Based on a meta-analysis, the overall estimated prevalence of pituitary adenomas was 16.7%, with 14.4% observed in autopsy series and 22.5% in radiographic series of volunteers or patients imaged for other diseases.[14] Over time, different criteria have been used for distinguishing hyperplasia from pituitary adenomas. The broader application of immunohistochemical staining for pituitary hormones and the differences in slice thicknesses for MRI may account for the wide variation in incidence reported in the literature.

The frequency of the various types of pituitary adenomas differs widely according to age and gender. Prolactinomas are the most common, followed by nonfunctioning adenomas, growth hormone (GH)–secreting adenomas, and adrenocorticotropic hormone (ACTH)–secreting adenomas. Nelson's syndrome (growth of an ACTH-secreting pituitary adenoma after bilateral adrenalectomy resulting from loss of adrenal suppression of pituitary inhibition) and thyroid-stimulating hormone (TSH)–secreting adenomas are rare.

PREVENTION AND EARLY DETECTION

No successful strategy has been described or is known to exist that prevents the development of these tumors. Given the prevalence of pituitary abnormalities on MRI scans in normal adult patients, the routine use of screening MRI or endocrine workup is not feasible and is not recommended. When imaging is performed not specifically for a pituitary lesion, an incidental finding of a pituitary lesion, the so-called "incidentaloma," may be diagnosed.[15] Most incidentalomas are <1 cm, nonfunctional, and may be associated with pituitary hormonal deficiencies, excess hormone secretion, or visual field defects.[16] The majority of incidentalomas in reality are pituitary adenomas with incomplete or limited biochemical work-up. Patients with macroincidentalomas (≥1 cm) should be evaluated for hypopituitarism and undergo visual field testing if the sellar mass abuts or compresses the optic chiasm. Based on autopsy series, pituitary incidentaloma occurs in 1.5% of children and adolescents.[17]

A patient with signs or symptoms suggestive of an endocrine abnormality should be referred to an endocrinologist for appropriate evaluation. Consultation with an endocrinologist and a medical geneticist is appropriate for patients if MEN1 or another familial syndrome associated with pituitary adenoma is suspected. For these patients, a baseline MRI of the pituitary can be considered, although routine imaging of the pituitary in a patient without clinical symptoms is not uniformly practiced. The management of inherited pituitary tumors is usually similar to that of sporadic adenomas.[18] Because pituitary tumors that arise as a part of MEN 1 and FIPA are more aggressive, occur at a younger age, and often respond poorly to treatment, earlier identification may be useful. To help identify carriers in whom regular clinical and biochemical monitoring would be useful, genetic screening for mutations in the relevant genes is recommended in patients with MEN 1 and Carney complex.

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

Despite the screening of common oncogenes and tumor suppressor genes in pituitary adenomas, the molecular and cellular pathogenesis of pituitary tumors is largely unknown.[19] Based on *X* chromosome inactivation analysis, it appears that most pituitary adenomas derive from a monoclonal expansion, which suggests that general principles of tumorigenesis may apply to pituitary adenoma formation.[20] The MAPK (mainly Ras/extracellular signal-regulated protein kinase

[ERK]) and the PI3K/Akt signaling pathways appear to have putative roles in pituitary tumorigenesis or continued growth because the activity of these pathways are often activated in pituitary tumors. Because the Raf/MEK (mitogen-activated protein kinase/ERK kinase)/ERK signaling is a major pathway in the regulation of cell growth, proliferation and survival, it is likely that these genetic alterations could contribute to several aspects of pituitary tumor growth and survival.[21] Although its role is not fully understood, a docking protein in the endothelial growth factor receptor (EGFR) pathway, EGF pathway substrate number 8 (Eps8), is overexpressed (almost sixfold higher) in pituitary tumors compared with normal anterior pituitary tissue.[22] Because pituitary tumors are mostly benign, a protective mechanism to restrict uninhibited growth of tumor cells is probably active. The concept of oncogene-induced senescence is one possible mechanism. High pituitary $p21^{Cip1/WAF1}$ levels appear to promote senescence and restrict tumor growth.[23] One study proposed the possible presence of pituitary adenoma stemlike cells,[24] which has encouraged the investigative development of newer pharmacologic agents.[25] HMGA1B and HMGA2 overexpression in mice induces the development of GH and prolactin (PRL) pituitary adenomas mainly by increasing E2F1transcriptional activity.[26] Upregulation of PIT1, a transcriptional factor that regulates the gene expression of GH, Prl, Ghrhr, and Pit1 itself, also has a role in pituitary tumorigenesis.[27]

For somatotroph (growth hormone) adenomas, an activating mutation of the alpha subunit of the guanine nucleotide stimulatory protein (Gs-alpha) gene is found in about 40% of patients, which results in activation of adenylyl cyclase.[28] Overexpression of the pituitary tumor transforming gene (*PTTG*) is also seen in most human somatotroph adenomas.[29] Mutations of fibroblast growth factor-4 (FGF-4) have led to development of lactotroph adenomas in transgenic mice.[30]

ANATOMY, PATHWAYS OF SPREAD, AND PATHOLOGY

Anatomy and Pathways of Spread

The pituitary gland is a midline intracranial organ that measures approximately 8 mm in the anteroposterior axis, 10 mm in the transverse axis, and 6 to 8 mm in the supero-inferior axis. It occupies the cavity in the sphenoid bone known as the sella turcica. The pituitary gland is separated from the structures above it (i.e., the optic chiasm, hypothalamus, anterior cerebral arteries, and floor of the third ventricle) by the sellar diaphragm, which is formed by a circular fold of dura. Immediately anterosuperior to the diaphragm sella lies the optic chiasm. The pituitary stalk (infundibulum) crosses the sellar diaphragm and connects the hypothalamus to the pituitary gland. Anteriorly, the tuberculum sellae lies in the floor of the sella and extends supero-laterally to form the anterior clinoid processes. The posterior aspect of the sella forms the dorsum sellae and extends supero-laterally to form the posterior clinoid processes. Laterally, the cavernous sinuses contain cranial nerves III, IV, V_1 (ophthalmic nerve), V_2 (maxillary nerve), and VI and the internal carotid artery. Given the proximity of the pituitary to these various structures, parasellar tumors can affect cranial nerves III, IV, V, and VI, and suprasellar tumor extension can lead to bitemporal hemianopsia via compression of the optic chiasm. Figure 29-1 demonstrates the complex anatomy of the parasellar region.

The pituitary has two distinct embryologic origins; the first gives rise to the anterior and intermediate pituitary lobes, and the second gives rise to the posterior pituitary lobe. The anterior (adenohypophysis) and intermediate lobes are derived from Rathke's pouch, which is an evagination of ectodermal tissue from the primitive oral cavity (pharyngeal pouches). The

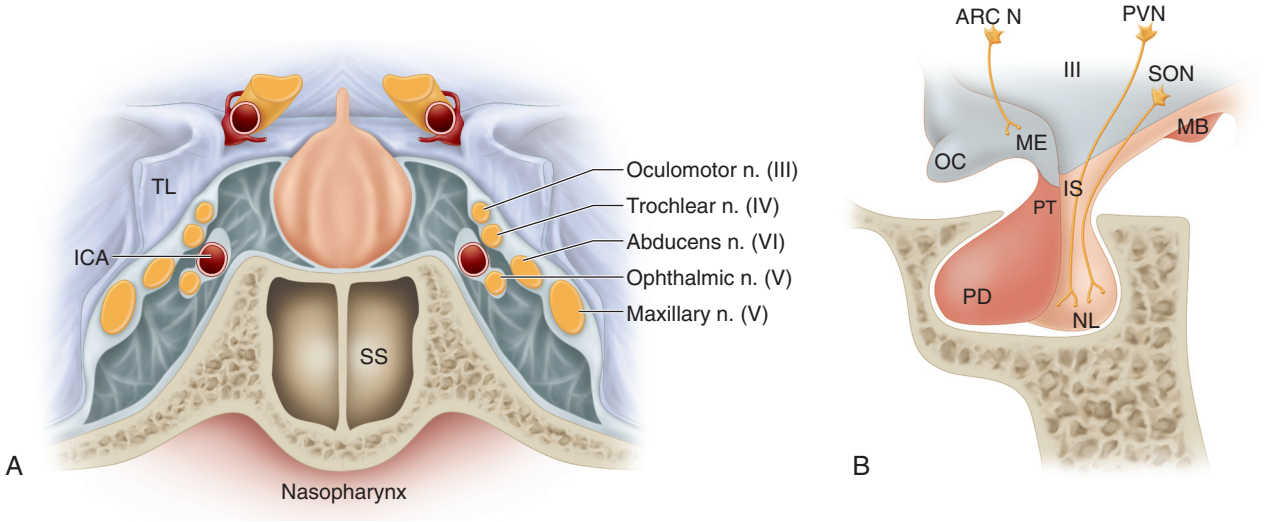

Figure 29-1 **A,** Anatomy of the sellar and parasellar regions. This coronal-view diagram illustrates the proximity of the pituitary gland to several important neural and vascular structures. The gland is laterally bordered by the cavernous sinuses *(black)*, which contain within their confines or their walls the carotid artery and the oculomotor, trochlear, maxillary, and abducens nerves and the first two divisions of the trigeminal nerves. The optic chiasm lies immediately superior to the gland. *ICA,* Internal carotid artery; *SS,* sphenoid sinus; *TL,* temporal lobe; *III,* third ventricle. **B,** Anatomy of the pituitary gland. This sagittal-view diagram of the pituitary gland shows the hypothalamus, pituitary stalk, and pituitary gland located in the sella turcica. The anterior gland, or adenohypophysis, is composed of the pars distalis (PD), rudimentary pars intermedia, and pars tuberalis (PT). The posterior gland, or neurohypophysis, is composed of the median eminence (ME), located in the hypothalamus, the infundibular stem (IS), and the neural lobe (NL). The large neurons located in the supraoptic (SON) and paraventricular (PVN) nuclei project to the neural lobe, where they store and release oxytocin and vasopressin into the systemic circulation under the appropriate stimulus. *ARC N,* Arcuate nucleus; *MB,* mammillary bodies; *OC,* optic chiasm.

posterior lobe (neurohypophysis) and stalk are derived from the diencephalon and, therefore, have a neuroectodermal origin. The anterior pituitary lobe accounts for most of the pituitary gland and produces at least six hormones: prolactin (PRL), adrenocorticotropic hormone (ACTH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), growth hormone (GH), and thyroid-stimulating hormone (TSH). The intermediate lobe produces melanocyte-stimulating hormone (MSH). The posterior lobe stores and releases two hormones, vasopressin (antidiuretic hormone [ADH]) and oxytocin, which are produced by the hypothalamus.

