free of this risk in any situation. We found no significant association between delay in RT and

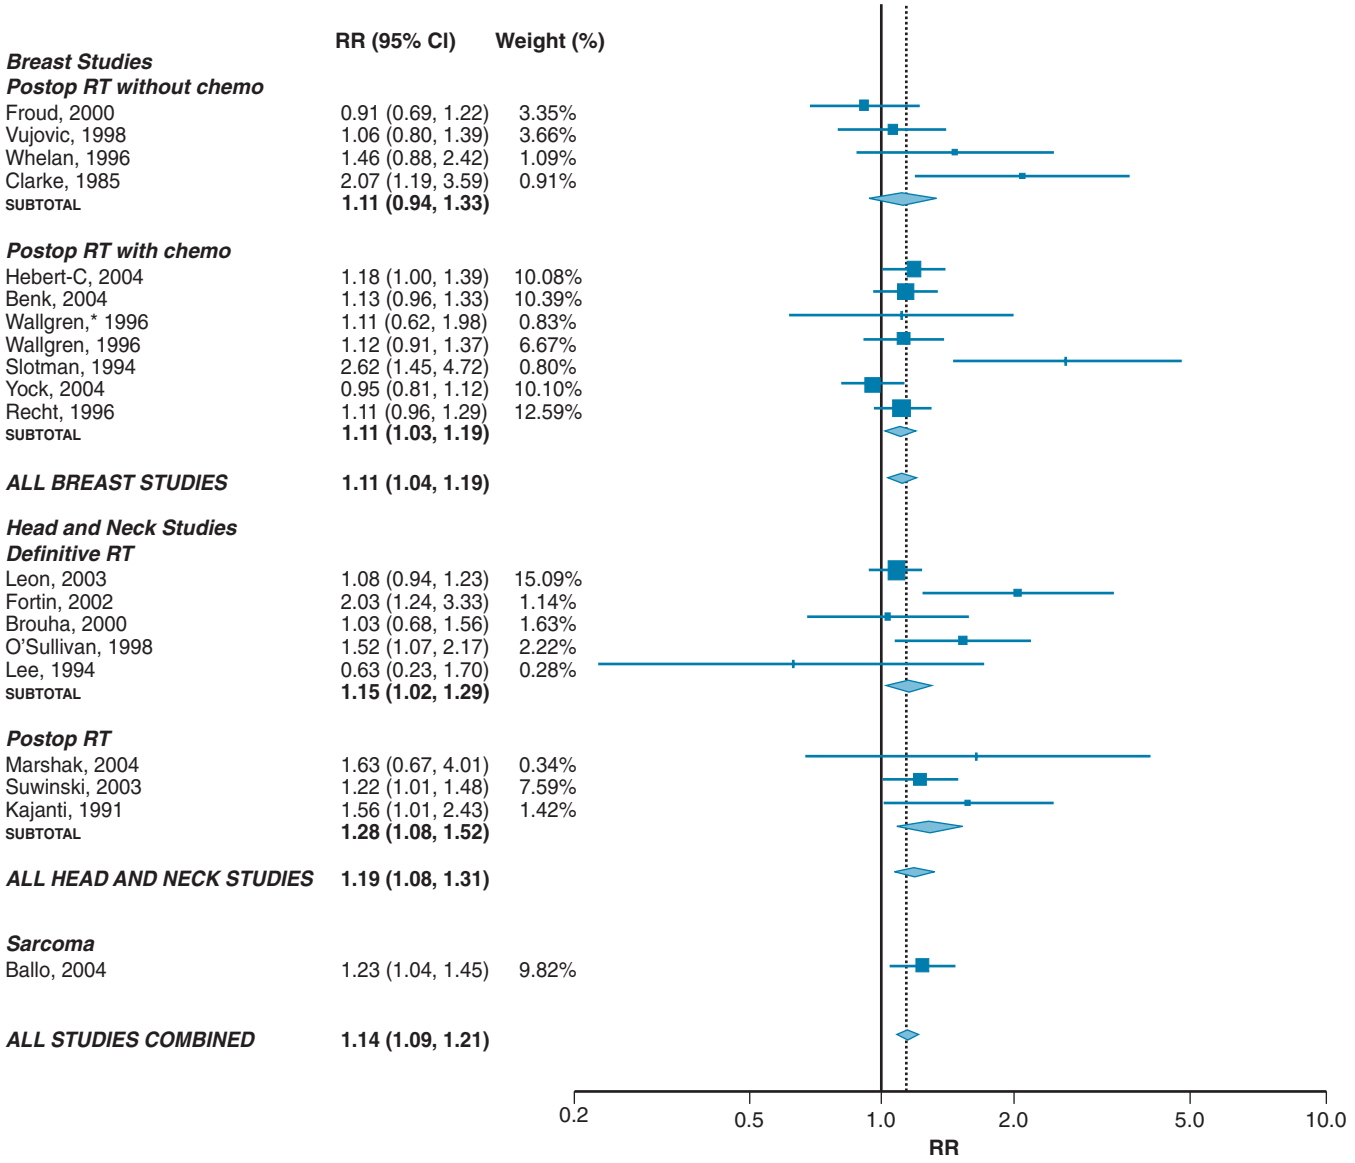

Figure 12-4 The association between delay in RT and the risk of local recurrence. The plot shows the results of a meta-analysis that included 20 high-quality studies that compared rates of local recurrence following RT.
(From Chen Z, King W, Pearcey R, et al: The relationship between waiting time for radiotherapy and clinical outcomes: A systematic review of the literature. Radiother Oncol 87:3-16, 2008.)

the risk of distant metastasis, although there was less information available about this outcome.[27] There was a small but significant decrease in survival with increasing delay in head and neck cancers.[27]

The relative risk of local recurrence of 1.1 per month of delay in starting postoperative RT for breast cancer translates into an absolute increase in recurrence rate of about 1% per month of delay in a population with a baseline rate of local recurrence of 10%.[27] Although this is a small risk for any individual it has the potential to cause an important increase in the number of recurrences at the population level. The increase in the relative risk of recurrence by 1.15 per month of delay in patients undergoing definitive RT for head and neck cancers translates into an absolute increase in risk of recurrence of 3% in a population with a baseline risk of failure of 20%, or an absolute increase of 6% in a population with a baseline risk of failure of 40%.[27] Interestingly, these findings are consistent with those predicted by the mathematical models described previously.[22,24] Thus, a few weeks delay in RT may have an adverse effect on outcome that is sufficient to cancel out all the improvements in outcome achieved by advances in the practice of RT over the last 20 years.[24,25] Given that there is no theoretical reason to believe that there is a threshold below which delay is safe, we have recommended that it would be prudent to adopt the principle that delays in RT should be as short as reasonably achievable (ASARA), modeled on the ALARA principle that guides risk management in the field of radiation protection.[25]

Indirect Effects of Waiting Lists for Radiotherapy on Patient Care

Box 12-2 summarizes the indirect effects of waiting lists on patient care and population health. The phenomenon of implicit rationing by which waiting lists reduce the use of RT

has already been described and the consequences of underutilization of RT will be discussed later in this chapter. Waiting lists may also increase the use of alternative treatments that may be less effective, more morbid, and more expensive than RT. There is evidence that long waiting lists may cause radiation oncologists to modify the way they prescribe RT. A study from the Queensland Radium Institute, for example, showed a significant negative correlation between waiting times and the number of fractions prescribed per course, as a result primarily of decreases in palliative fractionation as waiting times increased.[29] We have found a similar association between prevailing waiting time and the choice of fractionation for bone metastases in Ontario.[30] There are obviously serious risks in deviating from accepted practice in radiation oncology for the sole purpose of getting more patients treated. However, in circumstances in which randomized trials have demonstrated that shorter courses of RT are equivalent to longer courses of treatment, adoption of the more parsimonious approach has the potential to reduce overall workload and greatly increase the availability of RT, without adversely affecting outcomes.[31] The challenge is to ensure that shorter-than-standard courses of RT are used only in circumstances in which they have been shown to be medically appropriate. Explicit standards of care are required to prevent deterioration of quality in an attempt to maintain accessibility.

Societal Effects of Waiting Lists for Radiotherapy

Waiting lists for RT are potentially costly (Box 12-2). Patients require both care and counseling during delays and the costs of alternative treatments may be considerably higher than those of RT. Waiting lists have sometimes caused patients to be referred to distant centers for RT with loss of continuity of care and support for patients and added costs to the health system. The inability to provide timely RT may also be frustrating and distressing for the staff of RT programs. Waiting lists also expose RT providers to legal liability. In Quebec, a class action suit was launched against the hospitals responsible for providing RT, on behalf of approximately 10,000 women who had to wait long periods for adjuvant RT following surgery for breast cancer. At trial, the judge accepted the evidence that delay was associated with an increase in the risk of local failure and the case was ultimately settled with financial compensation for women who had waited for longer than 12 weeks to begin postoperative RT following lumpectomy.[32] Chronic waiting lists for RT and other important medical services eventually became an important political issue. Waiting lists are often used as evidence of the need for change, both by advocates of privatization of the health system and by those who favor reinvestment in the public system. By the early 2000s, public opinion polls showed that "wait times" for medical care had become the greatest concern of most Canadian voters, and there were increasing demands that government should set waiting time standards.

A Canadian Case Study

Why did waiting lists for RT become such a widespread problem around the world in the 1990s? Was there an increase in demand or a decrease in supply or both? Ontario's experience serves as a useful case study. Analysis of historical data showed that three different factors conspired to cause a huge increase in demand for RT over the critical period.[16] First, the incidence of cancer increased inexorably by approximately 3% per year, resulting primarily from the aging of the Ontario population.[16] Second, there was a dramatic increase in the number of patients referred for RT for breast cancer (consistent with the evidence-based trend toward breast conservation surgery[16]), for rectal cancer (consistent with the evidence-based adoption of postoperative RT and chemotherapy[31]), and for prostate cancer (as a result of a large increase in the number of early cases detected following the widespread adoption of prostate-specific antigen [PSA] screening[16]). Third, there was a significant increase in the average number of fractions prescribed per course of RT. This was driven by an increase in the number of fractions per curative or adjuvant course, which outweighed a concomitant but smaller decrease in the number of fractions per palliative course of RT.[16] There was no decrease in treatment capacity. In fact, the number of treatment machines in the province increased faster than the incidence of cancer.[16]

The demographic trends responsible for increasing cancer incidence and the changing patterns of practice that were responsible for Ontario's waiting list crisis are international phenomena, which explains why waiting lists developed more or less simultaneously in many other countries at the about same time. Countries where most or all of the RT system was publicly funded were hardest hit. The fact that the United States did not experience similar problems probably reflects the much greater reserve capacity available in the large private sector in the United States and also its ability to increase capacity rapidly in response to increased demand. In the private sector, increased demand represents an opportunity to increase revenues. When demand begins to outgrow supply, providers titrate additional resources into the system until demand is once again saturated. In contrast, in a publicly funded system operating on a fixed global budget there is rarely any reserve capacity, and it may be impossible to expand capacity rapidly. Increasing capacity often requires expanding facilities and acquisition of new equipment, and approval processes for new capital projects in publicly funded systems may take years to complete. These built-in delays may make it impossible ever to catch up on a growing problem once it becomes established. Only accurate forecasting of the future need for RT, linked to a proactive planning process for facilities, equipment, and personnel, can provide a way of avoiding similar problems in the future in slow-to-react public systems.

In Ontario, additional steps were used to prospectively monitor waiting times for radiotherapy as an indicator of quality of care. Prospective data collection was required to overcome the limitations to the retrospective analysis of waiting times, because such analyses are "blind" to patients who dropped off the waiting list before they were treated. Further, the data used in retrospective analyses may lack the information necessary to define the rate-limiting steps in the RT process or may lack information about other elements of the patient's care that are necessary to interpret waiting times for RT or to fine-tune the performance of an RT program. Prospective collection of the pertinent information is the preferred approach for tracking patients through the system. Figure 12-5 illustrates how this approach was adopted by the Ontario RT system using the framework presented previously (see Figure 12-1). Definitions were developed for overall wait times (and by waiting period) as indicators of performance, and the CARO definitions were used to set standards of performance as described. Methods were developed to prospectively collect wait-time data for each treating center, and proportion of patients meeting performance standard were routinely monitored and publicly reported. To improve wait times, investment in infrastructure was made. Further, each cancer center evaluated its treatment processes relevant to wait times and implemented process improvements (e.g., by running appropriate processes in parallel rather than sequentially). Patients with delays that were medically indicated (e.g., delayed wound healing) or with personal circumstances requesting delay were identified prospectively and accounted for in the analyses. As a result, analyses now reveal that the vast majority of patients meet wait-time standards across the province.[33]

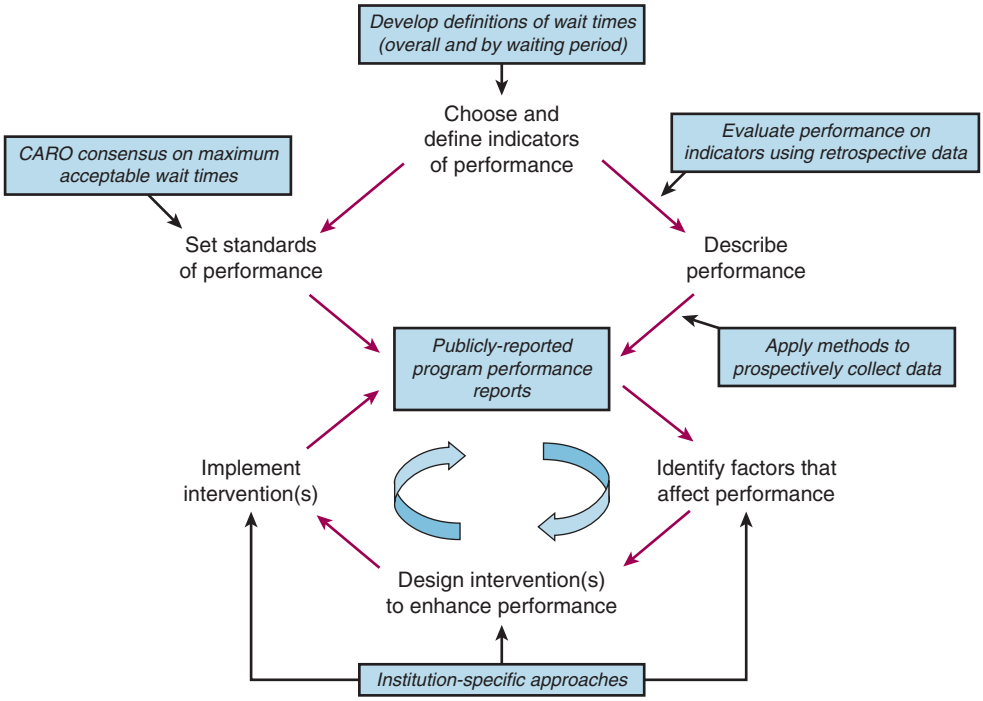

Figure 12-5 An illustration of the use of HSR to improve quality of care with regard to radiation wait times.

Measuring Access to Radiotherapy

Limitations of Waiting Times as an Indicator of Access to Radiotherapy

The existence of a long waiting list for RT is a symptom of inadequate access to RT. The duration of the waiting time for RT may be directly related to the probability of an adverse outcome, and waiting times may therefore serve as a quantitative measure of the quality of care. The length of a waiting list, however, provides no information about the magnitude of the shortfall between supply and demand, and waiting times cannot, therefore, serve as a quantitative measure of accessibility. The absence of a waiting list does not mean that access is optimal. Waiting lists develop only in response to supply-side problems in the availability of services. Waiting times are entirely insensitive to demand-side problems with respect to spatial accessibility, accommodation, affordability, or awareness (see Box 12-2). Problems in those dimensions of accessibility in fact reduce demand and may serve to reduce or avoid waiting lists. Thus, the absence of a waiting list does not imply that access is optimal. To ensure appropriate access to RT, it is also necessary to monitor RT utilization rates.

Defining Accessibility of Radiotherapy

The best quantitative measure of the accessibility of any service is the rate of its appropriate utilization, that is, the proportion of patients that need a service who actually receive it. The term *need* is used here as defined by Cuyler,[34] who states that "the need for medical care exists when an individual has an illness for which there is effective and acceptable treatment."

$$\text{Accessibility} = \frac{\text{Number of patients who need and receive treatment}}{\text{Total number who need treatment}}$$

Accessibility can have any value between 0 and 1, where 1 corresponds to optimal access. These values can also be multiplied by 100 and expressed as a percentage. Thus, to determine the accessibility of RT directly, we must measure both the utilization of RT and need for RT in the cancer population. In practice, the number of patients in a population who receive RT is relatively easy to determine, but the number who need RT is usually unknown. Proxy measures of need therefore have to be chosen.

Measuring Accessibility of Radiotherapy

The *incidence* of cancer (i.e., number of new cases diagnosed in the population of interest, over the period of interest) may be used as the denominator for describing the rate use of RT in the initial management of the disease. The best way to establish the proportion of cases that are treated with RT is to follow all of them forward in time from the date of diagnosis and find out if and when the patient received RT. The approach was first used in the Netherlands,[35] and we subsequently used it to describe the use of RT in Ontario.[15] The estimated rate of use of RT in the initial management of cancer depends on the cutoff point in time used to define initial RT. If a short cutoff point is chosen to define initial RT (e.g., RT within 3 months of diagnosis), the indicator will miss some patients who receive adjuvant RT following surgery. If a longer cutoff point is chosen (e.g., RT within 1 year), the indicator will include almost all patients who receive RT as part of their initial management, but it will also wrongly include some patients who are actually receiving RT for an early recurrence following primary surgery. The best cutoff point depends on the specific disease under consideration. For practical purposes, we have chosen to use the proportion of incident cases treated within 1 year of diagnosis to describe the initial use of RT in the general cancer population.[15] Figure 12-6, *A* describes variations in the use of RT in the initial management of cancer in Ontario in terms of this indicator ($R_{1\ year}$).

The incidence of cancer is a less suitable denominator for describing the utilization of palliative RT because a high proportion of incident cases will never develop indications for palliative RT, and many of those who ultimately do need

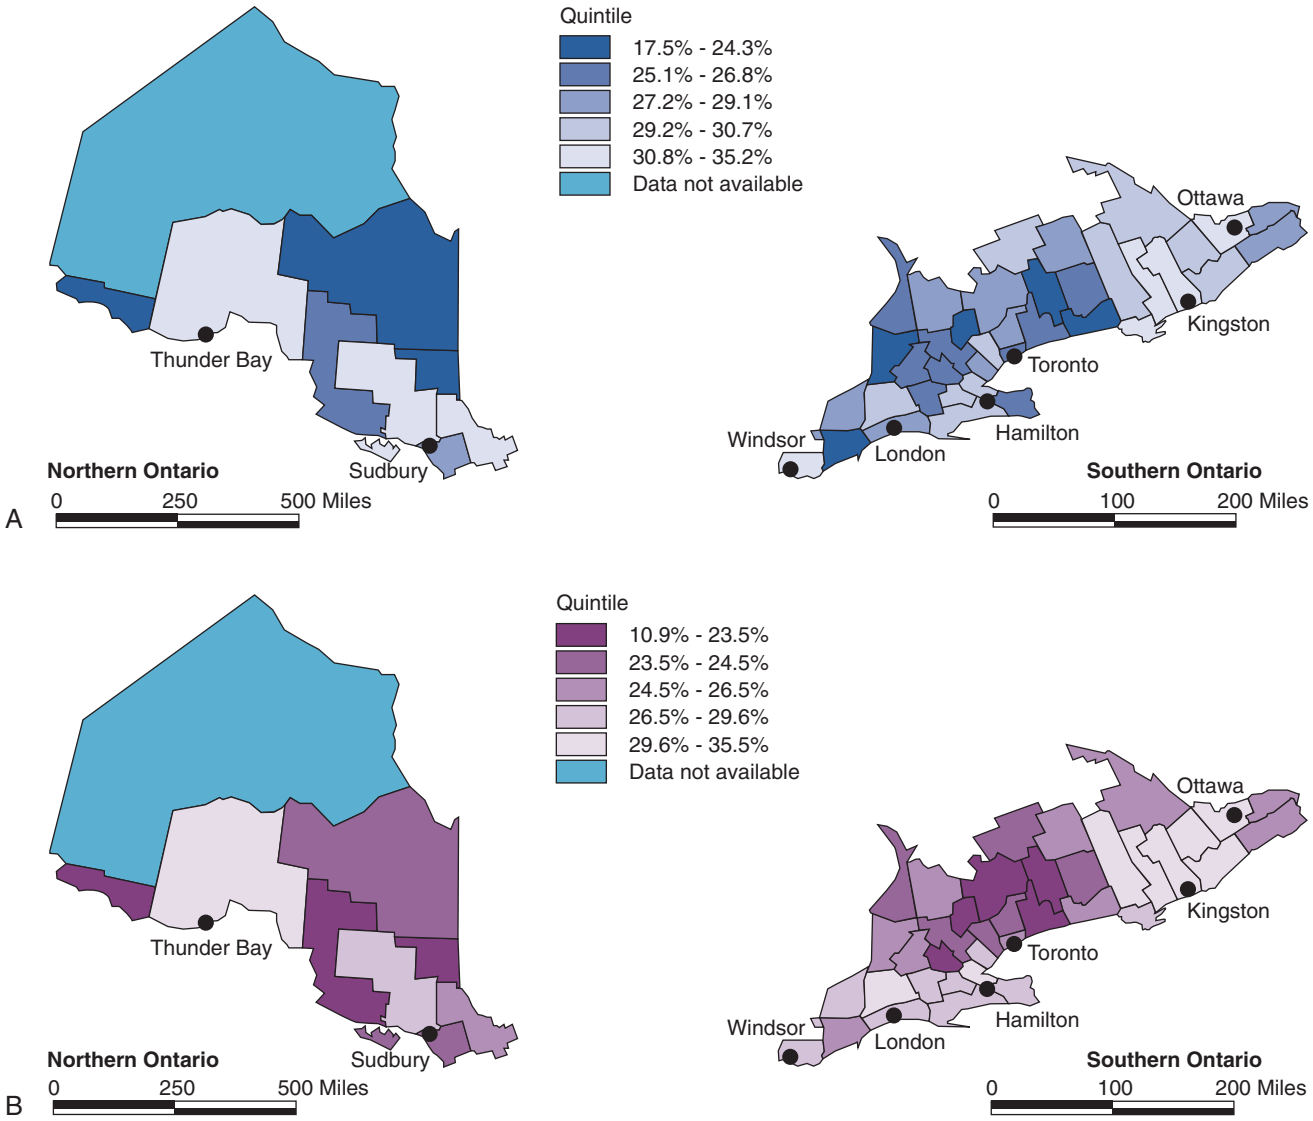

Figure 12-6 Geographic variations in the use of RT in Ontario. **A,** Intercounty variations in the rate of use of RT in the initial management of cancer within 1 year of diagnosis. **B,** Intercounty variations in the use of palliative RT in the last 2 years of life among patients who died of their cancer. The location of the provincial RT centers is shown for comparison.
*(**A,** Adapted from Mackillop WJ, Groome PA, Zhou Y, et al: Does a centralized radiotherapy system provide adequate access to care? J Clin Oncol 15:1261–1271, 1997; **B,** adapted from Huang J, Zhou S, Groome P, et al: Factors affecting the use of palliative radiotherapy in Ontario. J Clin Oncol 19:137–144, 2001.)*

palliative RT will not require it until years after the diagnosis. It is preferable to describe the use of palliative RT among patients who die of their cancer. This can be accomplished by identifying patients who died of their disease in a population-based cancer registry and following them back in time to identify those who received RT within a defined interval before death.[36] Figure 12-6, *B* describes variations in the use of palliative RT in the last 2 years of life among patients who died of their disease in Ontario. The same approach lends itself well to the description of the rates of use of other types of care in the terminal phase of the illness.

What Factors Affect the Rate of Radiotherapy in the General Cancer Population?

Figure 12-6 illustrates geographic variations in the rate of use of RT in Ontario, with the highest rates being observed in the counties where RT facilities are located.[15] It has generally been found that rates of RT use are higher in urban than in rural areas,[37] and that proximity to an RT facility is associated with higher utilization rates.[15] Taken together, these observations suggest that spatial accessibility is an important determinant of the accessibility of RT.

In studying geographic variations in practice, it is obviously important to be able to distinguish systematic variation from variations because of chance alone. Modeling techniques have been developed that can be used to isolate the systematic component of variation.[15] Multivariate analysis is helpful in distinguishing the impact of health system-related factors from other factors that are legitimately involved in determining patients' eligibility for RT. These include differences in cancer incidence, stage distribution, evolution of evidence supporting use of radiotherapy, patient functional status, and patient preference. Patient functional status and preference are important factors but are usually not available in administrative health data. Patient preference plays a significant role in observed rates of RT in cases in which there is more than one

TABLE 12-1 Factors Affecting the Use of Palliative Radiotherapy in Ontario*

	Odds Ratio	95% Confidence Interval
MEDIAN HOUSEHOLD INCOME		
Low, <Can $20,000	1.00	—
Medium, Can $20,000-$50,000	1.09	1.04-1.15
High, >Can $50,000	1.17	1.11-1.24
RT DEPARTMENT IN DIAGNOSING HOSPITAL		
No	1.00	—
Yes	1.35	1.30-1.40

standard-of-practice treatment. An example is treatment of low-risk prostate cancer.

Measurements of RT use have revealed unexpected inequities in access to care. One example is from a study investigating factors associated with use of palliative RT among patients who died of their cancer in Ontario (Table 12-1). In multivariate analysis, rates of use of palliative RT proved to be significantly lower among patients in whom the diagnosis was made in a hospital without an RT facility,[36] which confirms the concern of others that lack of awareness of the indications among other health professionals for RT may also be a significant factor in determining accessibility.[37] Additionally, even in the context of a publicly funded health system, the socioeconomic status of the patient influences the likelihood of receiving palliative RT. Figure 12-7 shows that rates of use of palliative and adjuvant RT decrease with increasing age and that this decrease is far greater than can be explained due to declining performance status.[38]

Measuring the Need for Radiotherapy

Given that the use of RT varies widely, it is important to ask what proportion of patients with cancer need RT. In the past, it was often stated that approximately 50% of patients with cancer should receive RT at some point in the course of the illness, but that recommendation was based almost entirely on expert opinion.[39] Two more objective methods have since been developed for estimating the need for RT.

Evidence-Based Requirements Analysis

Evidence-based requirements analysis (EBRA) is an objective method that has been used to estimate the need for RT. The indications for RT are first identified by systematic review. Next, an epidemiologic approach is used to estimate how frequently each indication for RT occurs in the population of interest. Finally, the results of the systematic review and the epidemiologic analysis are combined to estimate the overall need for RT. In this context, the term *need* can be equated with the *appropriate rate* of utilization of RT,[34] and the two terms may be used interchangeably. Tyldesley et al discovered this method and used it first to estimate the need for RT in patients with lung cancer.[40] We have subsequently refined the method and used it in several other major cancer sites.[41] The strengths of the method are: (1) that it is transparent in that all the assumptions involved are explicit; and, (2) that it is flexible, and models can be adapted to reflect the case mix in any community of interest or to explore the implications of changes in the indications for RT. The main weaknesses of the approach are that it is complex and time consuming and like any other type of modeling, its results are only as good as the information on which it is based. EBRA can be expected to produce valid results when it is applied to major cancers where the indications for RT are well defined and there is sufficient epidemiologic information available to estimate the frequency with which each indication occurs. Delaney et al extended the use of this method to measure the need for RT across the whole spectrum of malignant disease, and it is now being widely used to predict requirements for RT equipment.[42]

Criterion-Based Benchmarking

An alternative way of estimating the appropriate rate of the use of RT is to use a series of observations to derive a "benchmark." In the business world, *benchmarking* has been defined as "measuring products against the toughest competitors or those recognized as industry leaders."[43,44] In the field of health care, the equivalent is to measure outcomes against the best achieved anywhere or against those achieved in recognized centers of excellence. The same concept may be applied in setting benchmarks for the appropriate rate of utilization of any given treatment. The rate observed under certain specific conditions may be equated with the appropriate rate of

utilization—in other words, with the need for treatment. Benchmarks for the utilization of RT should be set in communities in which there is unimpeded access to RT and expert decision making about the use of RT. To ensure unimpeded access, there should be no financial barriers, referring physicians should be aware of the indications for RT, and patients should have convenient access to a nearby RT center that has sufficient capacity to provide prompt treatment. To ensure optimal decision making, decisions about the use of RT should be made by experts practicing in a multidisciplinary setting, and ideally the decision to treat should not affect their remuneration. If these criteria are met, it is reasonable to expect that the observed rate of utilization of RT will approximate the appropriate rate. We call this approach criterion-based benchmarking (CBB).[44]

We have been able to select a few communities in Ontario that meet most of the listed criteria and have used them to set benchmarks for the appropriate rate of utilization of RT for lung cancer.[44] Figure 12-8 shows that in this context, estimates of the appropriate rate of RT generated by this method are similar to those derived from the evidence-based approach. The CBB method has several strengths: (1) It is an inductive method that is grounded in observations in the real world; (2) it is applicable to both rare and common cancers because it does not require an accurate, comprehensive catalog of indications for treatment or detailed information about case mix; (3) it is relatively inexpensive and can be repeated easily if the indications for treatment change; and (4) it can be validated by replication in different communities. It also has several weaknesses: (1) It assumes that optimal structures and processes are associated with optimal practice, and this has not been proved; (2) the structures and processes that support optimal access and optimal decision making are not well defined; and (3) it requires a detailed knowledge of the structures in place in communities that are candidates to be benchmarks and this information may not readily be available. This CBB approach has been adopted by Ontario's provincial cancer agency and is now used for RT system planning. It is also used in the ongoing evaluation of the performance of the RT system performance by the Cancer Quality Council of Ontario which routinely reports on rates of RT use in relation to benchmarks established for the major malignant diseases.

Once utilization and need have been measured, it is straightforward to calculate the level of unmet need. Consider the data shown for lung cancer in Figure 12-8. It was estimated that approximately 41.6% of cases of lung cancer need RT as part of their initial management but the observed rate of RT use was only was 32.5%. Thus, only 32.5/41.5 = 78.3% of cases who needed RT actually received it. The ~22% shortfall between the observed rate and the appropriate rate represents an important opportunity for improving outcomes of lung cancer.

The Consequences of Underutilization of Radiotherapy

Adequate access to RT is a necessary component of any comprehensive cancer control program. At present, many patients who might benefit from RT have no access to the treatment that they need. This is a global problem that affects both developed and developing countries, but it is most prevalent and severe in low-resource settings where RT services are either nonexistent, or so limited as to be essentially nonexistent[43,45] (see discussion later in this chapter).

The consequences of lack of access to RT are most devastating for patients who have a radiocurable condition for which no other curative treatment is available (e.g., those with locally advanced cervical cancer). In situations such as this, the lack of access to RT inevitably translates into an avoidable and often unpleasant death. In contrast, failure to provide adjuvant RT when it is indicated, does not make death inevitable but does increase the risk of local recurrence and may also compromise long-term outcomes. Many patients who do not get palliative RT when they need it to relieve their pain or other symptoms will continue to suffer, whereas others who are more fortunate, must accept the lesser benefits and perhaps greater toxicity of alternative treatments.

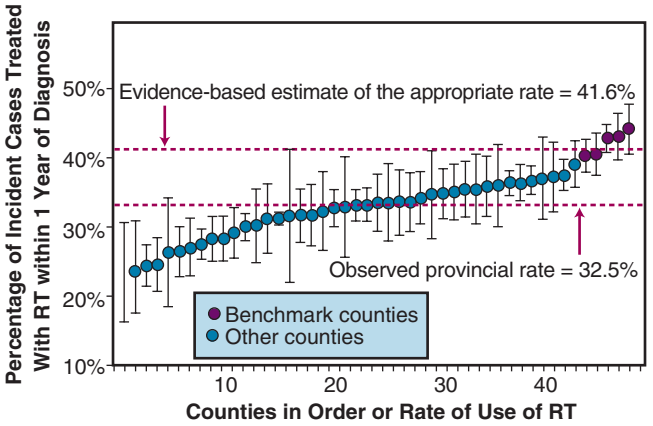

Figure 12-8 Evidence-based estimates and benchmarks of the appropriate rate of use of RT in the initial management of lung cancer. The rates of RT in the initial treatment of lung cancer are shown for each county in Ontario. The *error bars* represent the 95% confidence limits for these observations. Benchmark counties are those where cancer centers with relatively short waiting lists were located. The evidence-based estimate of the appropriate rate and the overall provincial rate are shown as *horizontal lines*; the distance between the lines represents the unmet need for RT.
(Adapted from Barbera L, Zhang-Salomons J, Huang J, et al: Defining the need for radiotherapy for lung cancer in the general population: a criterion based, benchmarking approach. Med Care 41:1074–1085, 2003.)

Beyond its effects on the patients themselves, the lack of access to RT may have serious consequences for their families and their communities. The unnecessary death of a young man or woman may have devastating economic as well as social consequences for their surviving family. The broader economic consequences of failure to use RT vary depending on the patient's condition and the socioeconomic status of the community. In rich countries, in which a range of other services are more readily available, failure to use RT when it is indicated may lead to the increased use of other, less cost-effective treatments, with a consequent overall increase in the cost of care. Even in poor countries where no alternative treatments are available, it may ultimately cost more not to treat a curable young patient than it would have cost to provide the necessary RT because failure to treat him or her results in the loss of a productive member of society.

STUDYING THE QUALITY OF RADIOTHERAPY

This section introduces the concept of quality in health care, describes what HSR has taught us so far about the quality of RT, and identifies what we still need to learn.

Concepts of Quality and Effectiveness in Health Care

In the field of HSR, the term *efficacy* is used to describe the extent to which a treatment achieves its objectives in the controlled setting of a clinical trial. The term *effectiveness* is

reserved for describing the extent to which a health program meets its stated objectives in the real world. The term *quality* is used to describe the effectiveness of the care provided, relative to the effectiveness of the best possible care. In this context, the term *quality* is therefore synonymous with the term *attainment factor* as defined previously.

Almost 40 years ago, Donabedian[46] defined *quality* as "a property of, and a judgment upon, some definable unit of health care, and that care is divisible into at least two parts: technical and interpersonal." The quality of technical care is measured by the extent to which "the application of medical science and technology maximizes its health benefits without correspondingly increasing its risks." The quality of interpersonal care is measured by "how well the physician-patient interaction meets the socially defined norms of the relationship."[46] Although others may define it somewhat differently today, there is universal agreement that quality is a multidimensional concept that embraces both the technical and personal elements of care.

Donabedian[46] also provided an approach for evaluating and improving quality, which Kramer and Herring soon astutely recognized as being appropriate for use in radiation oncology.[47] Donabedian's approach was to analyze the quality of programs in terms of *structure*, *process*, and *outcome*. The term *process* is used here to describe the way that care is delivered. In the context of radiation oncology, it includes pretreatment assessment, medical decision making, planning, delivery of RT, and supportive care during RT, and so on. The term *structure* is used broadly to include facilities, equipment, human resources, and organizational structures. The term *outcome* is used here, as in clinical practice, to describe the consequences of the care that has been provided. It is reasoned that: (1) optimal *process* is necessary for optimal *outcome*; (2) adequate *structure* is necessary, though not sufficient, for optimal *process*; and (3) *outcomes* may be enhanced by identifying and correcting deficiencies in structure, or deficiencies in process. This became the philosophy of the U.S. Patterns of Care Study that was established by Kramer in 1970. It operates on the premise that practice variations exist, differences in process and outcome can be measured, and deficiencies can be corrected.[47] The Patterns of Care Study (PCS) continues this important work today under the new title of Quality Research in Radiation Oncology (QRRO).

Studies of the Structure of Radiotherapy Programs

Two different types of research are being undertaken in this area. First, there are descriptive studies of the physical and organizational structures that prevail in RT programs around the world. In some instances, the observed structures are compared with predetermined standards. In others, the description of structures has been linked to studies of process and outcome with the goal of establishing which types of structure are associated with the best results. These studies may rely on mail surveys or involve on-site visits, but they are all cross-sectional or retrospective in design. Second, there is the field of technology evaluation, which is essentially prescriptive rather than descriptive in intent. It seeks to establish prospectively the usefulness of new technologies in patient care and thus contributes information that is important in setting standards for equipment in an RT program.

Descriptive Studies of the Structure of Radiotherapy Programs

In a highly technical specialty like radiation oncology, optimal care can be provided only when the necessary technological infrastructure is in place, including the correct mix and quantity of equipment and the correct mix and quantity of personnel. Nationwide surveys of RT facilities have now been done in many different countries. In the United States, the PCS/QRRO has taken the lead in describing the basic structural characteristics of radiation oncology facilities for the entire country. Its comprehensive survey of the structure of U.S. facilities serves as the starting point for national surveys of treatment processes and outcomes and permits stratified sampling of different types of facilities.[48] In addition to evaluating equipment and personnel, PCS/QRRO has described the structure of RT facilities in the following terms: (1) whether they have resident training programs or not, (2) volume of new cases treated per annum, (3) whether they were headed by a full-time or part-time radiation oncologist, and (4) participation in clinical trials.

In Europe, a variety of government,[49] agencies,[50] and individual investigators[51] have conducted national surveys of RT program infrastructure, primarily as a basis for planning. Most national surveys reveal considerable diversity with respect to the level of technology and expertise that is available in different RT centers, particularly with respect to brachytherapy. The European Society for Radiotherapy and Oncology (ESTRO) has more recently taken the lead describing and comparing the infrastructure of RT programs across Europe in a project called Quantification of Radiation Therapy Infrastructure and Staffing (QUARTS), funded by the European Commission.[52] QUARTS involves an international survey of equipment and personnel, the establishment of guidelines for levels of staffing and equipment, and the estimation of future needs based on projected incidence and estimates of the need for RT.