The hypothalamic-hypophyseal portal system, a vascular network that surrounds the infundibulum and connects the anterior lobe of the pituitary with the hypothalamus, has an important role in the regulation of the anterior pituitary hormones mediated by stimulating or inhibiting hormones derived from the hypothalamus. These hormones include GH-releasing hormone, GH-inhibiting hormone (somatostatin), prolactin-secreting hormone, prolactin-inhibiting hormone, corticotrophin-releasing hormone, thyrotropin-releasing hormone, FSH-releasing hormone, and LH-releasing hormone. The anterior pituitary hormones are also regulated by a hormonal feedback mechanism from the target glands such as the adrenals.

Pituitary tumors are generally classified as microadenomas or macroadenomas depending on the diameter of the tumor as described by Hardy.[31] A microadenoma is less than 1 cm in diameter, whereas a macroadenoma has a diameter of 1 cm or greater. Incidental microadenomas have been observed with a frequency of 3% to 25% in large, unselected autopsy series.[32] Microadenomas are more frequently seen in females, whereas macroadenomas occur with equal frequency in males and females. Macroadenomas are more common than microadenomas. For lesions less than 3 mm in diameter, the term *pico-adenoma* has been used.[33]

Pathology

Before the introduction of electron microscopy, modern immunohistochemical procedures, and modern staining and fixation techniques, pituitary tumors were classified according to Mallory's trichrome histologic staining technique as chromophobic, acidophilic (or eosinophilic), or basophilic tumors. Based on classic fixation and staining, Cushing's disease was associated with basophilic adenoma, acromegaly with eosinophilic adenoma, and nonfunctioning adenoma with chromophobic adenoma. With newer methods of immunostaining, it has become possible to identify cells as prolactin, ACTH, GH, LH FSH, alpha subunit, or TSH. It is important to note that the functional status of a pituitary adenoma is defined by clinical symptoms and not by immunohistochemical staining patterns.[34]

According to the World Health Organization (WHO) classification of pituitary tumors, they are defined as neoplasms located in the sella turcica. This classification is based on structural similarities of the normal parenchymal cells and the immunohistochemical demonstration of hormone secretion. Based on this definition, pituitary adenomas may express more than one or two hormones, based on immunohistochemical patterns. The classification includes a new entity designating a borderline adenoma or adenoma of uncertain behavior.[35] The atypical adenoma is defined as an invasive tumor with an elevated mitotic index (MIB-1-labeling index greater than 3%) and extensive nuclear immunostaining for TP53.[35] The German Registry of Pituitary Tumors reported the frequency of atypical pituitary adenomas as 2.7%.[36]

Most lesions are easily identified on routine histopathologic testing, but metastatic well-differentiated neuroendocrine carcinoma can present a diagnostic challenge.[37] For patients with acromegaly or Cushing's disease, hyperplasia may be clinically indistinguishable from an adenoma. Differentiation of hyperplasia from adenoma can be made using a reticulin stain. Normal pituitary tissue is composed of small acini of pituitary cells surrounded by an intact reticulin network. In hyperplasia, the architecture of the acini is maintained, but the acini are increased in size, and the reticulin stain demonstrates an intact network. Pituitary adenomas are characterized by a complete disruption of the reticulin fiber network.

The pathologic hallmark of pituitary adenomas is the monotonous and monomorphous proliferation of neoplastic cells that replaces the normal acinar pattern in the pituitary lobe. GH-producing cells are seen with greater frequency anteriorly in the lateral aspects of the pituitary. Prolactin-producing cells are distributed throughout the pituitary but have a greater density in the posterior lateral aspect of the gland. ACTH-producing cells are present in the median wedge. TSH-producing cells are seen in the anterior aspect of the median wedge. Gonadotropin-producing cells are distributed throughout the anterior pituitary. Nonfunctioning adenomas typically have solid sheets, nests, and sinusoidal patterns and are interrupted by pseudo-papillae and striking pseudo-rosettes around vascular channels. Overlap of the distribution of these functional hormonal secretory cells does exist, and they do not reside in well-demarcated zones of the pituitary. Mitoses are seen in 3.9% of noninvasive adenomas, 21.4% of invasive adenomas, and 66.7% of carcinomas.[38]

The usefulness of labeling-index and TP53 immunostaining is not clear because these assessments may not correlate with tumor behavior. Invasive pituitary adenomas usually exhibit a higher Ki-67 proliferation index.[39] Markers such as proliferating cell nuclear antigen (PCNA), Ki-67/MIB-1, and antiapoptotic Bcl-2 have not demonstrated consistent correlation with tumor invasiveness or recurrence.[40] Galectin-3, a β-galactoside-binding protein, may play a role in pituitary tumor progression, and immunostaining for this is also available.[41]

The pituitary is composed of at least six distinct cell types, which are responsible for the production of at least one hormone. Advances in molecular biology have identified three major pathways of cytodifferentiation of adenohypophyseal cells, T pit; Pit-1; and SF-1, GATA-2, ER.[42,43] These pathways are determined by a complex pattern of transcription expression, which help classify various adenomas.[44] In situations in which histologic and immunohistochemical profiles are atypical, electron microscopy can be helpful in achieving accurate classification.

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Clinical Manifestations

Patients with pituitary tumors can have a number of different symptoms and presentations, depending on the size and mass effect of the tumor and hormonal abnormalities. Headaches can occur with a lesion of any size. When the tumor extends superiorly into the suprasellar region, visual loss can occur, including bitemporal or homonymous hemianopsia, superior or inferior field cut deficits, and central scotoma. Extension into the cavernous sinus can lead to cranial nerve dysfunction (commonly III and IV cranial nerve palsies). Cranial nerves V and VI are less commonly affected. Lateral extension into the temporal lobe may cause seizures. The clinical presentations and endocrine abnormalities can vary, depending on the age and sex of the patient. Patients with large adenomas may have compromised pituitary function, which can lead to

hypogonadism, secondary hypothyroidism, and adrenal insufficiency.[45] Diabetes insipidus is extremely rare and most commonly is a manifestation of an invasive and infiltrative tumor (such as a metastasis), an inflammatory condition (such as neurosarcoidosis), or a lesion that arises from or is attached to the infundibulum or hypothalamus (such as a craniopharyngioma).[46] If the gland acutely infarcts or hemorrhages, pituitary apoplexy may result, which may require urgent surgical decompression.

Patient Evaluation

General Approach

For all patients, a detailed history should be obtained and a thorough physical examination performed. This will allow assessment of the possible manifestations of the underlying endocrine disorder and any neurologic deficits, such as bitemporal hemianopsia from superior compression of the optic apparatus by the tumor. Neurologic sequelae may include headache from pressure effects on the dura, cranial nerve (III, IV, V, and VI) abnormalities from extension into the cavernous sinus, visual symptoms from suprasellar extension to the optic chiasm or nerves, and behavioral changes.

Ophthalmologic evaluation with formal visual field testing should be done in patients with visual symptoms and those with extension of the tumor outside the sella. Bitemporal hemianopsia is classically associated with suprasellar extension of the pituitary tumor, causing compression of the anterior aspect of the optic chiasm. Other visual field deficits can also occur. Changes in ophthalmologic assessment can be used to monitor the response to therapy.

Laboratory Assessment

Initial tests help determine if a pituitary deficiency exists and diagnose the secretory status of the adenoma. Screening studies should include TSH, free thyroxine (T_4), ACTH, cortisol, prolactin, somatomedin C (insulin-like growth factor-1 [IGF-1]; this is the primary molecule mediating the effects of growth hormone at the cellular level, and its secretion, primarily from the liver, is directly regulated by growth hormone), LH, FSH, alpha subunit, and, in men, testosterone. The alpha subunit is common among the three glycoprotein pituitary hormones, FSH, LH, and TSH and is also found in placental chorionic gonadotropin; rarely pure alpha-subunit secreting tumors are identified, and these are generally otherwise "nonsecreting chromophobe adenomas." These patients often have visual field abnormalities and partial hypopituitarism. The elevated serum alpha subunit shows a variable response to stimulation by thyrotropin-releasing hormone and is generally not suppressed by thyroid hormone administration. Tumor immunocytochemical studies demonstrate the presence of only the alpha subunit. Following resection or radiotherapy, serum alpha level subunit levels decrease. These patients therefore represent a new subset of functioning pituitary tumors. Determination of alpha subunit concentration is useful in managing some patients with pituitary tumors previously thought to have nonfunctioning chromophobe adenomas.

In addition to endocrine evaluation, a complete blood count, blood chemistry assessment, and urinalysis should be obtained. Because physiologic hormonal variations in the blood and urine levels can occur, the interpretation of these results should be considered based on diurnal variations, age and gender of the patient, and pregnancy and menopausal status. The conditions and timing under which these samples are obtained also influence interpretations of the results. Because the diagnosis of Cushing's disease can be difficult, multiple tests are performed over time and at different times during the day to help make a conclusive diagnosis.[47]

For patients with suspected Cushing's disease, 24-hour urinary free cortisol (UFC), midnight salivary cortisol, and 1-mg overnight dexamethasone suppression tests have similar sensitivity and specificity. The most precise method of measurement for 24-hour urinary free cortisol is tandem mass spectrometry. Salivary cortisol levels can have a wide range of normal nighttime values, which can raise questions about accuracy. The overnight dexamethasone suppression test may be influenced by several medications and requires specific time constraints (i.e., the tablet needs to be taken at 11 pm and blood test performed at 8 am the next day). As a result, this test should not be used as the sole test for diagnosing Cushing's syndrome. The definitive test for Cushing's disease and exclusion of ectopic ACTH syndrome is inferior petrosal sinus sampling, which requires measurement of ACTH from the right and left petrosal sinuses and peripheral site before and after corticotropin-releasing hormone (CRH) administration.

For patients with prolactinoma who also have macroadenoma, the prolactin level is usually greater than 200 ng/mL. Other common conditions that have been associated with hyperprolactinemia include end-stage renal disease, renal insufficiency, depression, primary hypothyroidism, acquired immunodeficiency syndrome, sarcoidosis, and nonalcoholic cirrhosis.[48] On the other hand, pituitary stalk compression from tumor may also cause elevated prolactin levels in the range of 150 ng/mL or less. Because antidepressants, protease inhibitors, verapamil, and phenothiazines may elevate prolactin levels, careful review of the medications that the patient is taking is necessary. A pregnancy test is mandatory for women with amenorrhea or hyperprolactinemia. Elevated serum prolactin levels greater than 300 ng/mL are usually diagnostic of pituitary adenoma, and levels greater than 100 ng/mL in nonpregnant patients often are associated with pituitary adenoma.

For patients with acromegaly, most cases result from excess secretion of growth hormone by a pituitary tumor.[49] The definitive test is measurement of growth hormone response to 75 g or 100 g of oral glucose (oral glucose tolerance test). This glucose load should normally cause marked suppression of the GH release to a level under 2 ng/mL. To ensure accuracy, these measurements of serum glucose and GH must be performed every 30 minutes for 2 hours. IGF-1 is also elevated after adjusting for gender and age variation. IGF-1 levels provide the best intermittent method for monitoring response to treatment, although dynamic testing of GH kinetics with the oral glucose tolerance test (OGTT) is also frequently used.

Mild hyperprolactinemia (<200 ng/mL) may be seen in some patients with nonfunctional adenomas as this is a common finding when any sellar mass causes stalk compression, interrupts blood flow and leads to interference with the prolactin-inhibiting dopamine transport.[50,51] Because these patients do not have hormone-related symptoms, nonfunctioning adenomas can be quite large at the time of diagnosis.

Imaging

Dynamic MRI of the brain with gadolinium is the imaging test of choice[52] given its superior resolution compared with computed tomography (CT), which evaluates calcifications and bony changes better than MRI (Figure 29-2). Dynamic coronal imaging techniques after contrast administration enhance normal pituitary tissue earlier and more intensely and help delineate adenoma tissue, which tends to enhance later. Because pituitary adenomas are less vascular than the normal pituitary gland, they usually appear hypointense following gadolinium administration, in the early, or immediate postgadolinium phase, and later may either remain hypointense, hyperintense, or isointense to the rest of the gland, emphasizing the need for dynamic MR imaging. On noncontrast T1-weighted MR images

Regardless of the presentation, accurate diagnosis and implementation of appropriate therapy or therapies is desired. A multidisciplinary approach optimizes patient care.

Figure 29-2 Axial T1-weighted, contrast-enhanced MRI of a pituitary adenoma demonstrating a large macroadenoma extending beyond the sella.

they may appear hypointense or isointense to the normal pituitary gland.[53] The posterior lobe of the pituitary has a high signal intensity on T1-weighted images (posterior pituitary bright spot) that distinguishes it from the anterior lobe, which has signal intensity similar to that of white matter. Thin slices (at 2-mm to 3-mm intervals) obtained before and after gadolinium contrast administration with images in the coronal, axial, and sagittal planes provide detailed information for the initial diagnosis and allow detection of small lesions. For patients who have undergone previous surgery, fat suppression techniques can help differentiate surgical fat grafts from tumor tissue. For patients undergoing SRS, thin-slice (1-mm) imaging with contrast medium is obtained to define the tumor and optic apparatus. For hypersecretory adenomas, positron emission tomography (PET) imaging with coregistration may be valuable.[54]

For patients with suspected Cushing's disease, thin-slice images of 1-mm thickness have greater sensitivity; even so, the tumor may not be detected in about 50% of patients.[55] Spoiled gradient recalled acquisition sequences may have superior sensitivity (80%) compared with conventional spin echo images following contrast enhancement.[56] The degree of contrast enhancement does not differentiate one sellar mass from another. A clear distinction between an intrasellar mass and normal pituitary tissue is not consistent with a pituitary adenoma.

Macroadenomas can compress the adjacent pituitary and may distort the pituitary stalk. When larger lesions demonstrate extrasellar extension, MRI scans can help delineate the relationship of the cavernous sinus laterally and the optic chiasm superiorly. If a plane of normal pituitary tissue can be observed on coronal-view, T1-enhanced images, the likelihood of cavernous sinus involvement is extraordinarily low. When there is significant suprasellar extension, the optic chiasm can be difficult to identify and may be best seen on coronal-view, fast spin-echo T2-weighted images. Pituitary apoplexy is caused by intratumoral hemorrhage and can be seen on T1-weighted images as an area of high signal intensity.

Imaging studies other than MRI may be needed. High-resolution CT may be used when MRI is contraindicated (i.e., because the patient has a pacemaker). CT scans can be useful when planning for transsphenoidal surgery. Pneumatization of the sphenoid sinus and cortical thinning of the sellar floor can be determined by bone windows. Angiograms are useful when aneurysms are considered within the radiographic differential diagnosis.

Differential diagnosis for a sellar lesion includes pituitary adenoma, congenital lesions (craniopharyngioma and Rathke's cleft cyst), infiltrative disease (granuloma, lymphocytic hypophysitis, and tuberculosis), primary lymphoma, chordoma, germ cell tumor, metastases, arachnoid cysts, aneurysm, inflammatory lesions, and meningiomas.

Serial MRI should be performed on a regular basis to detect tumor recurrence. Following SRS or radiation therapy, the initial scan should be obtained 6 months after treatment and then yearly.

Staging

Classification of detectable or symptomatic pituitary tumors can be based on endocrine dysfunction, clinical presentation, and anatomic extent of disease. These tumors can also be broadly classified as functional or nonfunctional based on their secretory activity. As adenomas enlarge, they can extend into suprasellar, parasellar, or infrasellar structures. To aid with surgical and imaging assessment, Hardy and Verzina[57] developed a classification system. Wilson's[58] modification of this classification system incorporates imaging and intraoperative findings of sellar destruction (grade) and extrasellar extension (stage). Others have defined giant adenoma as a lesion with extension beyond the sella and suprasellar space or size greater than 4 cm.[59,60] No universally accepted staging system exists for pituitary tumors.

PRIMARY THERAPY

General Strategies

The primary objectives of therapy include preservation or restoration of normal hormonal function, reversal of endocrine dysfunction, removal or control of the tumor mass effect, and reversal of neurologic symptoms while minimizing potential morbidity such as hypopituitarism. Modern surgical approaches, medical management, and innovative radiation techniques have improved the likelihood of accomplishing these goals.

Surgery

Advances in transsphenoidal approaches with microsurgical techniques have made this procedure the initial treatment of choice for patients with nonfunctioning pituitary adenomas, acromegaly, Cushing's disease, and TSH-secreting adenomas. Surgery provides immediate decompression for patients with progressive visual loss, symptomatic pituitary hemorrhage (apoplexy), or other signs or symptoms of neurological mass effect such as cranial neuropathy or hydrocephalus. For patients with prolactinoma who do not tolerate or respond to medical therapy, surgery can be considered. Surgery has also been useful in reducing the tumor bulk for combined management with radiation therapy or medical therapy. For patients undergoing SRS, surgery may play an important role because

a distance of 2 mm to 5 mm is needed between the tumor and the optic apparatus to deliver a sufficient dose to the tumor and to minimize the risk for optic neuropathy. Reoperation results in lower rates of success compared with the initial surgery.[61]

Four different transsphenoidal approaches (transnasal, sublabial/transseptal, transethmoidal, or transantral) can be considered. The transsphenoidal technique is the preferred approach for microadenomas, for pituitary tumors with extension toward the sphenoid sinus, and for some macroadenomas with suprasellar extension. This technique provides decompression of the optic chiasm and removal of intrasellar and suprasellar tumor tissue.

Transcranial surgery is generally reserved for large intracranial extensions and for cases in which transsphenoidal surgery has technical limitations (e.g., small sella and inadequate pneumatization of the sphenoid sinus).

A wholly endoscopic approach, for which nasal septal or oral incisions are not needed, may be used, and appears to have results that are similar to minimally invasive transnasal or sublabial approaches, although no true randomized, head-to-head comparisons have been conducted to determine whether complications or length of hospitalization are altered.[62,63] For patients undergoing endoscopic endonasal approaches, nasal crusting (98%) and discharge (46%) were the most common postoperative symptoms based on a prospective cohort study.[64] It may also be used to complement microsurgical approaches.

Finally, a supraorbital approach (the Lynch or modified Lynch procedure) has also been used for recurrent and residual suprasellar tumors. This approach allows one to avoid scar tissue from previous approaches and provides access for optic apparatus decompression.[65]

The various approaches for giant pituitary tumors (>4 cm) have recently been compared in a systematic review by Komotar et al.[66] Endoscopic endonasal approach resulted in a higher rate of gross total resection (GTR) (47.2% versus 9.6%; $p < 0.003$) and improved visual outcomes (91.1% versus 45.7%; $p < 0.003$) than either the microscopic transsphenoidal or the open transcranial approach for these tumors. It is important to note that the open transcranial approach may remain the treatment of choice for certain tumors and factors such as suprasellar extension (particularly lateral extension) and the location of the optic chiasm should be accounted for during selection of the operative technique. Berkmann[67] described the use of intraoperative MRI in 32 patients with tumors exhibiting suprasellar extension and causing visual impairment. The authors used a 0.15 T MRI to perform intraoperative pituitary imaging after safe resection was thought to be complete. Following the intraoperative MRI, additional tumor was removed in 8 patients (25% of cases).

Based on a questionnaire study of 958 neurosurgeons reporting on their own experience with transsphenoidal surgery, the risk for complications was inversely proportional to the surgeon's level of experience.[68] Reported complication rates among experienced surgeons include perioperative mortality (<1%), central diabetes insipidus (2%), cerebrospinal fluid (CSF) rhinorrhea (2%), and meningitis (2%). Transient central diabetes insipidus is reported to occur in up to 22% of patients at an active pituitary surgery center.[69] These complications are more common in patients with macroadenomas. The experience of the surgeon may influence the rate of this and other complications.[63,70]

The incidence of postoperative CSF rhinorrhea after transsphenoidal surgery ranges from 0.5% to 15% with the majority reporting 0.5% to 6%.[71] Use of a synthetic collagen fleece may decrease CSF leak and can help avoid the use of a lumbar drain.[71]

Medical Therapy

Because management of hormonal dysfunction as a result of oversecretion or undersecretion can have significant effects on quality of life and longevity, medical therapies play an important role in the management of patients with pituitary tumors as either primary or adjuvant therapy. Primary goals include correction of hormonal dysfunction and reduction of the mass effect from a secretory adenoma.

The initial treatment of choice for most prolactinomas includes dopamine agonists such as bromocriptine or cabergoline because they are highly effective in controlling hyperprolactinemia. Dopamine is the primary neuroendocrine inhibitor for the secretion of prolactin from the anterior pituitary gland. Dopamine produced by neurons in the arcuate nucleus is secreted into the hypothalamo-hypophyseal blood vessels of the median eminence, which supply the pituitary gland. The lactotrope cells that produce prolactin secrete prolactin continuously in the absence of dopamine; dopamine inhibits this secretion. Thus, in the context of regulating prolactin secretion, dopamine was historically referred to as prolactin-inhibiting factor and is sometimes still referred to as prolactin-inhibiting hormone, or prolactostatin. Therefore, dopamine-agonists would be expected to and have been shown to be clinically effective at reducing prolactin secretion. In addition, partial tumor regression and improvement in mass effect from an enlarged adenoma are frequently observed with medical treatment alone. Long-term maintenance treatment is generally necessary to control hyperprolactinemia and growth of a prolactinoma.