International comparisons of radiotherapy structure have been performed by the International Atomic Energy Agency (IAEA). These studies have covered Europe, Asia, Africa, and Latin America.[53-56] A common theme has been wide variation in the supply of RT resources with undersupply a common international problem, especially in low-income (gross national income [GNI] per capita US$1,035 or less) and middle-income countries (GNI per capita US$1036-$12,615).[53-55,57] A strong relationship exists between a lower national economic status and the degree of greater undersupply of RT equipment.[58] At its extreme, 29 of 52 African countries, with a total population of 198 million people, have no known external beam RT facility.[53]

The concept of program structure embraces not only physical infrastructure but also organizational structures including systems of funding, management, and governance. These elements of structure in radiation oncology may also have important effects on processes, but they have generally received less attention than the physical elements of structure. Funding arrangements at European RT centers listed in the ESTRO directory were investigated as part of an international study of palliative RT.[59] A broad range of funding mechanisms for RT departments is described, including a global budget, per-case payments, fee-for-service, and all possible combinations thereof. RT centers in Spain, the United Kingdom, and the Netherlands were mainly funded by a global budget plus or minus per-case payments, whereas the majority of centers in Germany and Switzerland received most of their funding through a fee-for-service arrangement.[59]

Prescribing Technology Assessment

New technologies are being developed rapidly, and our specialty needs to develop better ways of evaluating them and of determining their appropriate place in routine clinical practice.[60,61] Wherever possible, new treatment techniques should

be evaluated in randomized clinical trials, but it is clear that this approach only lends itself to the study of relatively common presentations of relatively common diseases. A large component of the practice of radiation oncology, however, is directed toward patients who have one of the many less common cancers or one of the infinite range of unusual presentations of a common cancer. In neither of these situations is there ever going to be "level 1 evidence" to guide our practice, and it would be impossible for a new approach to treatment to achieve their full potential if we demanded level 1 evidence for its use in every situation. On the other hand, if we choose to make our decisions about the acquisition and use of new technologies based only on the manufacturers' claims of enhanced precision, we may expose our patients to added risks and added costs without real benefits.[60]

Studies of Process in Radiotherapy

The term *quality assurance* (QA) is used to describe processes intended to avoid error in medical care, that is, to ensure that every patient gets the right treatment delivered the right way. Much of what has been written about QA in radiation oncology concerns the avoidance of error in delivering RT, but avoidance of error in case selection for RT deserves equal attention. The term *error* is used here to describe a deviation from appropriate care. Operationally, deviations from appropriate care can only be identified when the boundaries of appropriate care have been defined. Any QA program therefore falls into two parts: setting standards (i.e., deciding what is appropriate) and ensuring compliance with standards (i.e., making sure that every patient is treated appropriately). Some processes in a RT program have the potential to affect every patient, whereas others concern specific groups of patients. We deal first with research in the area of general QA before considering the process of care for specific groups of patients with cancer.

Research on Quality Assurance Processes in Radiotherapy

The RT community has long recognized the importance of routine QA because of the potential for a malfunctioning or wrongly calibrated machine to cause systematic errors in the treatment of a large number of patients. Detailed guidelines and protocols have therefore been developed for commissioning, maintenance, and calibration of treatment machines.[61] However, neither the existence of such guidelines nor an organizational commitment to adhere to them is sufficient to guarantee patient safety. A seminal study undertaken some years ago by Horiot et al on behalf of the European Organization for Research and Treatment of Cancer (EORTC) revealed that some centers made systematic errors in radiation dosimetry.[62] It also showed that feedback of the results of the initial survey diminished the frequency of such errors when the study was later repeated.[63]

Although QA on equipment reduces the chance of systematic error, the requirement for individualization of treatment plans creates the added risk of random error caused, for example, by lapses in human judgment or miscommunication. It has been shown that although well-defined care paths or intervention-specific guidelines can minimize the frequency of this type of error, it does not eliminate them. Real-time audit is necessary to avoid rare but potentially serious errors in the context of routine practice,[64] and even in the controlled setting of clinical trials.[65] The general rule that emerges from these analyses is that human errors cannot all be avoided, but the vast majority can be detected before they have any adverse impact on the patient. Understanding why errors occur is now recognized as the key to development of better processes for their avoidance in future, and the epidemiology of medical errors is therefore a growing field of study.[66] Because actual errors are rare, it is important also to investigate near-misses[67] and this is the approach that is now widely being used in the field of RT.[68,69] Although several recent accidents have heightened awareness of the dangers of RT,[70] serious errors that result in harm to patients are exceptionally rare in comparison to error rates in other fields of medicine.[71] The low error rates in RT were not achieved by chance; they reflect a long-standing awareness of the dangers of RT and a tradition of commitment to QA that antedates the intense media attention directed to medical error over the last decade. Nonetheless, new technologies bring new risks of error and there is a need for continuing research in field of QA in RT.

Research on Practice Patterns in Radiotherapy

During the past 30 years, there have been numerous studies of patterns of care in radiation oncology using methods primarily developed by the PCS.[72] Many different clinical situations have been studied. Most work has been done in the major sites in which RT plays an important role in curative treatment, but there have also been a number of studies of the practice of palliative RT, particularly in the context of bone metastasis. Striking variations in practice have been discovered in every situation that has been studied in detail. Practice has been shown to vary at many different points in the pathway of care: in pretreatment assessment; in fundamental aspects of the RT prescription, including target volumes, treatment techniques, and dose and fractionation; in decisions about adjunctive systemic treatment; in the planning process; in treatment delivery; in the way that treatment details are recorded; in supportive care during and after treatment; and in arrangements for long-term follow-up.

Why Study Practice Variations in Radiotherapy?

Practice variations have been identified in every field of medicine where anyone has taken the trouble to look for them. As we have seen, radiation oncology is no exception. In the era of evidence-based medicine, practice variations represent a threat to the credibility of any medical specialty; it is difficult to defend variations in patient care except insofar they reflect variations in the needs of individual patients or unavoidable variations in the availability of resources. Practice variations in radiation oncology represent not only a threat but also an opportunity for improving practice and outcomes. The opportunities to improve the quality of care depend on the state of knowledge in the particular clinical situation under study. If optimal practice has already been established or can be established for the purposes of the study, deviations from the optimal represent opportunities for improving quality of care. It then becomes important to understand why practice deviates from the optimal, to design interventions that will improve practice. If, on the other hand, optimal practice has not yet been established, practice variations represent an opportunity for learning. Studies of practice patterns may identify controversies that should be addressed in clinical trials. In certain specific circumstances, it may be possible to explore the relationship between treatments and outcomes to determine which approach is superior. The scope and limitations of this type of study are discussed in Relating Structure and Process to Outcomes.

Why Does Practice Vary in Radiation Oncology?

In an ideal world, cancer treatment would be guided only by precise classification of the case and the application of scientific knowledge about the optimal treatment of that class of cases, taking into account the patient's personal values and preferences. In the real world, however, other environmental

factors may influence patient care. Treatment options are often constrained by the resources available. Scientific knowledge is variably disseminated and may be interpreted differently by individual physicians, depending on their training, experience, and work environment. Moreover, financial considerations have the potential to influence medical decisions, whenever there is more than one defensible treatment option available. We now review what is known about the impact of each of these factors on the practice of RT.

Impact of Program Structure on the Practice of Radiotherapy. Consistent with Donabedian's concept, there is abundant evidence that physical and organizational structures determine processes in RT (see Figure 12-12). If the total availability of personnel and equipment is not adequate to permit prompt access to RT, referring physicians may choose alternative forms of treatment. Many studies have revealed that radiation oncologists' choices of investigations, treatment techniques, and fractionation schemes are influenced by the resources available. The PCS has consistently found significant associations between the structural characteristics of facilities and the quality of processes involved in patient care. For example, in a now-classic study of work-up and treatment procedures in head and neck cancers,[73] the PCS found significantly poorer compliance with its criteria of appropriateness of assessment, treatment, and other aspects of care among patients treated at facilities headed by a part-time, rather than a full-time, radiation oncologist (Figure 12-9, *A*), and at nontraining facilities compared with training facilities (Figure 12-9, *B*).

Impact of Scientific Evidence on the Practice of Radiotherapy. Practice varies most where there is least evidence available. Decision making about the use of RT has been shown to be highly variable in the context of adjuvant RT. This is most evident where the value of RT has not been confirmed in randomized trials. Although many indications for RT are supported by the results of randomized trials, there have been far fewer formal comparative studies of the details of RT prescriptions and techniques. Not surprisingly, technical practice of RT is even more variable than clinical decision making in radiation oncology. Even in situations in which there have been several consistent published reports that appear to indicate that one approach is superior to another, it has been shown that physicians may interpret these data differently and therefore may still vary widely in their treatment recommendations.[74]

There has been much interest in enhancing the practice of medicine through the synthesis and dissemination of scientific knowledge in the form of treatment guidelines. Guidelines are clearly valuable for reference purposes, but it is not clear to what extent they have actually succeeded in modifying practice in the general population. For example, we observed no impact of a provincial guideline promoting shorter fractionation for postlumpectomy RT over and above changes attributable to prior reports of randomized trial evidence supporting this practice.[75] Changes in practice have sometimes been reported after the introduction of treatment guidelines, but it is usually impossible to conclude that the guidelines themselves were responsible for those changes.[76]

The existence of treatment guidelines does not guarantee appropriate clinical decision making. Misclassification of patients may lead to selection of an inappropriate care path or treatment plan. This may be caused by inadequate or inaccurate pretreatment assessment or misinterpretation of the results of an adequate assessment. If QA is directed only at the avoidance of errors in delivery of RT, patients remain at risk of receiving the wrong treatment, albeit flawlessly delivered. Clear specification of eligibility criteria for RT and real-time audit of compliance with those criteria is required to avoid this type of error.

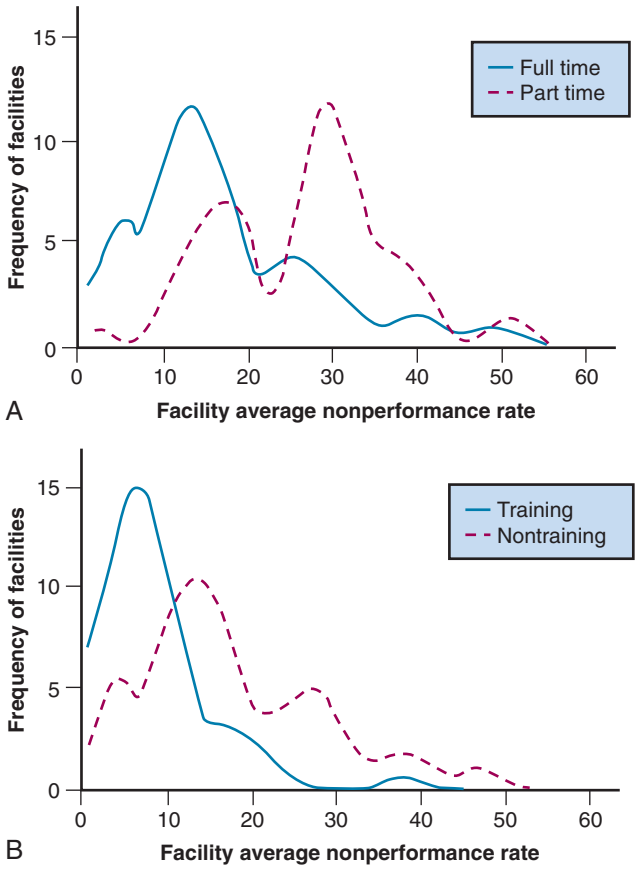

Figure 12-9 Relationships between the structural characteristics of RT programs and quality of practice. **A,** Nonperformance rates for part-time and full-time facilities. **B,** Frequency polygons of nonperformance scores for training and nontraining facilities.
(Adapted from MacLean CJ, Davis LW, Herring DF, et al: Variation in work-up and treatment procedures among types of radiation therapy facilities: the patterns of care process survey for three head and neck sites. Cancer 48:1346–1352, 1981.)

Scientific evidence appears to vary in its impact depending on the practice environment and also on the demographic characteristics of the patients. In 2001, the U.S. Commission on Cancer reported that breast-conserving surgery was still used in less than 50% of U.S. patients with stage 1 and 2 breast cancer and that variations in its use were not consistent with existing practice guidelines.[77] Breast conservation was more rapidly and completely adopted in urban than in rural areas and there were large geographic variations in its adoption across the United States, with much higher rates in the northeast than elsewhere. Older patients and patients from lower socioeconomic groups were less likely than others to have a partial mastectomy, and those who did were less likely to receive postoperative RT. There is also evidence that the characteristics of physicians and their type of practice influence the extent to which they rely on guidelines or other published information in reaching treatment decisions. Reliance on published information in decision making is greater in academic centers and decreases the longer the physician has been in practice.[78] Local policies may affect practice more than national guidelines. A study from the United Kingdom, for example, showed that much of the variation in the use of postoperative RT for breast cancer was attributable to variations in the local management protocols of surgical units.[79]

Impact of Physicians' Beliefs on the Practice of Radiotherapy. There is abundant evidence that physicians' beliefs

about appropriate treatment are shaped by factors other than universal knowledge. Physicians' views about the indications for RT are strongly influenced by their training and experience. Because the key decisions about referral are usually made by surgeons, the views of the surgical community are a major determinant of the role that RT plays in cancer care at the population level. It has repeatedly been shown that surgeons are less likely to recommend RT than radiation oncologists, particularly when a choice has to be made between primary RT and primary surgery. For example, in comparison to radiation oncologists, urologists are less likely to recommend primary RT for prostate cancer,[80] and otolaryngologists are less likely to recommend RT for laryngeal cancer.[81] Medical oncologists today have acquired a significant role in initiating referrals to radiation oncology, but their views about the indications for RT also differ significantly from ours.[74]

Impact of Financial Incentives and Disincentives on the Practice of Radiotherapy. There is evidence that funding mechanisms may affect case selection for RT. For example, a study based on administrative claims data from Pennsylvania showed that the patient's health insurance status was associated with the chance of receiving RT following partial mastectomy. Postoperative RT was given in only 45% of patients with Medicaid compared with greater than 75% of patients with private insurance and Medicare and similar observations have been made elsewhere.[82] Funding arrangements have also been shown to influence choices of fractionation in some studies. Lievens has explored the effects of funding on patterns of palliative RT in Belgium.[83] She found that fractionated courses of RT were prescribed more frequently than single treatments for bone metastases, at least in part because the funding mechanism in place at that time penalized the use of single fractions. In 2001, a new mechanism of funding of palliative RT was introduced in Belgium, which removed the disincentive to single treatments. Since that time, there has been a trend to reduce the number of fractions prescribed in all except 3 of the 23 centers that responded to her most recent survey. Many of those centers reported that the change in the fee schedule was a significant factor in their decision to change practice.[83] Lievens et al have also shown significant associations between funding models and the practice of palliative RT in an international survey of RT centers across Europe. They found that centers funded by a global budget or per-case payment used a significantly lower number of fractions per course and were less likely to use shielding blocks than were centers funded by fee-for-service. The growing evidence that funding may shape the way that RT is practiced suggests that it may be possible to improve practice by appropriately manipulating reimbursement systems. However, there is also a high risk that poorly designed fee schedules may compromise quality of care.[84] It has also been pointed out that, under per-case funding arrangements, profits may be inversely related to quality, making it important to set clear baseline quality standards.[85]

Role of Quality Indicators in the Practice of Radiotherapy

Assessment of quality of care allows healthcare providers to examine their clinical performance against established standards of care, allows payers to assess the quality of care they are purchasing, and is an increasingly important area of HSR.[86] As described previously, the general framework (see Figure 12-1) for a program of HSR describes how quality indicators may be used to assess quality of care and to improve health system performance. Quality indicators may be selected, defined, validated, and applied to target observed variations in practice by evaluating actual practice against targeted performance and to conduct explanatory studies aimed at identifying factors that are associated with better or worse performance.

Quality indicators specific to radiation oncology have been developed across the framework of structure, process, and outcome domains of quality of care and across a spectrum of clinical settings.[86-88] A recent comprehensive review by Albert and Das summarizes the current scope of quality indicator development and application in radiation oncology.[89]

The setting of radiation utilized in the curative management of prostate cancer can be used to illustrate these general principles of quality measurement. Prostate cancer has a high incidence and is commonly managed with either external-beam radiotherapy or brachytherapy as definitive treatment. The RT is highly technical, and continuous advances in technology require consideration in the definition and application of quality indicators in this setting.[88] In Canada, RT is delivered exclusively in 37 publicly funded cancer centers across the country, staffed by approximately 400 radiation oncologists. A Canadian HSR team undertook a modified Delphi process to identify existing candidate quality indicators for measuring the quality of technical medical care and to develop consensus on a suite of quality indicators based on best available evidence.[88] This process identified a suite of 25 quality indicators covering all aspects of prostate cancer radical RT management: pretreatment assessment, external beam RT, brachytherapy, androgen deprivation therapy, and follow-up.

These selected quality indicators were then used as criteria in an audit of patterns of practice, and to develop benchmarks of performance in highest-performing centers.[90] Thirty-two of 37 RT centers (84%) participated, providing 810 cases in total. Analysis of these cases revealed that compliance with 12 pretreatment assessment indicators varied considerably across indicators: from 56% (sexual function documented) to 96% (staging bone scan obtained in high-risk patients). For cases treated with external-beam radiotherapy (EBRT), 100% of EBRT cases were treated using three-dimensional conformal radiotherapy (3DCRT) or intensity-modulated radiotherapy (IMRT) techniques with computed tomography (CT) or magnetic resonance imaging (MRI) planning, whereas 81% of planned cases recorded dose-volume histograms for planning target, rectum, and bladder volumes. For patients treated with conventional fractionation, the dose to the prostate was >70 Gy in 100% of low-risk patients, was >70 Gy in 92% of high-risk cases, but was >74 Gy in only 78% of intermediate-risk patients treated without androgen ablative therapy (ADT). ADT therapy was used in 92% of high-risk cases. Figure 12-10 illustrates that centers varied with regard to how many indicators they were fully compliant on; no center was fully compliant on fewer than 4 of 16 indicators, and no center was fully compliant on all indicators.[90] Given that each quality indicator was selected as representing a minimum standard of care,[88] these data suggest room for improvement in quality of care, particularly for indicators such as dose, in which variation can affect cancer outcome.

Studies of Outcomes in Radiotherapy Programs

It is important to appreciate that although outcomes may seem to be the ultimate measure of quality, one cannot fine-tune the operation of a cancer program by measuring the long-term outcomes by which we usually judge the success of cancer treatment. It may take a decade to measure the 5-year recurrence-free rates associated with a particular pattern of practice. Any feedback from audit of outcome comes far too slowly to permit optimization of the program performance. Quality improvement programs in oncology largely have to operate on the principle that if you get the structure and the process right, the outcomes will look after themselves. That being said, there is some value in measuring outcomes and the opportunity to do this should not be overlooked.

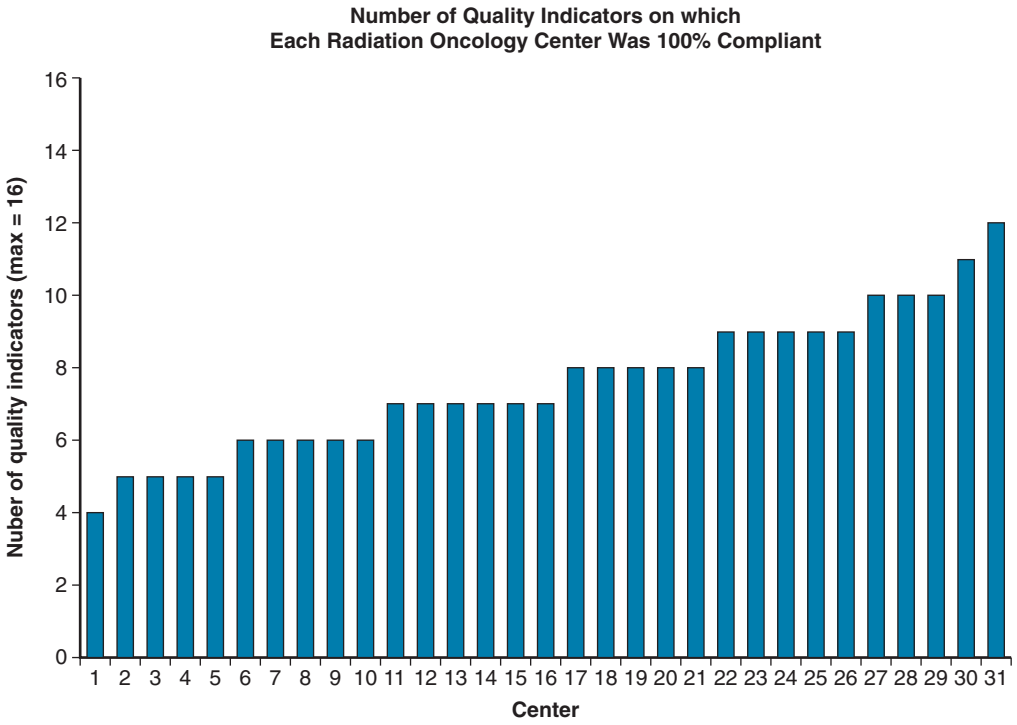

Figure 12-10 Center performance on a suite of 16 quality indicators across Canadian radiotherapy centers. The graph shows the number of indicators on which all cases sampled from that center met the specific quality indicator (demonstrating 100% compliance on that indicator). *(Data taken from Brundage et al: Radiother Oncol, 107:339–345, 2013.)*

Surprisingly, it may be easier to measure outcomes than processes in the general population. Accurate information about vital status is usually available in cancer registries, and it may be quite straightforward to measure survival at the population level. Hospital records and billing files may provide information about subsequent surgical procedures that can sometimes provide surrogate measures of local control by RT. For example, survival without subsequent laryngectomy has been used as a surrogate for local control in measuring the success of radical RT for laryngeal cancer, and survival without subsequent cystectomy has been used as a surrogate for local control after radical RT for bladder cancer (Figure 12-11). The high statistical power of population-based studies also makes it possible to detect and quantify rare but serious late effects that it might be impossible to detect based on the analysis of experience of any individual institution.[91]

Large variations in outcome have been observed among different countries and among different regions, demographic groups, and institutions within the same country. The challenge lies in distinguishing the component of variation in outcome attributable to differences in quality from the inevitable variations in outcome due to differences in case mix.

International variations in cancer outcomes are inevitably multifactorial in origin, and it is difficult to attribute them to any individual aspect of health system performance. Nonetheless, such comparisons have proved to be useful.[92,93] Figure 12-12 shows international variations in cancer survival as a function of proportion of gross domestic product spent on health care. It demonstrates a remarkably clear relationship between investment in health care and cancer survival. It is impossible to determine whether the worse outcome observed in countries that spent less on health care was the result of more advanced stage of disease at diagnosis, higher levels of comorbidity, poorer access to care, or poorer quality of care. However, despite these uncertainties the message is clear that you get what you pay for. These results had a direct influence on public policy in the United Kingdom and were used to justify an expansion in the budget of the National Health Service's cancer programs by almost $1 billion, permitting a massive expansion in the equipment and staffing of its radiation oncology programs.

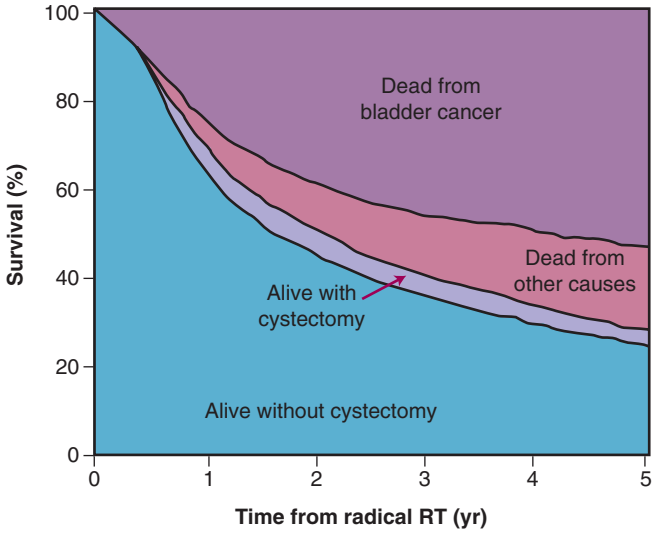

Figure 12-11 Outcome of radical RT for bladder cancer in Ontario. The graph illustrates the results of a population-based study of the outcome of radical RT for bladder cancer in Ontario. The curves show the probability of survival and cystectomy-free survival in 1370 patients who received radical RT for bladder cancer between 1982 and 1994. Deaths from cancer are differentiated from deaths from other causes. *(Adapted from Hayter CRR, Paszat LF, Groome PA, et al: A population-based study of the use and outcome of radical radiotherapy for invasive bladder cancer. Int J Radiat Oncol Biol Phys 45:1239–1245, 1999.)*

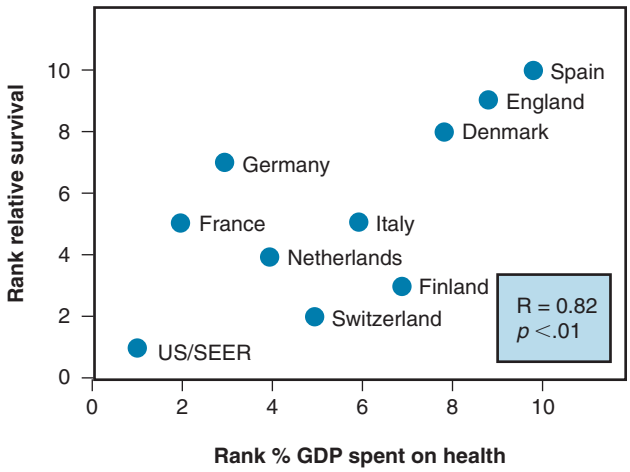

Figure 12-12 Correlation between relative survival and expenditure on health care. The scatter plot shows the relationship between relative survival for all cancer in female patients and the percentage of gross domestic product (GDP) spent on health care in 10 developed countries. *(Adapted from Evans BT, Pritchard C: Cancer survival rates and GDP expenditure on health: A comparison of England and Wales and the USA, Denmark, Netherlands, Finland, France, Germany, Italy, Spain, and Switzerland in the 1990s. Public Health 114:336–339, 2000.)*

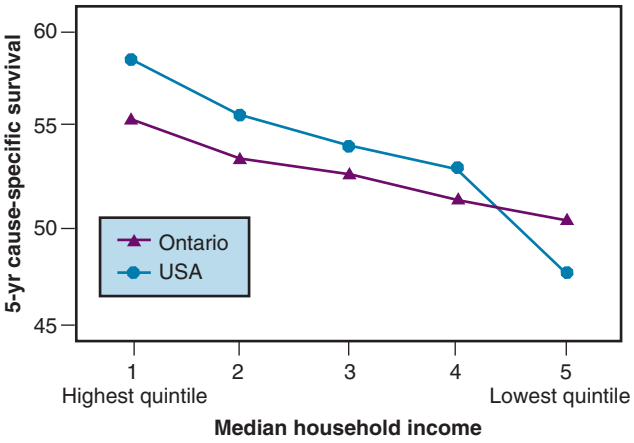

Figure 12-13 Associations between socioeconomic status (SES) and cancer survival in the United States and Canada. The graph shows 5-year, cause-specific cancer survival as a function of SES for all cancers combined (excluding prostate) in the Canadian province of Ontario and in the regions of the United States covered by the Surveillance, Epidemiology, and End Results (SEER) cancer registries. *(Data from Boyd CJ, Zhang-Salomons J, Groome PA, et al: Associations between community income and cancer survival in Ontario and the United States. J Clin Oncol 17:2244–2255, 1999.)*

It has also been shown that cancer outcomes are worse in residents of poorer communities than in residents of richer communities within the same country.[92] Figure 12-13 shows variations in 5-year survival among patients from richer and poorer communities in Canada and the United States. There is a clear gradient in survival across socioeconomic strata in both countries. Some, but not all, of the observed variation is the result of more advanced stage at diagnosis among the poorer groups, probably reflecting differences in access to care.[92] Differences in quality of care may be responsible for some of the observed differences in survival not explained by differences in stage mix. These differences in outcome represent potential opportunities for improving overall outcomes at the population level.

Before we can develop strategies for reducing these disparities, further studies are needed to explore their causes. Although the socioeconomic status–survival gradient is steeper in the United States, there is still a significant difference in outcome among residents of richer and poorer communities in Canada. This may seem somewhat surprising because Ontario has a single-payer, universal healthcare system with no parallel private healthcare sector, and in theory the rich do not have better access to care or quality of care than the poor. Clearly, however, the removal of financial barriers to access to care does not in itself abolish differences in outcome between rich and poor.[92]

Interregional comparisons within the same country may also be informative. When dissimilar populations are compared, it is necessary to control for differences in case mix, but in the absence of any major interregional variations in socioeconomic status, systematic variations in case mix are unlikely. Under these circumstances, variations in outcome, which exceed those expected because of chance alone, may reasonably be attributed to variations in access or quality. Figure 12-14 shows the observed 5-year survival for several major cancer sites in eight different regions of Ontario. Once the observed variations are reduced to take account of the expected variation because of chance alone, the best observed outcomes may be used as a benchmark for the achievable outcome. Figure 12-14 shows that, after adjusting for variation because of chance alone, there were no residual geographic variations in the outcome of cancers of the pancreas, colon, or cervix, but there remained important geographic variations of survival for head and neck cancers, Hodgkin disease, and testicular cancer. Table 12-2 shows the observed 5-year survival for the province as a whole compared with the estimated achievable survival for several diseases in which geographic variation in outcome exceeded that because of chance alone. Although such studies can demonstrate the potential to improve outcome by improving quality, they do not reveal where the defects in quality lie. Further studies are required to identify specific defects in the underlying processes and structures.

Relating Structure and Process to Outcomes

Whether you begin with variations in outcome and work back to try to find their causes or begin with variations in process and work forward to try to identify their consequences, there are significant problems that must be addressed before a causal relationship between process and outcome can be established. We will discuss these problems and describe how they should be addressed in the context of outcomes research.

Limitations of "Outcomes Research"

Studies that examine treatment and outcome in the context of routine care are often today referred as "outcomes research." This type of study should *not* generally be used to try to evaluate the efficacy of treatment. It is notoriously difficult to control for bias in retrospective reviews of institutional experience.[94] Comparisons of outcomes achieved in contemporaneous groups of patients who have received different types of treatment at the same institution are inevitably confounded by "treatment selection bias." Comparisons of outcomes between groups of patients who received different treatments more or less contemporaneously at different institutions are less subject to treatment selection bias but are vulnerable to "referral bias" resulting from interinstitutional differences in case mix.[94,95] The use of "historical controls" (i.e., the comparison of outcomes between patient groups who have received different treatment at different points in time) is also fraught with hazard.[96] Case mix may change systematically over time; investigations may change, resulting in "stage migration"; and collateral aspects of care may also change. It is possible to

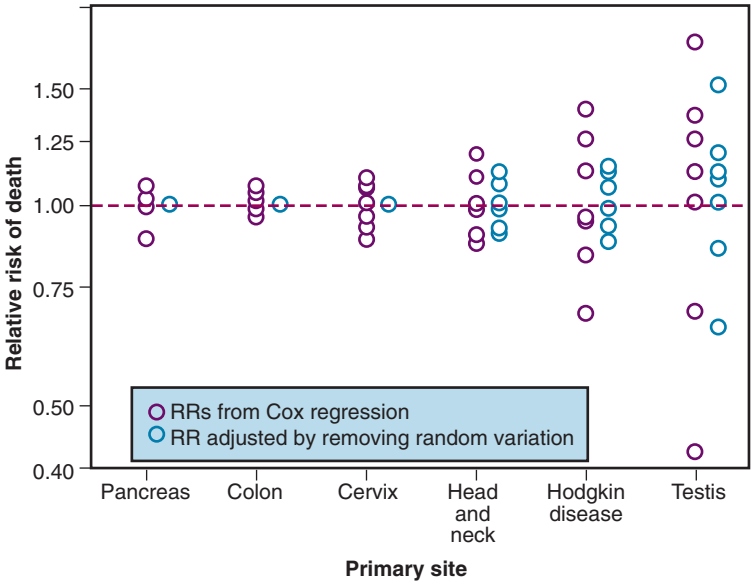

Figure 12-14 Interregional variations in cancer survival in Ontario. The scatter plot shows the relative risk of death from cancer in seven geographic regions of Ontario derived from a Cox regression that controlled for age, sex, and socioeconomic status. The *purple circles* represent the observed variations in survival. The *blue circles* represent the remaining variation after subtraction of the expected random component of variation. *(Adapted from Zhang-Salomons J, Groome PA, Mackillop WJ: Estimating the best achievable cancer survival by eliminating regional variations in Ontario. Clin Invest Med 363[Suppl 22], 1999.)*

TABLE 12-2 Observed versus Achievable 5-Year Survival for Selected Cancer Sites in Ontario*

Primary Site	Achievable 5-Year Survival Rate (95% Confidence Interval)	Observed 5-Year Survival Rate (95% Confidence Interval)	
		All Ontario	Worst Region
Head and neck	64% (63-65)	60% (59-61)	54% (49-59)
Hodgkin disease	88% (86-90)	86% (84-87)	81% (73-89)
Testis	97% (97-98)	95% (94-96)	92% (89-95)
Central nervous system	32% (31-34)	28% (27-29)	27% (24-30)
Rectum	52% (51-54)	50% (49-51)	48% (45-51)
Stomach	21% (20-22)	20% (19-21)	15% (12-17)
Lung	18% (18-19)	15% (15-16)	12% (11-13)
Ovary	49% (47-51)	46% (44-47)	40% (33-48)
Prostate	77% (76-77)	75% (74-75)	71% (69-72)
Bladder	74% (72-75)	73% (72-74)	68% (65-71)

**The best achievable survival was estimated from the highest observed survival in any of the seven regions in Ontario, by subtracting deviations from the provincial average that are expected, as a result of random variation. Cox regression was used to control for age, sex, and socioeconomic status. This model assumes that there are no systematic variations in case mix among the regions.*

reduce the impact of these types of bias by controlling for known prognostic factors, but these usually leave much of the variance in outcome unaccounted for. For these reasons, none of these types of retrospective, observational studies can substitute for prospective, experimental studies (i.e., randomized controlled trials) in the evaluation of efficacy of treatment. The credibility of our discipline is weakened to the extent that we rely on these less valid methods in situations in which a randomized trial is possible.

Legitimate Roles of "Outcomes Research" in Evaluating Effectiveness

It is important to recognize that there are some aspects of medical practice that cannot be evaluated in randomized trials and must be explored using observational methods.

There are some important aspects of treatment that cannot and should not be studied in a randomized trial. It may be important, for example, to know how much outcomes are affected by deviation from standard practice, such as by delay in initiation of RT, protraction of overall treatment time, the use of lower-than standard doses, or reliance on antiquated equipment. However, one cannot ethically randomize patients to receive nonstandard versus standard treatment when the only real purpose of the exercise is to measure the adverse consequences of the nonstandard approach. We can therefore only learn about this type of issue by investigating the impact of inadvertent or unavoidable deviations from standard practice in retrospective, observational studies of the type discussed previously.[25,26]

It is important to be cautious in the interpretation of "negative findings" in studies that attempt to explore the consequences of deviations from standard practice. Studies that fail to show a statistically significant difference in outcome between nonstandard and standard treatments often lack the statistical power that would be necessary to rule out small but clinically important adverse effects. When patient safety is on the table, the absence of evidence of adverse effects should never be misconstrued as evidence of their absence.

When a Randomized Trial Is Not Feasible. Some issues should ideally be addressed in a randomized trial, but either cannot, or will not, be addressed in this way. Rare clinical problems are often impossible to study in randomized trials because it is difficult to sustain enthusiasm for any trial or maintain the infrastructure necessary to support it over

a protracted period of slow accrual. Large well-organized, multicenter clinical trial groups have a greater chance of success in this situation than any individual institution, but there are limits to what any group can do. Nearly all of what we know about the relationship between treatment and outcome in rare situations has to come from observational studies. In other situations, a clinical trial may be theoretically feasible but is rendered impossible by entrenched opposing views about treatment that effectively preclude recruitment to any trial. One such example was the controversy regarding the primary management of more advanced cancers of the larynx. The issue was hotly debated for decades and opinions were highly polarized. The depth of the controversy is clearly illustrated in the results of an international mail survey of patterns of care in laryngeal cancer done in the early 1990s.[81] This showed, for example, that most otolaryngologists in Canada, the United Kingdom, and Scandinavia regarded primary RT, reserving surgery for salvage, as the standard approach for T3 glottic cancer, whereas most of their counterparts in the United States and Australia favored primary laryngectomy.

Under these circumstances, it may be possible to learn about the relative effectiveness of the competing approaches by comparing the outcome they achieve at the population level. The rationale for this approach is that variations in practice driven by differences in physicians' beliefs, or any other factors unrelated to the characteristics of the patients, can be treated as a natural experiment. For example, Groome et al performed a study comparing the outcomes of treatment for locally advanced laryngeal cancer between Ontario, Canada, and the United States. They found that primary laryngectomy was used much more frequently in the United States than in Ontario,[97] consistent with the results of the previous mail survey.[81] Survival at 5 years proved to be identical in the two populations, whereas laryngectomy-free survival was significantly higher in Ontario than in the United States. These observations lend support to the position that primary RT, reserving surgery for salvage, permits retention of natural voice without compromising survival.

Evaluating the Adoption and Generalizability of the Results of Clinical Trials. Randomized clinical trials are unquestionably the best way of comparing the efficacy of a new treatment with the previous standard treatment. However, clinical trials rarely involved more than a small fraction of potentially eligible cases. Therefore, it cannot be taken for granted that the benefits observed in the context of the trial will be reproduced when the treatment is adopted in the general population. It has therefore been argued that population-based "phase IV" studies should be carried out as new treatments are introduced into routine practice to evaluate their effectiveness in the real world.[98,99] Box 12-3 describes some of the unique advantages of phase IV studies.

Many phase IV studies have used temporal changes in practice to evaluate the effectiveness of RT. For example, Pearcey et al studied the impact of the rapid adoption of concurrent cisplatin-based chemoradiotherapy (C-CRT) in 1999 on population-based outcomes of cervical cancer in Ontario.[99] Use of C-CRT increased from <10% of RT cases diagnosed from 1992 to 1998 to >60% in those from 1999 to 2001. There was no observable change in survival for the subgroup of patients treated with surgery alone. Among those treated with primary RT with or without chemotherapy, survival significantly increased from 58.6% in 1995 to 1998 to 69.8% in 1999 to 2001 ($p < 0.01$). The magnitude of change in survival was in keeping with randomized trials. These findings supported the population-based effectiveness of C-CRT for cervical cancer.

An important assumption of a phase IV study is the comparability of treatment groups. This may often be assured through ecological comparisons such as in Pearcey et al's study of C-CRT for cervical cancer.[99] Over modest time periods, the spectrum of cases in the population usually does not change sufficiently to threaten study validity. This stability is not always the case, however, as demonstrated by Gupta et al's study of the impact of C-CRT on head and neck cancer population outcomes in Ontario,[100] which showed an increase in survival from 43.6% in the preadoption cohort to 51.8% in the postadoption cohort. However, the survival increase for oropharynx cancer was greater than predicted based on randomized trials of C-CRT (38.8% preadoption and 57% postadoption). The observed findings were in keeping with known increases in incidence of the prognostically favorable oropharyngeal cancer associated with human papillomavirus (HPV) over the study period. Notably, the survival increase for all other head and neck sites combined was in keeping with randomized trials (45.6% preadoption and 48.3% postadoption).

Phase IV studies provide information on treatment adoption and its consequences that is not available through any other means. For example, in the study of adoption of C-CRT for head and neck cancers, it was possible to study the impact of C-CRT on hospitalization rates in the general population. There was a significant increase in hospitalizations after C-CRT adoption for head and neck cancers (23.4% versus 43.3%), but no increase in treatment-related deaths. Additionally, the adoption of C-CRT was far more gradual for head and neck cancers than for cervical cancer. In both cases, however, when superiority of one treatment over another was demonstrated in randomized trials, practice changed.

In the case of equally effective options, this may not always be the case. Ashworth et al studied fractionation of post-lumpectomy radiation for invasive breast cancer in Ontario before and after the publication of the Ontario Clinical Oncology Group (OCOG) trial that demonstrated equivalence of 16- and 25-fraction schedules.[75] They found that after completion of the OCOG trial, shorter fractionation schedules increased from 48% to 71% of cases, though large intercenter variation existed, including two of nine centers treating the majority of patients with longer schedules.

BOX 12-3 Proposed Roles of Phase IV, Population-Based Outcomes Studies

1. To describe uptake of new therapy.
   - What is the prevalence or incidence of eligible cases?
   - What proportion of eligible patients has received therapy?
   - Are quasi-eligible patients receiving therapy?
   - To what extent is therapy appropriately delivered (i.e., complete versus partial adoption)?
2. To evaluate the association among a change in practice or policy and outcomes.
   - Is there benefit at the population level?
   - Is the magnitude of benefit commensurate with that observed in clinical trials?
   - Are there previously unrecognized (or underrecognized) adverse events?
3. To explore the real-world economic ramifications of a new medical therapy.
4. To provide an empirical process to determine which aspects of the randomized controlled trial design are associated with a minimal efficacy-effectiveness gap.
5. To provide a measure of the societal benefit of medical research.

From Booth CW, Mackillop WJ: Translating New Medical therapies into Society Benefit: The role of population-based outcome studies. [commentary] JAMA *300:2177–2168, 2008.*

There are a number of statistical techniques available to minimize treatment selection bias and confounding in observational studies of effectiveness. These include multivariable model risk adjustment, propensity score methods, stratification, time series analysis, matching, restriction, and instrumental variable analysis. A full discussion of the relative merits of these techniques is beyond the scope of this chapter. As a general rule, validity is strengthened when multiple techniques produce comparable results.

STUDYING THE EFFICIENCY OF RADIOTHERAPY

Health economics is the area of specialization within the field of economics that concerns itself with all economic aspects of health and health care. Much of health economics deals with health-related issues on a higher plane than HSR. Macroeconomic analysis of the societal impact of health and health care at the national and international levels lies well beyond the scope of HSR. On the other hand, microeconomic analysis of the costs and benefits of specific healthcare programs lies squarely within the domain of HSR. We briefly describe how health economic analysis fits into HSR, introduce the methods that are commonly used, and illustrate their relevance to radiation oncology.

The resources available for health care in any society are finite. What is achievable for patients with cancer depends on the size of the total healthcare budget, on how much of that total budget is directed to cancer care, and on how efficiently the available resources are used in providing cancer care. Health economics aims to provide the information necessary to make rational choices about how to deploy funding for health care and how to make the best possible use of the funds available. Economic analyses are useful at many levels in the health system. High-level decisions about allocation of resources to different healthcare programs are increasingly based on a comparison of their impact on health in relation to their cost. These decisions are most clearly visible in publicly funded systems, but in the private sector decisions made by insurers about which services will be reimbursed are based on similar considerations and have a similar effect. Information about the benefits of RT in relation to its costs is, therefore, required to ensure that an appropriate slice of the cancer budget is allocated to radiation oncology. Economic analyses are also needed to optimize the internal efficiency of RT programs. To ensure that we get the maximum value per dollar invested in RT, it is important that we should be aware of the relative costs of alternative approaches for providing RT.

Health economics involves much more than the measurement of healthcare costs, which most economists would regard as no more than accounting. However, economic analysis does require the measurement of costs, and a number of useful studies have been done in comparing alternative approaches for measuring the cost of RT,[101] and in defining units of workload to which costs can be assigned.[102] In assessing the overall costs of RT, it is important to consider not only the direct costs of providing treatment but also the indirect costs of supportive care for complications of RT. It is important to specify the perspective from which an economic analysis is carried out. If the analysis is being conducted from the perspective of the RT provider, it may be appropriate to focus primarily on direct costs, whereas if the perspective is that of the health system as a whole, indirect costs incurred in other sectors must also be considered. If the analysis is being conducted from the societal perspective, loss of productivity as a consequence of the treatment needs to be included and balanced against loss of productivity as a result of the untreated disease.

Economic analyses typically consider the benefits of health care as well its costs. Four different types of study are usually distinguished: cost minimization studies, cost-benefit studies, cost-effectiveness studies, and cost-utility studies.

Cost minimization studies, often simply called cost studies, compare the costs of alternative treatments or processes, on the explicit or implicit assumption that each produces similar health outcomes. In RT, this type of study has provided information pertinent to decisions about the acquisition of new equipment,[103] about the decision to purchase or lease equipment,[104] about service contracts,[105] and so on. In some instances, simple cost comparisons have been done between slightly different approaches to treatment, such as high-dose rate versus low-dose rate brachytherapy.[106]

In cost-benefit analysis, the health benefits of treatment are described only in terms of their dollar value; health outcomes are considered only insofar as they have an impact on costs or affect the productivity of those affected. This type of analysis may be useful in some circumstances in demonstrating to policy makers that apparently expensive programs of treatment or prevention may in fact be cost neutral or even save money when the overall financial consequences of providing the program are compared to those of not providing it. However, the idea that the benefits of health care can be adequately described in terms of the money they save is counterintuitive to most clinicians, and this type of analysis has not been widely used in the field of radiation oncology.

Cost-effectiveness studies compare alternative treatments or processes with respect to their effectiveness, as well as their cost. Effectiveness is usually described in terms of a single objective outcome measure, such as survival. This is useful in that it enables us to put a dollar value on the outcomes achieved by RT, and it has often revealed that RT is relatively inexpensive in relation to the benefits it delivers.[107,108]

Because cost-effectiveness analysis describes the benefits of treatment in terms of a single measure of outcome, it does not provide a satisfactory way of describing and comparing the value of treatments that are associated with different types of health benefit, such as radical RT for cervical cancer and palliative RT for bone metastases. Survival alone is an inadequate measure of palliative RT, and quality of life is an inadequate measure of the effectiveness of curative treatment. The concept of utility, a measure of the relative value of different life states, is useful in reducing the benefits of treatment to a common currency. If utility can be measured, and there is still some question as to whether this is really possible, years of survival can be adjusted for relative value and outcomes expressed as quality-adjusted years of life (QALYs). This measure is sensitive to both duration of survival and quality of life. Cost per QALY can be used to compare the value of treatment in curative and palliative contexts. The value of other forms of medical care has been measured in cost per QALY, and this permits comparison of the value of RT with the value of other treatments both in oncology and in other spheres of medicine.[109,110]

Information about the relative benefits of RT in different clinical contexts could be used as a basis for assigning priorities to one type of case over another in circumstances in which resources are insufficient to provide RT for everyone who needs it. This type of explicit rationing has not, to our knowledge, been used to control access to RT in any of the countries where access to RT is constrained by inadequate supply. Although this approach would serve to mitigate the adverse effects of inadequate access to RT and maximize the societal benefits of the available resources, it seems to have little appeal to policy makers. It has, however, been proposed that cost-effectiveness or cost-utility analysis be used as the basis for selecting the most effective components of care for inclusion

in healthcare programs. In the future, as both the demand for health services and the cost of care continue to increase across the developed world, we anticipate that decisions about which services will be provided within publicly funded systems or managed care programs will increasingly be based on these types of economic analysis. Research in the economics of radiation oncology is likely to be of increasing practical importance in optimizing the effectiveness of RT programs in the future.

SUMMARY

In the past, radiation oncologists and their traditional partners in physics and radiobiology have devoted most research efforts to creating the knowledge necessary to optimize the outcomes of RT in the individual patient. There is a lot of evidence to suggest that we currently fall far short of making the benefits of that research available to all the patients who might benefit from it. It has been demonstrated that in many parts of the world, access to RT is both inadequate and inequitable and that the quality of RT is variable and often suboptimal. These deviations from optimal practice cause us to fall far short of achieving what is theoretically achievable for patients with cancer today within the limits of existing scientific knowledge and technology. Deviations from optimal practice represent real opportunities for enhancing the results of RT, without placing reliance on the uncertain outcome of the slow process of basic research, which frequently promises much but delivers little. Although fundamental and clinical research must continue, a greater proportion of our efforts should be devoted to enhancing our understanding of the factors that influence access to RT and determine the effectiveness and efficiency of RT programs. RT provides major health benefits for a large proportion of patients with cancer, and even a small incremental gain in health system performance would be expected to translate itself into large societal benefits.

HSR in radiation oncology is still a relatively new field, and it offers new investigators a great opportunity to make a real difference. There are a number of good opportunities for training in health services and policy research, and the funding for HSR has greatly increased in recent years. There is real need for radiation oncologists to become involved in leadership roles in HSR because the clinician's insights are vital in choosing the right research questions. Getting the right answers, however, may require a high level of methodologic expertise in areas that are unfamiliar to most radiation oncologists. Success in HSR often depends on building effective collaborations with scientists in other fields such as epidemiology, health economics, and the social sciences. Those who enter the field should also be aware that getting the most out of HSR requires a degree of diplomacy and academic ability. Clinicians involved in HSR need to remember that in the pursuit of the goal of evidence-based management of healthcare programs, they need to influence health system managers as well as their peers. Investigators need to learn the skill of working collaboratively with the health system managers and policy makers who hold the power to implement some of the changes necessary to optimize outcomes, while keeping some control of the research agenda.

CHAPTER

13 Statistics and Clinical Trials

Qian Shi, Wenting Wu, and Daniel J. Sargent

In this chapter we address some of the statistical issues associated with clinical trials. We begin with a short description of the basic role of statistics and statisticians and illustrate some sample communications between investigators and statisticians. We provide an overview of the statistical issues relevant to each phase of clinical trials (phases I, II, and III) and discuss some of the unique aspects of phase II and III trials. We introduce standard and newly developed phase II experimental designs. We are particularly interested in the essential roles of randomization and stratification in comparing new and standard therapies. We discuss the important *intent-to-treat principle*, which is fundamental to analyzing phase III trials. We emphasize the importance of appropriate monitoring in ongoing trials. In addition, we consider some of the special problems that arise in the analysis of survival data that are caused by the phenomenon of *censoring*, which occurs when a patient's time to death cannot be completely determined either because he or she becomes lost to follow-up before death or is still alive when the data are to be analyzed. Finally, we briefly discuss several relevant topics in modern clinical trials: surrogate endpoints, biomarkers, and adaptive design.

Our intent in this chapter is to provide the reader with insight regarding the use of statistics (and statisticians) in the design and analysis of clinical trials rather than to provide all of the details required for an investigator to perform his or her own analyses. Several excellent texts provide the details required for performing analyses, and we cite several such references.

We define a clinical trial as a designed study involving the treatment of prospectively accrued humans that is specified by a document (protocol) with specific goals and analysis plans. Meinert[1] describes some of the unique aspects of clinical trials that distinguish them from other medical research studies, including, among others, observational studies and case-control studies, and enumerates the requirements of a good protocol document.

WHY ARE STATISTICS AND STATISTICIANS USEFUL?

It has been a long-standing paradigm that clinical research is best conducted through collaborations requiring multidisciplinary expertise. Among these scientists, statisticians are often viewed as technicians who provide statistical services, rather than collaborators who make critical scientific contributions to the research. For example, an improper opinion that occasionally exists is that the involvement of statisticians only starts with analyzing data after the completion of the study. Actually, optional collaboration between statisticians and clinical investigators is involved in every step of a clinical trial and can be extremely fruitful. These collaborations cover the whole cycle of a study—from design, conduct, continuous monitoring, data analysis, and interpretation to decision making and publishing results, as well as generating new hypotheses for subsequent studies. Furthermore, the methodology research centered on clinical trials is a driving force of innovative designs in clinical research.

The ultimate goal of conducting clinical trials is to make beneficial influences in future clinical practice, which requires that the conclusions made at the end of the trial have a high degree of credibility, reproducibility, and external validity.[2] Just like all experiments, realities of environment, conditions, and resources introduce both controllable and uncontrollable errors. This is especially true in oncology studies. Genetic, behavioral, environmental, and sociological heterogeneities introduce great complexities in disease progresses and the impact of the studied treatment. Generally speaking, there are two types of errors. One is random, which is purely the result of chance. Another is systematic, known as bias, which describes errors that are not a consequence of chance alone. A fundamental difference between random errors and bias is that pure random errors have no preferred direction, whereas biases present effects of distortion.

Random errors are commonly caused by sampling variability, subject heterogeneity, measurement error, and other source of noises. In reality, the random errors in any experiment can never be completed eliminated. For instance, two patients who have cancer may have nearly identical clinical (and pathologic) characteristics and receive the same treatment. But one may fail (experience relapse or die) within months whereas the other may be cured. A practical definition of *variance* could be the unexplained differences in outcomes that exist among seemingly similar patients. If one looks at two sets of 15 patients who differ in one characteristic (possibly treatment) and notices that one group has a median survival time that is 2 months longer than the other group, one cannot immediately conclude that the characteristic is truly associated with survival difference or just by chance. Statistical techniques will be required to evaluate the likelihood that a median survival difference of 2 months was quite likely to occur even if these two sets of patients who actually did not differ in the characteristic had been compared (a so-called type I error). Quantifying the magnitude and likelihood of the errors resulting from chance requires knowledge of probability and statistical theory. Reducing the relative impact of random errors can be achieved by averaging over a large number of observations. This is commonly known as the *sample size calculation* in clinical trial design.

Bias, on the other hand, cannot be reduced by averaging after repletion or taking additional observations. In clinical settings, although biases can arise in numerous ways, there are often a set of factors that have been studied and well known to contribute to the possibility of bias. In many cases, these sources of bias can be understood well enough to be controlled. For example, bias can occur in medical research studies if treatments are compared between groups of patients who are not equivalent in terms of characteristics that are associated with prognosis. The fundamental strategy used in clinical trials to avoid biased treatment comparisons is randomization of treatment assignments (with stratification), which guarantees the comparability of patients assigned to different treatments under the comparison(s) in terms of his or her prognosis under the condition of no treatments. In observational studies, such an assurance is simply not possible. Although it may be feasible to adjust for potential sources

of bias at the data analysis stage, based on our present knowledge of factors influencing disease outcomes within individual patients, there is no way to ensure that patients receiving two different treatments are comparable in the absence of randomization. There are other critical considerations to reduce bias and include concurrent controls, objective assessments, consistent active follow-up and endpoint ascertainment, no post-hoc exclusions, and so on.

Reducing and controlling random errors and systematic biases are essential elements of clinical trials to provide valid and generalizable trial inferences. These cannot be achieved without sound statistical design. Sophisticated analyses can almost never salvage design faults and poor implementation of the design.[2,3] Since the recognitions of statisticians' involvements in clinical trials in 1970s, a subgroup of statisticians have been actively contributing their knowledge and creativity in cancer therapeutic research by providing core techniques to transfer the conceptional clinical ideas into sound, efficient, and practical clinical trials throughout the entire lifetime of the study.

INTERACTION BETWEEN AN INVESTIGATOR AND A STATISTICIAN

Inadequate communication between an investigator and a statistician might be the most frequent cause of inappropriate designs or analyses in clinical research. This may occur because the investigator does not explicitly state what he or she is trying to learn from a particular study or because the statistician lacks the insight of what methods that satisfactorily address the study question. Planning and conducting a clinical trial is an interactive and iterative collaboration process between investigators and statisticians. For example, in the designing phase, many critical communications are centered on the following components:

1. What is the targeted disease population? This provides the set of critical disease characteristics and known (potential) confounders that the statistician needs to consider in the design or analyses for controlling biases or identifying effect modifier (e.g., predictive markers).
2. How is study "success" defined? This indicates the choice of study type including decision-making studies with superiority, noninferiority, or equivalence designs, exploratory studies aimed to quickly screen promising agents, or trials conducted to provide estimation of the key parameters of the new agents.
3. What is the existing knowledge of the tested agent? This describes the stage of the study design, for example, phase I trials for dose finding, phase II trials for preliminary evidence of efficacy, or phase III trials for confirming efficacy and regulatory approval for marketing. Commonly, the level of uncertainty tolerance (i.e., significance level and power) varies according to the phase of the design.
4. What is the clinical meaningful treatment effect? This requires an appropriate choice of endpoint, which is a measurement that reflects how patients feel and function and can be reliably and precisely measured. Historical data of this endpoint in the targeted population serves the benchmark of the design. Discussions of the expected clinical meaningful effect size give reasonable derivation of sample size and study operating characteristics.

Other details include whether a control group should be included; should a biomarker be used in the design, and if so how should it be incorporated; and what are the logistical and practical challenges in trial conduct? These components of communications between investigators and statisticians are never isolated from each other. Transparent, informative, comprehensive, and persistent communications are essential for a good trial design.

CLINICAL TRIALS

Clinical trials performed to develop and test new agents or modalities in oncology are often categorized as phase I, phase II, or phase III trials according to their primary aims.

Phase I Trials

Phase I trials are generally the first trials involving human subjects in which a new treatment is tested. The goal of a phase I trial is to test a new regimen's tolerability and toxicity. These trials usually enroll a limited number of patients who have exhausted other treatment options. Phase I trials may enroll patients with a specific tumor type only or be open to patients with different tumors. Different primary endpoints and study designs should be considered for regimens with different cancer therapeutic mechanisms.

Traditional Cohorts-of-3 Phase I Design

Historically, cancer therapies have been designed to act as cytotoxic, or cell-killing, agents. The fundamental assumption regarding the dose-related activity of such agents is that there exists a monotone nondecreasing dose-response curve, meaning that as the level of the dose increases, tumor shrinkage will also increase, and this phenomenon should translate into increasing clinical benefit. Under this assumption, both the toxicity and the clinical benefit of the agent under study will increase as the dose increases; therefore, an appropriate goal of a phase I trial is to find the highest dose with acceptable toxicity. Because the monotone nondecreasing dose-response curve has been observed for most cytotoxic therapies, toxicity has historically been used as the primary endpoint for identifying the dose that has the greatest likelihood of being effective, yet tolerable, in subsequent testing.

In this context, the typical goal for phase I clinical trials has been to determine the maximum tolerated dose (MTD), which is the highest dose level at which the rate of dose-limiting, toxicity (DLT) does not exceed the targeted toxicity level (TTL). Which adverse events will be considered as DLT vary depending on the type of cancer and the specific agent under study. The traditional design is the cohort-of-3 design, which is easy to use and requires no complicated statistical computations. Specifically, three patients are enrolled at the starting dose level. If no DLT is observed, three patients will be enrolled at the next higher dose level. If one DLT is observed, another three patients will be enrolled at the same dose level. Out of the six patients at a given dose level, if one DLT is observed, three patients will be enrolled at the next higher dose level. If two or more DLTs are observed (out of three or six patients at a given dose level), then the MTD will be considered to have been exceeded, and the next lower dose level will be defined as the MTD as long as six patients have been evaluated at that level.

Although the cohort-of-3 phase I design has considerable appeal (it is straightforward to conduct, easy to explain, and has considerable historical precedent), there are several limitations with this design. Particularly with newer agents that will be discussed, use of the cohort-of-3 design poses increasing challenges in modern clinical trials. For instance, the TTL is arbitrarily set to 33%, which may not suitable for every disease-agent setting. High uncertainty is unavoidable because of the inherited small sample size. For example, the exact 95% confidence interval for the observed rate of DLT at MTD is 0.00 to 0.64 when 1 of 6 patients experienced DLT. Also, it is a common misunderstanding that the true DLT rate at MTD

identified by this design is 0.33. It is actually closer to 0.22.[4] For the assumption of monotone nondecreasing dose-response curve for cytotoxic agents, this fact increases the risk of failure in phase II studies because the lower toxicity also indicates lower efficacy. When the true DLT rate presents small variations across dose levels, it may require a long time and many patients treated at suboptimal dose levels, such as in a cohort-of-3 phase I study[5] in which 56 patients were accrued during a period of 38 months to determining the MTD of CPT-11 in the regimen of CPT-11/5-FU/LV for patients with metastatic or locally advanced cancer.

Newer Phase I Designs

Over the last several decades, statistically based improvements have been proposed for phase I study design. One of the statistical theories (i.e., Markov Chain) demonstrates that when assigning patients to the next dose level, up or down, based on observed number of DLTs (0 or ≥1) and prespecified TTL, the dose assignment will converge to MTD when the number of assignments is sufficiently large.[6] A class of up-and-down designs was developed based on this theory. One example is biased-coin design (BCD) with dose assignment based on a single patient's DLT occurrence.[7] Later this method was extended to enroll patients in cohorts to each dose level.[8]

In parallel to up-and-down design, another class of nonfixed dose assessment design, using a model-based approach, was started with the first proposal of continual reassessment method (CRM),[9] with further improvements for practical use.[10,11] One of the key features of the CRM is that the DLT rates at different dose levels are reestimated based on data from treated patients across all dose levels examined to date, whenever there are new data observed. Each newly enrolled patient is assigned to the dose level whose current DLT rate estimate is closest to TTL. At the end of study, the MTD is determined by final DLT rate estimates using all treated patients' data. Garrett-Mayer gave an excellent tutorial on the CRM design.[12]

As the therapeutic development in oncology moves from cytotoxic to cytostatic or targeted agent, additional challenges are present in dose-finding studies. For example, the dose-response relationship for novel agents may take forms other than monotone nondecreasing curve, such as quadratic, or increasing with a plateau. In this case, evaluating toxicity and efficacy simultaneously is necessary to find the biologically optimal dose (BOD), which balances the needs of minimizing toxicity (to an acceptable rate) and maximizing the efficacy. Weighted-outcome[13] or utility-based[14] approaches were proposed to handle the tradeoffs between two endpoints. Another example is dose finding in combination treatment; CRM methods have been extended to generalized CRM[15] or partial order CRM[16] methods aimed to address this situation.

Despite the development of more effective designs, the standard chort-of-3 still remains the most popular phase I study design in practice. Rogatko et al examined more than 1,200 published phase I studies and found only 1.6% adapted more sophisticated design than chort-of-3 design.[17] The major reasons may be statistical complexity and lack of user-friendly software.[18] However, increased awareness and greater communication between investigators and statisticians increases the possibility of applying these newer methods.

Phase II Trials

In phase II trials, the goal is to establish clinical activity and further evaluate the treatment's toxicity. Unlike phase I trials, which commonly accrue patients with a variety of cancers, a phase II trial should restrict accrual to a reasonably well-defined patient population. Historically, the response rate has been the most common endpoint for phase II trials. However, in the last decade, progression-free survival/disease-free survival (PFS/DFS) and overall survival (OS) rates have been used increasingly as the primary endpoint in the phase II setting.

Traditional Single-Arm Phase II Designs: One-Stage Design

The starting point for a discussion of phase II trials is the single-arm, one-stage design. In these trials, patients are accrued to a single arm and are treated at a single dose level that has been suggested by previous phase I trials. If the treatment appears sufficiently active in comparison with historical success rates (typically, tumor response) in patients with disease and prognosis similar to those accrued to the phase II trial, the treatment may be considered a viable candidate for the phase III setting. Toxicities, expense, and other considerations will often influence the decision as to whether the drug or radiation versus chemoradiation regimen has enough promise compared with standard regimens to warrant further interest.

We explain this type of design by means of an example. Suppose that in recent treatment trials for a given disease, the response rate ranged between 15% and 20%. A new trial might then be designed to show that the new treatment will not be worth continuing if the true response rate is 10% or less and that the new treatment should be continued if the true response rate is 25% or greater. Such a design implies, by default, that if the response rate is in the range of 15% to 20%, the probability of either decision being made (i.e., to abandon the new therapy or to bring it to phase III testing) may be nearly equal. One critical consideration is to make sure that patients in the new study are comparable to those enrolled in the previous studies, a factor that in many cases is impossible to verify.

As described, the typical phase II trial is structured to provide the basis for a recommendation either to abandon the therapy or to consider it for further testing. Working together, the investigator and the statistician choose an "unacceptable" response rate, p_0 (10% in our example) and a "promising" response rate, p_1 (25% in our example). The study is designed so that if the response rate is as low as p_0 there will be little chance that the treatment will be recommended, whereas if the response rate is as high as p_1 there is a high probability that the treatment will be recommended. These benchmark response rates should in no case be chosen arbitrarily; considerable thought must be given to their selection, and they should be fully justified by comparison with historical data in patients with comparable disease and prognosis.

The considerations just given might lead to the following study design criteria:

1. If the true response rate is $p_0 = 10\%$, there should be no more than a probability of 0.10 (significance level) of erroneously concluding that the treatment should be carried forward.
2. If the true response rate is 15% to 20%, it will not be harmful to have a fairly high probability of reaching either conclusion.
3. If the true response rate is $p_1 = 25\%$, there should be a probability of at least 0.90 (power = 0.90) of concluding the treatment is effective enough to be carried forward.

Using well-known methods, the statistician could determine that each of these criteria would be satisfied if 40 patients were accrued, and the treatment would be recommended for further consideration if, and only if, at least 7 of the 40 patients responded. Table 13-1 gives the probabilities that the treatment will be carried forward for various hypothetical response rates.

It is worth noting that the formal decision rule is to conclude the treatment is worth carrying forward if the estimated

TABLE 13-1 Operating Characteristics of a One-Stage Phase II Study Design

	True Response Rate					
	5%	10%	15%	20%	25%	30%
Probability of recommending treatment for further consideration	0.003	0.10	0.39	0.71	0.90	0.98

TABLE 13-2 Operating Characteristics of a Two-Stage Phase II Study Design Allowing Early Stopping for Zero Responses in the First 15 Patients

	True Response Rate					
	5%	10%	15%	20%	25%	30%
Probability of recommending treatment for further consideration	0.003	0.10	0.39	0.71	0.90	0.97
Probability of stopping after first stage of accrual	0.46	0.21	0.09	0.04	0.01	0.005

TABLE 13-3 Operating Characteristics of a Two-Stage Phase II Study Design Allowing Early Stopping for Zero Responses or One Response in the First 15 Patients

	True Response Rate					
	5%	10%	15%	20%	25%	30%
Probability of recommending treatment for further consideration	0.003	0.09	0.35	0.66	0.86	0.95
Probability of stopping after first stage of accrual	0.83	0.55	0.32	0.17	0.08	0.04

response rate is at least $7/40 = 17.5\%$ but not if the response rate is less than or equal to $6/40 = 15\%$. As Table 13-1 indicates, the probability of observing a response rate of at least 17.5% in our trial if the true response rate is 10% is only 0.10. In contrast, the probability of observing a response rate of at least 17.5% is 0.90 if the true response rate is 25%, and a positive recommendation is extremely likely (probability = 0.98) if the true response rate is as high as 30%. Other factors may enter into the final decision, particularly if the observed response rate is close to 15% or 20%.

Traditional Single-Arm Phase II Designs: Two-Stage Design

Because many experimental treatments ultimately do not demonstrate efficacy, ethical considerations lead to the usual recommendation of an early stopping rule for lack of efficacy in phase II trials. For example, suppose that the first 15 patients who are accrued do not respond to the therapy. At that point, an investigator might begin to believe that the treatment is no better than standard therapy and might even be worse. This raises the question of whether the trial should be terminated. On the one hand, there is some probability that 7 of the next 25 patients will respond, resulting in a recommendation for continued consideration of the treatment. Statisticians have developed clinical trial designs that allow a prospectively specified examination of the data from the ongoing trial to address this issue.

Generally, the issue of *early stopping rules* is as follows: When designing a trial, it may be appropriate to introduce the possibility of stopping early if there is strong evidence that the treatment is no more and possibly less effective than the standard treatment, as long as doing so would not substantially reduce the probability of detecting a true beneficial effect (power). Of course, one might also want to stop early if the treatment appears to be extremely effective, although there is no ethical constraint against assigning patients to an apparently effective treatment, unless doing so would unduly prolong the further development of a promising therapy.

Consider the following modification of the phase II study design just described. Accrual will proceed in two stages. In the first stage, 15 patients will be accrued, treated, and observed for clinical response. If no patients respond, the trial will be terminated, and the candidate treatment will not be recommended for further consideration; otherwise, an additional 25 patients will be accrued. If in total at least eight responses are observed, the treatment will be recommended for further consideration; otherwise, it will not be so recommended.

This new design has some nice properties. The maximum number of patients required is the same as before, and, as shown in Table 13-2, the new design still satisfies each of the desired criteria 1 to 3 listed previously. However, if the new treatment has a true response rate of 5% or less, the study has a 0.46 chance of stopping after 15 patients have been accrued, therefore sparing 25 patients from treatment with an inactive regimen.

Now consider a design that requires early stopping if only 0 or 1 of the first 15 patients responds; otherwise, 25 more patients are accrued, and the treatment is recommended for further consideration if at least 7 patients respond. This design provides much better protection against the possibility of accruing an excessive number of patients to an ineffective regimen. However, if this design is used, it would be slightly less likely that a truly effective regimen would be recommended for further consideration. Table 13-3 shows the properties of this design.

Notice that with this design, there is a 0.83 probability that the study will terminate after 15 patients are entered if the regimen has only a 5% response rate. However, the probability of recommending the treatment is now only 0.86 if there is a 25% response rate. Numerous authors have discussed optimal strategies for choosing phase II designs, including Gehan,[19] Herson,[20] Lee, Staquet, and Simon,[21] Fleming,[22] Chang et al,[23] Simon,[24] Therneau, Wieand, and Chang,[25] Bryant and Day,[26] and Thall, Simon, and Estey.[27]

Newer Phase II Designs: Randomized Phase II Design

Single-arm phase II designs can demonstrate biologic activity of an agent with relatively small sample size and short study duration. However, the potential for patient selection bias, the evolving methodologies for the assessment of "success" (i.e., changes in computed tomography [CT] scanners, changes in

response criteria), and a general lack of robustness of historical rates of this type of design result in a high possibility that a positive single-arm phase II trial will be followed by a negative phase III study.[28] A potential solution to this fundamental limitation of single-arm phase II designs is the use of a randomized design. Two types of randomized phase II designs, the randomized selection designs and the randomized screening designs, have been proposed and used widely.

In a selection design, all arms are considered experimental arms. These could be different new regimens or different doses or schedules of the same regimen. The sample size is calculated to guarantee that with a small probability, perhaps 10%, an inferior arm (for instance, one in which the response rate is 15% lower) will be selected for the future phase III study. In a standard selection design, the arm with the highest estimated success rate for the primary endpoint will be recommended for a follow-up phase III study, no matter how small the difference of estimates might be among arms.[29] On the other hand, a flexible selection design, or "pick-the-winner" design, will recommend the arm with the best estimated primary endpoint if the difference is larger than a prespecified criterion.[30] Otherwise, toxicities, expense, and other factors will be taken into consideration when making the decision.

If a standard of care is included in the comparison, a screening design should be applied.[31] A screening phase II design is similar to a randomized phase III trial but has larger type I and type II errors. For instance, a range of 10% to 20% for both error rates is acceptable. A screening phase II design provides a head-to-head comparison between the experimental regimen and the standard of care using a relatively smaller sample size and clear guidance as to the likelihood of success if the agent is moved forward into phase III testing.

Overall, randomized phase II designs balance prognostic factors among all arms, avoid patient selection bias, and provide robust arm comparison results. The major concerns for randomized phase II designs are (1) the larger required sample size, (2) the relatively high risk of false-negative and false-positive rates resulting from the small sample size, and (3) the possible desire (or ethical mandate) to skip a confirmatory phase III study given a positive phase II result.

Another type of newly developed randomized phase II design is the phase II/III design. A phase II/III design starts with a phase II component. Patients are randomized among several experimental arms or a standard-of-care arm versus one or more experimental arms. Experimental arms could be compared with the historical control or the standard-of-care control to select arms for entering the phase III component. The main advantage of this type of design is (1) the speed of transition from phase II to phase III and (2) the fact that data obtained from the phase II component could be applied toward the phase III comparison as long as the protocol treatment is not altered between phases.

Phase III Trials

It is generally recognized that judging the value of a new therapy by comparing it with historical data may give an erroneous impression of the therapy's efficacy. Pocock[32] related a number of illuminating examples of this phenomenon. Therefore the phase III trial, in which a new agent, modality, or combined treatment modality is tested against an accepted standard treatment in a randomized comparison, is considered the most satisfactory method of establishing the value of the proposed treatment.

Under most circumstances, the goal of a phase III trial is to determine whether the proposed treatment is superior to the standard treatment (superiority trial). Alternatively, if the alternative treatment is easier to administrate, costs less, or is less toxic than standard of care, showing superiority is not necessary; a definitive demonstration of noninferiority (noninferiority trial[33]) is all that would be required. Because the goal of a phase III trial is to make a definitive conclusion regarding a new treatment's efficacy, enough patients need to be accrued to guarantee a small probability of false-positive results (i.e., declaring that a regimen is effective when in fact it is not) and a large probability of true-positive results (i.e., declaring that a regimen is effective when in fact it is). The probability of false-positive results is also called the size of the study, which usually is limited to 5% or less. The probability of true-positive results is also called the power of the study, which usually is set at 80% to 95%. The primary endpoints for comparison are usually OS and PFS/DFS, and a common secondary endpoint is quality of life (QOL). In this section, we discuss the rationale for requiring randomized treatment assignment and stratification in a phase III trial. We introduce the intent-to-treat principle, and we emphasize the importance of monitoring in ongoing trials.

Rationale for Randomization

A random assignment is defined as any assignment resulting from a mechanism ensuring an equal probability to all possible assignments. The most obvious reason for randomized assignment is to eliminate the possibility of bias, that is, the intentional or inadvertent assignment of treatments by means of procedures that allow patient characteristics to influence the assignments in a way that may promote an imbalance in patient characteristics between the two treatment arms. The basic idea is simple. If chance alone determines treatment assignments and enough patients are accrued, the law of averages will ensure that the characteristics of patients in different treatment arms will be nearly identical.

Treatments must be assigned in such a way that the accruing physician or coordinator will have no reasonable basis for predicting the arm to which a patient will be assigned. For example, if an accruing physician suspects that at some point their next patient may be assigned to a new treatment study, he or she may recruit patients who might have more favorable outcomes, thereby allowing subtle differences in patient characteristics to influence treatment comparisons. For this reason, it is common for the randomization of patients to be permitted only through contact with a centralized randomization coordinator.

Other potential sources of bias exist that cannot be eliminated by randomized treatment assignment. In some diseases, application of a treatment may convey psychological effects or promote expectations that affect some endpoints of interest. In cancer research, the most obvious example is that treatment with chemotherapy or other agents gives rise to expectations of toxicity. Therefore, whenever it is feasible without causing undue hardship to patients, treatment assignments should be masked by use of placebos. Perhaps even more important is the need to keep medical personnel unaware of actual treatment assignments whenever possible to eliminate bias in assessing response, relapse, or attribution of causality to adverse events.

Stratification of Treatment Assignments

For trials with large sample sizes, randomization of treatment assignments—together with the law of averages—will result in nearly balanced patient characteristics across treatment arms. However, if certain patient characteristics are known to be strongly prognostic of outcome, a better balance can be achieved by allowing separate randomization of treatments to patients within subpopulations defined by the various levels of prognostic variables. Such a restricted randomization scheme is referred to as *stratified random assignment*, and the

prognostic variables are referred to as *stratification variables*. For example, in clinical trials of adjuvant therapy for breast cancer, it is known that rates of relapse are strongly related to the number of axillary nodes found to be positive for tumor on histologic examination and are less strongly related to the age of the patient. Therefore, the assignment of treatments to patients might be stratified within eight subpopulations, defined by combinations of nodal status (node negative, 1 to 3 positive nodes, 4 to 9 positive nodes, 10+ positive nodes) and age at randomization (≤49 years, ≥50 years). In this way, stratification (to balance the effects of strongly prognostic characteristics) and randomization (to prohibit bias resulting from less obvious or even unforeseen factors) may be used together to promote an unbiased comparison of treatments.