Medical therapy can be used in several situations for patients with GH-secreting tumors as well. Somatostatin analogs such as octreotide or lanreotide can be used to lower elevated GH levels before surgery, for patients with persistent GH and IGF-1 elevation after surgery and for patients who continue to receive medical therapy until radiation therapy or radiosurgery has taken full effect. Pegvisomant is a modified version of human GH designed to bind to and block the GH receptor. It blocks the action of GH at the GH receptor level, especially in the liver, to reduce the production of IGF-1, which is responsible for most of the symptoms of acromegaly, thus normalizing its levels is effective in controlling the symptoms of acromegaly.[72] A number of concerns remain regarding its use, including high cost, a number of side effects such as reactions at the injection site, swelling of the limbs, chest pain, hypoglycemia, nausea, and hepatitis, but more importantly the fact that blocking of the GH receptor reduces feedback control of the GH regulation leading to increase in GH levels, the long-term effects of which remain ill-defined.

Medical management of Cushing's disease is generally reserved for patients who have failed surgery or radiation therapy, although this is controversial. Agents that modulate pituitary ACTH release (cyproheptadine), glucocorticoid antagonists (RU486), or agents that inhibit steroidogenesis (ketoconazole) must be taken for the rest of the patient's life and are associated with a number of side effects.

Medical treatment of hormonal deficiencies resulting from the pituitary tumor may be optimally managed by an endocrinologist, at least at those times when rapid or significant replacement or medication adjustment is needed. Hypopituitarism can have variable clinical manifestations, and management should be individualized to minimize the impact of this condition. Depending on the deficiency, glucocorticoids, gonadal steroids, and thyroid hormones may be needed. Commonly used medicines include hydrocortisone and cortisone acetate for glucocorticoid replacement and L-thyroxine for hypothyroidism. Gonadal steroids used include estrogen and progestin for women and testosterone for men. Careful

optimization of medication supplementation, especially to avoid supraphysiologic doses of steroids, appears to be important in minimizing the effect of hypopituitarism.[73]

Radiation Therapy and Stereotactic Radiosurgery

Radiation therapy and SRS are important and useful treatment options for select patients with pituitary tumors. They can be considered as postoperative treatment after subtotal removal of a pituitary adenoma, as treatment for recurrent or progressive tumors after surgical or medical treatment, and as primary treatment when surgery or medical therapy is contraindicated or ineffective. Unlike medical therapy, radiation options offer the potential for definitive control of the tumor and permanent reduction of hormone hypersecretion. Radiographic control of the tumor occurs in the vast majority of patients. Normalization of excess hormone production is, however, relatively slow, and quite variable, and depends on a number of factors. Because the effect of radiation on tumor control or hormone suppression may take years, the use of radiation therapy and SRS is variable among institutions. The type of radiation used depends on a number of factors, including tumor size, proximity of the tumor to the optic apparatus, technology availability and expertise, and physician preference.

The lack of prospective, randomized data comparing different radiation delivery methods has resulted in strong proponents for fractionated versus radiosurgical approaches.[74-76] Most of the literature is based on single-institutional results. Fractionated radiation therapy has the benefit of limiting radiation damage to nearby radiation-sensitive structures such as the optic apparatus, whereas SRS can be conveniently performed in a single session and results in more rapid biochemical remission.[77]

Advances in radiation therapy have led to techniques that allow more focused delivery of radiation to the tumor and decreased dose to the normal brain. Sophisticated treatment planning systems, incorporation of CT and MRI studies, stereotactic guidance, radiation therapy approaches such as intensity-modulated radiation therapy (IMRT) and image-guided radiation therapy (IGRT), micro-multileaf collimators, and relocatable frames or masks have improved precision.[76,78,79] Results with radiation therapy, including specifics regarding dose and margin selection, will be discussed in greater detail later in the chapter.

SRS delivers a highly focused, single, large fraction of ionizing radiation to a small intracranial target volume (Figure 29-3). Frame-based systems (e.g., proton beam, helium ion, Gamma Knife, and linear accelerator SRS techniques) and frameless systems (e.g., CyberKnife and linear accelerator-based units) have been used to treat pituitary tumors. Given the sharper dose gradient of SRS versus fractionated approaches, the potential for radiation injury to normal brain and vessels and secondary tumor formation may be less with SRS.

Because the results with SRS vary widely, the comparison of SRS with other treatments is difficult. Many of the published studies have used a wide range of tumor delineation approaches, doses, different prescription isodose line selection, different definitions for response or cure, and short follow-up times, and of course there is selection bias because larger tumors are often not selected for SRS. A wide spectrum of peripheral doses, ranging from 12 Gy to 35 Gy prescribed to the 30% to 100% isodose line have been used, although higher doses are typically reserved for secretory tumors. It is generally believed that lower doses (14 Gy to 18 Gy) are sufficient for nonfunctioning adenomas where the primary goal is radiographic tumor control, whereas higher doses (18 Gy to 35 Gy) are needed for functioning pituitary tumors, where the primary goal is ablation of endocrine oversecretion. Because the efficacy of SRS for functioning pituitary adenomas may be compromised by the concomitant use of cytostatic hormone-suppressing medical therapies, these drugs are typically stopped 6 to 8 weeks before and after SRS.

Given the proximity of the pituitary tumor to adjacent critical structures, particularly the optic nerves and chiasm, appropriate selection of patients for SRS is needed. The optic apparatus (optic chiasm and nerves) is the major dose-limiting critical structure in SRS and fractionated treatment planning. A single-fraction dose to the optic chiasm should be limited to 8 Gy to 9 Gy to minimize damage to the visual pathways. A retrospective review to evaluate the risk of clinically significant radiation optic neuropathy (RON) for patients having undergone SRS for tumors adjacent to the optic apparatus showed that 1.9% developed RON with a median maximum radiation dose to the optic nerve of 10 Gy.[80] RON developed at a median of 48 months after SRS. The authors suggested a clinically significant risk of RON of 1.1% for those who receive 12 Gy or less to a small segment of the optic apparatus. Accurate localization of the target volume and the optic chiasm using MRI is essential. For patients undergoing fractionated treatment, the dose to the chiasm should not exceed 54 Gy and the dose per fraction should be

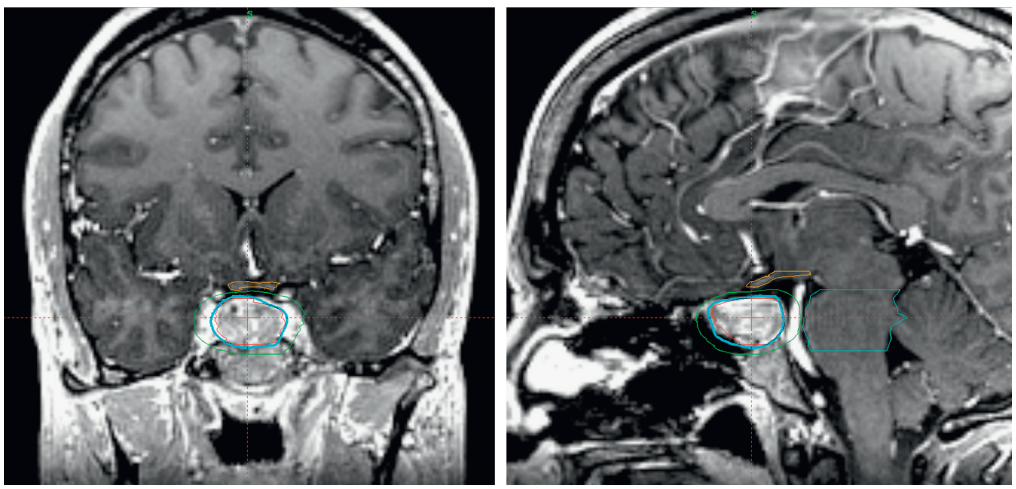

Figure 29-3 Stereotactic radiosurgery plan (coronal and sagittal) for a patient with a nonsecretory pituitary adenoma. A dose of 16 Gy was prescribed to the 50% isodose line *(blue)*. The 8-Gy isodose line is shown in green. The maximum dose to the optic chiasm *(outlined in orange)* was 6.4 Gy.

1.8 Gy/day. It is important to minimize the hot spot around the optic nerves and chiasm.

Unlike the optic nerves, the cranial nerves in the cavernous sinus are more resistant to radiation effects.[81] This may be a result of the increased sensitivity of sensory nerves such as the optic and acoustic nerves compared with the nonsensory nerves of the parasellar region. After repeat SRS, nonsensory cranial neuropathy, however, has been reported.[82]

TREATMENT STRATEGIES FOR SPECIFIC TUMORS

Nonfunctioning Adenoma

Nonfunctioning adenomas are the most frequent type of macroadenoma and typically present with decrease in visual acuity and constriction of the visual field defects, and in some cases, varying degrees of hypopituitarism.[83,84] Nonfunctioning adenomas account for approximately 30% of all pituitary adenomas and often extend beyond the sella turcica. Other presenting symptoms may include headaches from local mass effect or obstruction of the third ventricle causing hydrocephalus, cranial nerve deficits from cavernous sinus involvement, and hypopituitarism resulting from compression of the pituitary gland. Evaluation should include visual field testing, MRI scanning, and an endocrine workup. Generalized, schematic treatment algorithms for a nonfunctioning pituitary microadenoma and macroadenoma are outlined in Figures 29-4 and 29-5, respectively.

Surgery

Management of a nonfunctioning pituitary adenoma is influenced by the size of the tumor, symptoms, physical examination findings, and associated endocrine disorders. For a microadenoma or asymptomatic nonfunctioning adenoma, observation is generally recommended. For a symptomatic tumor or one with mass effect causing progressive symptoms or measurable visual impairment, surgery is the best option because it provides pathologic tissue confirmation, immediate debulking of the tumor, and amelioration of the mass effect, especially relative to the optic chiasm, in 90% to 95% of patients. The results with surgery are variable and depend on the extent of resection possible because of location of invasion (within the subarachnoid spaces intracranially, the cavernous sinuses, or the nose/paranasal sinuses). Recurrence rates range from 10% to 18% at 5 to 6 years and 20% to 80% at 10 years.[85-87]

Medical Therapy

No medical treatment has consistently reduced the size of nonfunctional pituitary adenomas. The use of a dopamine agonist is not recommended because response is uncommon.

Radiation Therapy Options

If the tumor cannot be completely removed, surgical decompression followed by radiation therapy or SRS can provide excellent results. For patients with recurrent tumors or those who are not good surgical candidates, fractionated radiation therapy or SRS can be considered, depending on the proximity of the tumor to the optic apparatus, as well as growth rate on

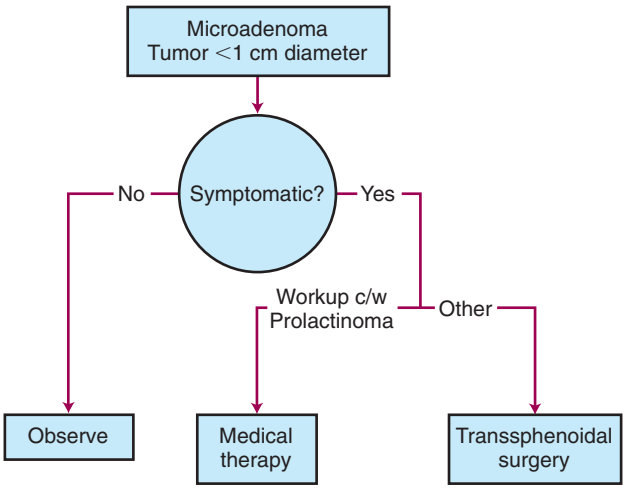

Figure 29-4 Generalized treatment algorithm for pituitary microadenoma.

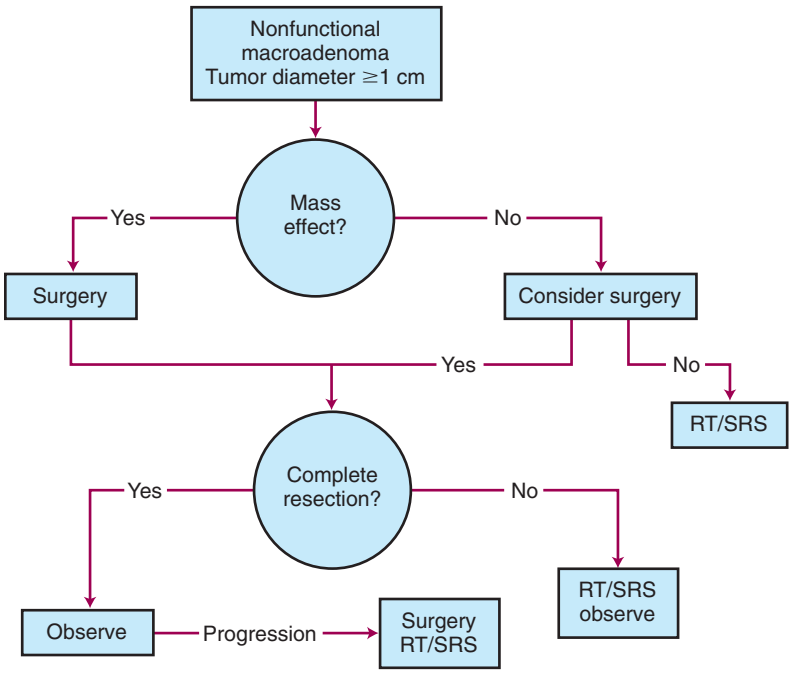

Figure 29-5 Generalized treatment algorithm for nonfunctional pituitary macroadenoma. *RT*, Radiation therapy; *SRS*, stereotactic radiosurgery.

sequential MRI scans. Table 29-1 summarizes some of the recent larger studies of SRS using doses ranging from 13 Gy to 20 Gy.[88-95] Using these doses, the local radiographic control rates are excellent (90% to 100%). The tumor volume in more than half of these patients decreases on follow-up MRIs. Hypopituitarism occurs in up to 39% of patients. More recent series have not reported visual complications, especially when the maximum dose to the optic apparatus is kept below 8 Gy to 9 Gy.

Numerous retrospective studies have demonstrated excellent local control rates with conventional fractionated radiation therapy (45 Gy in 25 fractions). The largest series from Brada et al[96] of 252 patients reported local control rates of 97% and 92% at 10 and 20 years, respectively. Another large study from Sasaki et al[97] demonstrated a 98% local control rate at 10 years. No prospective trials have compared fractionated radiation therapy to SRS.

Prolactinoma

Prolactinomas are the most common functioning pituitary tumors, with the vast majority occurring as microadenomas in women. Symptoms may include amenorrhea, galactorrhea, and infertility in women and decrease in libido, infertility, and visual disturbances in men. Diagnosis is typically made from sustained elevation of serum prolactin levels above the normal range. MRI of the brain can help confirm the diagnosis, although a negative MRI can be seen in women with microadenomas.[98]

Goals of treatment include restoration of sexual and reproductive function, normalization of prolactin levels, control of galactorrhea, and improvement of neurologic symptoms. It is important that other causes of increased prolactin levels such as effects of medicines, pregnancy, and renal insufficiency are considered in the differential diagnosis. Treatment options include observation, medical therapy, surgery, and irradiation.[48] A generalized schematic treatment algorithm for a prolactinoma is outlined in Figure 29-6.

Surgery

Surgery is standard second-line therapy and is reserved for patients who cannot tolerate medical therapy or are not responsive to maximally tolerated dose of dopamine agonists,[99] have rapid progressive vision loss, or women who wish

to conceive. Based on a review of 50 surgical series of more than 4000 patients, the curative surgical resection rates for microprolactinomas and macroprolactinomas was 74.7% and 33.9%, respectively, using a normalization of prolactin levels before 12-week follow-up as the definition of remission.[100] Biochemical recurrence, however, occurs in 20% of patients within the first year. The best predictor for persistent cure is a prolactin level less than or equal to 5 ng/mL on postoperative day 1. The long-term surgical cure rates for microprolactinomas and macroprolactinomas are 50% to 60% and 25%, respectively, where a cure is considered normal prolactin levels. Surgery is also sometimes used in women with a large adenoma who want to become pregnant.

Medical Therapy

The initial treatment of choice for patients with prolactinoma is medical therapy with a dopamine agonist such as bromocriptine or cabergoline because these drugs decrease secretion and tumor size in most patients. Medical therapy can rapidly normalize prolactin levels and reduce tumor size in 80% to 90% of patients.[100] Bromocriptine, which is taken two or three times per day with meals, is associated with a greater number of side effects (e.g., nausea, vomiting, fatigue, and orthostatic hypotension) compared with cabergoline, which is taken once or twice a week. In a double-blinded study of 459 female patients comparing bromocriptine with cabergoline over 8 weeks, normal prolactin levels were achieved in 59% and 83% of patients, respectively.[101] Cabergoline was better tolerated, with 3% discontinuing its use versus 12% who stopped taking bromocriptine. Because cabergoline has been associated with an increased risk for cardiac valve thickening in patients with Parkinson's disease, who take much higher doses compared with patients with prolactinoma, this potential risk needs to be reviewed and carefully monitored.[102] For some patients, medical therapy may be gradually withdrawn every 2 years to 3 years to assess remission. This strategy is most effective for patients with low prolactin levels and small tumors. Approximately 8% of patients with prolactinoma are intolerant to or unresponsive to medical treatment.

Because the risk of symptomatic tumor enlargement during pregnancy is low for microprolactinomas (3% to 5%), it is recommended to stop medical treatment as soon as diagnosis of pregnancy is established[103,104]

Radiation Therapy Options

Based on the success of dopamine agonists and because of the risk for hypopituitarism in young female patients, radiation therapy or SRS is usually reserved as third-line therapy. For patients who do not respond to or are intolerant of medical therapy and are not candidates for surgical salvage, radiation options may be considered.

The results with conventional radiotherapy from the late 1970s to the early 1990s have been modest. One of the earliest studies from Sheline et al[105] of 28 patients demonstrated a prolactin normalization rate of 29%. Littley et al[106] found a decrease in serum prolactin levels in all 58 patients treated with external beam radiation therapy (EBRT) and a 50% probability of prolactin level reduction to 500 mU/L in 10 years. Patients more likely to achieve normalization of serum prolactin levels after EBRT had smaller tumors, pretreatment prolactin levels higher than 6000 mU/L, and tumors with positive immunostaining for prolactin. Tsagarakis[107] reported normal serum prolactin levels at a mean of 8.5 years after EBRT in 18 of 36 patients. Pituitary irradiation can lead to hypothalamic dysfunction and impairment of dopamine secretion, which causes hyperprolactinemia. This may explain the mildly elevated prolactin levels (usually, <50 mU/L) in some patients after radiotherapy of pituitary adenomas.

SRS has also been used after failure of medical therapy or surgical treatment. Table 29-2 summarizes recent larger publications on the results of SRS for prolactinomas with normalization rates for prolactin ranging from 17% to 43.5%.[108-113] A multidisciplinary approach is important to optimize treatment.[114]

Because it may take some time for normalization of prolactin levels to occur after EBRT or SRS, the use of dopamine agonists may be required. Landolt[115] reported worse outcomes for patients receiving dopamine agonists at the time of SRS. Pouratian[116] also reported worse outcomes in patients receiving antisecretory medication at the time of SRS. Antisecretory medications may alter the cell cycle, which makes the tumor cells less radiosensitive. As a result, a 2-month break between medical therapy and SRS has been suggested.[115]

Acromegaly

Acromegaly is a rare condition, with a prevalence of approximately 60 per million. GH hypersecretion leads to metabolic and functional disturbances of multiple organs (i.e., cardiovascular, musculoskeletal, and respiratory dysfunction) and an increased incidence of colonic polyps, although whether this increases the incidence of colorectal cancer is not fully determined.[49] The overall life span of patients with acromegaly is shorter than their normal counterparts, implying a significant risk of disease-associated mortality in the long term. In addition, characteristic bony and soft-tissue enlargement occurs in the frontal bones, hands, feet, spine, nose, and mandible. As a result, early diagnosis and treatment are essential to minimize the impact on life expectancy and morbidity. Unfortunately, the gradual onset of symptoms and changes as a result of excessive GH secretion delays diagnosis in many patients.

Although surgery is the initial treatment of choice for most patients, a multidisciplinary approach is often needed given

the complexity of this disease.[117] Because liver-derived IGF-1 mediates the effects of GH at the tissue level, the primary goal of therapy is to normalize IGF-1 levels to within the reference range for the patient's age and gender; additional therapeutic goals are to preserve pituitary function and to prevent tumor growth. Normalization of age- and sex-matched IGF-1 levels and the suppression of serum GH levels to less than 0.4 mg/L in response to a 75-g oral glucose load are generally used to define biochemical cure for acromegaly.[118] Normalization of IGF-1 levels is a better criterion for cure than GH levels because some patients with acromegaly can have normal GH levels.[118,119] Untreated or incompletely treated acromegaly is associated with significant morbidity and excess mortality, which may be as high as three times that of the general population.[73,117] The treatment options for acromegaly include surgery, irradiation, medical therapy, or a combination of treatment approaches. A generalized treatment algorithm for acromegaly is outlined in Figure 29-7.