In some cases, it is difficult or even impossible to achieve completely balanced treatment assignments within every combination of the levels of all potential stratification variables. For example, in multicenter cancer clinical trials, it is generally thought to be good practice to balance treatment assignments within each accruing institution because patient selection may differ from institution to institution. However, it is not unusual for cooperative groups in oncology to conduct phase III clinical trials using several hundred accrual sites. Clearly, it would be difficult to stratify completely in the accruing institutions together with other potentially prognostic variables, because the number of resulting combinations of levels of all the stratification variables would be excessive. To circumvent this problem, cooperative groups commonly use algorithms that dynamically maintain nearly balanced assignment of treatments across the levels of all stratification variables marginally but that do not guarantee balance within all combinations of the levels of all of the stratification variables. This approach also results in nearly balanced treatment assignments at all times, which will be beneficial if, as often happens, the characteristics of patients for whom the trial is considered most appropriate in the judgment of accruing physicians tend to change as the trial matures. Details of several such dynamic balancing algorithms may be found in articles by Taves,[34] Pocock and Simon,[35] Freedman and White,[36] and Begg and Iglewicz.[37]

Intent to Treat

If treatment assignments are randomized as described previously, one can be reasonably confident that important prognostic factors will be balanced across treatment arms. However, if any patients are excluded at the time the data are analyzed, the possibility of bias arises once again. An analysis that includes all randomized patients, regarded as though each had received precisely the treatment to which he or she had been randomized, irrespective of compliance or administrative errors (e.g., errors in eligibility or other protocol deviations), is an intent-to-treat (ITT) analysis. Another type of analysis is called per-protocol (PP) analysis, in which only eligible patients who adhered to the treatment according to the protocol are included. In this section, we show how treatment comparisons may be seriously biased by excluding patients from an analysis, even for apparently valid reasons. We then show how an intent-to-treat analysis may effectively reduce biases that can creep into analyses when not all patients actually receive the treatments to which they have been randomized. We discuss these issues in the context of the following example:

Example 1. A clinical trial was designed to compare the effect of radiation therapy relative to observation in patients with rectal cancer. Three hundred patients were randomized between radiation therapy (arm A) and observation (arm B), 150 to each arm. Suppose that all patients actually received all of their intended therapy and that after 7 years of follow-up,

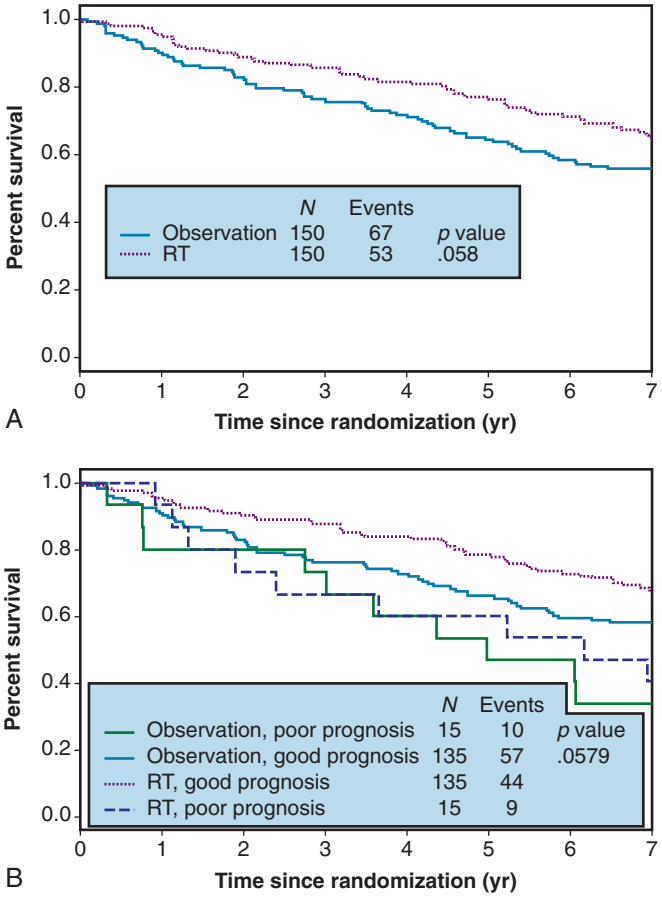

Figure 13-1 **A,** Survival curves that would be observed if all patients receive the prescribed therapy (percent survival versus years from randomization). **B,** Survival curves that would be observed if all patients receive the prescribed therapy, stratified by risk group (percent survival versus years from randomization). *RT*, Radiation therapy.

survival curves were as shown in Figure 13-1, *A*. Although the survival curve for patients receiving radiation therapy lies above that for patients in the observation-only arm, suggestive of a benefit from radiation therapy, the difference is not quite statistically significant ($p = 0.058$).

In any clinical trial, the patients who are accrued exhibit considerable variation in their prognoses. Suppose that we could make use of certain prognostic patient characteristics that were unavailable in the analysis summarized previously. Suppose further that by using this new information, we could identify the 10% of patients with the worst prognoses. Then we might redraw the survival curves after stratifying according to risk, resulting in the plots shown in Figure 13-1, *B*. An analysis of these data that takes this stratification into account again yields a p value of 0.058, which agrees with the p value from the unstratified analysis to three decimal places. This insensitivity of analysis to stratification is a direct consequence of the randomization used in the design of the trial, which tends to balance the poor-prognosis patients equally across the two arms of the trial.

Returning to the original analysis of these data, suppose that not all patients in arm A had actually received the radiation therapy to which they had been randomized. The statistician must decide what to do with these noncompliant cases. There are at least three ways to proceed: (1) it may seem logical to discard data corresponding to the noncompliant patients because they did not receive the radiation therapy that was assigned to them; (2) it might even seem reasonable to analyze

the noncompliant patients as though they had been randomized to arm B rather than arm A because, in fact, they received no adjuvant therapy, similar to those patients who were randomized to observation; (3) the ITT principle states that the noncompliers should be analyzed just as though they had received radiation therapy, even though in actuality they did not.

We now consider the possible consequences associated with these three possibilities. Under the assumption that patients' reasons for refusal of treatment are completely unassociated with prognosis, methods 1 and 2 just presented should lead to estimated treatment differences that are essentially identical to the analysis of Figure 13-1, *A*. If there is a treatment difference, the ITT analysis will tend to underestimate this difference because some of the patients who were not irradiated are counted as having received that therapy. The differences in the three analyses should be rather small under this assumption of no association between refusal of treatment and prognosis.

Alternatively, it is rather likely that reasons for refusal of treatment will be associated with patient prognosis. For example, patients with poorer performance status, or their physicians, may be less liable to accept assignment to a treatment that is known to be associated with significant toxicity. Deteriorating health may lead to difficulties in traveling to receive treatment; advancing disease may correlate with a patient's level of depression or anxiety, which, in turn, may correlate with compliance. Suppose that it is the 10% of patients with the worst prognosis who refuse to accept their radiotherapy. Under these conditions, analysis of the data after deleting the noncompliant patients overstates the effect of radiotherapy, as shown in Figure 13-2, *A*. This is because the patients with the worst prognosis are deleted from consideration in arm A, but no similar deletion of patients with poor prognosis is made in arm B. The result is a spuriously significant p value of 0.021. Treating the noncompliers as though they had been randomized to observation (see Figure 13-2, *B*) results in an even more serious overstatement of the radiotherapy effect, associated with a p value of less than 0.009. In contrast, the ITT analysis yields a slightly attenuated treatment effect ($p = 0.065$) (Figure 13-2, *C*) but no serious misrepresentation of the true effect.

Why did the ITT analysis correspond to the "truth" more closely than the analysis that omitted the subset of patients who did not receive their assigned radiation? This is because the effect of the prognostic factor (risk group) was larger than the treatment effect and the likelihood of patient refusal was associated with both the treatment received and the prognostic group of the patient. Although patient prognoses were balanced as randomized, they are not balanced as treated. In this case, the baseline prognosis of patients who actually received radiation was better than the baseline prognosis of those who were under observation. It is precisely this type of imbalance that the ITT analysis is designed to prevent.

There is no one correct answer as to the best approach to analysis when not all patients receive their assigned therapy. However, there is general agreement among statisticians that it is always appropriate to perform an ITT analysis in which each patient is analyzed according to the treatment assigned at randomization, regardless of what treatment was actually received. Results of any other analysis should be compared with the results of the ITT analysis, and if the results differ substantively, the interpretability of the data must be questioned.

The prior examples illustrated only one type of problem that may be addressed by an ITT analysis. Biases similar to those just described can occur if patients elect to cross over study arms, accept a nonstudy therapy, or receive only a portion of the assigned therapy or if they are determined to be ineligible. Therefore, we advocate attempting to obtain complete follow-up for all patients registered to every phase III trial and performing an ITT analysis. Sometimes this may not be possible because patients who refuse protocol therapy may also refuse to be followed. If only 1% or 2% of patients

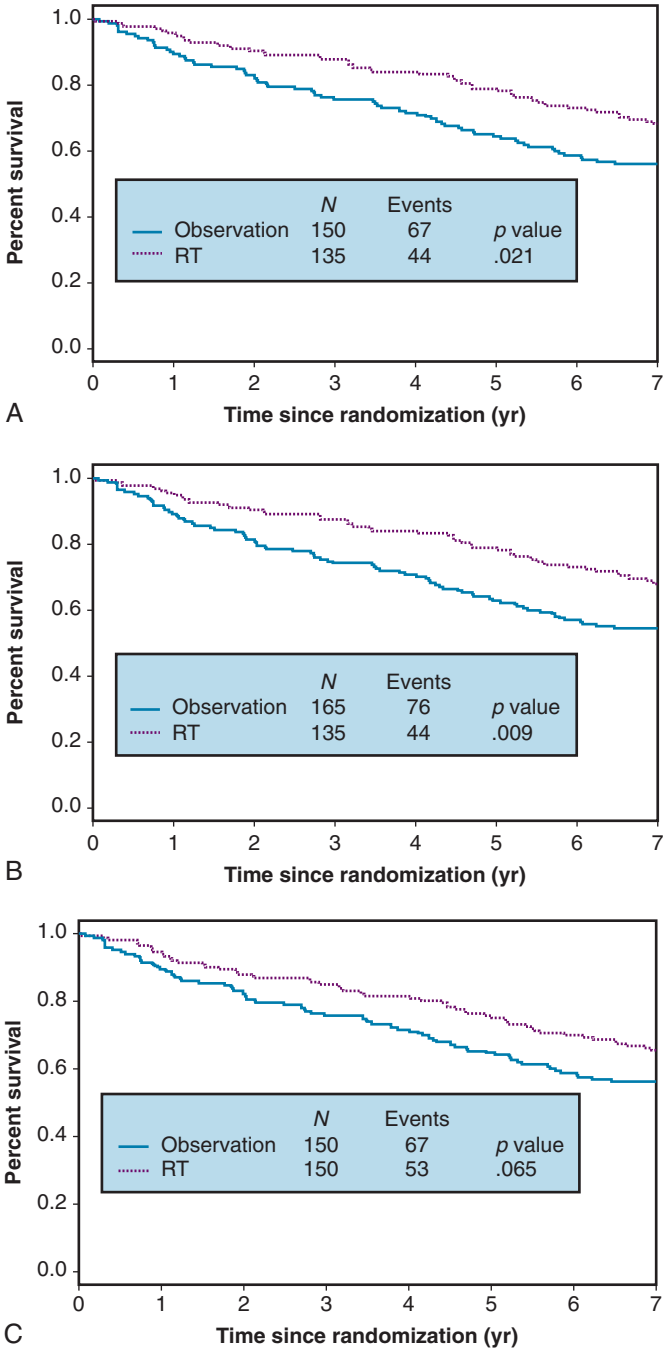

Figure 13-2 **A,** Survival curves that would be observed if the patients of poor risk who refuse radiation therapy *(RT)* are excluded from the analyses (percent survival versus years from randomization). **B,** Survival curves that would be observed if the patients of poor risk who refuse radiation therapy are included as untreated patients (percent survival versus years from randomization). **C,** Survival curves that would be observed if the patients of poor risk who refuse radiation therapy are included as radiation therapy patients (i.e., the results that would be obtained using an intent-to-treat analysis [percent survival versus years from randomization]).

fall into this category, there is little danger of important bias, but if this number is larger, say 5% to 10%, there is a real danger that the study results may be biased. One might then want to perform what are called sensitivity analyses to examine the possible effect of having so many patients without follow-up. In its simplest form, one might perform one analysis assuming that all of the patients without outcome data on arm A failed early on, whereas those on arm B survived; and then perform an analysis assuming that all of the patients without outcome data on arm A survived, whereas those on arm B failed. If one reaches the same conclusion about treatment effect in either analysis, then the exclusions do not represent a serious problem.

There is often disagreement concerning the inclusion of ineligible patients in analyses, particularly in analyses dependent on patient covariates because ineligible patients may not fit any reasonable classification. The decision as to whether it is appropriate to exclude ineligible patients depends on the methods used for determining ineligibility. For example, in some studies, each patient is reviewed for eligibility in a uniform way by a reviewer (or review committee) who is unaware of the assigned treatment and uses only information that was obtained before randomization. If that is the only mechanism for classifying patients as ineligible, one could reasonably exclude such patients from analyses. However, any less stringent approach that allows patients to be classified as ineligible after randomization could introduce subtle biases. For example, in a trial of radiation versus observation, one might routinely perform a pretreatment examination immediately after a patient is assigned to radiation therapy. If, during that examination, it is determined that the patient had not met an eligibility requirement, exclusion would cause a bias because a similar patient not assigned to radiation would not have had the pretreatment examination and would, therefore, not have been determined to be ineligible.

To summarize, we recommend always performing an ITT analysis using all patients as randomized and reporting the results of that analysis in any publication. Further analyses may be performed, especially for noninferiority trials, but one should be aware of potential biases similar to those described previously. Further discussion of these issues can be found in articles by Pocock[32] and Gail.[38]

The data used in Example 1 were generated using the following assumptions. The expected 5-year survival rate for an untreated good-risk patient was 0.73, and for an untreated bad-risk patient, 0.54. The reduction in the death rate associated with radiation treatment was assumed to be 20% in each group. For Figure 13-2, we assumed that all the patients with poor risk had an expected 5-year survival rate of 0.54 because none received treatment.

Monitoring Ongoing Trials

In clinical trials, patients enter a study sequentially over time; therefore, information about the treatment accumulates as the trial progresses. An interim analysis is a planned analysis conducted before the final planned analysis, which allows the study sponsor to evaluate the trial's success probability while controlling the overall statistical error rates. As the trial progresses, interim analyses are usually conducted at prespecified time points, which are quantified by the number of total events. Interim analyses could be used to monitor superiority, futility, or both: If a new regimen is convincingly demonstrated to be superior to the active control, there is an ethical obligation to stop the randomization and provide the new regimen to every patient. If an interim analysis shows that there is little chance for the new regimen to outperform the control, it would be prudent to terminate the trial and save patients for other promising regimens.

There are different approaches in setting interim monitoring boundaries for superiority. For instance, Pocock[39] proposed to spend the type I error (false-positive rate) equally throughout all interim and final analyses. O'Brien and Fleming[40] proposed to reserve most of the type I error for the final analysis. The general approach is to set the interim boundaries conservatively so that the trial will not stop early for efficacy unless convincing evidence is present.

Typically, setting the interim boundaries for futility is not done as conservatively as is setting them for superiority. A nice rule of thumb proposed by Wieand et al[41] is as follows: Assuming that a study has a time-to-event primary endpoint, an interim futility check will be conducted when 50% of events targeted for final analysis have been observed. If the hazard ratio of the experimental treatment versus the control is larger than 1 (i.e., the outcomes on the experimental arm are poorer than those on the control arm at that time), the trial should be stopped for reasons of futility. The rule is simple to follow, and the probability of falsely determining that an experimental regimen is no better than the control situation when, in fact, the experimental regimen actually works is 2% or less.

Interim monitoring mainly focuses on treatment efficacy. To monitor additional aspects of a trial—for instance, to protect the safety of enrolled patients, to ensure the validity of study results, or to identify unacceptably slow accrual rates, unusually high dropout rates, or unacceptable ineligibility rates—a Data Safety Monitoring Board (DSMB) is usually recommended, if not required. The DSMB is composed of an independent panel of experts. Usually, a physician and a statistician are required. Other representatives could include epidemiologists, laboratory scientists, a patient representative, or representatives of different groups. DSMB members have access to all data and report directly to the study sponsor. In current clinical trial practice, the U.S. Food and Drug Administration (FDA) strongly recommends using a DSMB for all phase III trials and many institutional internal review boards now require use of a DSMB.

SURVIVAL ANALYSIS

Survival analysis differs from other types of statistical analysis in that the analysis of time to an event often is complicated by the lack of complete follow-up for every patient (i.e., there is censored data). An example illustrates why this is important. The example uses hypothetical data chosen to illustrate clearly the problem that censoring can cause.

Example 2. Suppose a radiation oncologist decides to review the outcomes of patients with rectal cancer treated with radiation therapy. Of primary interest is the determination of the proportion of patients who remain relapse free for 5 years. Suppose patients have been accrued over the past 7.5 years, and by chance the patients have started treatment in pairs at intervals of 1 year. Suppose, furthermore, that if no more patients were accrued and the oncologist could wait 5 more years to obtain 5-year follow-up for every patient, he or she would find that half of them were relapse free for more than 5 years. This (unobserved) relapse pattern is shown in Figure 13-3.

Twelve years after the first patient was entered, the 5-year relapse-free pattern would be as shown in Figure 13-4 (time 0 is the date of entry for each patient). If the investigator had waited 12 years (i.e., until 5-year data for all 16 patients were complete), he or she would have observed that half of the patients were relapse free 5 years after entry (i.e., the 5-year relapse-free rate is 0.50). Suppose, in fact, that the investigator decided to look at the patients' experience 7.5 years after the first patient had entered. Then the investigator would have observed everything to the left of the vertical line in

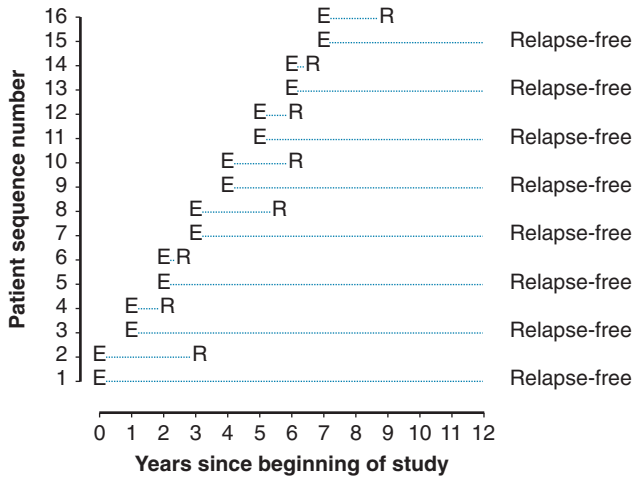

Figure 13-3 Date of entry *(E)* and relapse *(R)* of 16 patients monitored over a 12-year period; 8 did not experience relapse.

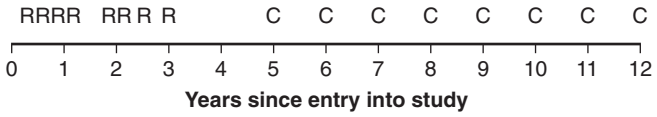

Figure 13-4 Relapse history of 16 patients seen 12 years after the beginning of the study: time from entry into the study until relapse or last follow-up. *C*, Censored; *R*, relapsed.

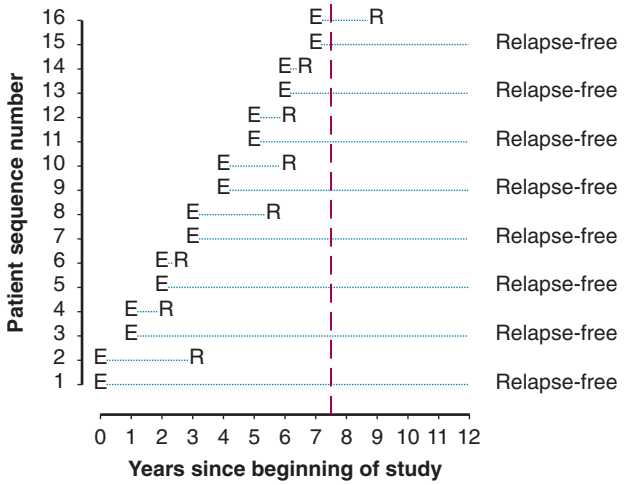

Figure 13-5 Status of follow-up 7.5 years after the first patient was entered in the trial. *E*, Entry; *R*, relapse.

Figure 13-5. Translated into time from entry, this would be represented as shown in Figure 13-6. In that case, the investigator would have complete 5-year data for 7 of the 8 patients who relapsed and for 3 patients who were relapse free at 5 years (those who were entered at year 0, 1, or 2). For the other 6 patients, his or her knowledge would be that they were relapse free for some length of time less than 5 years. The investigator's first instinct might be to exclude these 6 patients from analysis because he or she does not know what their relapse status will be after 5 years of follow-up. Of the remaining 10 patients, 7 are known to have relapsed and 3 are known to be disease free for more than 5 years, so that the estimated relapse-free rate at 5 years is 0.30. This estimate does not seem to reflect the data accurately.

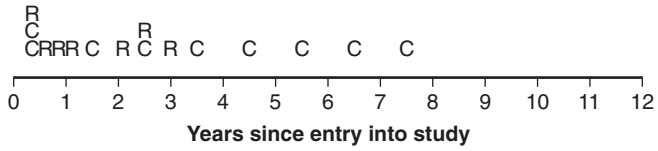

Figure 13-6 Relapse history of 16 patients seen 7.5 years after the beginning of the study: time from entry into the study until relapse or last follow-up. *C*, Censored; *R*, relapsed.

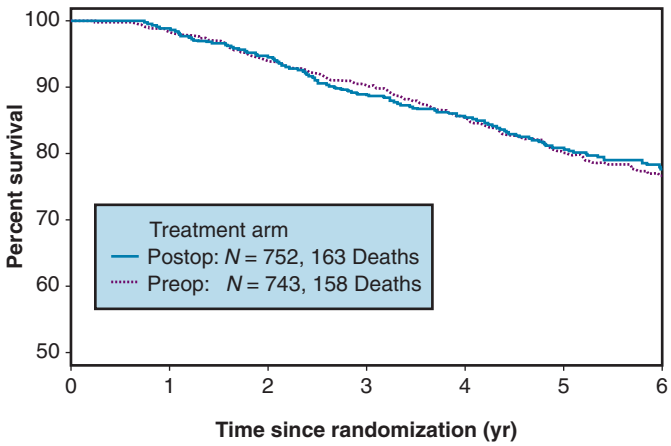

Figure 13-7 Survival of patients with operable breast cancer treated with doxorubicin and cyclophosphamide.

The estimate is so different from 0.50 because the method of calculation is biased. The cause of the bias can be seen by studying the seventh and eighth patients in the series of patients (i.e., the patients entered 3 years after the first patient entered). Notice that the seventh patient entered was still relapse free when the radiation oncologist performed his or her analysis but had only been followed for 4.5 years (i.e., did not have a known status at 5 years) and, hence, was excluded. However, the eighth patient (who was entered on the same day) had relapsed by the time of analysis and, therefore, was included. The bias is that patients who relapse have a better chance of being included in the analysis than those who do not relapse. One way to avoid a biased estimate would be to exclude all patients who did not have the potential to be monitored for 5 years. Therefore the oncologist would only be able to use the information from the first six patients entered. In this artificial example, this would have led to a correct estimate of the 5-year relapse-free rate because three of the first six patients relapsed within 5 years.

This method is unsatisfying because not all of the available information is used. In statistical terms, the disadvantage of our proposed solution is that there is considerably more variance associated with an estimate that uses the data from only six patients than one that uses all of the available data. For example, if patients 6 and 7 had entered the study in the opposite order, the relapse-free estimate would jump from 50% to 67%. A better method is described in the next section.

Kaplan-Meier Method

A common way to summarize survival data is to estimate the "survival curve," using a method proposed by Kaplan and Meier.[42] The Kaplan and Meier curve shows—for each value of time—the proportion of subjects who survive at least that length of time. Figure 13-7 shows survival curves for patients with operable breast cancer who have been treated with either preoperative or postoperative chemotherapy (doxorubicin

and cyclophosphamide) in a large clinical trial. Here, we offer two examples that provide some insight regarding the Kaplan-Meier method. The first example concerns a data set having no censored observations; the second example extends these ideas to accommodate censored observations.

Example 3. Suppose four patients are entered into a study, possibly at different times, and all four die, with death times of 10 months, 20 months, 25 months, and 40 months, respectively, from time of entry. We want to estimate the 3-year survival rate. Three of the four patients died within 3 years from entry, and one patient remained alive more than 3 years from entry (i.e., one fourth of the patients entered lived at least 3 years). Therefore, a reasonable estimate of the 3-year survival rate is $S(3) = 0.25$. This estimate (the proportion of patients who remained alive at 3 years) is referred to as the empirical survival estimate, and the graph of estimates obtained this way at all time points is called the *empirical survival curve.*

Example 4. Suppose that in the previous example three of the patients have died at 10 months, 25 months, and 40 months, respectively. The fourth patient is still alive but has been monitored for only 20 months. We want to estimate the 3-year survival rate. Notice that if we could wait another 16 months to obtain the estimate (so that we would have 3-year data for all patients), we would obtain an estimate of either one fourth (if the fourth patient dies soon) or one half (if the patient remains alive for another 16 months). The rather intuitive approach we used in Example 3 to estimate the 3-year survival rate does not work here because we do not know whether there will be two or three survivors when all the patients have died or have been monitored for 3 years (i.e., we do not know how to handle the patient whose follow-up was censored at 20 months). Kaplan and Meier proposed an approach that updates the survival estimate at the time of each death using only those patients who are at risk of failing at each update.

Because none of the patients died during the first 10 months, the Kaplan-Meier estimate of the probability of surviving to any time point less than 10 months is equal to 1. Because four patients are alive at 10 months but only three quarters of them survive beyond 10 months, the Kaplan-Meier estimate changes to three quarters for time points beyond 10 months but before the next death. Although one patient is censored at 20 months, this gives no information regarding the likelihood of a death, so the Kaplan-Meier estimate remains at three quarters for all time points between 10 months and 25 months. One of the two patients who are still at risk just before 25 months dies at that time. Therefore, the estimate of the probability of a patient surviving beyond 25 months, given that the patient survived at least 25 months, is one half. The Kaplan-Meier estimate of surviving more than 25 months is the product of three quarters (the estimated probability a patient will survive until 25 months) times one half (the estimated probability that a patient will survive more than 25 months given that the patient was alive at 25 months), which is three eighths. There are no other deaths before 3 years, so the Kaplan-Meier estimate of the 3-year survival rate is three eighths. The Kaplan-Meier method uses all the relevant available data from each patient but excludes the patient who was censored at 20 months from all computations beyond that time.

If the Kaplan-Meier approach is applied to the data in Example 3, the estimate $S(3)$ is equal to the (probability of surviving 10 months) × (probability of surviving more than 10 months given survival of 10 months) × (probability of surviving more than 20 months given survival of 20 months) × (probability of surviving more than 25 months given survival of 25 months), or $1 \times \frac{3}{4} \times \frac{2}{3} \times \frac{1}{2} = \frac{1}{4}$, which matches the empirical survival estimate. In fact, the Kaplan-Meier estimate and the empirical estimate always match when they are applied to uncensored data.

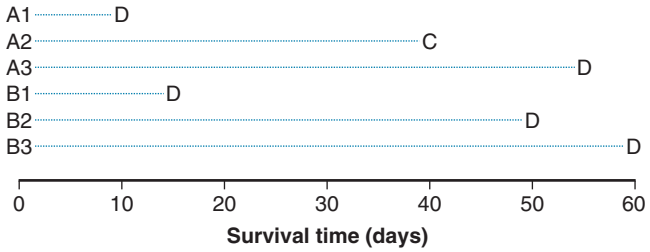

Figure 13-8 Survival times of six patients treated with one of two regimens. *C*, Censored; *D*, death.

TABLE 13-4 Observed Deaths (t=10)

Treatment	Dead	Alive	Total
A	1	2	3
B	0	3	3
Total	1	5	6

The reader may verify that application of the Kaplan-Meier approach to the data in Figure 13-6 will result in an estimate of 0.45 for the probability of remaining relapse free through 5 years.

Log-Rank Statistic

Perhaps the most common application of survival analysis techniques is the comparison of survival times (or other times to event, such as time to disease relapse) between two or more groups of patients that differ in some aspect (e.g., male versus female, or treated versus untreated). The log-rank statistic, the stratified log-rank statistic, and the Cox proportional hazard model are commonly used to compare survival times between groups.

The log-rank statistic deals with the problem of censoring by comparing the groups only when a patient within any of the groups experiences an "event" (if survival times are to be compared across groups, an event would be a death; if times to relapse are to be compared, an event would be a relapse, and so on). This idea is most easily explained in the context of a simple example. Suppose we monitored three patients receiving a standard treatment regimen (this might even be no treatment), which we refer to as treatment A, and three other patients receiving an experimental regimen, which we refer to as treatment B. Suppose, furthermore, that the survival times for the patients receiving treatment A are 10, 40+, and 55 days, respectively, and for the patients receiving treatment B, 15, 50, and 60 days, respectively (a plus sign after a value refers to a censored time; i.e., a patient with a time of 40+ days was last known to be alive at 40 days and no further follow-up is available). These data are represented graphically in Figure 13-8; the three patients receiving treatment A are labeled A1, A2, and A3, and those receiving treatment B are labeled B1, B2, and B3. Deaths are denoted by the letter D, and censored survival times are labeled with the letter C.

When evaluating the log-rank statistic, the first computation occurs at time $t = 10$, the time at which the first death is observed. Just before this point in time, all six patients are known to be alive (and, hence, are "at risk" to die at time $t = 10$). Three of these patients received treatment A and three received treatment B. Exactly one of these six patients is known to have died at time $t = 10$, and he or she received treatment A. Table 13-4 summarizes the status of patients at this time point. Notice that at the time of this computation

TABLE 13-5 Observed Deaths (t=15)

Treatment	Dead	Alive	Total
A	0	2	2
B	1	2	3
Total	1	4	5

TABLE 13-6 Observed Deaths (t=50)

Treatment	Dead	Alive	Total
A	0	1	1
B	1	1	2
Total	1	2	3

TABLE 13-7 Observed Deaths (t=55)

Treatment	Dead	Alive	Total
A	1	0	1
B	0	1	1
Total	1	1	2

there are three patients on each arm. Therefore, if treatment B was equivalent to treatment A and only one death occurred on one arm or the other, there would be a one half chance that the death is on arm A. In fact, the death is on arm A; hence, we observe one death when the probability of observing a death on arm A is one half (i.e., there is one half more death on arm A than is expected).

Observations at time $t = 15$ are listed in Table 13-5. At this point there would be a two fifths probability that the death would occur on treatment A (if the treatments were equivalent), but the death did not occur on treatment A, so there were two fifths fewer deaths on arm A than expected (i.e., the observed deaths minus the expected number is $0 - \frac{2}{5} = -0.4$).

The next computation occurs at time $t = 50$; observations are listed in Table 13-6. Notice that patient A2 is not included in this table, even though she is not known to have died at any time before $t = 50$. Because she was lost to follow-up (censored) at time 40, she is no longer "at risk" at time 50. At this time, there would be a one third probability that the death would occur on treatment A (if the treatments were equivalent), but the death does not occur on treatment A, so there are one third fewer deaths on arm A than expected (i.e., the observed deaths minus the expected number is $0 - \frac{1}{3} = -0.33$).

One may go through the same computations at time $t = 55$ (Table 13-7) and will determine that the number of deaths minus expected deaths on treatment A is $1 - \frac{1}{2} = 0.5$. At time $t = 60$, all remaining patients are on the same arm, so the observed minus the expected number of deaths must be 0. Adding up the observed minus the expected number of deaths at times 10, 15, 50, and 55, one obtains 2 observed deaths minus 1.733 expected deaths, so that there were 0.27 deaths more than expected on arm A, indicating that this treatment might be harmful. However, one's intuition is that this is not a significant difference (i.e., such a small difference could easily be attributed to the play of chance), and in fact this is true. Therefore, there is no strong evidence in this example that treatments A and B differ.

More formally, the log-rank statistic is defined to be the difference in observed and expected numbers of deaths on one of the two treatment arms. The statistic may be standardized by dividing by the square root of its variance, yielding a score that, under the hypothesis of equivalent treatments, is approximately standard normal. In the present example, the variance of the log-rank statistic can be shown to equal 0.9622, so the standardized test statistic is $(2 - 1.733)/0.9622 = 0.27$, corresponding to a two-sided p value of about 0.79.

Cox Proportional Hazard Model

When controlling for the association of a single variable with patient survival, the stratified log-rank test can be used. However, in terms of adjusting for additional explanatory variables, the most popular method is the Cox proportional hazards model.[43] The Cox model explores the relationship between survival experience and prognostic variables or explanatory variables. It estimates and tests the hazard ratio between different groups. In the Cox regression model, explanatory variables could be continuous (for instance, age or weight or systolic blood pressure), categorical (for instance, gender or race or Eastern Cooperative Oncology Group [ECOG] performance score), or an interaction between different categorical variables. The Cox regression model does not make any parametric assumption about the survival probability distribution of each group; however, it does assume a proportional hazard between two groups. If we use $h_i(t)$ and $h_0(t)$ to denote the hazards of death at time t for the ith patient and the baseline patient, that is, the patient with all explanatory variables taking values 0, respectively, the proportional hazard model can be expressed as

$$h_i(t) = \exp(\beta_1 x_{1i} + \beta_2 x_{2i} + \beta_3 x_{3i} + \ldots + \beta_p x_{pi}) h_0(t),\ t \geq 0$$

where $x_1, x_2, \ldots x_p$ are p different explanatory variables, $h_0(t)$ is called the baseline hazard function, and $h_i(t)/h_0(t)$ is a constant, called the hazard ratio. The βs are the regression coefficients. For a continuous explanatory variable x_p, β_p stands for the log of the hazard ratio between the ith patient and the baseline patient. For a categorical explanatory variable x_1, for instance, assume that $x_1 = 0$ if the patient is randomized to the control group, or $x_1 = 1$ if the patient is randomized to the experimental group. Then β_1 stands for the log of the hazard ratio between patients in the experimental group versus the control group, whereas all other explanatory variables are the same.

Because the Cox regression model assumes the proportional hazard between different groups, it is necessary to check this assumption before concluding the estimations. Most of the model check procedures are based on graphs or plots of model-fitting residuals. If the proportional hazard assumption does not fit the data even after the data transformation, other models should be considered.

CURRENT TOPICS IN PHASE III CLINICAL TRIALS

Surrogate Endpoints

The primary endpoint is one of the most critical elements in formulating the study design, data collection, and statistical analysis plan of a clinical trial. It is a quantitative measurement implied or required by the primary objective of a study. The best endpoint is a clinical measurement reflecting the most relevant potential treatment effect of the new regimen that can be defined with rigorous mathematical and statistical properties. The OS rate has historically been the primary outcome for most phase III oncology trials because of its clear virtues: it is simple to measure, unambiguous, the least susceptible to investigator bias, and of unquestionable clinical relevance. Despite these many advantages, the role of OS as a primary endpoint is challenged in modern phase III clinical trials. Two primary challenges to the OS endpoint

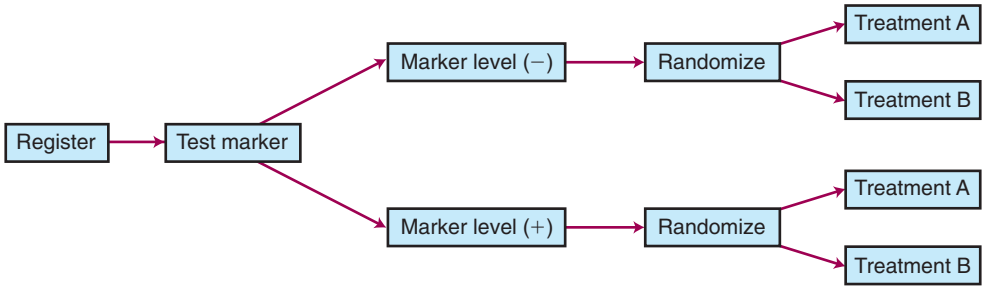

Figure 13-9 Marker by treatment interaction to test a predictive factor question; same treatments in both prognostic groups.

are that in many cases an extensive follow-up period is needed to obtain survival status and that in many diseases, multiple effective therapies are now available. In this case, OS is affected by all therapies given to a patient and, as such, this endpoint is insensitive to the impact of changing a single line of therapy.

One of the alternatives is to use a surrogate endpoint instead of a clinical endpoint in a phase III trial. A surrogate endpoint is an endpoint obtained sooner, at lesser cost, or less invasively than the long-term clinical efficacy endpoint. The Biomarkers Definitions Working Group (BDWG) defines a surrogate endpoint as "a biomarker that is intended to substitute for a clinical endpoint. A surrogate endpoint is expected to predict clinical benefit (or harm, or lack of benefit or harm)."[44] When using a surrogate endpoint, one would like to make the same inference as if one had observed a true endpoint. Therefore, a critical requirement of a valid surrogate endpoint is that the treatment effect observed on a surrogate endpoint should reliably predict the treatment effect on the clinical endpoint. This implies a stronger requirement for a surrogate endpoint than simply a significant correlation between it and the clinical endpoint. In circumstances where the speed of the study is a major concern, where second-line therapies that affect the OS potentially obscure the assessment of first-line treatment benefit, or where crossover becomes unavoidable, a surrogate endpoint might be considered in place of the long-term clinical endpoint.