Surgery

The initial treatment of choice for acromegaly is surgery.[117,120] Goals of surgery include alleviation of mass effect from suprasellar extension and complete removal of the GH-secreting adenoma. Because the criteria used for biochemical cure have changed with time and the duration of follow-up varies, surgical series are not directly comparable. When surgery is performed by experienced pituitary neurosurgeons, the GH levels fall to normal in 80% to 90% of patients with microadenomas.[121,122] The success rate is lower in patients with higher preoperative GH concentrations or macroadenomas (<50%).[123] Recurrence rates after surgery are estimated to be approximately 20%.[124] Using modern criteria for cure (i.e., normal serum IGF-1 and glucose-suppressed GH concentrations of less than 1 ng/mL), the surgical remission rates are 70% and 61%, respectively.[125] The largest series evaluated 506 patients who underwent transsphenoidal surgery. Overall remission was 57.3% as defined by normalization of IGF-1 levels.[126] The normalization results for microadenomas and macroadenomas were 75% and 50%, respectively. A recent retrospective study of 46 patients with acromegaly with no residual tumor on postoperative MRI and nadir GH of less than 0.4 mg/L on a postoperative oral glucose tolerance test reported that the mean duration from surgery to IGF-1 normalization was 10 months (range, 3 days to 57 months).[127] Longer remission times were required for patients with higher postoperative IGF-1 levels.

Medical Therapy

Three different types of medicines (somatostatin analogs, dopamine agonists, and a GH receptor antagonist) are used to treat patients with acromegaly who have failed surgery, are not surgical candidates, or are refractory to radiation options. Given the latency for normalization of IGF-1 and GH levels after irradiation, medical therapy is also used as an adjunct after radiation treatments. The most commonly used medicines are the somatostatin analogs (octreotide and lanreotide) rather than somatostatin, given the much higher potency and half-life of the analogs. These analogs bind to somatostatin receptors subtypes 2 and 5, reduce IGF-1 levels in 38% to 66% of patients and lead to tumor shrinkage in 30% to 45% of patients.[128-130] Response is best predicted by determining whether the subtype of somatotroph adenoma is sparsely or densely granulated.[131] The most common side effects of somatostatin analogs include nausea, abdominal cramping, diarrhea, and gallstones. A disadvantage of these agents is the lifelong dependence. Dopamine agonists such as cabergoline are generally not effective and are not used frequently unless a patient is unable to tolerate somatostatin analogs.

Pegvisomant, a GH receptor antagonist that is administered daily via the subcutaneous route, has been tested in a placebo-controlled randomized trial and shown to normalize IGF-1 levels in 90% to 97% of patients.[132-134] Side effects include flu-like symptoms, nausea, diarrhea, and abnormal liver function tests. Because pegvisomant does not inhibit GH secretion or tumor growth, it is not used as first-line therapy. Pegvisomant requires lifelong treatment, may cause elevated aminotransaminases in 20% of patients, and may carry a small risk for increase in tumor size. In addition, pegvisomant is extraordinarily expensive compared with other medical therapies.

Radiation Therapy Options

Irradiation can be used in the definitive or adjuvant setting for patients with acromegaly. Given the relatively long lag time for normalization of the IGF-1 and GH levels after radiation treatment, it is important that these patients be followed closely with blood work every 3 to 6 months and yearly MRIs. If patients are taking a short-acting (daily) somatostatin analog (SSA), they may need to be off medication for about 1 month, or longer, to assess the efficacy of radiation; the interval for a patient on a long-active SSA, given once monthly, may need to be on a medication holiday up to 3 months, which means that perhaps only once yearly IGF-1 level will be measured. The published reports on radiation therapy and SRS have typically used varying definitions of cure relative to GH levels. Earlier publications, which defined remission as growth hormone levels below 5 ng/mL to 10 ng/mL, reported remission rates of 80% to 100%.[135,136] Using modern definitions for normalization of both GH levels (<2 ng/mL) and IGF-1 levels, the results for radiation therapy and SRS are less impressive. Table 29-3 summarizes the recent radiation therapy results.[137-141]

The rate of hormone remission and hypopituitarism at 10 years is approximately 50% to 60% and 60% to 80%, respectively. The largest study, a retrospective review of 884 patients with acromegaly undergoing radiotherapy, demonstrated that 63% of patients had normalization of IGF-1 levels by 10 years.[139] In this series, new hormone deficiencies included 18% for LH and FSH, 15% for ACTH, and 27% for TSH. Variability in the success rates in normalization of IGF-1 levels for patients undergoing radiation therapy may be a result of differences in pretreatment serum GH concentrations. Within the first 2 years mean GH values drop to 50% to 70% of their maximal values, followed by a slow decrease over years.[142] Higher doses of EBRT may be considered when treating patients with acromegaly (50.4 Gy to 54 Gy versus 45 Gy for nonfunctional tumors).

Table 29-4 summarizes the recent SRS results that have used IGF-1 level normalization as the definition for cure.[108,112,143-147] Using peripheral doses of 20 Gy to 26.5 Gy, IGF-1 level normalization rates range from 17% to 60%. The local control rates are excellent, suggesting that SRS could possibly also have a definitive role in this condition. Mean time to remission ranges from 24 to 36 months for patients undergoing SRS. Although the time to remission appears to be faster with SRS compared with radiation therapy, the ideal SRS candidate should have a well-defined target volume that is far enough away from the optic chiasm, and this limits the use of SRS.[146]

It is important to note that the latency period to achieve the hormonal control is directly related to hormone level and therefore the tumor volume before treatment.[148] Medication may be used as an adjuvant treatment after radiation therapy to help lower the growth hormone and IGF-1 levels. Given the concern for the potential suppressive effects of somatostatin analogs, which may compromise the effectiveness of radiation therapy, some centers do not recommend using these medications for, typically, 6 to 8 weeks before and after radiation.[143,149]

Cushing's Disease

Cushing's disease results from an ACTH-secreting adenoma of the anterior pituitary, which is responsible for 70% to 80% of ACTH-dependent Cushing's syndrome cases in adults. Given the many nonspecific symptoms and signs, the diagnosis is often delayed. This syndrome, which is associated with increased morbidity and age-corrected mortality, occurs more commonly in women and is a heterogeneous disorder. Clinical findings include truncal obesity, hirsutism, acne, easy bruisability, muscle weakness, and moon facies. These patients can have menstrual irregularities, gonadal dysfunction, hypertension, diabetes mellitus, and osteoporosis. Tests used to diagnose Cushing's disease include a 24-hour urine collection to

measure urinary-free cortisol levels, midnight testing of ACTH levels, and dexamethasone suppression test among others.[47] Untreated or incompletely treated hypercortisolism is associated with significant morbidity and excess mortality, which may be as high as two to three times, or more, the rates of the general population.[73]

The treatment options for Cushing's disease include surgery, irradiation, medical therapy, total bilateral adrenalectomy, or a combination of treatment approaches.[150,151] Most centers define remission as urinary-free cortisol levels in the normal range with resolution of clinical findings or a series of normal serum cortisol levels obtained throughout the day.[152] A generalized, schematic treatment algorithm for Cushing's disease is outlined in Figure 29-8.

Surgery

Surgical removal of the pituitary adenoma is the best initial treatment for Cushing's disease because it can rapidly correct the hypersecretion of ACTH. Most patients have a microadenoma; 25% to 50% of patients with Cushing's disease will have no discernible lesion on MRI of the brain. Although a tumor is identified in 70% to 90% of cases, it is more likely that no tumor may be identified at the time of surgical exploration in patients with MRI-negative Cushing's disease.[153,154] For patients with no discernible lesion in whom surgery is being contemplated, bilateral inferior petrosal sinus sampling (BIPSS) may help improve the outcome, through better localization and lateralization. The inferior petrosal sinuses receive drainage from the pituitary without blood from other sources. Therefore, if the patient has pituitary Cushing's, the ACTH levels in the IPS are high compared to an ACTH level drawn in the periphery. In contrast, in ectopic Cushing's, the ACTH in the IPS and the periphery should be equivalent because the tumor is located elsewhere.

Ideally, an experienced neurosurgeon should remove the tumor in its entirety, leaving the normal pituitary intact. Although an abnormality may not always be seen on MRI of the brain, surgery leads to hormonal control in 80% to 90% of patients with microadenomas and in up to 50% with macroadenomas.[122] If a microadenoma cannot be identified in an adult patient in whom fertility is not an issue, one may perform either a hemihypophysectomy related to the potential side of localization suggested by BIPSS, although there remains concern about the localization capability of BIPSS. Total hypophysectomy is usually reserved for patients who undergo reoperation without visual identification at the second (or later) surgery of an adenoma, with remission rates of 50% to 70% even with this strategy.[155-158] Because dural invasion by ACTH-producing adenomas usually occurs laterally into the wall of the cavernous sinus, identification and removal of the invaded dura including the medial cavernous sinus wall allows for better biochemical cure.[159]

For most patients, the surgical approach is transsphenoidal. A series from Cavagnini of 300 patients with a follow-up time of 10 years demonstrated a remission rate of 70% and a recurrence rate of 15%.[160] In another study, low ACTH levels (<10 ng/mL) during the early postoperative period correlated with remission in 97.9% of cases, whereas an ACTH level of more than 30 ng/mL correlated with a remission rate of only 18%.[161] A more recent series from Patil et al[162] noted a 25% recurrence rate at 5 years for patients who achieved initial remission after transsphenoidal surgery. Given the varied results, experience with transsphenoidal surgery for Cushing's disease appears to be an important factor in terms of remission and recurrence.

If a patient does not achieve remission after surgery, a bilateral adrenalectomy can be considered. Patients undergoing bilateral adrenalectomy can develop Nelson's syndrome with

Under local anesthesia, femoral catheters are advanced bilaterally up to the IPS. After fluoroscopic confirmation of catheter position, multiple blood samples are drawn simultaneously from the right and left IPS and from a peripheral vein for ACTH level assessment, and the pituitary-to-peripheral ACTH ratios are calculated. If the ratio is greater than 2 the patient has Cushing's disease. If the pituitary-to-peripheral ratio is less than 1.5 to 1 the patient has ectopic Cushing's, and pituitary surgery should not be performed. Because each half of the pituitary drains into the ipsilateral IPS, BIPSS may also help lateralize the tumor.

a risk of 8% to 43% in adults[163] and 25% to 66% in children.[164,165] Bilateral adrenalectomy removes the peripheral source of cortisol, and hence the negative feedback suppression of ACTH production at the level of the pituitary is impaired; this can result in oversecretion of both ACTH and MSH (which is structurally similar to ACTH, and the loss of negative feedback results in oversynthesis of proopiomelanocortin, a precursor for both ACTH and MSH synthesis). This results in skin and mucosal hyperpigmentation, muscle weakness, and growth of the pituitary adenoma. For some patients, the growth of the adenoma can be quite rapid, leading to visual complications. Invasion of the cavernous sinus may cause cranial nerve palsies. In addition, the adenoma may be less responsive to radiation options, which is used in 20% to 30% of patients. Given its rarity and complexity and the controversies regarding diagnosis and treatment, it is one of the most challenging endocrine conditions.[166]

Medical Therapy

Medical management is reserved for patients who do not respond to surgery or irradiation options; lifelong therapy is needed. Medicines used to inhibit steroidogenesis include ketoconazole, aminoglutethimide, metyrapone, mitotane, and etomidate.[167] Ketoconazole is the best tolerated drug and is effective as monotherapy in up to 70% of patients. Because this drug can be hepatotoxic, it is important to monitor liver function tests. Metyrapone, an 11 alpha-hydroxylase inhibitor, is often used as an adjuvant to ketoconazole or radiation therapy.