From statistical perspectives, there are two branches of surrogate evaluation methodologies: a single-trial or meta-analytic evaluation. In the single-trial approach, the "proportion of treatment effect" (PTE)[45,46] explained by the surrogate, has been the predominant approach. However, a single study is unable to provide reliable information regarding the prediction of the treatment effect on the clinical endpoint based on the observed treatment effect on potential surrogate endpoint. Therefore, to validate an endpoint as a legitimate surrogate endpoint, a meta-analysis is usually required. In addition, heterogeneity between the trials included in the meta-analysis strengthens the robustness of results from individual trials. In conducting a meta-analysis, using individual patient data instead of summary data is highly recommended, and, ideally, both positive and negative trials should be included. Examples of meta-analyses conducted to examine potential surrogate endpoints can be found in articles by Sargent and colleagues[47] and Burzykowski and associates.[48]

Biomarkers

A marker is a single trait, or a group of traits, that differentiates patients with respect to an outcome of interest. If a marker can be used to identify patients with differing risks of a clinical outcome (such as progression or death) in the absence of therapy or when receiving nontargeted standard treatment, the marker is usually called a *prognostic marker.* If a marker predicts differential efficacy of a specific therapy, the marker is called a *predictive marker.*

Validation of a prognostic marker is usually conducted retrospectively in patients treated with placebo or a standard treatment. Validation of a predictive marker could also be conducted retrospectively based on data from a randomized controlled trial.[49] However, a prospective randomized controlled trial would be ideal. Two types of clinical designs can be used to validate a predictive marker: a targeted/selection design or an unselected design. A targeted trial enrolls only patients who are most likely to respond to the experimental therapy based on their molecular expression levels. On the one hand, a targeted trial could result in a large savings of patients for other trials. On the other hand, it could miss efficacy in other patients and miss the opportunity to test the association of the biologic endpoints with clinical outcomes.

Different types of unselected designs have been proposed and discussed. For instance, the marker-by-treatment interaction design (Figure 13-9) stratifies patients according to their marker status and randomly assigns patients in each marker group to two different treatments. Hypothesis setting and sample size estimation could be different in each marker-defined subgroup. Either a formal test for marker-by-treatment interaction or a separate superiority test within each marker group could be conducted. Another popular unselected design is the marker-based strategy design (Figure 13-10), in which the random treatment assignment could be based on the patient's marker status or could be independent of it. Examples for each type of design can be found in the article by Sargent and colleagues.[50]

Adaptive Design

An adaptive design could be defined as a design "that allows adaptations to trial procedures (for instance, eligibility criteria, study dose, or treatment procedure, etc.) and/or statistical procedures (for instance, randomization, study design, study hypothesis, sample size, or analysis methods, etc.) of the trial after its initiation without undermining the validity and integrity of the trial."[51] Many types of adaptation could be applied to an ongoing trial. For instance, a study could be resized based on an interim review of the outcomes in the control group. Assume, for example, that in the design of a study, the progression-free survival (PFS) under the standard of care was assumed to be 12 months. However, on an interim review of accrued data from the control arm, the estimated PFS was 15 months. In this case, more patients need to be accrued for the study or patients need to be followed longer for the same hazard ratio to be detected. No statistical penalty is required for this review, because only data from the control arm have been analyzed.

For another example of an adaptive design, assume that a study started with n experimental arms and one control arm. Within this study, based on a prespecified plan, all

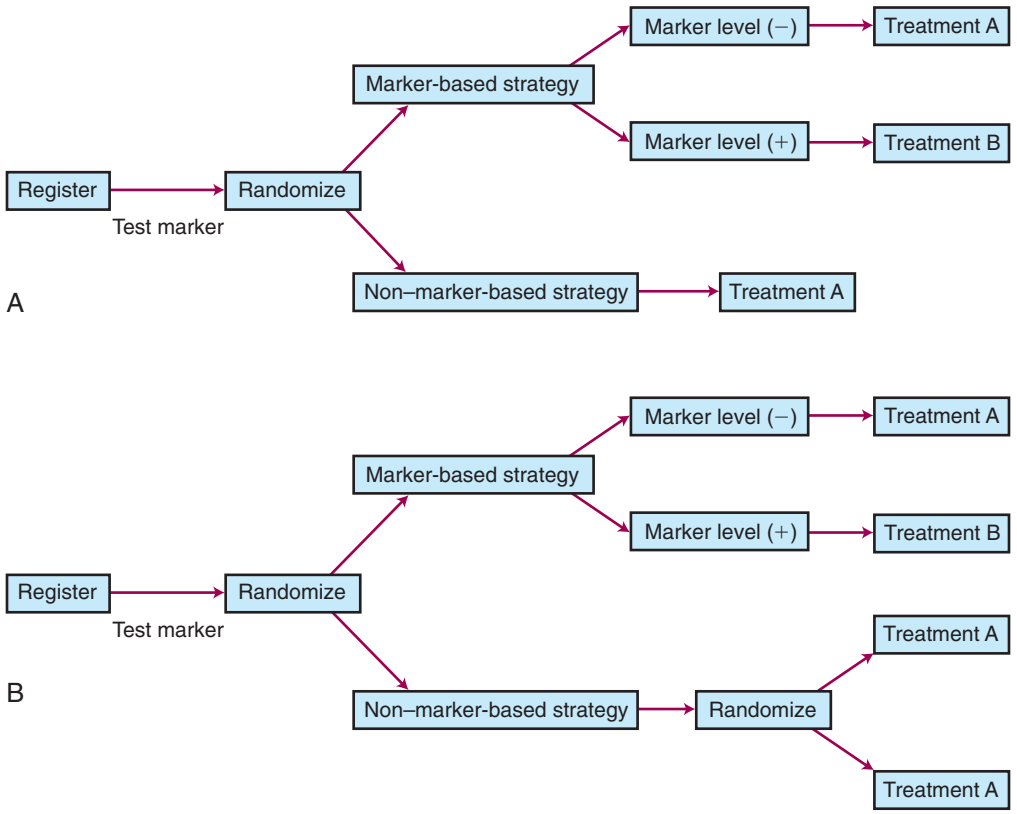

Figure 13-10 **A,** Marker-based strategy design to test predictive factor question; no randomization in non–marker-based arm. **B,** Marker-based strategy design to test predictive factor question; randomization in both arms.

experimental arms are to be compared with the control arm, at the interim analysis, and only the most promising experimental arm and the control arm will continue to accrue when patient accrual is resumed. In other words, the study will have started with $n+1$ arms and ended with 2 arms, and $n-1$ arms will have been dropped after the interim analysis. Because no conclusions regarding superiority were allowed to be made at the interim analysis, no statistical penalty for the interim review is needed. Under other circumstances, if an adaptation relates to (1) altering the randomization ratio between the arms, (2) resizing the trial based on interim comparison between the experimental and control arms, or (3) changing the primary endpoint, then a penalty for looking at the data before the end of the study is definitely needed. In planning an adaptive design, possible adaptations must be specified in the protocol before accrual takes place. In applying an adaptive design, an efficient mechanism for processing and analyzing data is critical.

As drug development moves toward targeted agents with particular treatment mechanisms through a targeted pathway, the disease population for testing the treatment effects may need to be refined and subseted based on a relevant biomarker signature. By subgrouping the disease population, the traditional design becomes challenging. Under this circumstance, Bayesian adaptive designs guided by biomarkers have been explored and applied. For example, the Biomarker-integrated Approaches of Targeted Therapy for Lung Cancer Elimination (BATTLE) trial and Investigation of Serial Studies to Predict Your Therapeutic Response with Imaging and Molecular Analysis 2 (ISPY-2) trials are two recent biomarker-based adaptively randomized studies. In the BATTLE trial, four treatments (Erlotinib, Vandetanib, Eroltinib + bexarotene, Sorafenib) and four biomarker profiles (EGFR mutation, KRAS/Braf mutation, VEGF/VEGFR-2 expression, RXRs/Cyclin D1 expression and CCND1 copy number) were considered. The trial started with equal allocation randomization to four treatments, then was switched to adaptive randomization that would increasingly assign patients into treatments with greatest potential for efficacy based on their individual biomarker profile.[52] Similarly, ISPY-2 was aimed to identify regimens which can improve outcomes for patients with particular biomarker signatures in the neoadjuvant chemotherapy setting for patients with breast cancer. A concurrent randomization between experimental and standard care regiments was conducted within the patient populations defined by biomarkers. The adaptation was based on the Bayesian predictive probability of the experimental agent being more effective than standard therapy to allow "graduation" or "dropping out" of the pair of regimen and biomarker.[53] Both studies highlight the feasibilities of applying advanced trial designs in practice and also illustrate powerful collaboration between statisticians and clinical, laboratory, and bioinformatics investigators.

CHAPTER

14 Late Effects after Radiation

Michael T. Milano, Lawrence B. Marks, and Louis S. Constine

INTRODUCTION AND GENERAL CONSIDERATIONS

Statement of the Problem

Incidental irradiation of normal tissues is unavoidable during radiation therapy. Predicting the risk of radiation-induced injury is challenging. The primary determinants of injury are the radiation dose (total dose and dose per fraction) and the volume of normal tissue irradiated. Additional treatment factors that influence risk include dose rate, overall treatment time, treatment energy, the use of concurrent chemotherapy, radiation protectors, or other biological modifiers, and the interval between radiation courses in patients undergoing a second course of radiation. Host-related factors include comorbid conditions (e.g., diabetes, collagen vascular disease), inherent radiation sensitivity (e.g., underlying genetics), and patient age. Organ related variables include preradiation organ compromise or loss, development of severe acute toxicity (resulting in consequential late effects), regional variation of radiosensitivity within an organ, and hierarchal organization of the organ (i.e., whether damage to a portion of the organ affects only that portion or has more widespread effect). Furthermore, an organ may have more than one type of late toxicity that may or may not have different tolerance doses. Tumors can infiltrate into normal tissues, either at presentation or after treatment (i.e., local failure), compromising organ function and leading to late sequelae.

What Are the Target Cells/Tissues for Radiation-Associated Normal Tissue Injury?

Different organs have different dose/volume thresholds for the development of radiation-associated injury. The critical question arising from this observation is: what are the dose-sensitive targets in normal tissues resulting in late toxicity. Damage to either the functional (parenchymal) or stromal cells of the organ, or the fine vasculature, have been implicated. Differences in radiation susceptibility of different organs may therefore be as a result of different sensitivities of these functional cells, regional variation in the susceptibilities of small vessels because of the stroma or microenvironment, different capacities for neo-vascularization, or differences in the redundancy of the blood flow (i.e., those tissues relying on fewer vessels may be more susceptible to radiation damage), or functional reserve.

Utility and Limitations of Dose-Volume Histograms

The focus of this chapter will be on the review of credible data associating radiation dose/volume parameters with the risk of normal tissue injury. Three-dimensional (3D) planning has become standard practice, allowing the radiation oncologist to quantitate doses to normal tissues in the region of interest. 3D dose/volume data can be difficult for clinicians to easily comprehend because the distributions are two dimensional (2D). Visualizing isodose distributions is challenging and comparing competing distributions is largely subjective. Therefore, dose-volume histograms (DVHs; essentially 2D representations of the 3D data) were embraced as a rapid way to summarize the dose distribution. A DVH is generated by tallying the doses delivered to each (or a representative sample of) voxel of tissue and represents that information as a cumulative histogram of dose (x-axis) and volume (y-axis). Each point along the histogram represents the volume of that organ receiving more than or equal to that dose (e.g., V20 is the volume of an organ receiving at least 20 Gy). A DVH can be readily visualized and provides a quick and easy way to describe the dose/volume characteristics of the 3D dose distribution. However, a DVH achieves this by discarding all spatial information and the DVH does not account for variations in fraction size. Functional and structural complexities, and spatial variations in function or sensitivity, are thus not considered in DVHs. Possible interactions between organs are also not considered with this construct.

Despite the marked data reduction in going from a 3D plan to a DVH, DVHs also remain challenging for clinicians to consider and compare because of the previously mentioned issues relating to functional heterogeneity but also incomplete knowledge about radiation sensitivity of tissues. Therefore, it has become attractive to further data reduce and extract "figures of merit" from the DVH. The critical metrics that will considered in this review are the mean organ dose and discrete points on the DVH. These include (Figure 14-1):

1. *Vx* reflects the volume of tissue (generally a percentage) receiving ≥*X* Gy. This is probably the most commonly used metric for parallel-type organs such as the lung and kidney. For these, as discussed, the portions of the organ exposed to a "regionally injuring" dose of radiation will become dysfunctional. Thus, the percentage of the organ exposed to that dose is a useful parameter.
2. *Dx* reflects the minimum dose to the hottest *x*% (generally percentage of total volume) of tissue. This parameter is not widely used clinically. It might be most useful for parallel-type organs where the percentage of an organ's function that can be lost is known (e.g., let's say 30%). Then, if the D30 is less than the locally injuring dose, global organ function should remain. Similarly, for organs where an injury might be clinically manifest if there is a hot spot of a particular size, the *Dx*, where *x* is equal to that critical size, might be a useful parameter to predict outcomes.
3. *Dmax* is the maximum dose delivered to an organ and is most useful for series organs. *Dmax* is analogous to *Dx* as the volume *x* decreases toward zero.
4. Mean dose is the simple arithmetic average of the dose to an organ. For parallel organs where there is a gradual dose-response function for radiation-induced regional injury, the mean dose might reasonably correlate with outcomes.

More complex modeling has also been widely used to extract figures of merit that better reflect the entire DVH, rather than a single point (e.g., *Dmax, Dx, Vx*). These models will "sum up" the risk associated with each component of a DVH and apply different methods of summing, depending on the type (or architecture/structure) of the organ. For example, for a series-structured organ, the high-dose region of the DVH

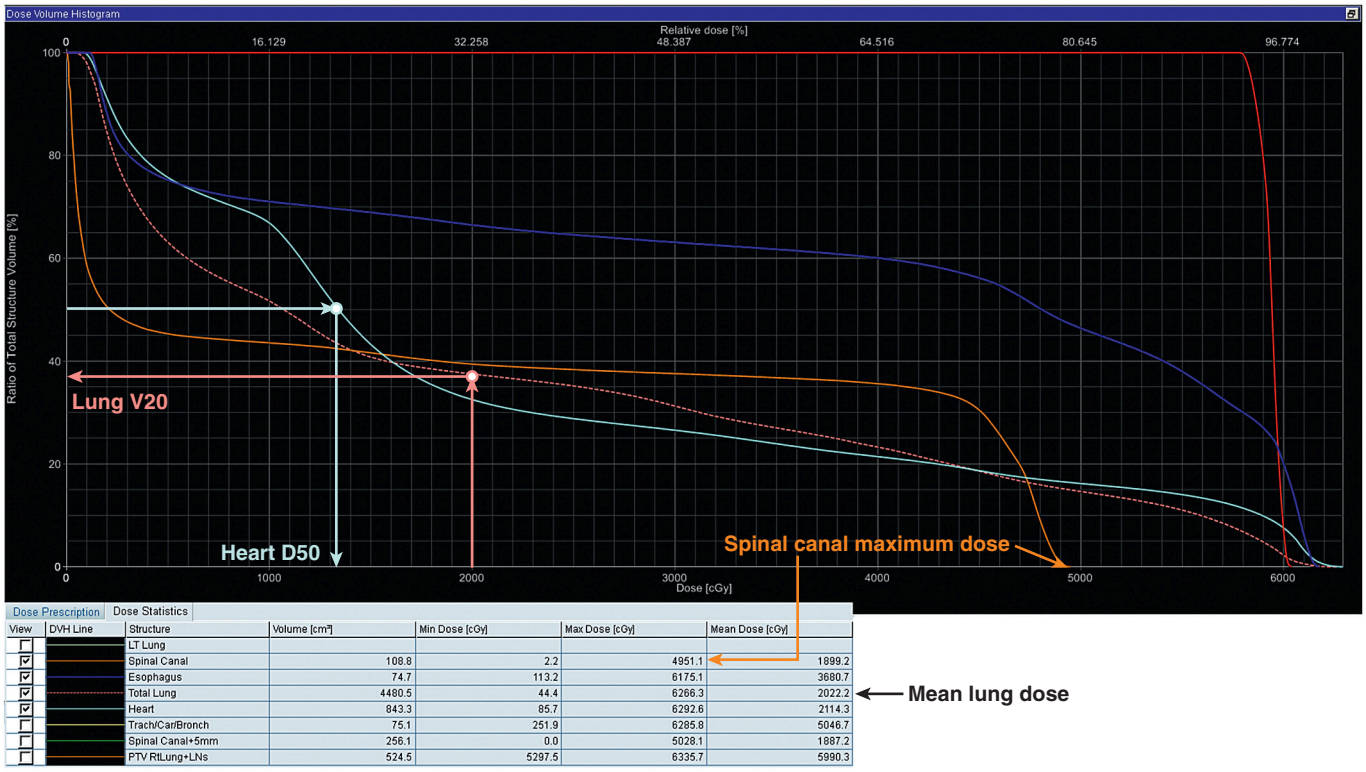

Figure 14-1 Illustration of *Vx*, *Dx*, and *Dmax*. Mean organ dose is calculated by averaging the dose to each voxel of a tissue and is generally calculated by the treatment planning software. The volume of lung receiving greater than 20 Gy (V20) and mean lung dose are shown (37% and 20.2 Gy, respectively). The dose to 50% of the heart (D50) is shown (13.3 Gy), which is not a commonly used dose-volume metric but presented for illustrative purposes. The maximal dose to the spinal canal is depicted as well (49.5 Gy).

might be most weighted more heavily in the "summing," although this is less strongly considered in a parallel-structured organ. Early work in this area led to the Lyman, Kutcher Burman (LKB) model, and more recently the equivalent uniform dose (EUD) model, that both reduce a DVH to a single normal tissue complication probability (NTCP). These models and their relationships are summarized elsewhere.[1]

The Opportunities and Challenges of Modern Radiation Technologies

Several new radiation planning and delivery tools, such as intensity modulated radiation therapy (IMRT), image-guided radiotherapy (IGRT), stereotactic body radiotherapy (SBRT), and charged particle irradiation give the physician increased flexibility in determining how to deliver the desired target dose while minimizing or redistributing the dose exposure to normal tissue. The clinical application of these new technologies requires that the physician and dosimetrists/physicists have an in depth knowledge of the dose/volume/outcome relationships for critical normal tissues, hence the need for this chapter in this book. However, these new technologies have altered the relationship between the target doses and the doses to surrounding normal tissues that might impact the applicability of historic data for our modern era. With conventional beams (often opposed beam pairs treated sequentially), the normal tissues were exposed to fraction sizes similar to that of the tumor. With these newer approaches, the fractional radiation doses delivered to the normal tissues adjacent to the target are typically lower than that received by the target. Further, there is a movement toward the use of shorter hypofractionated regiments. Ironically, the use of increasing fractions sizes, along with an increasing number of beams, leaves (at least some of) the surrounding normal tissue receiving a daily fraction size close to what is typically seen with conventional approaches. However, with the more modern techniques, the heterogeneity of dose within the normal tissues is increased. Despite these caveats, much of the published data regarding radiation-associated normal tissue injury remains applicable in the modern era. Continued study of this important topic is clearly needed.

Broadly Defining Organ Structure

Normal tissues can be functionally defined as "serial," "parallel," or a combination of both, analogous to the terminology used for electrical circuits (Figure 14-2). In parallel functioning organs, the functional subunits function independently (i.e., functional redundancy exists). Thus, when some functional subunits of a parallel organ are damaged, the surrounding functional subunits continue to function. Examples of parallel functioning organs include lung, liver, and kidney. Small to moderate, and perhaps even large, volumes of parallel organs can be damaged without causing global dysfunction because there is enough reserve in the undamaged portion of the organ or there is a capacity to regenerate (e.g., liver). In "serial" organs, the functional subunits are arranged in a linear or branching fashion, and hence there is interdependence. Damage to the subunits of a serial organ can result in compromise or incapacity of the entire organ. Examples of series organs include spinal cord, portions of the central nervous system, peripheral and cranial nerves, gastrointestinal tract, and tracheal-bronchial tree. Although the concept of serial and parallel functioning organs is useful in assessing risk to tissues,

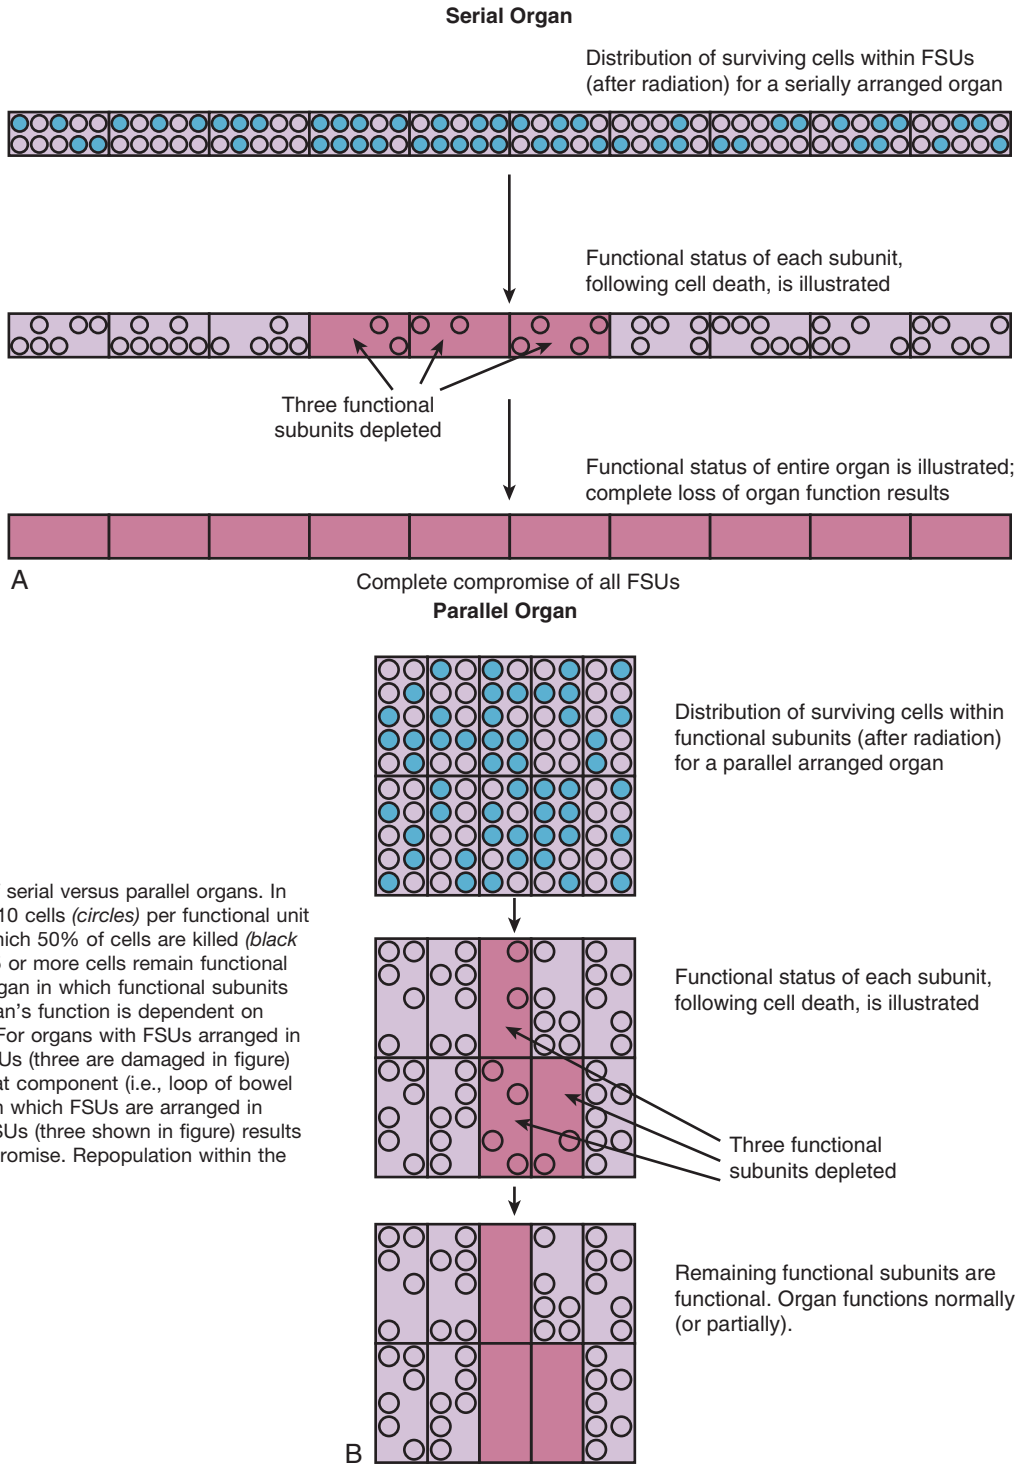

Figure 14-2 Illustrative comparison of serial versus parallel organs. In this figure, a hypothetical example of 10 cells *(circles)* per functional unit *(square)* is shown, after radiation in which 50% of cells are killed *(black circles)*, and functional subunits with 5 or more cells remain functional after radiation. Figure 1A shows an organ in which functional subunits (FSUs) are arranged in series; the organ's function is dependent on connectivity to its neighboring FSUs. For organs with FSUs arranged in series **(A),** damage to one or more FSUs (three are damaged in figure) results in complete compromise of that component (i.e., loop of bowel or region of spinal cord). For organs in which FSUs are arranged in parallel **(B),** damage to a portion of FSUs (three shown in figure) results in partial, or no apparent, organ compromise. Repopulation within the FSUs is not shown.

it should be appreciated that this is only a model. The function of many organs requires the integrity of both serial and parallel components (e.g., the lung requires the "parallel" alveoli, as well as the "series" conducting airways).

Further complicating this issue is the fact that, in both serial and parallel organs, there are often regional heterogeneities in function (e.g., gray matter and white matter tracts of the "parallel" spinal cord). These anatomic subregions may have different functions and different susceptibilities to treatment-related damage.

QUANTEC

This chapter will summarize and expand on several reviews published as a special issue in *International Journal of Radiation Oncology Biology Physics* (volume 76, issue 3, Supplement), all of which were written as part of the Quantitative Analysis of Normal Tissue Effects in the Clinic (QUANTEC) initiative. Because the QUANTEC reviews were published in 2010, this chapter also summarizes some studies published after QUANTEC.

QUANTEC arose from a proposal from the Science Council of the American Association of Physicists in Medicine (AAPM) to revise and update guidelines published by Emani in 1991.[2] QUANTEC's goals are (1) to provide a critical review of the current literature on quantitative dose-response and dose-volume relationships for clinically relevant normal-tissue endpoints; (2) to produce practical guidelines to allow reasonable toxicity risks based on dose-volume parameters; (3) to identify future research initiatives. Using the QUANTEC reviews as a backbone, this chapter will focus on recently published data relevant to late toxicity from radiation, with an emphasis on relevant dose-volume metrics. Key summary points of the QUANTEC reviews are briefly summarized at the end of each section, and the QUANTEC reviews are referenced after each subheading. Table 14-1 summarizes the dose-volume metrics that are supported by the literature; this table has been modified from the one published in the QUANTEC issue.[1]

Although the QUANTEC initiative and associated reviews addressed a broad range of issues relating to normal tissue damage, this chapter will focus on late toxicity after an initial course (i.e., excluding reirradiation) of conventional radiation (i.e., excluding hypofractionated regimens). Many of the individual QUANTEC reviews discussed brachytherapy, reirradiation, or hypofractionated radiation, particularly in the context of hypofractionated stereotactic body radiation and stereotactic radiosurgery. Future AAPM initiatives will focus on hypofractionated stereotactic radiation, a topic that is also reviewed elsewhere.[3,4] A separate initiative is under way addressing quantitative dose-volume relationships for pediatric survivors of cancer. This chapter will primarily focus on studies relating three dimensional dose-volume metrics to clinical outcomes.

NERVOUS SYSTEM: BRAIN

Organ Function and Clinical Significance

The structural and functional complexity of the brain puts this organ at risk for a spectrum of radiation-associated toxicities. Some specific functions of the brain can be correlated with

TABLE 14-1 Dose-Volume Metrics Supported by Published Data

Organ	Volume Segmented: Irradiation Type	Endpoint	Dose-Volume Parameters	Rate	Comments
Brain	Whole organ: 3DRT	Symptomatic necrosis	Dmax <60 Gy	<3%	Data at 72 and 90 Gy, extrapolated from BED models
	Whole organ: 3DRT	Symptomatic necrosis	Dmax <72 Gy	5%	
	Whole organ: 3DRT	Symptomatic necrosis	Dmax <90 Gy	10%	
Brainstem	Whole organ: whole brainstem	Permanent cranial neuropathy or necrosis	Dmax <54 Gy	<5%	
	Whole organ: 3DRT	Permanent cranial neuropathy or necrosis	D1-10 mL ≤59 Gy	<5%	
	Whole organ: 3DRT	Permanent cranial neuropathy or necrosis	Dmax <64 Gy	<5%	Point dose <1 mL
Optic nerve/ chiasm	Whole organ: 3DRT	Optic neuropathy	Dmax <55 Gy	<3%	Given the small size, 3DRT is often whole organ
	Whole organ: 3DRT	Optic neuropathy	Dmax 55-60 Gy	3%-7%	
	Whole organ: 3DRT	Optic neuropathy	Dmax >60 Gy	7%-20%	
Spinal cord	Partial organ: 3DRT	Myelopathy	Dmax 50 Gy	0.2%	Including full cord cross-section
	Partial organ: 3DRT	Myelopathy	Dmax 60 Gy	6%	
	Partial organ: 3DRT	Myelopathy	Dmax 69 Gy	50%	
Cochlea	Whole organ: 3DRT	Sensory neural hearing loss	Mean dose ≤45 Gy	<30%	Mean dose to cochlea, hearing at 4 kHz
Parotid	Bilateral whole parotids: 3DRT	Long-term parotid salivary function reduced to <25% of pre-RT level	Mean dose <25 Gy	<20%	For combined parotid glands
	Unilateral whole parotid: 3DRT	Long-term parotid salivary function reduced to <25% of preradiation level	Mean dose <20 Gy	<20%	At least one parotid gland spared to <20 Gy
	Bilateral whole parotids: 3DRT	Long term parotid salivary function reduced to <25% of preradiation level	Mean dose <39 Gy	<50%	For combined parotid glands
Pharynx	Pharyngeal constrictors: 3DRT	Symptomatic dysphagia and aspiration	Mean dose <50 Gy	<20%	
Larynx	Whole organ: 3DRT	Vocal dysfunction	Dmax <66 Gy	<20%	With chemotherapy
	Whole organ: 3DRT	Aspiration	Mean dose <50 Gy	<30%	With chemotherapy
	Whole organ: 3DRT	Edema	Mean dose <44 Gy V50 <27%	<20%	Without chemotherapy
Lung	Whole organ: 3DRT	Symptomatic pneumonitis	Mean dose 7 Gy	5%	Excludes purposeful whole lung irradiation
	Whole organ: 3DRT	Symptomatic pneumonitis	Mean dose 13 Gy	10%	
	Whole organ: 3DRT	Symptomatic pneumonitis	Mean dose 20 Gy	20%	
	Whole organ: 3DRT	Symptomatic pneumonitis	Mean dose 24 Gy	30%	
	Whole organ: 3DRT	Symptomatic pneumonitis	Mean dose 27 Gy	40%	

TABLE 14-1 Dose-Volume Metrics Supported by Published Data—cont'd

Organ	Volume Segmented: Irradiation Type	Endpoint	Dose-Volume Parameters	Rate	Comments
Esophagus	Whole organ: 3DRT	Grade ≥3 acute esophagitis	Mean dose <34 Gy		A variety of alternate threshold doses have been implicated
	Whole organ: 3DRT	Grade ≥2 acute esophagitis	V35 <50%		
	Whole organ: 3DRT	Grade ≥2 acute esophagitis	V50 <40%		Appears to be a dose/volume response
	Whole organ: 3DRT	Grade ≥2 acute esophagitis	V70 <20%		Similar constraints are applicable to late toxicity
Heart	Pericardium: 3DRT	Pericarditis	Mean dose <26 Gy		
	Pericardium: 3DRT	Pericarditis	V30 <46%		
	Whole organ: 3DRT	Long-term cardiac mortality	V35 <10%		Overly safe risk estimate based on model predictions
Liver	Whole liver—GTV: Whole liver or 3DRT	Classic RILD	Mean dose <30-32 Gy	<5%	Excluding patients with preexisting liver disease or hepatocellular carcinoma
	Whole liver—GTV: 3DRT	Classic RILD	Mean dose <42 Gy	<50%	
	Whole liver—GTV: Whole liver or 3DRT	Classic RILD	Mean dose <28 Gy	<5%	In patients with Child-Pugh a preexisting liver disease or hepatocellular carcinoma, excluding hepatitis B reactivation
	Whole liver—GTV: 3DRT	Classic RILD	Mean dose <36 Gy	<50%	
Kidney	Bilateral kidneys (not TBI) Bilateral kidneys or 3DRT	Clinically relevant renal dysfunction	Mean dose <15-18 Gy	<5%	
	Bilateral kidneys (not TBI) Bilateral kidneys	Clinically relevant renal dysfunction	Mean dose <15-18 Gy	<50%

All at standard fractionation (i.e., 1.8 Gy to 2.0 Gy per daily fraction). All data are estimated from the literature summarized in the QUANTEC reviews and in the chapter. Clinically, these data should be applied with caution. Clinicians are strongly advised to use the individual QUANTEC articles to check the applicability of these limits to the clinical situation at hand. They largely do not reflect modern IMRT.

discrete location(s) within the brain, whereas others are spread throughout the brain. Primary toxicity endpoints include frank brain necrosis with associated symptoms or signs and neurocognitive decline.

Dose-Volume Data

Prospective studies in adults have shown that partial (and limited) brain irradiation in the dose range of 50 Gy to 60 Gy, causes minimal to no discernible effect on memory and cognition.[5-10] However, another study has suggested that patients undergoing partial brain radiation for low-grade glioma, versus patients who do not undergo radiation, are at greater risk for neurocognitive deficits, particularly attention, executive functioning, and information processing.[11] More detailed studies, correlating neurocognition with susceptible regions within the brain, are needed. Certainly, ample data suggest that the volume of brain that is irradiated affects the degree of radiation-associated neurocognitive decline (with whole brain radiation faring worse).[12] In adult patients who have received whole brain radiation, neurocognitive decline is well described. However, the degree to which the brain radiation (versus other factors such as surgery, a history of hydrocephalus, other chronic diseases and comorbid illnesses, chemotherapy exposure, and tumor progression) impacts neurocognitive function is not clear.[10,13,14]

There has been growing interest in the hypothesis that minimizing radiation dose to the hippocampal or subventricular zone stem cell niches can reduce the risk of neurocognitive deficits.[15] However, it is not known if there are particular critical individual avoidance structures (or regions) or combination of avoidance structures, nor whether there are well-defined dose-volume thresholds and what these dose-volume limits might be. In a prospective study of 18 patients with low-grade glioma treated at the University of Wisconsin, a dose of >7.3 Gy (in 2 Gy equivalents) to the bilateral hippocampi was significantly associated with impairment in delayed recall, whereas any dose (i.e., dose in excess of 0 Gy) trended toward significance.[16] In the RTOG 0933 Phase II study of hippocampal sparing (100% dose and maximum dose to not exceed 10 Gy and 17 Gy, respectively) in 113 patients with brain metastases, memory preservation at 4 and 6 months (measured by the Hopkins Verbal Learning Test Delayed Recall) was significantly better than historical controls.[17] In a study of 75 patients with pituitary adenoma, 30 of whom had undergone 3-5 field pituitary irradiation to a dose of 45 Gy, neither hippocampal dose nor prefrontal cortex dose correlated with cognitive outcomes.[18]

A prospective study of pediatric patients correlated hippocampal, temporal, and cerebral doses with objective neurocognitive measures.[19] For children, younger age at radiation and larger irradiated volumes (with higher doses having a greater impact) are associated with objectively worse neurocognitive function.[20-23] For example, central nervous system prophylaxis for acute lymphoblastic leukemia with 24 Gy whole brain radiation in addition to intrathecal methotrexate (versus methotrexate alone) resulted in a median 13 point IQ reduction at 5 years postradiation and poorer academic achievement, self-image, and greater psychological distress at 15 years.[24] Lower risks are associated with lower doses of 14 Gy to 18 Gy.[25-27] For medulloblastoma, increasing brain dose in the 18- to 36-Gy range has been correlated with greater neurocognitive decline.[20-22,28,29] Girls were observed to be more vulnerable to injury than boys.[30] Reported toxicities were lower (or not detected) when 14 Gy to 18 Gy was used.[25-27] A recent study has shown that increased dose (from 0 Gy to 24 Gy) and younger age at diagnosis are correlated with worse neurocognitive outcomes that increased with time from diagnosis; furthermore, chemotherapy in the absence of radiotherapy (particularly methotrexate-based chemotherapy), resulted in severe impairment of complex neurocognitive processes, similar to impairment after cranial radiation dose in excess of 18 Gy.[31]

Radiation necrosis can occur in any part of the brain. Although there may be regional variations of susceptibility within the brain related to differences in vascularity, glial cell population, and so on, this data is sparse, and it is generally believed that location does not generally affect susceptibility to necrosis. However, certain regions, such as the brainstem, are more likely to cause symptoms. There is a paucity of data correlating dose-volume parameters with the risk of radiation necrosis with conventional fraction, though many studies have documented an association of fraction size with the risk of necrosis.

In a study from Queen Elizabeth Hospital in China, 1008 patients with nasopharyngeal cancer, treated prior to 1985, received 45.6 Gy to 53.2 Gy in 3.8 Gy fractions, 50.4 Gy in 4.2 Gy fractions or 60 Gy in 2.5 Gy fractions.[32] The 10-year risk of temporal lobe necrosis was 18.6% in those treated with 4.2 Gy fractions versus <5% for the other dose schemes ($p < 0.001$). A multiinstitutional Chinese study examined 1032 patients with nasopharyngeal cancer treated after 1990 with one of several fractionation schemes (mostly 2 Gy to 3.5 Gy fractions, though one scheme used a 1.6 Gy twice-daily component).[33] The 5-year actuarial incidence of necrosis ranged from 0% (after 66 Gy in 2 Gy fractions) to 14% (after 2.5 Gy × 8 followed by 1.6 Gy twice daily to 71.2 Gy). In both of the aforementioned studies, the product of total dose and dose per fraction significantly impacted risk; shorter overall treatment time and twice-daily fractionation also increased risk. A Chinese study comparing 71.2 Gy in 1.6 Gy twice-daily fractions versus 60 Gy in 2.5 Gy fractions was terminated early because of excessive neurologic toxicity, including temporal lobe toxicity, in both arms. The risk of toxicity was greater, and the interval to developing toxicity was shorter, with the twice-daily regimen.[34] In another Chinese study, 27% of patients receiving an accelerated hyperfractionated regimen (64 Gy in 1.6 twice-daily fractions) versus 0% receiving hyperfractionated radiation (70.8 Gy in 1.2 Gy twice-daily fractions) developed symptomatic radiation necrosis.[35]

Radiation necrosis has also been studied in patients with primary brain tumors. The risk is dose dependent, with doses of <50 Gy rarely causing necrosis.[36-38] In patients treated for brain metastases, there was a low (<2%) risk of necrosis developing after 1.6 Gy twice daily to the whole brain (32 Gy) followed by a boost to 54.4 to 74.4 Gy, and no necrosis was seen after a boost to 48 Gy.[39,40]

Summary and Other Key Points from QUANTEC Review[41]

A high level of evidence to quantify the risks of radiation-induced brain injury is lacking. For brain necrosis, the brain appears to be especially sensitive to fraction size in excess of 2 Gy, and to twice-daily fractionated treatment. Symptomatic necrosis is uncommon with doses <60 Gy with conventional (1.8 Gy to 2 Gy) fractionation, though the risk increases with increasing dose (see Table 14-1). More detailed studies correlating neurocognition with susceptible regions within the brain are needed. Long-term (>5 years) follow-up is necessary to best assess neurological and cognitive decline. For children, younger age and higher whole brain dose strongly correlate with cognitive decline. Future studies should provide a clear definition of toxicity and report actuarial (as opposed to crude) rates that can be correlated with detailed normal brain dose-volume metrics.

NERVOUS SYSTEM: BRAINSTEM

Organ Function and Clinical Significance

The brainstem serves as a conduit from the brain to the cranial nerves and spinal cord. As a result, the brainstem is involved with motor, sensory, and special sensory function, as well as regulation of temperature, cardiac function, respiratory function, and consciousness. It is well accepted that the entire brainstem may be treated to 54 Gy using conventional fractionation with minimal risk of late brainstem toxicity. Small volumes of brainstem may tolerate higher doses. Similar to the brain, the brainstem is heterogeneous, and it is not well known which regions are most susceptible to radiation-induced damage.

Dose-Volume Data

Several institutions have published their dose-volume constraints for brainstem, most of which have not reported any brainstem toxicity. These constraints for patients undergoing external beam radiation therapy for head and neck cancers include V60 <5 mL, V65 3 mL,[42] V55 <0.1 mL,[43] D1 <54 Gy,[44] and maximum <50 Gy[45]; for patients undergoing proton or combined proton/photon therapy for base of skull lesions the constraints include: <63 Gy to 64 Gy CGE to the brainstem surface and 53 to 54 CGE to the brainstem center.[46-49]

Some patients in these studies received a maximum brainstem dose of 66 CGE to 68 CGE (greater than the recommended constraints) to adequately treat the tumor.[46,48,49] In one study, the dose constraint of 63 CGE to the brainstem surface and 54 CGE to the brainstem center was "relaxed" in 38% and 17% of patients, respectively, with no reported neurologic toxicity. In these patients, the volume receiving more than the threshold dose was 0.2 mL and 1.2 mL for the brainstem surface and center, respectively.[48] In another study, two of four patients developing neurologic toxicity received brainstem maximal doses in excess of 64 Gy CGE to the surface and 53 CGE to the center.[49]

In an analysis of 367 patients from Massachusetts General Hospital, an increased risk of late toxicity was associated with the maximal delivered dose (>64 CGE), V50 (>5.9 mL), V55 (>2.7 mL), V60 (>0.9 mL), history of diabetes, hypertension, and more than two surgical procedures of the base of skull, on univariate analysis.[50,51] On multivariate analysis, only V60, history of diabetes and more than two surgical procedures remained significant. A V60 <0.9 mL compared to >0.9 mL resulted in toxicity-free survival of 96% compared to 79% (p = 0.0001), and on multivariate analysis resulted in an 11.4 risk ratio (p = 0.001). In a study from St. Jude Children's Research Hospital on 68 patients with infratentorial ependymoma, several interrelated variables were associated with brainstem injury, including tumor volume (and thus radiation volume), surgical morbidity, male gender, younger patient age, and cerebral spinal fluid shunting. The radiation dose was homogeneous between 54 Gy and 59.4 Gy.[52]

In a study of 40 patients undergoing IMRT for meningioma, one patient developed fatal brainstem necrosis after receiving a maximum dose to the brainstem of 55.6 Gy, with 4.74 mL exceeding 54 Gy.[53] This demonstrates that other poorly understood factors likely increase the risk of brainstem toxicity because this dose constraint would be considered acceptable in most of the studies referenced previously.

Summary and Other Key Points from QUANTEC Review[54]

Investigating radiation-induced brainstem injury is challenging because of the low incidence of toxicity with conventional doses, the short survival of patients, and the challenges of distinguishing between tumor progression and toxicity. Whole brainstem doses <54 Gy appear to be safe. Small volumes of brainstem appear to tolerate doses in excess of 55 Gy to 60 Gy. The risk of brainstem necrosis is low if the volume receiving >60 Gy is <0.9 mL.

NERVOUS SYSTEM: SPINAL CORD

Organ Function and Clinical Significance

The spinal cord consists of the motor and sensory tracts, communicating information between the peripheral nerves and the brain. Radiation-induced spinal cord injury can result in pain, paresthesias, sensory deficits, paralysis, Brown-Séquard syndrome, and bowel/bladder incontinence.

Dose-Volume Data

It is well accepted that the spinal cord can tolerate 45 Gy to 50 Gy with conventional fractionation, though the dose resulting in 5% toxicity risks (TD5) is most likely much higher. The spinal cord is generally limited to 45 Gy to 50 Gy because the anticipated risk of cord injury must be low to be clinically acceptable. In an analysis of several studies, Schultheiss calculated the probability of cervical cord myelopathy, after full cross-sectional irradiation, as 0.03% after 45 Gy, 0.2% after 50 Gy, and 5% after 59.3 Gy.[55] The thoracic spinal cord was calculated to be less sensitive than the cervical spinal cord (though because of the dispersion of data, a good fit could not be obtained). This model does not incorporate spinal cord volume, which might be acceptable given the "series" nature of the cord. Nevertheless, Schultheiss cautions that long lengths of cord, concomitant chemotherapy, and other factors may increase risk.

Little data exists exploring the dose-volume tolerance of the spinal cord. No spinal cord toxicity was reported in a study in which the V50 was <0.1 mL,[43] or in another study in which the D1 <45 Gy.[44] Massachusetts General Hospital studied 85 patients treated to the cervical spinal cord in the range of 45 Gy to 59.4 Gy (1.5 Gy equivalent fractions) equivalent uniform dose (EUD), 42 Gy to 57.5 Gy maximal dose to cord center, and 57 Gy to 74 Gy maximal dose to cord surface.[56] Fifteen percent of these patients experienced L'hermitte syndrome (self-limited symptoms of electric shocklike sensation most notable with neck flexion, attributable to focal demyelination) and 5% developed objective neurologic findings at or below cord level treated. Toxicity was not significantly correlated with cord length, cord volume, maximal dose to cord center, maximal dose to cord surface or effective uniform dose. The authors conclude that an EUD to the cervical cord of 60 Gy in 1.5 Gy fractions or 52.5 Gy in 2 Gy fractions is safe. In a recent study of 437 patients with laryngeal or oropharyngeal carcinoma (with maximum spinal cord dose of 22 Gy to 69 Gy) none developed myelopathy (at a median follow-up 27 months) whereas 17 developed L'hermitte's sign; the average spinal cord V45 of these 17 patients was 14 mL compared to 8 mL for those without L'hermitte's sign.[57] It has been postulated that the dose to the spinothalamic tract is most clinically significant for the occurrence of L'hermitte's sign.[58]

Summary and Other Key Points from QUANTEC Review[59]

There is not yet a consensus on the best approach to delineating the spinal cord, with options including delineating the entire thecal sac, the spinal canal, the spinal cord (as seen on magnetic resonance imaging [MRI]) or the spinal cord plus a

several millimeter margin. Though rare, radiation-induced spinal cord injury can be clinically devastating. With conventional fractionation of 1.8 Gy to 2.0 Gy per fraction to the full thickness of the spinal cord, the estimated risk of spinal cord myelopathy is <1%, <10%, and 50% at 54 Gy, 61 Gy, and 69 Gy, respectively. Although there is limited data on high dose per fraction using conventional radiation techniques, the estimated α/β ratio of 0.87 suggests a strong dependence of spinal cord toxicity on dose/fraction. Small volumes of spinal cord can likely receive doses in excess of 55 Gy to 60 Gy (with the high doses limited to the surface) with low risk of toxicity, though long-term data are lacking to derive a dose/volume relationship for myelopathy risk. Thus, recommendations for safe dose-volume metrics above 55 Gy to 60 Gy are lacking.

NERVOUS SYSTEM: OPTIC NERVES AND CHIASM

Organ Function and Clinical Significance

The optic nerve and chiasm serve as the neural conduit connecting the retinal fibers to the optic tracts, which, via the lateral geniculate body, terminate in the visual cortex. It is generally accepted that the entire optic nerves and chiasm may be treated to 54 Gy using conventional fractionation with minimal risk of late visual toxicity, though lower doses can result in other ophthalmologic toxicity.[60] A classic study showed that among patients treated to the same dose for pituitary adenomas or craniopharyngiomas, those who developed optic neuropathy (5 to 34 months after radiation) had received ≥2.5 Gy per fraction.[61] In a study from M. D. Anderson Cancer Center (MDACC), in which 219 patients were treated in the pre-3D radiation era, 10-year actuarial rates of optic neuropathy were 0%, 3%, and 34% for 43 Gy to 49 Gy at ~1.9 Gy/fraction, 50 Gy to 60 Gy at ~2.1 Gy/fraction, and 61 Gy to 76 Gy at ~2.2 Gy/fraction, respectively. Chiasm damage was similar with rates of 0%, 8%, and 24% for 15 Gy to 49 Gy at ~1.5 Gy/fraction, 50 Gy to 60 Gy at ~2.0 Gy/fraction, and 61 Gy to 76 Gy at ~2.1 Gy/fraction, respectively.[62] Greater total dose as well as larger fraction size impact risk.[63-66] With 3D planning, small volumes of optic nerve and chiasm may tolerate higher doses.

Dose-Volume Data

Several institutions have published their dose-volume constraints for the optic nerves and chiasm, most of which have not reported any neurologic visual toxicity. These constraints for patients undergoing external beam radiation therapy for head and neck cancers include V55 <0.1 mL of optic nerves/chiasm,[43] D1 <54 Gy for optic nerves, and D1 <45 Gy for optic chiasm[44] and maximum <54 Gy to the optic nerves and 52 Gy for the chiasm. These dose constraints are more conservative compared to what has been reported with proton therapy for base-of-skull tumors; base-of-skull tumors may be in close proximity to the optic apparatus, and tumors such as chordomas and chondrosarcomas are prescribed relatively high doses. For patients undergoing proton or combined proton/photon therapy for base-of-skull lesions, published dose constraints include <55 CGE to 56 GGE[47-49] or <60 Gy CGE[46] to optic nerves and optic chiasm.

Several studied have reported ophthalmologic toxicity after radiation. In a study from the University of Florida, the optic nerve dose (defined as the minimum dose delivered to one third of the optic nerve) in patients who developed optic neuropathy was 50.4 Gy to 79 Gy (median 68 Gy).[66] In a University of Michigan study, seven patients developed ophthalmologic toxicity: one patient received a chiasm maximum of 59.5 Gy; six patients received an optic nerve maximum of 47.5 Gy to 75.5 Gy (average 63 Gy).[67] Moderate to severe optic nerve complications (four patients) were associated with doses >64 Gy. In one study, four patients developed ophthalmologic toxicity, of whom three received a maximal dose of 56 CGE to 62 CGE to the optic chiasm/nerves and one received a maximum dose of >62 CGE. In two studies, bilateral visual loss occurred, with no evidence of tumor progression, ~8 months after conventional radiation; in one, the prescribed target dose was 49.3 Gy (maximum dose 56.1 Gy; chiasm maximum not reported, but <1 mL received >45 Gy)[68]; and in the other the chiasm maximum was <58 CGE.[47]

Some patients appear to tolerate a maximum optic nerve or chiasm dose of >60 Gy or >63 CGE to 69 CGE.[45,46,48,49,67] This demonstrates that other poorly understood factors likely increase the risk of optic nerve and chiasm toxicity. Optic nerve maxima >80 Gy and chiasm maxima >70 Gy were tolerated in some patients in the University of Michigan study discussed previously.[67] In another study, the dose constraint of 56 CGE to the optic nerve and chiasm was "relaxed" in 28% and 48% of patients, respectively, with no reported visual toxicity. In these patients, the volume receiving above the threshold dose was 0.11 mL and 0.12 mL for the optic nerves and chiasm, respectively; the volume receiving >105% of the threshold dose was 0.05 mL and 0.01 mL.[48]

Summary and Other Key Points from QUANTEC Review[69]

Data clearly show that the total dose and fraction size are the most important treatment-related risk factors for optic nerve/chiasm injury. There are scarce data to suggest a dose-volume effect on the optic nerve and chiasm. The risk of visual problems is <3% with <55 Gy, 3% to 7% for 55 Gy to 60 Gy, and >7% for >60 Gy. In the 55 Gy to 60 Gy experience, almost all of the reported cases of optic nerve injury received doses in the 59- to 60-Gy range (i.e., the high edge of that dose range).

NERVOUS SYSTEM: HEARING

Organ Function and Clinical Significance

The cochlea and acoustic nerve are the essential auditory structures that are susceptible to radiation injury and consequential sensory neural hearing loss. These are small structures, and therefore dose-volume measures are less determinable and clinically relevant. Other dose-dependent susceptible parts of the auditory system include the external ear and ear canal, tympanic membrane, ossicles, and eustachian tube.[70] Platinum based chemotherapy also is a well-established cause of sensory-neural hearing loss. Other factors such as baseline function and patient age are also relevant.

Dose-Volume Data

Several studies suggest that the dose to the cochlea correlates with the rate of sensory-neural hearing loss. A study from University of Florida showed that incidence of sensory-neural hearing loss increased consistently with dose to the cochlea; the 10-year actuarial risk of sensory neural hearing loss was 3% at doses <60.5 Gy compared to 37% at doses >60.5 Gy.[70]

Several other studies have shown hearing loss to be directly related to the inner-ear dose,[71-76] with sensory neural hearing loss becoming more apparent at doses >45 Gy to 50 Gy.[72,74,75,77] A German study examined hearing loss during and after radiotherapy for patients with head and neck cancers; for bone and air conduction after radiation, a 15-dB reduction in 50% of

patients over a range of frequencies was in the 20-Gy to 30-Gy range of doses to the inner ear (which ranged from 1.7 Gy to 64.3 Gy).[76] Cisplatin dose is also relevant to the threshold for auditory impairment. Cisplatin doses as low as 270 mg/m^2 can result in hearing loss when combined with cranial radiotherapy dosages of 40 Gy to 50 Gy.[78] In one study of patients with head and neck cancers, in those treated with radiation alone, hearing loss developed with cochlear doses >40 Gy; however, among those who received cisplatin (100 or 40 mg/m^2) and radiation, hearing loss developed with cochlear doses >10 Gy,[79] although the risk is likely low below doses of 30 Gy. The sequence of chemoradiotherapy also appears to influence risk. Risk and severity of ototoxicity are greater when cisplatin is administered after cranial radiation.

In a recent study of patients with base-of-skull tumors treated with radiation (median 50.4 Gy) radiographic opacification of the middle ear or mastoid, which correlates with subacute/chronic otitis media with effusion, occurred in 40 of 61 patients (with median follow-up of 21 months); this resolved in 17 of 40 patients 2 to 45 months (mean 17) after radiation.[80] Dose-volume analyses were performed for the eustachian canal, middle ear, mastoid air cells, vestibular apparatus, cochlea, internal auditory canal, lateral and posterior nasopharynx, and temporal lobes. Multivariate analysis showed that mastoid dose >30 Gy (odds ratio = 28.0, $p < 0.001$) and posterior nasopharynx dose >30 Gy (odds ratio = 4.9, $p = 0.009$) were associated with Grades 2 to 3 middle ear effusions.

Summary and Other Key Points from QUANTEC Review[81]

Because of the small volume of the cochlea, quantifying mean dose to the cochlea is more feasible than a dose/volume measure. Based on available data, the cochlear mean dose should be limited to ≤45 Gy (or more conservatively ≤30 Gy) and should be more strictly limited when delivered with cisplatin chemotherapy.

SALIVARY GLANDS

Organ Function and Clinical Significance

The salivary glands produce saliva, which aids in the swallowing, lubricating the oral cavity, taste, and food digestion. The parotid glands generate ~60% of saliva, and the majority of serous saliva, with the remainder of saliva secreted by submandibular, sublingual, and minor salivary glands. Radiation-induced salivary gland dysfunction—xerostomia—can result in difficulty swallowing, altered taste, and an increased risk of dental caries and oral infections. Because of the proximity of the parotid glands to the Level II lymphatics, IMRT is often used in the treatment of patients with head and neck cancers to reduce the parotid dose, in an attempt to prevent xerostomia.

Dose-Volume Data

The University of Michigan has published several studies investigating radiation dose-volume effects on serially measured stimulated and unstimulated salivary flow (directly from a given parotid gland). With salivary flow measured up to 12 months after radiation, significant parotid sparing was observed after a mean parotid dose below 24 Gy (for unstimulated flow) to 26 Gy (for stimulated flow).[82-84] Mean doses correlated with V15 of ≤67%, V30 of ≤45%, and V45 of ≤24%. The TD50 was 28.4 Gy.

Investigators at Washington University also examined whole salivary flow. Their technique differed from that from the University of Michigan in that they measured flow from all glands, though they included only patients whose submandibular glands received >50 Gy in an attempt to minimize this confounding variable.[85,86] Salivary flow was noted to be exponentially reduced by ~0.054/Gy of mean parotid dose (i.e., $e^{(-0.054^* \text{ mean dose})}$), equating to a reduction to 25% of the pr-treatment salivary flow with a mean dose of 25.8 Gy, essentially equivalent to the University of Michigan number.[87] The mean dose model was more predictive of the risk of late effects than threshold dose levels of V5 to V70 as well as other models studied.

Other groups have corroborated the mean dose as significant variable impacting salivary function,[88-93] with a Belgian study suggesting a lower threshold mean dose of 22.5 Gy.[94] A Dutch group demonstrated the TD50 for stimulated salivary function (risk of <25% of pretreatment rates) to improve with time, with TD50s of 34 Gy at 6 weeks to 40 Gy at 6 months, 42 Gy at 12 months, and 46 Gy at 5 years.[95,96] In a University of Michigan study, with flow rates measured in 142 patients up to 24 months after radiation, salivary flow rate was modeled as a function of time.[97] With mean parotid doses <25 Gy, the model predicted salivary function recovery to pretreatment functioning at 12 months. For mean parotid doses >30 Gy, stimulated saliva did not return to pretreatment functioning after 2 years.

In the parotid-sparing intensity modulated versus conventional radiotherapy in head and neck cancer (PARSPORT) trial, 94 patients with T1-4N0-3M0 pharyngeal squamous cell carcinoma were randomized (of whom 73 were evaluable for xerostomia).[98] IMRT compared to conventional radiotherapy allowed significant lowering of the ipsilateral (mean 25.4 Gy versus 61.0 Gy) and contralateral (mean, 47.6 Gy versus 61.0 Gy) parotid dose and resulted in a significantly lower incidence of xerostomia and greater recovery of salivary function 1 and 2 years after therapy. Randomized studies of IMRT in patients with nasopharyngeal cancer have shown similar findings.[99,100] In a recent study of 126 patients from Germany, restraining the mean dose to both parotids <26 Gy (versus only one) significantly reduced xerostomia and dysphagia.[101]

Radiation dose to the submandibular glands also impacts salivary function.[102] In a study from Helsinki University, the mean unstimulated salivary flow was 60% of the pretreatment function among patients who had one submandibular gland spared (mean dose of 26 Gy and range from 21 to 34 Gy) and 25% among those who did not ($p = 0.006$).[103] However, sparing of a submandibular gland did not affect the *stimulated* saliva flow rates. Another study showed that intentional sparing of submandibular glands (average mean dose of 20.4 Gy and V30 of 14.7%) versus no submandibular gland sparing (average mean dose 57.4 Gy and V30 99.8%), resulted in a nonsignificant trend toward better recovery of salivary flow.[104] Investigators at Vrije University in Amsterdam have demonstrated that mean submandibular dose is a significant variable impacting the sensation of sticky saliva.[105] In addition to submandibular dose and parotid gland dose, the University of Michigan group showed that oral cavity dose (containing the minor salivary glands) is also predictive; although no well-defined thresholds were observed, an oral cavity mean dose of <40 Gy was associated with low xerostomia rates.[106] The Radiation Therapy Oncology Group (RTOG) has demonstrated the feasibility and efficacy of surgically transferring the submandibular salivary gland to the submental space and shielding (>70%) of this gland during radiation to mitigate xerostomia.[107]

NTCP modeling of 178 patients treated with IMRT showed that baseline salivary function and mean contralateral parotid gland dose were predictors for xerostomia, and that mean contralateral submandibular gland dose, mean sublingual dose, and mean dose to minor salivary glands in the soft palate were predictive for sticky saliva.[108,109]

Summary and Other Key Points from QUANTEC Review[110]

Several studies have nicely demonstrated a dose response relationship between the salivary flow and mean parotid dose. From the available data, it appears that severe long-term salivary dysfunction (generally defined as reduction of salivary flow to less than 25% of baseline) can be avoided if one parotid gland is spared to a dose of less than 20 Gy or if both parotid glands have a mean dose of less than 25 Gy. A recent clinical study confirmed that adherence to these guidelines effectively avoids xerostomia.[111] Much of the data on submandibular gland and minor salivary gland dose-volume effects discussed previously were published in recent years, after QUANTEC was published.

LARYNX AND PHARYNX

Organ Function and Clinical Significance

The larynx and pharynx are involved with phonation and swallowing, respectively. Late complications include laryngeal edema and fibrosis, laryngeal dysfunction, dysphagia, and necrosis. A study from University of Michigan showed that damage to the pharyngeal constrictors and the glottic and supraglottic larynx may cause dysphagia and aspiration after chemoradiation.[112]

Dose-Volume Data: Larynx

For laryngeal edema, in a study from University of Texas, Galveston (with most patients receiving radiation alone), the mean laryngeal dose and laryngeal V30 to V70 were significantly associated with grade ≥2 edema with a univariate analysis, whereas mean laryngeal dose and N stage were significant with multivariate analysis.[113] V50, which was highly correlated with mean laryngeal dose, was significant in a multivariate analysis in which mean laryngeal dose was replaced by V50. The 1-year rate of grade ≥2 edema was 20% after a mean laryngeal dose of 43.5 Gy (or V50 <27%) versus 45% after a mean dose of 44 Gy to 57 Gy (or 94%< V50 >27%) versus >80% after a mean dose >57 Gy (or V50 >94%).

There is a paucity of data correlating dose-volume metrics with vocal dysfunction. Generally, after therapeutic doses of 60 Gy to 66 Gy for early stage glottic cancer, the risks of vocal dysfunction are low. In a study from University of Iowa, point doses in excess of 66 Gy to the aryepiglottic folds, preepiglottic space, false vocal cords, and lateral pharyngeal walls resulted in a sharp increase in risk of vocal function.[114]

Summary and Other Key Points from QUANTEC Review[115]

Radiation-induced laryngeal edema is a common and expected side effect. Progressive edema and associated fibrosis[116] can lead to long-term problems with phonation as well as swallowing. Tumor infiltration, particularly with locally advanced cancers can cause voice and swallowing symptoms, and may exacerbate radiation toxicities. To minimize risks of laryngeal edema, a larynx V50 ≥27% and the mean laryngeal dose of ≤44 Gy are recommended.

Dose-Volume Data: Swallowing

Several studies have investigated dose-volume metrics predictive of swallowing dysfunction, with many studies published after the QUANTEC report. In a study from University of Michigan, mean dose to the pharyngeal constrictors was correlated to risk of aspiration.[117] The risk of aspiration increased with a mean dose of >60 Gy to the pharyngeal constrictors, and with a V40 >90%, V50 >80%, V60 >70%, and V65 >50%, and with a V50 >50% for the larynx. Three patients who developed strictures had a pharyngeal constrictor V70 >50%.

In a study from Aarhus University, several significant correlations were found between both subjective and objective swallowing problems and DVH parameters of the base of tongue, pharyngeal constrictors, supraglottic larynx, esophageal sphincter, and glottic larynx.[118] Doses less than 60 Gy to the supraglottic region, the larynx, and upper esophageal sphincter resulted in a low risk of swallowing difficulties and aspiration.

In a study from University of Iowa, point doses to the false vocal cords, lateral pharyngeal walls, and the upper esophageal sphincter were correlated with dietary difficulties.[114] As an example, the dose to the left lower pharyngeal wall for patients who had no oral intake 1 year after treatment was 79.7 Gy versus 65.1 Gy for those with an unrestricted diet. A greater radiation dose to the aryepiglottic folds was associated with greater weight loss and a great radiation dose to the false vocal cords was associated with gastrostomy tube use.

In a study from Rotterdam, doses >50 Gy to the middle and superior pharyngeal constrictors resulted in a 20% probability of dysphagia, with an incremental 19% risk for each additional 10 Gy.[119] Another study (of 39 patients) suggested that the dose (V60 to V65 and mean) to the inferior pharyngeal constrictors is most predictive of gastrostomy tube dependence,[120] whereas in two other studies (of 50 and 53 patients),[121,122] the V50 (one study) and mean dose (both studies) of the middle pharyngeal constrictors were most predictive of dysphagia, along with mean supraglottic larynx dose (one study).[122] In an analysis of 96 patients from the Dana-Farber Cancer Institute, the inferior pharyngeal constrictor V50 and larynx V50 were significantly associated with aspiration and stricture risk.[123] MDACC investigators recommended a V30 <65% and V35 <35% for anterior oral cavity and V55 <80% and V65 <30% for superior pharyngeal constrictors, which was predictive for swallowing dysfunction in 31 patients.[124] University of Alabama at Birmingham investigators recommended V60 <24% to the larynx and <12% to the inferior pharyngeal constrictors to reduce risk of aspiration and gastrostomy tube dependence, and V65 <75% to the middle pharyngeal constrictors, and <33% to the superior pharyngeal constrictor to reduce risk of stricture requiring dilation.[125] In a Nordic study of 354 patients,[126] mean dose to the superior pharyngeal constrictor and supraglottic larynx were most predictive of radiation-induced swallowing dysfunction; different models (resulting in different significant dosimetric variables) were developed specifically for dysphagia to liquids, soft foods, or solids.

A recent analysis, based upon 53 of 189 patients who developed grade ≥3 dysphagia, designed a predictive model by analyzing clinicopathologic, treatment, and dosimetric parameters (dose to pharyngeal constrictor and esophageal structures) as well as genetic polymorphisms; the best model incorporated concurrent chemotherapy, dose to 2% of the pharyngeal constrictors and an XRCC1 polymorphism.[127]

Summary and Other Key Points from QUANTEC Review[115]

Because swallowing is complex, involving voluntary and involuntary stages coordinated through several cranial nerves and muscles, defining the most important anatomic structures whose dose-volume parameters have a major impact on dysphagia has been challenging. Emerging data has demonstrated

significant correlations between pharyngeal constrictor doses and dysphagia. With limited available data, it is recommended to limit the volume (to the extent possible without compromising target coverage) of the pharyngeal constrictors and larynx receiving ≥60 Gy, and reducing when possible the volume receiving ≥50 Gy. From data published after the QUANTEC review, it is readily apparent that mean dose and dose in excess of 50 Gy to 60 Gy to the larynx and pharyngeal constrictor muscles are predictive of swallowing difficulties, though it is unclear which of the pharyngeal constrictor muscles and which component(s) of the larynx are most critical.

LUNG

Organ Function and Clinical Significance

The lung's main function is gas exchange of oxygen and carbon dioxide. Radiation damage to the lung can result in symptomatic pneumonitis and fibrosis. Symptomatic radiation pneumonitis is characterized by dyspnea, cough, and sometimes a low-grade fever, typically occurring several weeks to months after radiation. More long-term lung fibrosis can lead to respiratory insufficiency. It is often challenging to distinguish radiation-related pulmonary symptoms from comorbid illnesses (e.g., exacerbation of chronic obstructive pulmonary disease, infection, cardiac events).[128] Objective reductions in the lung's ability to move and exchange gas can be measured by formal pulmonary function tests (PFTs).

Recent meta-analyses have shown that patient-related adverse risk factors for radiation pneumonitis among patients with non–small-cell lung cancer include older age,[129,130] history of chronic lung disease or diabetes,[131] and low preradiotherapy lung function.[131] Smoking was an adverse risk factor in one meta-analysis,[131] whereas not being an active or prior smoker[129] was an adverse risk factor in another, a discrepancy that is attributed to the complexity of the relationship between smoking, chronic lung disease, and pneumonitis.[131] Chemotherapy concurrent with radiation therapy,[131] particularly carboplatin/paclitaxel chemotherapy,[130] has been reported to increase the pneumonitis risk.

Cytokines appear to play a role (at least perhaps as a marker and maybe as a mediator) in the development of clinical radiation pneumonitis. Seminal work implicates transforming growth factor beta (TGF-β).[132,133] A powerful association between native circulating IL-1 and IL-6 levels and radiation pneumonitis have been reported from the University of Rochester.[134] A French study has also shown a correlation between circulating levels of IL-10 and IL-6 and the development of radiation pneumonitis.[135] Nevertheless, the literature reports in this area are not totally consistent. Cytokines may not be important for pulmonary fibrosis.[136] More recent data have also demonstrated pneumonitis risks correlated with polymorphisms of DNA repair[137-139] and TGF-β[140] genes correlating with pneumonitis risks. Positron emission tomography (PET) avidity of lung tissue after radiation has also been correlated with pneumonitis risk.[141]

Dose-Volume Data: Pneumonitis and Fibrosis

Several dosimetric parameters have been shown to be associated with the risk of radiation pneumonitis, including V5 to V70, mean lung dose (MLD), and model-based parameters.[142-146] These variables are correlated with each other, accounting for the fact that in most studies examining a range of *Vx* variables, many/most are significant.[147-161] The dosimetric parameters predictive of pneumonitis can also be used to predict fibrosis risks.[136] How normal lung is defined (i.e., lung minus gross target volume [GTV] or PTV) will affect the magnitude of the calculated dose-volume metrics.[162]

Table 14-2 summarizes many of the studies discussed here. Most of the published dose-volume data describes pneumonitis risks in patients with lung cancer, though data also exist for patients with breast cancer[150,163,164] and Hodgkin lymphoma.[165,166] In patients with Hodgkin lymphoma, pneumonitis risks appear to be lower for given dose-volume metrics that may relate to the younger age of this patient population.

An NTCP analysis from the Netherlands, in collaboration with the University of Michigan, suggests that using the MLD (linear function) is more predictive than using VX (step function).[150] However, V13 tended to be more predictive in situations where the MLD exceeded 20 Gy or V13 exceeded 50%. The TD50 values in this study were MLD of 30.8 Gy, V13 of >77%, and V20 of >65%, similar to the MLD of 31.8 Gy reported in a previous multiinstitutional study.[167] From an NTCP analysis from the Memorial Sloan Kettering Cancer Center (MSKCC),[148] a mean lung dose of ~26 Gy, V13 of >80% to ipsilateral lung, or V40 of >32% to lower lung results in a 50% risk of developing late complications. A mean lung dose of ~12 Gy or a V13 of >40% to ipsilateral lung results in a 5% late complication risk. A V13 of 36% of the lower lung, 42% of the total lung, or 62% of the ipsilateral lung results in a 20% risk of developing late grade ≥3 complications.

In a 1997 study from MSKCC, of patients treated with radiation alone, there was a significantly increased risk of grade ≥3 pulmonary toxicity, 38% with a V25 of >30% compared to 4% with a V25 of <30% ($p = 0.04$).[168] In subsequent studies from this same group, significant variables for predicting grade ≥3 pulmonary toxicity included mean lung dose, the range of V5 to V40 of total lung, V5 to V40 of ipsilateral lung, and V5 to V50 of lower lung.[148,153] The range of V5 to V20 ipsilateral lung was most predictive.

Investigators at Washington University also showed that the risk of pneumonitis significantly correlated with the V20; the 2-year incidence of grade ≥2 radiation was 36% versus 13% versus 7% versus 0% with a V20 of >40%, 32% to 40%, 22% to 31%, and <22% ($p = 0.0013$), respectively.[142] In another study from Washington University, radiation pneumonitis was significantly correlated with V5 to V80, with peak significance in the V5 to V15 and V70 to 75 ranges; radiation pneumonitis was also significantly correlated with the dose delivered to 5% to 100% of the lung (D5-100), with peak significance in the D30 to D40 and V90 to V95 ranges.[156]

In a 2001 study from Duke (in which 18% of patients received concurrent chemoradiotherapy) a V30 of >18% versus <18% was associated with a risk of grade ≥1 radiation pneumonitis of 24% versus 6% ($p = 0.0003$).[147] MLDs of <10 Gy, 10 Gy to 20 Gy, 21 Gy to 30 Gy, and >30 Gy were associated with risks of 10%, 16%, 27%, and 44%, respectively. A Japanese study of patients treated with platinum-based chemoradiotherapy found a 6-month risk of grade ≥2 radiation pneumonitis to be 85%, 51%, 18.3%, and 8.7% ($p < 0.0001$) with a V20 of ≥31%, 26% to 30%, 21% to 25%, and ≤20%, respectively.[169] In a University of Michigan study, a 10% risk for grade ≥2 pneumonitis and fibrosis was associated with a V20 >30% and an MLD >20 Gy. These thresholds provided a positive predictive value of 50% to 71% and a negative predictive value of 85% to 89%.[170] In a study from MDACC, the mean lung dose and V5 V65 were highly correlated with risk of pneumonitis, and V5 was the most significant factor in a multivariate analysis.[155] For a V5 ≤42% versus >42%, the risk of grade ≥3 pneumonitis at 1-year was 3% versus 38% ($p = 0.001$). In a Mayo Clinic study, V10 to V13 were most predictive of radiation pneumonitis; a V10 of 32% to 43%, V13 = 29% to 39%, V15 = 27% to 34%, and V20 of 21% to 31% resulted in a 10% to 20% risk of pneumonitis.[160] From a recent meta-analysis of 836

patients, lung V20 of <20%, 20 to <30%, 30 to <40%, and >40% were associated with symptomatic pneumonitis risks of 18.4%, 30.3%, 32.6%, and 35.9%, respectively, and fatal pneumonitis risks of 0%, 1.0%, 2.9%, and 3.5%, respectively.[130]

Several dose escalation studies have used V20, V_{eff} or NTCP to allocate patients into given dose levels.[171-174] In the RTOG 93-11 dose escalation study, patients with a V20 of <25% experienced a 7% to 16% 18-month actuarial rate of grade ≥3 late lung toxicity with prescribed doses of 70.9 Gy to 90.3 Gy; the absolute risk of grade ≥2 late lung toxicity was 30% to 45%, with one fatal lung complication at the 90.3-Gy dose level. Patients with a V20 of 25% to 36% treated to doses of 70.9 Gy to 77.4, Gy experienced 15% grade ≥3 late toxicity at 18 months, and an absolute risk of grade ≥2 late lung toxicity of 40% to 60%.[171] D15 was the most predictive variable for radiation pneumonitis.[159]

In Dutch study, the effect of regional dose on the lung was investigated, with the lung divided into: central and peripheral; ipsilateral and contralateral; caudal and cranial; and anterior and posterior subvolumes.[175] The mean regional dose to the posterior, caudal, ipsilateral, central, and peripheral lung subvolumes significantly correlated with the incidence of steroid-requiring radiation pneumonitis; caudal location was correlated with greater pneumonitis risks, whereas no statistical difference in risks were observed between anterior and posterior locations or central and peripheral locations. In a similar study from MSKCC, the risk of radiation pneumonitis was better correlated with the radiation dose to the inferior aspect of the lung, rather than the superior aspect.[148]

Tumor location in the lower lung also appears to be an adverse factor affecting risk of pneumonitis in patients with lung cancer.[129-131] In the aforementioned study from Washington University,[156] inferior tumor location was the most significant predictor of radiation pneumonitis. Tumor location was not a strong correlate to radiation pneumonitis in a study from patients treated on RTOG 93-11, perhaps attributable, in part, to differences in treatment (with RTOG 93-11 designed to treat smaller volumes to higher doses) and differences in tumor size and location (the RTOG 93-11 tumors tended to be smaller and more superiorly located).[159] Using a combined data set of patients from RTOG 93-11 and Washington University, tumor location, in addition to MLD were significant. In a recent Washington University study of 209 patients, cardiac dose, specifically V65 and D10, was more predictive of radiation pneumonitis than lung dose-volume metrics; the reason is unknown and the authors demonstrate that that heart variables are not simply surrogates for lung variables.[176]

For some patients with advanced stage non–small-cell lung cancer, IMRT yields unique dose distributions, with improved target conformality and increased (albeit modest) target heterogeneity.[177] The IMRT-based dose distributions appear to reduce the risk of normal tissue injury in patients with non–small-cell lung cancer. Investigators at MDACC compared their rates of lung toxicity in patients with treated IMRT versus 3D planning and noted a reduction in toxicity with the IMRT approach.[178] Investigators at MSKCC noted a similarly low rate of clinical lung injury in patients with non–small-cell cancer treated with IMRT.[179] In the MDACC study, a V5 >70% was associated with a 21% risk of grade ≥3 pneumonitis versus a 2% risk with a V5 ≤70% (p = 0.017). Proton therapy also allows for reduction of lung volume receiving a given dose, and data are emerging on its utility.