Pasireotide, approved by the Food and Drug Administration (FDA) in December 2012, is a multireceptor-targeted somatostatin analog with high binding affinity to four of the five known somatostatin receptor subtypes (sst1, sst2, sst3, sst5)[168] and regulates anterior pituitary hormone secretion. Unlike other somatostatin analogs, pasireotide binds with the highest affinity to sst5, with 40-fold increased affinity to sst5 compared to other somatostatin analogs. Sst5 is the most prevalent somatostatin receptor expressed on ACTH-secreting pituitary adenomas.[169] In a double-blind Phase III, randomized, multicenter study (PASSPORT-CUSHINGS B2305) in 162 patients with de novo (if not surgical candidates), persistent or recurrent Cushing's disease, pasireotide demonstrated a rapid (approximately 50% decrease by 2 months) and sustained reduction in urinary-free cortisol levels, with significantly improved clinical signs and symptoms of Cushing's disease. Among those with a measurable pituitary tumor on MRI at baseline and month 12, mean percentage decrease in tumor volume was 43.8% in patients receiving pasireotide 900 µg bid.[170]

Radiation Therapy Options

Irradiation is typically used as an adjuvant for patients who are not cured after surgery. It can also be used definitively for patients unable to undergo surgery. For children, some consider this as the initial therapy because the cure rates are similar to those of surgery.[171,172] Both fractionated radiation therapy and SRS have been used to treat patients with Cushing's disease. For patients who are treated with EBRT, doses of 50 Gy to 54 Gy may be considered. One study from Estrada used postoperative irradiation (mean dose, 50 Gy) and reported an 83% remission rate at 5 years.[173] Minniti et al[174] reported on 40 patients with Cushing's disease who received 45 Gy of EBRT. The normalization rate of cortisol levels was 78% at 5 years and 84% at 10 years. Other EBRT series have yielded remission rates ranging from 46% to 56%.[175,176]

Most of the SRS series are small and report endocrine cure rates that are similar to the EBRT results. Recent series have reported remission rates of 28% to 53%,[82,108,109,112,177] which are listed in Table 29-5. As with other secretory tumors, the peripheral dose used is higher (>20 Gy). The largest series from Jagannathan[82] reported on 90 patients with a median follow-up of 45 months. In this series, a 54% remission rate was achieved. The timing of hormone normalization can be quite variable (2 months to 8 years), although most patients will achieve remission within the first 2 years. Patients with persistent disease should be considered for adrenalectomy or repeat SRS, which has been associated with higher rates of cranial nerve damage.[82] No trials have compared SRS with fractionated EBRT.

Nelson's Syndrome

Some Cushing's disease patients do not achieve remission after surgery or irradiation and may require bilateral adrenalectomy as salvage treatment. As a result, some patients may develop Nelson's syndrome, which is characterized by hyperpigmentation, rapid growth of the adenoma, and invasion of the tumor into the parasellar regions.[178] The few reports of SRS for Nelson's syndrome have resulted in endocrine remission rates of 36% or less.[179,180]

Thyroid-Stimulating Hormone–Secreting Adenomas

TSH-secreting adenomas are rare (0.5% to 1.5% of all pituitary tumors) and typically present as macroadenomas with mass effect and features of thyrotoxicosis.[181] Surgical removal of the TSH-secreting adenoma is the best treatment option after the hyperthyroidism has been controlled with medications. Because these tumors are usually large at diagnosis and can invade the sella or extend beyond it, complete removal can be difficult; for this reason, remission rates may be only 50% after surgery.[182] When the tumor cannot be completely removed or the patient is not a surgical candidate, irradiation can be considered. Somatostatin analogs or dopamine agonists have been used to decrease TSH hypersecretion. The use of octreotide results in normalization of TSH levels in 79% of patients.[183]

TABLE 29-5 Summary of Recently Published Larger Studies of Stereotactic Radiosurgery for Cushing's Disease

Author	Year	No. Pts	FU (mo)	Peripheral Dose (Gy)	Cortisol Normalization (%)†	Local Control Rate (%)	Visual Complication Rate (%)	Hypopituitarism Rate (%)

Etomidate can reduce cortisol levels within hours and is used for acute control of elevated cortisol levels. Etomidate, developed as an anesthetic induction agent, suppresses corticosteroid synthesis in the adrenal cortex by reversibly inhibiting 11-beta-hydroxylase; it leads to primary adrenal suppression and is associated with increased risk of pneumonia, sepsis, and death. In a retrospective review of almost 32,000 patients, etomidate, when used for the induction of anesthesia, was associated with a 2.5-fold increase in the risk of dying than those given propofol. Patients given etomidate also had significantly greater odds of having cardiovascular morbidity and significantly longer hospital stay. These results strongly suggest that clinicians should use etomidate judiciously.

Mitotane causes adrenal suppression of cortisol secretion and is cytotoxic to adrenocortical cells. It is typically used for patients who have failed multiple medical therapies. Until the effects of irradiation have normalized ACTH levels, hypercortisolism can be decreased by use of the aforementioned medications.

Gonadotropin-Secreting Adenomas

Gonadotropin-secreting adenomas usually present as macroadenomas with mass effect and hypogonadism. They secrete LH or FSH, alpha subunit, or a combination of these hormones. The results with irradiation are limited.

Pituitary Carcinomas and Aggressive Pituitary Tumors

Pituitary carcinomas are very rare (0.2% of all pituitary tumors).[184] They have clinical features of pituitary adenomas, with most secreting prolactin or ACTH. Because the malignant nature of these tumors cannot be clearly determined by pathologic testing, the diagnosis is a clinical one based on findings of subarachnoid spread, brain involvement, or systemic metastases from a pituitary tumor.[141] The overall prognosis for these tumors is poor despite aggressive treatments that have included radiation therapy with mean survival of 1.9 years.[185] Rare examples of persistent response to chemotherapy (temozolomide) have been reported.[186]

For patients with aggressive pituitary tumors, a significant number of the published cases have demonstrated a response to temozolomide. Overall, 24/40 (60%) of the published cases demonstrated a response to temozolomide. The highest response rates were seen among prolactinomas (73%) and ACTH-secreting tumors (60%), whereas nonfunctioning pituitary tumors exhibited lower response rates (40%). Responsivity became typically evident in the first 3 months of therapy and low MGMT expression, as determined by immunohistochemistry, was associated with a high response rate (76%), whereas high MGMT expression was not associated with responses. MGMT promoter methylation, however did not correlate with temozolomide response. Temozolomide is therefore the first chemotherapeutic agent to show substantial response rates in aggressive pituitary tumors. MGMT immunohistochemistry, but not MGMT methylation analysis, shows promise as a predictive tool.[187]

LOCALLY ADVANCED DISEASE AND PALLIATION

Repeated Course of Irradiation

If tumors recur after fractionated radiation therapy, a repeat course of fractionated treatments may be considered after careful consideration of alternative treatment options, the interval that has elapsed since the first course of radiation therapy, and the details of the prior radiation treatment (e.g., technique used, dose given, and fractionation schedule used). Schoenthaler reported on 15 patients who were reirradiated with a median dose of 42 Gy in 1.8-Gy to 2-Gy fractions.[188] Local control was achieved in 12 patients. All patients developed hypopituitarism from the initial or repeat course of radiation therapy. Two patients later developed pituitary carcinoma and temporal lobe radionecrosis. Flickinger et al[189] reported on 10 patients with suprasellar or pituitary tumors who were reirradiated with doses ranging from 35 Gy to 49.6 Gy in 1.8-Gy to 2-Gy fractions. Six patients had pituitary tumors. One patient developed optic neuropathy a little more than 1 year after completing the therapy. The study authors suggest that a 40% estimation of the original radiation dose effect is a reasonable guideline to account for prior radiation therapy.

Palliation of Metastases

Metastases to the pituitary occur infrequently and most commonly arise from breast and lung cancers.[190] The reported rates of breast cancer metastasizing to the pituitary range from 6% to 8%. The most commonly reported symptoms include diabetes insipidus, anterior pituitary dysfunction, visual field defects, and headaches. Most metastases occur in the neurohypophyseal region, although breast cancer metastases have a predilection for the adenohypophyseal region. Because these are invasive tumors, surgery is difficult. SRS (median dose, 13 Gy) has been used for select patients with a progression-free survival (PFS) rate of 66.7%, a 12-month survival rate of 18%, and a median survival time of 5.2 months.[191]

IRRADIATION TECHNIQUES AND TOLERANCE

Techniques of Irradiation

Before the advent of sophisticated radiation delivery techniques, imaging techniques, and treatment planning efforts, the field arrangement for pituitary tumors included a two-field, opposed lateral field technique, a three-field technique of two opposed lateral, and an anterior vertex field. Bilateral 110-degree coronal arcs with a 30-degree wedge and 330-degree rotational arcs were also used. Comparison of these various techniques demonstrated that the three-field technique delivered less dose to the temporal lobes than the two-field technique, the rotational techniques were superior to the stationary field techniques in terms of sparing the temporal lobes, and the four-field noncoplanar arc technique delivered less dose to the frontal lobe.[192] When comparing the three-field coplanar technique to the four-field noncoplanar arrangement, the mean volume of normal brain receiving dose was higher with the coplanar techniques.[193]

Modern techniques of fractionated radiation therapy and SRS have capitalized on improvements in immobilization, imaging, planning, and treatment delivery. Using a fixed head frame, SRS is delivered in one fraction using a linear accelerator (see Figure 29-3), cobalt unit (Gamma Knife), or protons. The use of SRS is limited to smaller tumors (<4 cm in diameter) that are 2 mm to 5 mm away from the optic apparatus.