IMRT has also been used to treat patients with mesothelioma. In a study from Dana Farber, in which patients received thoracic IMRT after pneumonectomy for mesothelioma, 6 of 13 patients developed fatal pneumonitis.[180] The median V20, V5, and MLD for patients who developed pneumonitis was 17.6%, 98.6%, and 15.2 Gy, respectively, versus 10.9%, 90%, and 12.9 Gy for those who did not develop pneumonitis. Although these differences were not significant, the severity of the toxicities merits caution in treating patients to large volumes after a pneumonectomy. In a study from Duke, 1 of 13 patients treated with IMRT for mesothelioma died from pneumonitis, and 2 others developed symptomatic pneumonitis.[181] The median V20, V5, and MLD for patients developed pneumonitis was 2.3%, 92%, and 7.9 Gy, respectively, versus 0.2%, 66%, and 7.5 Gy for those who did not develop pneumonitis, versus 6.9%, 92%, and 11.4 Gy for the patient who developed fatal pneumonitis. In a study of mesothelioma patients from MDACC, 6 of 63 patients died from pulmonary-related causes (including 2 patients with fatal pneumonitis).[182] The V20 was significant on univariate and multivariate analyses (p = 0.017), with a V20 >7% corresponding to a 42-fold increase in the risk of pulmonary death.

Summary and Other Key Points from QUANTEC Review[183]

A variety of studies note a dose-response relationship for a variety of metrics predictive of radiation pneumonitis. The QUANTEC review pooled the data from many centers. This shows that there is no specific threshold for pneumonitis, with risks increasing gradually with increased dose. Because many dose/volume parameters of the lung (i.e., V5 through V30, MLD) are correlated with each other, there likely is not an "optimal" parameter. For patients with non–small-cell lung cancer, it is prudent to limit the V20 to <30% to 35%, and the mean lung dose to <20 Gy to 23 Gy, to limit the risk of pneumonitis to less than 20%. In patients irradiated postpneumonectomy for mesothelioma, it is prudent to limit the V5 <60%, the V20 <4% to 10%, and the mean lung dose to <8 Gy. Radiation-induced pneumonitis appears more commonly in

patients with lower- versus upper-lobe tumors and may be better correlated with radiation doses to the lower versus upper lung. The cause of this correlation is unknown and requires further investigation. Perhaps it is related to differences in ventilation and perfusion of different lung regions.

Dose-Volume Data: Pulmonary Function

The majority of studies have considered shortness of breath as the relevant endpoint. This is what is typically recorded in patient records, and, from the patient's perspective, perhaps the most meaningful endpoint. However, symptoms can be non specific and difficult to quantify. Therefore, investigators have also considered more specific and objective endpoints such changes in PFTs and imaging.

Changes in PFTs following thoracic radiation reflect a combination of improvements because of tumor shrinkage (typically acutely), and declines because radiation-induced injury (both acute and chronic).[184] Several studies have noted long-term declines in PFTs following thoracic radiation,[185-187] although changes can be transient.[188] The association between shortness of breath following radiation and declines in PFTs is complex.[189] Duke University studies have shown a correlation between V30 and NTCP with changes in forced expiratory volume in 1 second (FEV1) and diffusion capacity (DLCO).[190] The University of Michigan investigators, however, did not find any correlation of V20, MLD, or V_{eff} with changes in FEV1 or DLCO.[191] Attempts have been made to model the risk of changes in PFTs,[192,193] though certainly this is a complicated area of study. Recent data from MDACC suggest that severity of pneumonitis is correlated with reduction in DLCO.[194]

Similarly, imaging tests provide clear objective metrics. Several studies have noted an association between regional radiation doses and changes in regional imaging tests (CT-defined density or single-photon emission computed tomography [SPECT]-defined perfusion/ventilation).[195-198] The extent or severity of these imaging changes is related to changes in global lung function (assessed as either symptoms or changes in PFTs), but the correlations are relatively weak.[184,192,193,198]

Summary and Other Key Points from QUANTEC Review[183]

For pulmonary function, it appears that minimizing the V30 minimizes risk of decline in pulmonary function test parameters, though, as is the case with pneumonitis, other dose-volume measures may be predictive as well. The study of radiation-induced lung injury is confounded by the use of ambiguous endpoints, as well as toxic exposures (e.g., smoking) and treatment with chemotherapy (e.g., bleomycin and cisplatinum). Many toxicity scoring systems combine radiologic, functional, and symptomatic criteria in their grading system. However, each pulmonary toxicity endpoint may have different dose/volume dependence, and future studies should be explicit in defining endpoints.

HEART

Organ Function and Clinical Significance

The heart is the muscular organ, located in the left hemithorax (with the rare exception of dextrocardia) which, via continuous rhythmic contraction, pumps blood throughout the blood vessels. The functional and structural complexity of the heart places it at risk for a spectrum of radiation and chemotherapy injuries that can manifest months to years following therapy. All components of the heart and the surrounding pericardium are susceptible to radiation damage. Radiation-induced cardiac injury includes pericarditis, congestive heart failure, restrictive cardiomyopathy, valvular insufficiency and stenosis, coronary artery disease, ischemia, and infraction. A history of anthracycline chemotherapy can exacerbate radiation-elated cardiac toxicity.

Dose-Volume Data

Abundant studies have demonstrated an increased risk of cardiac morbidity following left-sided thoracic radiation versus right-sided thoracic radiation in patients irradiated for breast cancer. It is well accepted that reducing the dose prescribed to the mediastinum and reducing the volume of heart in the radiation field reduces the risk of late toxicity.[199-201] Studies from Duke demonstrated that an increased percentage of the left ventricle irradiated correlates with a greater risk of cardiac perfusion defects.[202-204] Even over the range of low dose exposure (~8 Gy to 20 Gy) to small volumes of the cardiac apex, an increased risk of heart disease has been reported.[205]

A study from Stockholm used normal tissue complication probability modeling to predict the risk of late heart toxicity in women treated for breast cancer.[206] In their models, the TD50 was optimized to a value of 52 Gy to the myocardium. A 5% risk of excess cardiac mortality at 15 years was associated with a myocardial dose of ~30 Gy, a V33 of >60%, V38 of >33%, or a V42 of >20%. Calculations using the whole heart volume (as opposed to myocardium) yielded similar values.

The same group from Stockholm used a similar analysis to assess cardiac risk in patients with Hodgkin disease.[207] Patients were stratified into two risk groups: those with a V38 of >35% and those with a V38 of <35%. The excess mortality risk at 15 years was 7.9% and 4.7%, respectively. The TD50 was calculated to be 70 Gy. A heart dose of 42 Gy resulted in a 5% normal tissue complication probability, whereas a heart dose of 53 Gy resulted in a 10% NTCP. The corresponding values in the patients with breast cancer were 37 Gy and 44 Gy respectively (lower threshold doses and steeper gradient). The differences in complication probabilities and TD50 between the breast and Hodgkin disease cohorts suggest that radiation exposure to different portions of heart results in differences in cardiac risk,[207] though there may be other confounding variables not easily identified (e.g., patient age at treatment, similar risk factors between breast cancer and cardiac disease, etc.)

Mean heart dose to the left ventricle, both ventricles, or whole heart were not predictive for cardiac toxicity in a study of 328 survivors of non–small-cell lung cancer.[208] A Wayne State University study of 102 survivors of esophageal cancer, demonstrated thresholds for symptomatic cardiac toxicity to be heart V20, V30, and V40 above 70%, 65%, and 60%, respectively.[209]

A recent landmark Swedish/Danish study analyzed 960 survivors of breast cancer who experienced major coronary events and 1,205 controls, treated from 1958 to 2001.[210] The authors showed a linear relationship with mean heart dose and coronary events, with the risk being increased by 7.4% per Gy with no apparent threshold and persisting decades after treatment. The concept of no-threshold dose conflicts with our historical understanding (that "low doses" were likely inconsequential) as well as a recent University of Michigan study looking at myocardial perfusion scans after low-dose exposure (average heart mean dose <5 Gy) in patients with breast cancer; the authors found no correlations between cardiac doses and assessed cardiac function.[211] A potential criticism of the Swedish/Danish study is that radiation fields were reconstructed using a CT scan of a "typical woman" to generate DVH information. This undoubtedly introduced uncertainties

in their analysis that are acknowledged by the authors. Nevertheless, this was really the best that could humanly be done because the patients were treated in the pre-3D planning era. The investigators performed in-depth dosimetric reconstructions based on the available information.

The lack of a dose threshold might be related in part to the techniques used and potential differences between the delivered and planned doses. Radiation is delivered in daily fractions over many weeks. Inter- and intrafraction variations (e.g., because of daily set-up and motion from breathing) result in differences between the planned and delivered dose. The planned dose is *not* necessarily a good representation of the "average" of the delivered fractions, particularly for patients with a low planned mean heart dose. Such a patient likely has a beam edge close to, or encroaching to a small degree on, the heart. Because the dose gradient is steep near the beam edge, setting-up the beams too deep will markedly increase the cardiac dose. Setting them up too shallow does *not* yield a corresponding decrease in dose, because if the planned dose is already low, one cannot reduce dose appreciably lower. Thus, although set-up irregularities *might* be geometrically equally distributed relative to the planning scan, the dosimetric effects are not symmetrical, and such set-up variations often tend to *increase* the cardiac exposure. This might, to some degree, explain the low-dose effects seen by Darby.[212]

The findings from Darby et al may not be necessarily applicable to women treated with modern radiation planning and deliver methods because the doses are far lower, and the set-up techniques are likely more robust. In fact, the lead author previously showed no increase in cardiac mortality among women treated with radiotherapy after 1992 in the United States.[213] Nevertheless, the recent Darby study is a reminder that radiation-induced cardiac injury is a serious consideration.

In the Darby study, the mean heart dose was as good (or better) a predictor of risk than doses to the coronary arteries. This is surprising because the coronary arteries are often implicated as the main target for radiation-associated heart injury. Darby's observation may be the result of uncertainties in their estimation of coronary artery doses. Nevertheless, several studies note reduced perfusion in irradiated cardiac regions that do *not* correspond to a coronary artery's territory,[202] thus implicating microvascular injury as a potential mechanism for radiation-associated heart injury and an endpoint more plausibly associated with mean dose. The mean heart dose is likely largely a surrogate for dose to critical substructures such as the left-ventricular muscle and arteries.[212]

In another Swedish study, which correlated angiography findings with coronary artery dose-exposure extrapolated from the radiation treatment fields, an approximate twofold increase risk in high-grade coronary artery stenosis was found in women who received high-risk radiotherapy (i.e., specific coronary arteries were exposed to the highest radiation doses during breast cancer radiotherapy).[214] Furthermore, stenosis in these high-risk patients was more likely to occur in irradiated regions, specifically the right coronary artery (not accounted for[215] in the Swedish/Danish study) and distal left anterior descending artery.

There is little data on correlating heart dose-volume metrics with subsequent ejection fraction. In a study of patients with esophageal cancer treated with chemoradiation at Roswell Park Cancer Institute, the radiation dose to heart, left ventricle, and left anterior descending artery (quantified as V20 to V40) were not clinically or statistically associated with changes in the ejection fraction (albeit in a small study, with limited follow-up).[216] The aforementioned University of Michigan study likewise did not show a dose correlation with ejection fraction.[208]

A study from MDACC described the risk of pericardial effusions in patients treated for esophageal cancer.[217] A mean dose >26 Gy and relative volumes of the pericardium treated to doses greater than 3 Gy to 50 Gy (rV3 to rV50) was associated with effusions, with the strongest association being rV30. At 18 months postradiation, for a rV30 of >46% versus <46%, the rate of pericardial effusion was 73% versus 13% (p = 0.001); for a mean pericardium dose >26 Gy versus <26 Gy, the rate of pericardial effusion was 73% versus 13% (p = 0.001). A study from the University of Michigan also demonstrated that a mean dose >27 Gy and maximum dose 47 Gy correlated with risk of pericardial effusion; however, only patients treated with 3.5 Gy fractions developed pericardial effusions.[218]

Radiotherapy has been associated with valvular heart disease.[219] The incidence has been related to mediastinal radiation doses >30 Gy and younger age at irradiation. Subclinical valvular disease has been detected at 2->20 years postradiation,[219] but it appears to take much longer for clinical symptoms to become apparent (median interval 22 years from radiation to symptoms). For patients receiving radiation for Hodgkin lymphoma, at a median of >10 years after radiation aortic valvular disease usually consists of mixed stenosis and regurgitation and is more common than mitral and right-sided valvular disease.[219,220] From NTCP modeling of radiation-induced asymptomatic heart valvular defects, among 20 of 56 survivors of Hodgkin lymphoma, the cardiac chamber (left ventricle and left atrium) V30, cardiac chamber volume, and lung volume were predictive.[221]

Antracyclines and Other Risk Factors

In patients with Hodgkin disease, radiation exposure, in conjunction with anthracyclines, may impair ejection fraction and increase risk of myocardial infarction, congestive heart failure, and valvular disorders. Data on the combined effects of anthracycline and radiation remain sparse. A report of 1474 survivors of Hodgkin lymphoma younger than 41 years at treatment and followed for a median of 18.7 years has shed some light.[222] Risks of myocardial infarction and congestive heart failure were significantly increased, with standard incidence ratios of 3.6 and 4.9, respectively for survivors of Hodgkin lymphoma versus the general Dutch population. Mediastinal radiation alone increases the risks of myocardial infarction, angina pectoris, congestive heart failure, and valvular disorders (two- to sevenfold). The addition of anthracyclines further elevated the risks of congestive heart failure and valvular disorders from mediastinal radiation, with hazard ratios of 2.81 and 2.10, respectively. The 25-year cumulative incidence of congestive heart failure following combined radiation and anthracycline chemotherapy was 7.9%.

Other risk factors for cardiac disease, particularly coronary artery disease, must be considered. For example, data from the University of Rochester assessed the risk of coronary artery disease in survivors of Hodgkin lymphoma and also the prevalence of cardiac risk factors. The relative risk of cardiac death was 3.1 for males versus 1.8 for females. Other risk factors were more common than in the general population; among patients with Hodgkin lymphoma experiencing morbid cardiac events, 72% smoked, 72% were male, 78% had hypercholesterolemia, 61% were obese, 28% had a positive family history, 33% had hypertension, and 6% had diabetes.[223]

Summary and Other Key Points from QUANTEC Review[224]

The substructures of the heart, as well as the intersection of the heart and great vessels can be challenging to differentiate with

axial CT imaging, and the heart border is often difficult to differentiate from the adjacent liver and diaphragm. The heart moves with the respiratory and cardiac cycles, with different regions moving to different degrees. Several clinical factors, such as increasing age, comorbidities, and anthracycline exposure, appear to increase the risk of radiation-induced injury. Whereas based on limited data, there appears to be a dose or volume dependence for pericardial disease, cardiac mortality, and perfusion abnormalities. A heart V30 of >45% and a mean cardiac dose of >26 Gy are associated with a higher risk of pericarditis. A heart V30 to V40 of ~30% to 35% is associated with a ~5% excess risk of cardiac death at ~15 years. These dose-volume metrics likely oversimplify risk estimates related coronary artery disease, which are probably best correlated with high dose (>50 Gy) to small volumes of coronary artery.[215] In patients with breast and lung cancer, it is recommended that the irradiated heart volume be minimized as much as possible degree without compromising target coverage. In patients with lymphoma the whole heart should be limited to <30 Gy if the patient is treated with radiation alone, and 15 Gy for those also receiving anthracycline chemotherapy.

GASTROINTESTINAL SYSTEM: ESOPHAGUS

Organ Function and Clinical Significance

The esophagus is the muscle lined organ that allows and facilitates the transit of solids and liquids from the mouth to the stomach. The esophagus is a moveable (slightly), hollow, distensible organ. On CT images, the cross-sectional esophageal area/volume is highly variable. This may not accurately reflect the true anatomy of the organ. In gross esophageal specimens, the cross-sectional area of the esophagus is fairly uniform at all axial levels.[225]

Acute esophagitis is common, and is often severe, in patients receiving radiation for thoracic malignancies (e.g., esophageal cancer, primary lung cancer). Some patients may require a feeding tube or treatment interruptions due to acute esophagitis. Because most patients with thoracic cancers have a poor prognosis, acute toxicity may be considered more clinically relevant than late injury. Late esophageal complications include dysphagia, stricture, dysmotility, odynophagia, and rarely necrosis or fistula.

Dose-Volume Data

In a series from Washington University, grades 3 to 5 esophageal toxicity (acute and late) was associated with a maximal dose (*Dmax*) of >58 Gy, a mean dose of >34 Gy and the administration of concurrent chemotherapy.[226] The V55 was not significant. A Chinese study reported that maximal dose >60 Gy, as well as the use of concurrent chemotherapy were significant factors for esophageal toxicity (acute and late).[227] In a series from Duke University, the V50, the surface dose receiving ≥50 Gy (S50), the length of esophagus receiving >50 Gy to 60 Gy, and a circumferential *Dmax* >80 Gy were significant predictors of late esophageal toxicity.[228] A V50 of >32% or an S50 of >32% resulted in crude rates of ~30% late esophageal toxicity versus 7% below these thresholds ($p = 0.02$ and 0.04, respectively). With >3.2 cm of the esophagus receiving >50 Gy, late toxicity occurred in ~30% versus 4% in those with <3.2 cm receiving >50 Gy ($p = 0.008$). In another series from Duke, late grade ≥1 toxicity was correlated with several dose parameters: the entire circumference receiving ≥50 Gy and ≥55 Gy; 75% of the circumference receiving ≥70 Gy; and maximal percentage of circumference receiving ≥60 Gy to 80 Gy.[229] The rate of grade ≥1 late toxicity was ~5% in patients with a V50 to V70 of 0% to 30% versus ~25% in those with a V70 of 31% to 64% and ~10% in those with a V50 >60% (nonsignificant). Acute esophageal toxicity was the greatest predictor of late toxicity. In two studies, most of the patients who developed late grade ≥3 toxicity had developed acute grade ≥3, though roughly 25% to 40% of patients who developed grade ≥3 late toxicity had only grades 0 to 2 acute esophageal toxicity.[226,227]

From the data analyzed for QUANTEC, several studies noted an increased risk with increasing dose/volume parameters. However, because different studies considered different variables, optimal dose/volume predictors were considered elusive. Further, because different dose/volume parameters are correlated to each other, it may be that there are no true "optimal" parameters and that alternative predictive models will be equally useful. From a 2013 meta-analysis of 1082 patients treated with chemoradiation for non–small-cell lung cancer, esophageal V5 to V70 parameters (in 5-Gy increments) were all significant predictors of grade ≥2 esophagitis; on multivariate analyses V60 proved to be the most significant predictor of grades ≥2-3 esophagitis.[230] Recursive partitioning identified three risk groups: low (29% and 4% risk of grades ≥2 and ≥3 esophagitis with V60 <0.07%), intermediate (41% and 10% risk of grade ≥2 and ≥3 esophagitis with V60 ≥0.07% to 17%), and high (59% and 22% risk of grades ≥2 and ≥3 esophagitis with V60 ≥17%). These authors did not consider dose-surface metrics or esophageal length or circumference.

Summary and Other Key Points from QUANTEC Review[231]

The esophagus can be difficult to differentiate from surrounding soft tissues. Acute esophageal injury is much more common, and thus most studies have explicitly analyzed acute toxicity (which is not explicitly reviewed here). For acute and late injury, there is a dose response for a variety of threshold volumes (V20 to V70). A *Dmax* >55Gy to 60 Gy as well as esophageal surface, volume, length, and circumference receiving >50 Gy to 60 Gy appear to correlate with toxicity. Acute esophageal toxicity can result in late toxicity. It was not possible to identify a single-best threshold volumetric parameter for esophageal irradiation because a wide range of dose-volume parameters correlate with toxicity. Based on the RTOG 0617 dose escalation study for non–small cell lung cancer, it was suggested that the mean dose to the esophagus be kept <34 Gy; in that study, the esophageal V60 will also be reported. A recent meta-analysis suggests that V60 is most predictive for esophagitis.

GASTROINTESTINAL SYSTEM: STOMACH AND SMALL BOWEL

Organ Function and Clinical Significance

The stomach and small bowel aid in the digestion and absorption of food and nutrients. Symptoms from radiation-related late toxicities include dyspepsia, gastric ulceration, diarrhea, bowl obstruction, and bowel ulceration, fistula, or perforation. The primary long-term endpoints considered for the small bowel are stricture and diarrhea. For the stomach, perforation and ulceration are commonly considered. Several patient-related variables, such as history of diabetes, age, race, body habitus, and prior surgery, likely impact the risk of late toxicity.[232] Because stomach and small bowel are mobile and distensible, determining accurate dose-volume (or dose-surface) constraints are challenging. Factors affecting risk of late toxicity include total dose (with doses in excess of 40 Gy to 50 Gy increasing the risk of late complications), fractional dose, prior abdominal surgery (which increases the risk of bowel obstruction), and concurrent chemotherapy use.

Dose-Volume Data

Dose

Late radiation induced stomach injury has been reported to occur with increasing frequency with increasing doses. In a study from Walter Reed, the rates of gastric ulceration were 4% and 16% after treatment of <50 Gy versus >50 Gy. Similarly, the rates of perforation were 2% and 14% in the same dose cohorts. Overall, the dose of approximately 50 Gy to the stomach was associated with about a 2% to 6% incidence of severe late injury. The volume affect for late stomach injury is not well defined. For late small bowel toxicity, a dose of approximately 50 Gy is associated with obstruction or perforation rates that are approximately 2% to 9%. Prior abdominal surgery appears to increase the risk of late small bowel injury following radiation. In the European Organization for Research and Treatment of Cancer (EORTC) study, the rate of complications was 3% without prior abdominal surgery versus 12% with prior abdominal surgery.[233]

Dose Volume

There is a paucity of good quantitative data on dose-volume metrics that predict for gastric or bowel late toxicity. Nevertheless, there are data that demonstrate a volume effect. The risk of bowel obstruction among patients with rectal cancer whose fields extended to L1 or L2 was 30% versus 9% in those treated with pelvis only fields.[234] The University of Michigan investigated gastric and duodenal bleeding after radiation of patients with liver tumors.[235] Normal tissue complication modeling was consistent with a dose threshold (~60 Gy) for bleeding without a large volume effect.

A few studies published after QUANTEC correlated small bowel toxicity risks with dose-volume metrics. In a study of 46 patients with locally advanced pancreatic cancer, treated with concurrent gemcitabine and radiotherapy, duodenal V35 >20% was associated with a 41% risk of grade ≥3 small bowel toxicity (acute or late), versus 0% for a V35 <20%.[236] In another study of patients with locally advanced pancreatic cancer (n = 106), in which V40 to V60 was analyzed, a V55 ≥1 mL versus < 1 mL was significantly correlated with grade ≥2 toxicity (47% versus 9%, p = 0.0003).[237] In a study of 46 women treated with extended field radiation for gynecologic malignancies up to 65 Gy, only three patients experienced acute grade ≥3 gastrointestinal toxicity and thee patients experienced late grade ≥3 gastrointestinal toxicity (none of which was duodenal toxicity); V5 to V65 did not correlate with toxicity risks.[238] From a recent systematic review of women undergoing extended field radiation, a point maximum of 55 Gy to small bowel was estimated to yield a 10% toxicity risk within 5 years.[239]

Summary and Other Key Points from QUANTEC Review[240]

The stomach and the intestines are mobile structures with definite inter- and intrafraction motion. This makes some of the doses/volumes/outcomes data less certain. Two different approaches have been considered when defining small bowel volumes. Either the entire potential space of small bowel-containing volume (i.e., incorporating all regions where bowel can be situated),[241] or the actual visualized loops of bowel on the planning CT[242] can be considered as an organ at risk. Using the entire potential small bowel space, it is suggested that the small bowel exposed to V45 to V50 should be less than 195 cc to reduce acute toxicity (not discussed previously)[241]; while using the visualized loops of bowel, it is recommended that the V15 should be less than 120 cc.[242] A study (with neoadjuvant radiation for rectal cancer) published after QUANTEC predicts a 10% risk of grade ≥3 small bowel toxicity with a V15 <275 cc for contoured bowel loops and <830 cc for the peritoneal space.[243] Although these dose constraints were derived from acute toxicity data, they do provide guidelines that should help minimize risk of late toxicity as well. For the stomach, it is recommended to maintain the dose to the whole stomach to <45 Gy; a maximum point dose might be an important predictor of toxicity, but more data are needed to confirm this hypothesis.

GASTROINTESTINAL SYSTEM: RECTUM

Organ Function and Clinical Significance

The rectum is the terminal portion of the large intestines that functions as a temporary storage for feces, as well as providing the urge to defecate. The most common late radiation related rectal complication is bleeding. Rectal ulceration and fistula are much less common. Other late injuries include stricture and decreased rectal compliance, which can result in frequent small stools. The anus is also at risk of late complication including stricture and laxity, leading to fecal incontinence. Patients are at a higher risk of late rectal sequelae, including gastrointestinal bleeding, proctitis, diarrhea, and tenesmus, with higher maximal and mean rectal doses. Several patient-related variables, such as history of diabetes or vascular disease, inflammatory disease, and age may impact the risk of late toxicity.[232,244-246] Acute bowel toxicity appears to be correlated with late proctitis and increased stool frequency.[246] Prior abdominal surgery is also relevant.[247] An XRCC1 polymorphism has also been implicated as a risk factor for late rectal toxicity.[248]

Dose-Volume Data

Abundant dosimetric data has shown a correlation of risk with rectal volume and surface/rectal wall doses.[249-264] Table 14-3 summarizes many of these studies, also discussed here.

MSKCC has shown a significant difference in the DVHs between patients who developed rectal bleeding versus those who did not after conformal radiation for prostate cancer.[249] The percentage of rectum exposed to 62% and 102% of the prescription dose (70.2 Gy or 75.6 Gy) was significant; the rectal wall being encompassed by the 50% isodose line, higher maximal dose to the rectum, and smaller rectal volume were also significantly adverse risk factors.[249,250] In a study of 1571 patients treated at MSKCC, the use of IMRT and the lack of acute rectal toxicity predicted for lower risk of late rectal toxicity.[251]

An Austrian study found that a V59 of ≥57% resulted in increased grade 2 rectal toxicity (31% versus 11%, p = 0.003).[252] Two Italian multicenter studies found a significant dose volume effect from V50 to V70, with suggested cutoff values of V50 ≤60% to 65%, V60 ≤45% to 50%, and V70 ≤25% to 30%; the risk of grade ≥2 rectal complications was ~4% to 8% versus ~20% to 30% risk above and below the cutoff values.[253,254] A rectal volume <55 mL was also a significant risk factor for late bleeding. In the postprostatectomy setting, this Italian group demonstrated that a mean rectal dose ≥54 Gy, V50 ≥63%, V55 ≥57%, V60 ≥50%, and rectal volume <60 mL were predictive of late bleeding.[255]

In a randomized trial of 70 Gy versus 78 Gy from MDACC in the treatment of early- to intermediate-risk early stage prostate cancer, the risk of late grade ≥2 rectal complications was significantly greater with a rectal V70 ≥25% versus V70 <25% (46 versus 16%, p = 0.001).[256] A retrospective analysis from MDACC showed that the risk is a continuous function of dose and volume, with suggested cut-off points for lowering the

TABLE 14-3 Summary of Selected Studies Analyzing Dose-Volume Parameters Predictive of Rectal Toxicity

Author, Year (*Center*)	Patient population	Endpoint	Subgroup	Toxicity Rate
Wachter, 2001 (*Univ. Hosp. Vienna*)	Prostate cancer	Grade 2 Rectal toxicity	V59 ≥57% V59 <57%	31% 11%

**Published after QUANTEC review.*

complication risk: V60 ≤41%, V70 ≤26%, V76 ≤16% or 3.8 mL and V78 ≤5% or 1.4 mL.[257] At 6 years, the risk of late grade ≥2 rectal complications was 54% for patients with a rectal V70 ≥26% versus 13% for a V70 <26%.

Among patients treated on the Dutch randomized trial of 68 versus 78 Gy,[245] the mean anal dose (as well as V5 to V60) significantly predicted the rate of grade ≥2 gastrointestinal toxicity (at 4 years, 16% versus 31% for a mean dose <19 Gy versus >52 Gy).[258] The mean dose (as well as V5 to V70) also predicted the risk for use of incontinence pads (at 5 years, <5% versus >20% for a mean dose <28 Gy versus >46 Gy). The anorectal V65 (as well as V55 to V60) was significantly predictive of rectal bleeding (4-year risk <1% and >10% for a V65 <23% versus >29%).[258]

The percentage of rectum or rectal wall receiving a given dose can be subjective (i.e., based on how much of the rectum

is segmented); using the absolute volume of rectum[262] or rectal wall is less subjective, though defining the rectal wall is not standardized. The rectum extends from the rectosigmoid junction to the anus, with the inferior extent generally defined as the level of the anal verge, above the anus, the ischial tuberosities or 2 cm below the ischial tuberosities. Dosimetric parameters of the rectal wall or rectal surface may be more predictive of some late toxicities.[265] William Beaumont Hospital demonstrated that the rectal volume as well as rectal wall V50 to V70 values predict late toxicity, with rectal wall being more predictive of grades 2 to 3 late effects; acute toxicity is also predictive of late toxicity.[259] MDACC has also shown rectal wall to be better predictive of late rectal bleeding.[260] From a 1998 Dutch study, recommendations for the volume of rectal wall exceeding 65 Gy, 70 Gy, and 75 Gy are <40%, <30%, and <5%, respectively.[261] Data from the Cleveland Clinic[262] and William Beaumont[259] showed a significantly increased risk of grade ≥2 rectal toxicity with rectal or rectal wall V70 to V78 of ≥15 mL versus <15 mL (~20% >30% versus ~5% to 10%).

More than a dozen NTCP modeling studies have been published. In one study, many individual models did not fit clinical data accurately, so the authors suggested that consolidating risk estimates from multiple models could yield more accurate predictions of toxicity risks.[266]

Summary and Other Key Points from QUANTEC Review[267]

The rectum is mobile and distensible, and therefore its position and volume can vary between and during radiation fractions. The superior and inferior borders of the rectum are not always easy to define on CT imaging. Most of the published studies of rectal toxicity address late rate rectal bleeding. However, most toxicity scoring systems are nonspecific, in that a patient can be considered as having a grade 2 or 3 event on the basis of diarrhea, stool frequency, rectal mucus, or bleeding. For patients undergoing radiation therapy for prostate cancer, it is recommended to limit the V50, V60, V65, V70, and V75 to less than 50%, 35%, 25%, 20%, and 15%, respectively. From a Phase I/II RTOG study published after the QUANTEC review,[268] in which 1009 men received 68.4 to 79.2 Gy, in 1.8 to 2.0 Gy fractions, rectal doses <60 Gy had no detectable impact on the fit of the NTCP model, and multivariate modeling showed only V75 to be significantly associated with late rectal toxicity.[269]

GASTROINTESTINAL SYSTEM: LIVER

Organ Function and Clinical Significance

The liver is a vital organ, with a breadth of metabolic functions including metabolism of ingested nutrients, detoxification, protein synthesis, bile production, glycogen storage, and red blood cell decomposition. Sequelae of radiation-induced liver damage include elevation of liver enzymes, ascites, jaundice, asterixis (tremor), encephalopathy, or coma. One of the most important patient-related predictors of susceptibility to liver damage is the baseline liver function, which is characterized by the Child-Pugh scoring system and accounts for serum bilirubin, albumin, coagulation times, the presence of ascites, and encephalopathy. The risk of radiation toxicity appears to be greater in the patient population with primary liver malignancies as opposed to liver metastases.

Dose-Volume Data

The RTOG 84-05 Phase I study, in which patients with liver metastases received whole liver radiation with 1.5 Gy twice daily fractions, none of the 122 patients who received 27 Gy to 30 Gy developed biochemical evidence of liver toxicity, compared to 5 of 51 who received 33 Gy.[270] In a study of 79 patients treated with liver radiotherapy at the University of Michigan, only those patients who received whole liver radiotherapy (1.5 to 1.65 Gy BID, with or without a boost) developed late radiation toxicity (crude risk of 9/33 versus 0/46 treated with partial liver radiation). Those who received a mean dose of >37 Gy (delivered twice daily with infusional fluorodeoxyuridine) and less sparing of normal liver had greater risk of late radiation toxicity (crude risk of 9/34 versus 0/45).[271]

Several studies have explored partial liver radiation in more detail, many of which used mean liver dose as a dose-volume metric. In a later study from University of Michigan, no late liver toxicity was observed with a mean liver dose <31 Gy, with NTCP models being optimized with a TD50 of 43 Gy and TD5 of 31 Gy for whole liver radiation; the risk of complications was strongly dependent on volume of liver irradiated.[272] Other risk factors for late toxicity included primary hepatobiliary carcinoma (as opposed to metastatic disease), use of bromodeoxyuridine chemotherapy (as opposed to fluorodeoxyuridine), and male gender. The NTCP models predict a TD5 in excess of 80 Gy if less than one third of the liver is irradiated. With irradiation of two thirds of the liver, the TD5 is on the order of 50 Gy and TD50 on the order of 60 Gy.

In a series from Taipei, patients with irradiated hepatocellular carcinoma who developed late liver toxicity had received a mean hepatic dose of 25 Gy (versus 20 Gy in patients without toxicity, $p = 0.02$).[273] The TD50 for whole liver, two thirds liver, and one third liver radiation were modeled to be approximately 43 Gy, 50 Gy, and 67 Gy, respectively. The TD5 for whole liver, two thirds liver, and one third liver radiation were modeled to be approximately 25 Gy, 28 Gy, and 38 Gy, respectively. The volume effect of liver radiation was less in this series. In another study from the same group, the mean liver dose and hepatitis B virus positivity were significant predictors or radiation toxicity; with NTCP modeling, the TD50 was ~50 Gy.[274]

In a Korean study of 105 patients with hepatocellular carcinoma, the mean dose and V20 to V40 parameters to total liver and normal liver (total liver minus GTV) were investigated.[275] The total liver V30 was the only significant parameter ($p < 0.001$). Grade ≥2 liver toxicity was observed in only 2.4% of patients with a total liver V30 ≤60% and 55% of patients with a total liver V30 >60% ($p < 0.001$). Another Korean study demonstrated a correlation of V15 with reduction in Child-Pugh score and recommends a V15 cutoff of <43.2%.[276]

The data from Asia differ from Western data, perhaps reflecting differences in the treated malignancy (mostly metastases in the West versus primary liver cancer in Asia, which often occurs in the setting of liver cirrhosis), radiation fractionation, and or concurrent therapies delivered with radiation.

Summary and Other Key Points from QUANTEC Review[277]

An understanding of radiation-induced liver toxicity necessitates an appreciation of liver motion. Extensive work has described liver motion as a result of breathing, which can displace the liver in excess of 2 cm. Preexisting liver dysfunction secondary to comorbid conditions such as hepatitis B or C infection and cirrhosis appears to increase the susceptibility to radiation-induced liver injury. For patients with liver metastases undergoing partial volume liver radiation, the risk of radiation induced liver toxicity appears to be more dependent upon the volume of liver irradiated. Partial volumes of liver can tolerate relatively high doses. Tolerances however

are lower for patients with primary liver cancer (who are more apt to have underlying liver disease). For whole liver radiation, doses ≤28 Gy to 30 Gy in 2 Gy fractions (28 Gy for liver metastases and 30 Gy for primary liver cancer) and ≤21 Gy in 3 Gy fractions are recommended. For partial liver radiation, treated with standard fractionation, the mean dose to normal liver (liver minus GTV) is suggested to be <30 Gy for liver metastases and <28 Gy for primary liver cancer.

GENITOURINARY SYSTEM: KIDNEY

Organ Function and Clinical Significance

The kidney functions to remove wastes, regulate electrolytes, produce erythropoietin, which stimulates red blood cell production, and modulate blood pressure through the renin-angiotensin pathway as well as through fluid/electrolyte balance. Perhaps late-kidney toxicity is underreported because of its long latency as well as toxicity being attributed to more common causes. Late renal complications include decreased kidney function, azotemia, hypertension, and kidney atrophy. Chronic radiation nephropathy in its mildest forms may not be diagnosed until years after therapy. Clinically silent abnormalities may include only proteinuria and azotemia with urinary casts and mild or no hypertension. Certainly, patients with only one functioning kidney or poor baseline renal function, are more vulnerable to damage (with or without symptoms) for any given volume of renal irradiation. Platinum and ifosfamide based chemotherapeutics can also impact renal function. Cisplatin at dosages greater than 200 mg/m^2 can result in glomerular or tubular injury and renal insufficiency.[278] Ifosfamide can cause glomerular and tubular toxicity, with renal tubular acidosis, or Fanconi syndrome. A study examining grades 3 to 4 ifosfamide-induced nephrotoxicity among adult and pediatric patients found a prevalence of 17% in both; neither age nor cumulative ifosfamide dose were risk factors.[279]

Dose-Volume Data

Several studies have investigated whole kidney dose tolerance, either after whole abdominal radiation or total body irradiation (generally delivered with lower fractional doses). Renal toxicity can occur after bilateral kidney doses ≥10 Gy, and the risk is quite high (50% to 80%) after 20 Gy. Thus, the kidneys have a relatively low threshold for damage. The dose volume-effect on the kidneys has been long recognized, even before the planning CT because kidneys are well visualized on plain simulation films. From these studies, when greater than half of the kidney receives doses >20 Gy to 30 Gy, or greater than one third receives >30 Gy to 40 Gy, patients are at increased risk of developing renal atrophy, decreased kidney function, and hypertension.[2,280-282]

There is little published on dose-volume parameters to predict late renal toxicity, in part because clinicians make an effort to minimize the volume of kidney exceeding the accepted tolerance dose. Low doses, 10 Gy to 15 Gy, to large volumes of kidney increase the risk of nephrotoxicity,[283-285] whereas smaller volumes of kidney exceeding ~20 Gy to 25 Gy can result in late renal toxicity.[283,285-287] In a series from Heidelberg, normal tissue complication modeling was used estimate the risk of late complications.[286] A median dose of ~17.5 Gy to 21.5 Gy and 22 Gy to 26 Gy corresponded to a 5% and 50% late complication risk (anemia, azotemia, hypertension, and edema), respectively. In another German study, reduced kidney function, as measured by scintigraphy changes, was analyzed as a function of dose and volume.[283] After irradiation of 10% to 30%, 30% to 60%, and 60% to 100% of the kidney volume to 20 Gy, the incidence of reduced activity was <10%, ~40%, and >70%, respectively. After irradiation of 10% to 30%, 30% to 60%, and 60% to 100% of the kidney volume to 30 Gy, the incidence of reduced activity was ~35%, >90%, and >98%, respectively. In a Dutch study of patients with gastric cancer (treated with concurrent radiation and cisplatin or capecitabine), the left kidney V20 ≥64% and mean left kidney dose of ≥30 Gy were associated with a significant decrease in left kidney function as compared to the right.[287] In a recent study of 125 patients with upper gastrointestinal malignancies, kidney V5 to V20 and mean kidney dose were significantly correlated with reduction in creatinine clearance.[288] A 15% to 20% decrease in creatinine clearance was associated with a V5 >50%, V10 >30%, V20 >30% (or >100 mL), and mean kidney dose >10 Gy.

Summary and Other Key Points from QUANTEC Review[289]

Radiation-associated kidney injury has a poorly understood pathophysiology and is likely underreported because of its long latency. For whole (bilateral) kidney radiation (not discussed), recommendations are for doses <10 Gy delivered over 5 to 6 fractions (at <6 cGy/min dose rate) and <15 to 18 Gy for radiation delivered over ≥5 weeks. For partial kidney radiation, the volume of kidneys receiving >20 Gy predicts risk of renal toxicity. The recommendation for partial kidney radiation is to maximally spare the kidneys and maintain a mean dose of <18 Gy to both kidneys or maintain a V6 <30% if one kidney cannot be adequately spared.

GENITOURINARY SYSTEM: BLADDER

Organ Function and Clinical Significance

The bladder is a highly distensible organ that collects urine. Symptoms from late radiation related toxicities include increased urinary frequency, hematuria, and dysuria. Necrosis, contracted bladder, and hemorrhage are less common, severe effects. Perhaps late-bladder toxicity is underreported because of its long latency as well as toxicity being attributed to more common causes. Because the bladder is mobile and distensible, determining accurate dose-volume (or dose-surface) constraints are challenging. Endpoints for bladder injury can reflect focal damage (e.g., bleeding) or more global injury (reduced bladder capacity with secondary urinary frequency). Recent data suggests that acute toxicity is predictive of late toxicity (particularly urinary frequency and hematuria) risks and pretreatment bladder dysfunction is predictive of late urinary symptoms (particularly urinary frequency, incontinence, and slow stream).[246]

Dose-Volume Data

Detailed dose-volume (or dose-surface) constraints have not been published, in part because of the complexities of assigning dose-volume metrics to a mobile, distensible structure. For whole bladder irradiation, doses in excess of 60 Gy, particularly with fraction sizes >2 Gy or accelerated radiation regimens, result in a significant risk of late grade ≥3 toxicity. Risks are lower when the whole bladder receives 45 Gy to 55 Gy, followed by a boost to >60 Gy to a portion of the bladder, though toxicity risk has not been correlated to dose-volume metrics. A recent Fox Chase Cancer Center study of 503 patients with prostate cancer examined urinary bladder V60 to V70 and area under the DVH, with bladder defined as just the bladder wall ("hollow" structure) or entire bladder and contents ("solid" structure); with multivariate analyses, the

mean bladder dose and area under the DVH were significant predictors of grade ≥2 genitourinary toxicity.[290] In a recent University of Chicago study of 296 patients with prostate cancer (in which the bladder was contoured as whole organ, after drainage and infusion of 120 mL of saline), no bladder dose-volume relationships were associated with the risk of grade ≥2 genitourinary toxicity.[263] With prostate cancer treated to high doses (≥72 Gy), the inferior portion of the bladder (e.g., trigone area) also receives ≥70 Gy. This tends to be well tolerated with respect to bladder toxicity. Arguably, the urinary toxicity that does develop after radiation results in part from the prostatic urethra receiving suprathreshold doses.

Summary and Other Key Points from QUANTEC Review[291]

The primary limitations of deriving strict dose-volume guidelines for the urinary bladder include the lack of robust 3D dose/volume data as well as the complicating factor that the bladder is a mobile structure of variable volumes/position. For whole bladder radiation, the reported risks of grade ≥3 toxicity in doses of 50 Gy to 60 Gy range from ≤5% to 40%. This variation is likely attributable to the challenges of correlating toxicity with dose delivered to a mobile structure, which is even more problematic when correlating partial volume exposures to toxicity. With the caveat of these issues, bladder constraints of ≤15%, ≤25%, ≤35%, and ≤50% receiving ≥80 Gy, ≥75 Gy, ≥70 Gy, and ≥65 Gy, respectively, as recommended in the RTOG 0415 study of prostate cancer, are suggested. The protocol advises an empty bladder at the time of simulation and treatment; the bladder is segmented from the base to the dome.

GENITOURINARY SYSTEM: PENILE BULB

Organ Function and Clinical Significance

The penile bulb is located at the base of the penis, caudal to the prostate.[292,293] Radiation dose to the penile bulb can affect erectile function, either as a direct result of damage to this structure (less likely) or damage to surrounding structures, whose radiation-induced damage is correlated with the dose exposure of the penile bulb. The most common scenario in which the penile bulb is irradiated is in the treatment of prostate cancer. IMRT is often used to minimize the dose to the penile bulb.[294,295] Interpretation of erectile dysfunction and the effect of penile bulb dose is complicated by preexisting function, comorbid conditions, and other therapies that may hinder (e.g., hormonal therapy) or help (e.g., drugs used to treat erectile dysfunction) erectile function. Also, determining which patients experience erectile dysfunction—a toxicity with varying severity—also complicates data interpretation.

Dose-Volume Data

Several studies have investigated dose-volume parameters to predict risk of erectile dysfunction. In several studies, no correlation was discerned for penile bulb dose and erectile function.[295-297] In one study, attempts were made to reduce the dose to the penile bulb (mean dose of 25 Gy), and thus few patients received high dose to the penile bulb.[295] In another study of 70 patients, no correlation was found for mean dose or maximal dose to the penile bulb, penile crura, or superiormost 1 cm of the penile crura; DVHs were also compared and found to be similar.[296]

In a small (21 patients), early study from University of California–San Francisco, patients receiving a D70 of <40%, 40% to 70%, and >70% to the penile bulb had a 0%, 80%, and 100% risk, respectively, of experiencing radiation-induced impotence.[298] In a study (29 patients) from Thomas Jefferson University, several dose-volume metrics were analyzed; a D30 >67 Gy, D45 >63 Gy, D60 >42 Gy, and D75 >20 Gy to the proximal penis were correlated with increased erectile dysfunction as well as ejaculatory function.[299] In a study from Royal Marsden Hospital, a D90 >50 Gy to the penile bulb was associated with significantly worse erectile function, whereas D15, D30, and D50 showed similar (albeit not significant) trend toward increased doses in impotent vs. intermediate potency versus potent patients.[300] Another recent small (19 patients) study found that mean dose <50 Gy was predictive of erectile potency.[301]

The largest study (158 patients) to date to investigate penile bulb dose is an analysis of the RTOG 9406 dose-escalation study.[302] A median dose of ≥52.5 Gy was associated with a greater risk of impotence (50% versus 25% at 5 years).

Summary and Other Key Points from QUANTEC Review[303]

There is some uncertainty regarding the critical anatomic structures for radiation-induced erectile dysfunction. Several studies from different academic centers have correlated the dose-volume exposure to the penile bulb with erectile dysfunction and have impressively similar results. Based on published data, it is recommended to keep the mean dose to 95% of the penile bulb <50 Gy and to limit the D70 and D90 to 70 Gy and 50 Gy, respectively.

CONCLUSIONS

The study of radiation-associated normal tissue injury has interested investigators for decades. Much progress has been made over the last 20 years. Additional technologies (e.g., gating, image-guided therapy) will provide some refinements in these physical advances. The emergence of novel technologies such as stereotactic body radiotherapy/stereotactic ablative body radiotherapy (SBRT/SABR), image-guided radiotherapy (IGRT), intensity-modulated radiotherapy (IMRT), charged particle therapy and four-dimensional planning have resulted in the increasing use of hypofractionated radiation, more conformal radiation delivery, and heterogeneous dose distributions (i.e., dose painting). Thus, future studies should account for fraction size and small-volume high-dose exposures. Eventually, models predicting dose/volume injury will likely more consistently consider the underlying physiology and substructures of organs, potential interactions between organs and differences in regional physiologic importance (e.g., different regions of the kidney being more important such as the cortex versus the medulla, different regions of the heart being more important, such as the coronary arteries or the left ventricle). There is a need to gain further understanding of the biological underpinnings of radiation-associated normal tissue damage. This will hopefully improve our abilities to predict, prevent, and treat radiation-associated normal tissue injury. As we employ more advanced technologies to further limit normal tissue exposure to lessen the risk of radiation-associated injury, we need to be careful not to compromise target coverage. Missing the tumor to avoid a grade 2 (or even grade 3 injury) might not be a reasonable trade-off, as a local tumor recurrence can be morbid. There are several published data sets that demonstrate that this is not a theoretical concern. In patients with orbital tumors and prostate cancer, more conformal techniques (applied to reduce normal tissue risks) have been associated with poorer clinical tumor control outcomes.[304,305] Radiation oncology is a dynamic field with constantly emerging technologic advances. In tandem with these advances is the critical

need for radiation oncologists to build their understanding of the normal tissue consequences of radiation administration. Not only do we need to explore associations of normal tissue damage with volume, dose, fraction size, and particle type, but we need to integrate this with the equally rapid evolution of novel systemic therapies and our pursuit of the pathophysiologic (including molecular genetics) basis of normal tissue injury.

CHAPTER

15 Brachytherapy

Caroline L. Holloway, Desmond A. O'Farrell, Phillip M. Devlin, and Alexandra J. Stewart

GENERAL PRINCIPLES

Brachytherapy is arguably the most conformal of all the modes of radiotherapy. Accurate placement of sources directly in the target area allows for precise dose delivery to the target with unparalleled sparing of normal adjacent tissue. Although a conformal therapy, it is by nature nonhomogenous in dose delivery, with the advantage that much of the central regions of target get a greater dose than the minimum prescribed dose covering the target volume.

The physics and radiobiology of brachytherapy are areas of great breadth and scholarship and are described elsewhere. In this chapter our aim is to provide the reader with a set of up-to-date references and more importantly an experience-based guide to the initiation and development of a brachytherapy program.

Brachytherapy takes advantage of the physical process of radioactive decay; an exponential phenomenon represented in general terms by the equation: $A = A_0\, e^{-\lambda t}$

Where A_0 is the initial activity, t is the elapsed time, and λ the decay constant (ln2/half-life).

This decay releases energy, which is deposited as dose to the target structure.

The primary clinical isotopes in use currently are shown in Table 15-1. Generally photon-emitting beta, gamma, and x-ray emitters are employed. High linear energy transfer (LET) emitters such as neutron and alpha sources are seldom encountered clinically in brachytherapy. The dose rates of treatment delivery vary and are detailed in Table 15-2. Isotope selection is based on the emission type, the energy of the emission and half-life of the isotope. Cost and availability of the isotope are also a practical consideration.

Developing a brachytherapy physics treatment program can at first seem daunting. However the fundamentals of any program can be reduced to:

- What source do we wish to use in terms of energy, half-life, and emission?
- Can we confirm its position?
- Can we control its duration?
- Can we accurately anticipate, calculate, and verify dose distributions?
- Can we minimize risk to the patient and staff?

Practitioners are referred to American Association of Physicists in Medicine (AAPM) TG 43[1] and supplements for standardization of dose calculation.

Time, Distance, and Shielding

Good practice allows the practitioner to use the aforementioned physical entities to maximize efficiency and safety. Of the three parameters, distance, because of the inverse square relationship with dose, can be most useful in reducing dose to staff. The use of long-handled implements for source handling is recommended. Preplanned choreography of source loading and unloading and thoughtful layout of sources and equipment can reduce the time of exposure and hence dose to staff or patients. Finally the use of appropriate afterloading techniques and appropriate barriers can maximize the shielding of personnel from the radioactive sources. In the United States, the Nuclear Regulatory Commission has a guidance and compliance document 10CFR35,[2] which specifies regulations pertaining to authorized users of radioactive by-products, license requirements, equipment specifications, and the reportage of medical events. Some states—agreement states—have local regulation that meet or exceed these federal requirements.

Essential to a brachytherapy program is the ability to independently verify the stated activity of any received radioisotope before administration. The physics unit should have a variety of appropriately calibrated and traceable well-chambers and electrometers with seed specific seed holders.

Planning

Central to good brachytherapy planning practice is the importance of good geometry. The spacing of sources or catheters in regular arrays and patterns mitigates the later need to overmodulate the source dwell times or position. The historical planning techniques of Paterson-Parker,[3] Quimby,[4] and Paris[5] systems serve as safe starting points from which minor planning modifications can be made.[6]

Brachytherapy practitioners may use three principal planning approaches. A single site example, Iodine-125 (^{125}I) seed placement for prostate cancer, is used for illustration.

Preplanning

The prostate volume is assessed using three-dimensional (3D) imaging: ultrasound, magnetic resonance imaging (MRI), or computed tomography (CT). An initial plan is run to evaluate pubic arch interference, volume of target and the number, and activity of sources required. With practice each institution can make an accurate determination of the number and activity of seeds to be ordered based on the target volume. The configuration of needles, seeds, and spacers is determined and prepared before the procedure and brought into the operating room (Figure 15-1, *A, B*).

Real-Time/Dynamic Planning

In this scenario, the plan is developed during the operative procedure. Some prepreparation is needed to assure adequate supplies are available for any eventualities. Advantages include the ability to dynamically compensate for any needle or seed misdirection that may occur during insertion with adjustments to subsequent needle or seed insertion. Secondly, during the brachytherapy procedure edema secondary to needle insertion can be compensated for.

Postplanning

This is used as a passive assessment following the implant. This technique is best practiced by experienced users who will position seeds or catheters a priori with a good idea of the likely dosimetric outcome. Manual or automated seed finding is employed, usually using CT imaging. Postsurgical edema

TABLE 15-1 Radio-Isotopes in Common Clinical Use with Their Relevant Physical Properties

Isotope	Half-Life	Emission Type	Mean Therapeutic Energy	Half Value Layer mm of Lead
Iodine-125	59.6 d	Gamma	28 keV	0.025
Palladium-103	17 d	Gamma	21 keV	minimal
Cesium-131	9.6 d	Gamma	29 keV	minimal
Cesium-137	30 yr	Gamma	662 keV	5.6
Iridium-192	74.2 d	Gamma	380 keV	2.5
Gold-198	2.7 d	Gamma/Beta	412 keV	2.7
Strontium-90/Yttrium-90	28.8 yr/2.7 d	Beta	2.27 MeV	>1
Ruthenium-106	373 d	Beta	3.54 MeV	>1
Californium-252	2.6 yr	Neutron	2.3 MeV	*

TABLE 15-2 Brachytherapy Dose Rates and Common Clinical Sites of Use

Definition	Rate of Dose Delivery	Common Clinical Sites
High dose rate (HDR)	>12 Gy/hr	Cervix, endometrium, vaginal
Low dose rate (LDR)	0.4-2 Gy/hr	Gynecologic, sarcoma
Very low dose rate (vLDR)	<0.4 Gy/hr	Prostate, lung
Pulsed dose rate (PDR)	>12 Gy/hr delivered over multiple pulses per day	Gynecologic, head and neck

and resolution of the same may be tracked at intervals; day 0, day 1, and day 30 may be used as proxies for initial, near maximum edema, and steady-state seed configurations, respectively.

Planning Systems

Brachytherapy planning systems are commonly license add-ons to external beam systems and require modules for DICOM import/export, contouring, 3D display dose volume analytics. The AAPM TG 53[7] offers a quality assurance (QA) strategy to assure contour quality, positional fidelity, and accurate dose calculation in the system. Commercial isotopes have been evaluated using the TG 43[1] protocols and competent systems will have standard seed configurations preloaded and accommodate manual entry of new seed data.

CLINICAL SCENARIOS

Gynecologic Cancers

Cervical Cancer

Cervical cancer was one of the first tumors to be treated with brachytherapy with initial reports of cervix low dose rate (LDR) brachytherapy using radium published in 1903. The original principles of treatment with a central tandem and ovoids placed against the cervix have remained, although fortunately we have moved away from the use of wine corks as applicators. For many years, a fixed dosimetry technique based on the Manchester principles was used to deliver a defined dose to point A 2-cm superior and lateral to the external os. This was then enhanced by the use of the International Commission on Radiation Units (ICRU) rectal and bladder points to predict toxicity to organs at risk. However, the advent of 3D imaging moved cervix cancer brachytherapy away from point dosing and estimation of dose to organs at risk to volumetric dosing and precise determination of maximal dose received. This has resulted in fewer toxicities and the ability to deliver higher doses, which results in higher cure rates.[8,9] It has also moved treatment in general away from LDR and toward high dose rate (HDR) and pulsed dose rate (PDR) brachytherapy with the ability to optimize dose and sculpt it around the organs at risk. Randomized studies have shown the equivalence of LDR to HDR with the possibility of lower toxicity with HDR.[10] There are no randomized studies of PDR versus LDR or HDR but retrospective data indicate they are likely to be comparable.

The brachytherapy applicator is generally placed operatively. A preoperative MRI close to the time of brachytherapy improves applicator selection and target definition.[11] The

patient may receive general anesthesia or regional anesthesia. Analgesia can be maintained throughout the length of a PDR implant or a single-insertion fractionated HDR implant using a spinal catheter.[12] Spinal anesthesia does not cause tumor hypoxia during an HDR implant.[13] Examination under anesthesia confirms the preoperative imaging findings. The cervix is dilated and a uterine tandem is placed, preferably using ultrasound guidance; see Figure 15-2, *A, B*.[14] A variety of applicators are available for intracavitary brachytherapy. For tumors more than 5 cm, the addition of interstitial needles into specialized applicators[15] is becoming more common because it has brought the ability to deliver interstitial brachytherapy to a wider group; see Figure 15-3. Interstitial template applicators such as the MUPIT[16] or the Syed-Neblett[17] applicator should be used to treat disease with marked lateral or vaginal extension, although it is important to maintain a degree of central dose heterogeneity (in contrast to the heterogeneity preferred in interstitial implants in other areas of the body) to maintain the central cervix doses needed for cure.[18] Studies of intensity modulated radiation therapy (IMRT) versus brachytherapy show that external beam radiation therapy (EBRT) techniques cannot deliver the high-dose regions that are required for cure, so brachytherapy remains a necessary component of treatment.[19]

Because of anatomy of the pelvis, the bladder and rectum always receive a proportion of the radiation dose. This dose varies according to physiological variations (e.g., the bladder dose may vary according to the extent of bladder filling, which may also affect the amount of small bowel in the field).[20] The traditional ICRU reference points[21] have been widely used in gynecologic brachytherapy since their inception. However, in the era of CT- and MRI-based gynecologic brachytherapy treatment planning, it has been shown in cervix cancer brachytherapy that the ICRU reference points do not provide a good surrogate for normal tissue dose evaluation in the pelvis.[22] The GEC/ESTRO and ABS recommendations for normal tissue

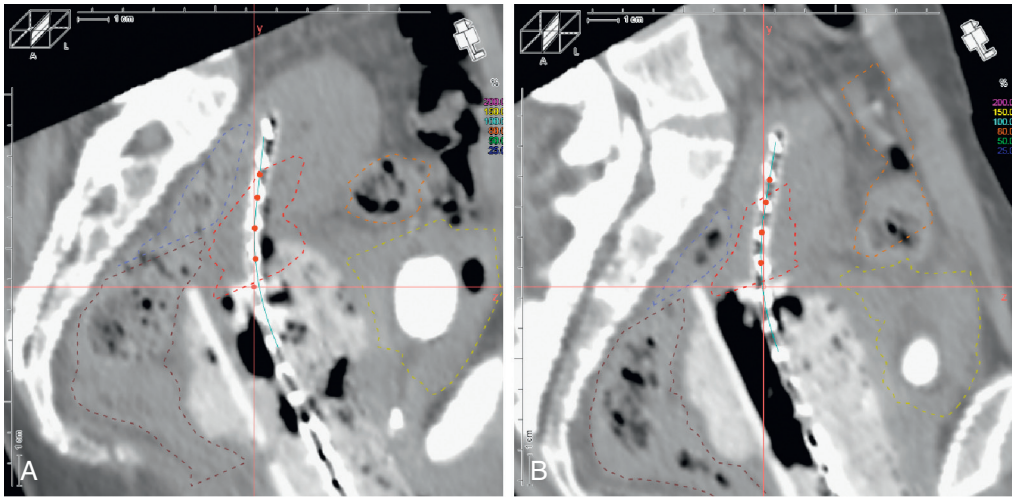

Figure 15-2 Sagittal planning CT image demonstrating placement of uterine tandem without ultrasound guidance, causing a posterior myometrial perforation (not penetrating serosa), and with ultrasound guidance, showing the tandem within the uterine cavity.

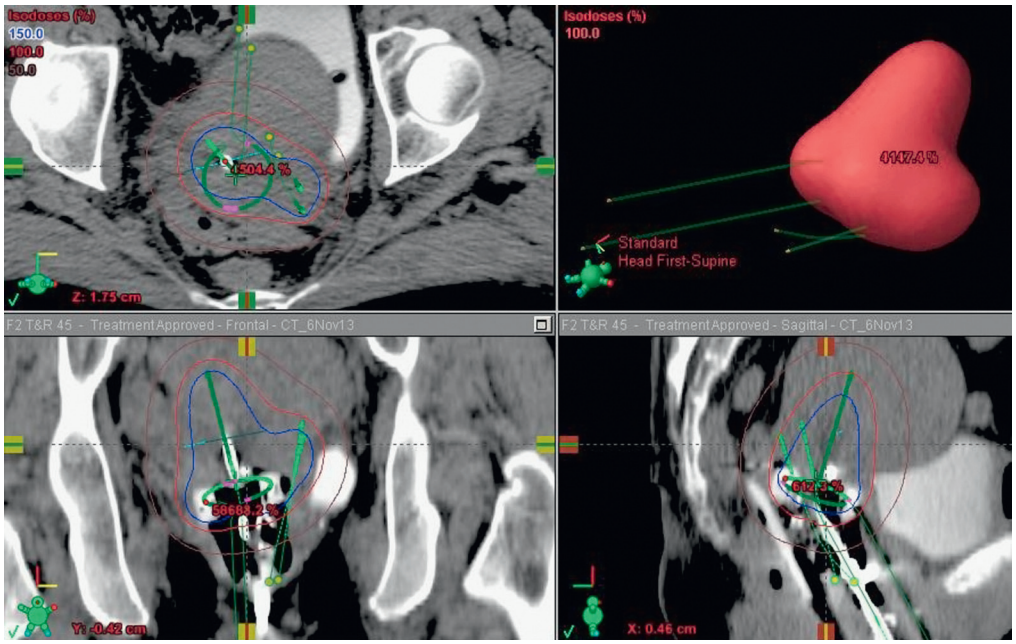

Figure 15-3 Illustration of tandem and ring with interstitial needles allowing additional dose coverage to tumor.

dose evaluation in cervical cancer based on CT- or MRI-based treatment planning allow a much more accurate determination of the doses received by the bladder and the rectum during cervical tandem and ring brachytherapy.[23] This allows not only better prediction of late effects but also dose sculpting using HDR optimization to ensure clinical target volume (CTV) coverage while minimizing normal tissue irradiation. Although devised for cervical brachytherapy dosimetry, these recommendations are generally used for evaluation of treatment plans in all areas of gynecologic brachytherapy.

Endometrial Cancer

Brachytherapy for the management of endometrial carcinoma was first described by Heyman in 1935, before the routine use of hysterectomy for uterine cancer.[24] Endometrial cancer is the most common gynecologic malignancy in the United States and the incidence is predicted to rise as obesity rates increase. Fortunately, the majority of patients with endometrial cancer are caught at an early stage because of vaginal discharge and bleeding. The use of radiation alone has now evolved and the primary treatment for endometrial cancer is surgery, total abdominal hysterectomy (TAH), and bilateral salpingo-oophorectomy (BSO).

Vaginal cylinder brachytherapy can be used in the treatment of selected gynecologic malignancies.[25-27] It may be indicated as adjuvant treatment following hysterectomy or for vaginal recurrence of gynecologic cancer in selected patients. The majority of patients receiving adjuvant radiotherapy will have EBRT to the whole pelvis followed by a fractionated course of brachytherapy. The use of pelvic radiotherapy in selected stage I patients has been examined in randomized trials[28-30] and a Cochrane meta-analysis.[31] The three main trials (including PORTEC[29,30] and GOG 99[32]) showed that the addition of pelvic radiotherapy to surgery resulted in significantly lower rates of local relapse but no difference in overall survival (OS). The lack of a difference in OS may be because of these patients already have a low risk of relapse and the sample sizes of the trials may be too low to accurately assess OS, especially in view of high rates of intercurrent illness in this patient population. Also, salvage radiotherapy to the vagina in the event of relapse is generally successful. The Cochrane meta-analysis found that the number of patients needed to treat to prevent one local recurrence was 16.7.[31] In patients with multiple high-risk factors there was a trend toward improved OS with pelvic radiotherapy.

The most common site of relapse in early stage endometrial cancer following surgery alone is the vaginal vault.[33] Adjuvant primary vaginal vault irradiation has been shown to decrease the incidence of vaginal apex recurrence in endometrial cancer from 12% to 15% to as low as 0% in selected patients, although it has no impact on OS.[25,34] Selected patients may have vaginal cylinder brachytherapy alone as adjuvant radiotherapy (e.g., patients with a well-differentiated adenocarcinoma of the endometrium with myometrial invasion >50%, which gives similar regional control rates to pelvic EBRT with significantly less toxicity).[25,34] The use of HDR vaginal cylinder brachytherapy is well established.[35-37] The role of pelvic lymphadenectomy and postoperative radiotherapy in that setting is a controversial and less well-defined area.[38,39]

Vaginal vault brachytherapy can be administered using a variety of different applicators. The most commonly used applicator is a single-channel cylinder that comes in a variety of widths, chosen according to patient anatomy and comfort (Figure 15-4). HDR afterloading has become increasingly common for vaginal cylinder brachytherapy, with no increase in morbidity or local control rates seen in retrospective analysis.[37] The target for vaginal vault brachytherapy is the vaginal mucosa and the operative scar. Ninety percent of recurrences occur at the vaginal vault and 10% in the distal vagina; therefore, in the majority of cases the upper third to half of the vagina is treated. This decreases the morbidity associated with treating the whole vagina, such as vaginal dryness or shortening.[40] Brachytherapy can be prescribed at the cylinder surface or at 5 mm into tissue, a depth which approximates the vaginal lymphatics.

The conversion of LDR dose to HDR dose is the area of the greatest variation between investigators, with fractionation schemes chosen as much because of the availability of local resources as radiobiological parameters. For HDR to be radiobiologically equivalent to LDR, the dose per fraction should be kept as low as is practically possible, usually requiring the total dose to be split into several fractions. The most common endometrial cancer HDR postoperative vaginal vault brachytherapy fractionation schedule in the United States in 2002 was 15 Gy in three fractions when given with EBRT and 21 Gy in three fractions when brachytherapy alone was used, both prescribed at 0.5 cm from the cylinder surface.[36] The dose and fractionation of HDR administered is closely correlated with local control and late complications in gynecologic brachytherapy.[41,42] Sorbe et al showed equivalent locoregional

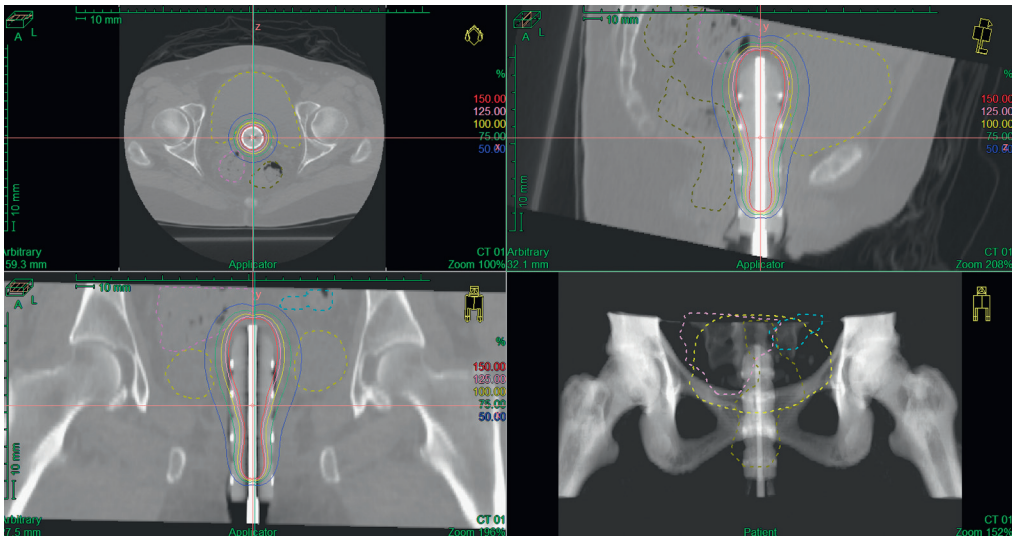

Figure 15-4 Single-channel cylinder to deliver vaginal brachytherapy. Axial and sagittal images show relation to the rectum and bladder.

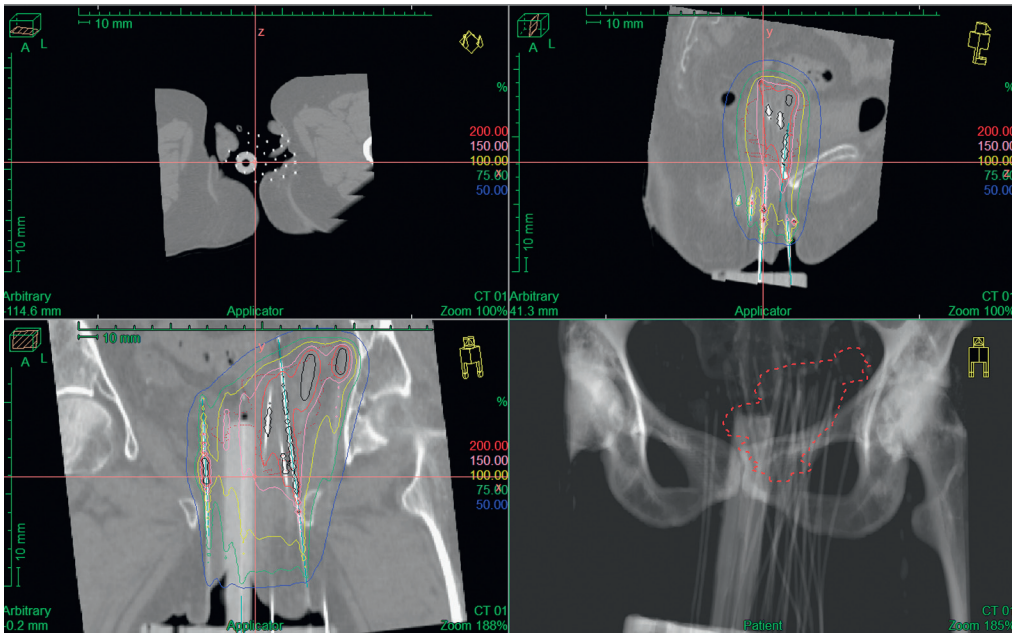

Figure 15-5 Interstitial brachytherapy treatment for endometrial cancer recurrence at the vaginal vault. A central obturator is placed into the vagina with sources allowing for central vaginal dose. A template is placed over the obturator to allow placement of interstitial needles allowing coverage of disease.

recurrence rates when treating the vaginal vault with HDR brachytherapy alone, randomizing to a schedule of 15 Gy in six fractions or 30 Gy in six fractions at 0.5 cm from the cylinder surface over 8 days.[43] However, there were much lower rates of late vaginal morbidity in the lower dose per fraction group. The biological effects increase faster with an increasing dose per fraction in late reacting than early reacting normal tissue.[43,44] Therefore, a small dose per fraction in HDR may be associated with a lower risk of late complications and a better therapeutic ratio providing that overall treatment time is not overprotracted. Vaginal vault brachytherapy can also be used to treat other gynecologic malignancies such as postoperative early stage cervix cancer[27] or early stage vaginal cancer.

For patients with >1-cm residual disease at the vaginal vault at the time of brachytherapy, an interstitial applicator should be used for the boost treatment. There are commercially available vaginal cylinders with interstitial needles integrated within them or alternatively a full interstitial template should be used. The central dose heterogeneity as described with interstitial cervix implants is not as easily achieved in this situation because of the lack of a uterus (Figure 15-5).

As endometrial carcinoma is linked to obesity and hypertension, some patients have medical comorbidities that preclude surgery; for those, radiation therapy may be the definitive treatment of choice. In this group, treatment is delivered via intracavitary uterine brachytherapy applicators, with or without EBRT. A variety of brachytherapy techniques have been described including Heyman capsules, and double-lumen intrauterine catheters, with acceptable rates of OS in this group of patients with high levels of intercurrent illness. Initial experiences described techniques using LDR brachytherapy[45,46] with applicator insertion under anesthesia and the patient immobilized throughout the treatment often for several days. Immobilization prevents complications such as applicator movement or uterine perforation, but the risk of morbidity such as deep vein thrombosis and decubitus ulcers increases. Retrospective analysis has shown similar disease control comparing LDR and HDR remote afterloading brachytherapy in inoperable disease.[27] HDR carries the advantage over LDR in this subset of patients with significant comorbidities that treatment times are greatly reduced, from several days to multiple fractions of several minutes. Various series have reported the use of different applicators, showing that multiple channels are generally preferable to a single channel and 3D planning achieves better target coverage while still constraining the surrounding normal structures, particularly the rectum, to below recommended doses[47,48]

Genitourinary Cancers

Prostate

Brachytherapy for prostate cancer is evolving. In the past, brachytherapy was most commonly used for men with low-risk prostate cancer. The use of prostate brachytherapy has widened over recent years and now incorporates both permanent implant of very low dose rate (vLDR) sources and temporary implants of HDR sources. Both techniques are now used as monotherapy for patients of low- or intermediate-risk disease or as a boost for patients with high-risk disease. Prostate brachytherapy is also being evaluated as a salvage treatment option after previous EBRT.

Image guidance is the principle factor that guides both vLDR and HDR prostate brachytherapy. The most common technique for vLDR brachytherapy is with transrectal ultrasound (TRUS) guidance using preoperative or intraoperative planning techniques (Figure 15-1, *A, B*). HDR brachytherapy for prostate cancer also involves image guidance, using ultrasound or CT, with placement of catheters into the prostate (Figure 15-6, *A, B*).

Relative contraindications for vLDR brachytherapy include high International Prostate Symptom Score (IPSS), prior pelvic radiotherapy, transurethral resection defects, large median lobe, gland size >60 cc, and inflammatory bowel disease.[49] Different loading techniques can be used to achieve dose coverage to the CTV as well as protect organs at risk.[50] Pre- and postprocedure dose evaluation should include dose to 90% of

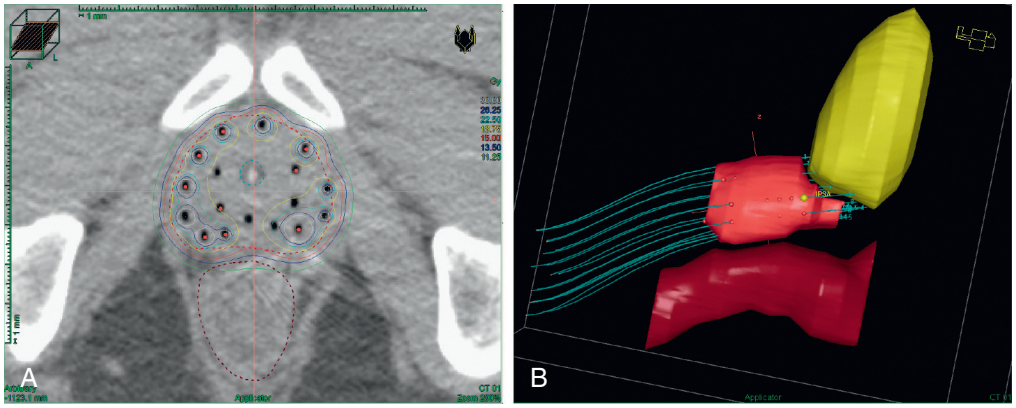

Figure 15-6 **A,** HDR prostate axial image showing placement of HDR catheters and dose distribution around the prostate. **B,** 3D rendering of the prostate with catheters and relation to the bladder and rectum.

the CTV (D_{90}), volume receiving 100% of the dose (V_{100}), volume receiving 150% of prescription dose (V_{150}), rectal D2cc, urethral volume receiving 150% of dose (UV_{150}).[51]