Given the success of SRS in treating pituitary tumors, fractionated irradiation with highly conformal fields is being used more frequently for patients who are not ideal candidates for SRS or in centers that do not have access to SRS. The use of relocatable frames and precision thermoplastic masks and the daily verification of proper positioning before treatment have replaced conventional fractionated approaches at most centers. This precision allows for sparing of more normal brain tissue. As a result, the treatment margin around the tumor can be decreased to 3 mm to 5 mm. Minniti et al[76] reviewed the results of eight studies with 490 patients with functioning or nonfunctioning pituitary adenomas treated with stereotactic conformal radiotherapy. With a median follow-up of 39 months, tumor control was 98%. More recently, Kim reported 7-year PFS and disease-specific survivals (DSS) of 97.1% and 100%, respectively, for patients undergoing fractionated stereotactic radiation therapy.[194] The preliminary results suggest that conformal radiation techniques are equivalent to those of conventional radiation therapy, with significantly smaller brain volumes being irradiated, and in particular, with much lower doses to the temporal lobes. The potential difference in biologic effectiveness of SRS versus fractionated courses has not been tested in a prospective manner.

Treatment Morbidity

Both SRS and fractionated radiation therapy are well tolerated during and shortly following the course of treatment. Some patients undergoing fractionated irradiation may experience

temporary alopecia, fatigue, skin erythema, and headaches. Worsening of vision or other cranial nerve deficits during radiation therapy is uncommon. Patients undergoing frame-based SRS may notice headache, temporary tenderness and numbness of the pin sites, and fatigue. Because the treatment volumes with SRS are generally smaller compared with those of EBRT, the side effects are generally less for patients undergoing SRS. Unfortunately, no prospective trials have compared SRS with radiation therapy with regard to acute and long-term side effects. Unlike patients with some brain tumors, patients with pituitary tumors need to be followed for long periods of time because these tumors can recur 20 years or longer after primary treatment has been completed.

The most commonly reported long-term side effect from SRS and fractionated EBRT is hypopituitarism, and in particular hypothyroidism, which occurs in 30% to 80% of patients within 10 years after treatment. The cause for hypopituitarism (damage to the hypothalamus versus damage to the pituitary) is an area of debate.[195] Dosimetric data suggest that minimizing radiation dose to the pituitary and to the hypothalamus may reduce the incidence of radiation-associated hypopituitarism.[196] The risk of developing hypopituitarism following radiosurgery is lowered when the mean radiation dose to pituitary is kept below 15 Gy and the dose to the distal infundibulum is kept below 17 Gy.[197]

For patients undergoing conventional EBRT with older irradiation techniques, the incidence of optic neuropathy is 1% to 3% and the risk of radiation necrosis is 0% to 2%.[198,199] Fractionated radiation is associated with a low risk for optic pathway injury with estimate incidence of 0.8% to 1.3% at 10 years and 1.5% at 20 years.[96,200] A review of 34 studies of SRS for pituitary adenomas reported a 1% risk of decrease in visual acuity and a 1.3% risk for other cranial nerve neuropathies (trigeminal, oculomotor, trochlear, or abducens nerve) after SRS.[75] The Quantitative Analyses of Normal Tissue Effects in the Clinic (QUANTEC) report recommends optic chiasm dose tolerance ranges from 8 Gy to 10 Gy for single fraction and 55 Gy to 60 Gy for conventional fractionation.[201] If radiation-induced optic neuropathy occurs, it usually presents as painless vision loss within the first 3 years of treatment. Using modern radiation approaches and MRI-based planning, the risk for radiation necrosis and optic neuropathy should be 1% or less when using doses of 45 Gy in 25 fractions.

Vascular complications can also occur following EBRT and SRS although the risk of stroke is an area of debate. An increased incidence for cerebrovascular accidents has been reported for patients undergoing radiation therapy, although the relative contribution from irradiation remained to be determined.[202,203] The risk of injury to the cavernous portion of the carotid artery is low, with only a few case reports published.[204] Recently, 462 pituitary adenoma patients (236 of whom received radiotherapy) treated with surgery as primary therapy between 1959 and 2008 at the University Medical Center Groningen in The Netherlands were studied regarding the incidence of stroke.[205] The comparison of events was therefore between the two groups of patients with pituitary adenoma, treated with or without radiotherapy. Postoperative radiotherapy, mostly 45 Gy in 25 fractions, was not associated with an increased incidence of stroke (5.5% versus 5.3%, $p = 0.23$) or differences in causative mechanism or anatomic localization of stroke compared with surgery alone even though the follow-up was more than twice as long for the patients who had been irradiated. Preexisting coronary or peripheral artery disease was the primary stroke risk factors.

The effect of irradiation on neurocognitive status is not clear given the effects of other therapies, such as medications and surgery, and of the tumor.[206] It appears that patients who underwent surgery before radiation therapy may be at a higher risk for cognitive deficits.[207,208] A large study investigating radiotherapy effects on cognition,[209] noted a significant worsening in anterograde memory performance when comparing healthy controls to those with pituitary tumors treated with surgery or radiotherapy. This study showed that although treated pituitary tumors in general were associated with worsening memory, there was no significant difference when comparing the surgery and radiotherapy treatment groups.

Patients undergoing radiation therapy or SRS are at higher risk for secondary brain tumors. Brada reported that the cumulative risk for developing meningiomas and gliomas after the treatment of pituitary adenoma at 20 years is 2%.[210] An update from the Royal Marsden Hospital reviewed 426 pituitary adenoma patients treated with radiotherapy after resection and found a cumulative risk of second brain tumors of 2% at 10 years and 2.4% at 20 years with 12 years median follow-up.[211] Because the risk of second brain tumors may also be higher in patients with pituitary adenomas than the general population, estimating the relative risk of second brain tumors compared to general population may be flawed. Loeffler et al[212] reported on two patients with pituitary adenomas who developed new tumors following SRS. He concluded that the risk for new tumors after SRS appears to be significantly less than that after fractionated EBRT. Another study of 5000 Gamma Knife SRS patients followed for more than 10 years reported no increased risk of malignant disease.[213]

TREATMENT ALGORITHMS, CHALLENGES, CONTROVERSIES, FUTURE POSSIBILITIES, AND CLINICAL TRIALS

The optimal management of pituitary neoplasms requires a multidisciplinary and individualized approach because these tumors are diverse, are associated with morbidity and mortality, and present a challenge regarding the best treatment approach. Because the treatment management strategy varies depending on a number of factors, including the type of tumor (secreting tumor versus nonsecreting tumor), the imaging characteristics, and the clinical presentation and symptoms, a multidisciplinary approach ensures that the most effective therapy is being considered for each patient (see treatment algorithm by the five specific tumor types within prior section). Because surgical treatment, medical therapy, and radiation treatment options can be effective options, choosing the optimal treatment for an individual patient may be controversial and challenging. The patient's age, medical condition, compliance with medicine, treatment tolerance, and preference should also influence the decision, as should an assessment of the potential long-term effects of hypopituitarism on excess morbidity and mortality.[50] Close collaboration among the various disciplines is necessary for comprehensive long-term care. Clinical findings, endocrine evaluation, and MRI findings can establish the diagnosis of pituitary tumors in most patients and help define the initial treatment decisions.

Laboratory investigations and pituitary imaging provide detailed information concerning endocrine dysfunctions and anatomic relationships of pituitary tumors. Sophisticated surgical approaches and irradiation techniques provide safe and successful treatment of patients with pituitary adenomas. Pathobiologic assessments of pituitary tumors are yielding new insights into the genetic and molecular biologic makeup of these tumors and may help to predict which tumors are at higher risk for recurrence.

Because proponents exist for both SRS and fractionated EBRT, prospective, randomized controlled trials are needed to help answer questions. In the future, radiation sensitizers or combinations of medicines with radiation therapy may help

to improve the therapeutic ratio and decrease the latency of response, which would allow irradiation to become a more valuable treatment option.

CRANIOPHARYNGIOMA

Craniopharyngiomas are histologically benign neuroepithelial tumors that are postulated to arise from the hypophyseal duct or Rathke's pouch, or its remnants in the adult. They comprise 5% to 10% of pediatric and 1% to 4% of adult brain tumors and have a bimodal distribution with peak rates at childhood (5 year to 14 years) and older adulthood (50 year to 74 years).[214] Although these tumors are generally slow growing, circumscribed, and encapsulated, the frequent involvement of structures such as the pituitary stalk, hypothalamus, adjacent basal vasculature, and optic apparatus complicates their management.[215]

A large number of treatment modalities are used including GTR, limited surgery followed by radiation therapy, SRS, and intracystic radiotherapy and chemotherapy. In 1997, the 5-year survival rate was estimated at 80% and decreased with older age at diagnosis.[216] From more modern series, for adults treated with surgery and radiotherapy, the 5- and 10-year PFS rates were 85% and 69%, and cause-specific survival (CSS) rates were 88 and 88%, respectively.[217] In the pediatric population, a review of modern studies demonstrates a 5-year disease control of at least 90%.[218]

Treatment

Typical upfront management consists of either GTR or limited surgery followed by adjuvant radiotherapy. The timing of radiotherapy remains controversial and some series have demonstrated good salvage with radiotherapy at the time of progression.[227,228] Aggressive surgical resection can result in excellent long-term control and survival but can also be associated with significant morbidity including hypothalamic dysfunction, optic pathway damage, frontal lobe executive function damage, and rarely, mortality.[217] Surgical series demonstrate 10-year overall survival (OS) ranging from 85% to 92% and 10-year local control ranging from 42% to 81% depending on extent of tumor removed and whether radiotherapy was given.[227,228]

Radiotherapy

The group at Princess Margaret Hospital (PMH) reported their long-term follow-up results in 53 adult patients treated with surgery and radiotherapy (median dose 50 Gy in 25 fractions).[217] The 5- and 10-year PFS rates were 85% and 69%, OS rates were 76% and 70%, and CSS rates were 88% and 88%, respectively.

The long-term morbidity associated with this disease and its treatments includes hypopituitarism, increased cardiovascular risk, hypothalamic damage, visual and neurological deficits, reduction in quality of life, cognitive and behavioral function, vasculopathies, and secondary malignancies.

Biologic Characteristics and Pathology

The two major histopathologic subtypes of craniopharyngioma are adamantinomatous and papillary. The papillary subtype is also referred to as squamous papillary and comprises 11% to 14% of all craniopharyngiomas and is only seen in adults.[219,220] Papillary craniopharyngiomas appear similar to Rathke cleft cysts that have undergone squamous differentiation and consist of mature squamous epithelium and pseudopapillae.[221] Macroscopically, they can have a combination of solid and cystic components. The cysts tend to contain a yellowish fluid. There is no evidence for a distinct mutation in this subtype.[222]

Adamantinomatous tumors are a more frequently observed subtype and are most commonly associated with childhood disease, although they can be seen across the age spectrum.[223] These tumors likely arise from the transformation of embryonic rests during the development and involution of the Rathke's pouch.[222] They also have solid and cystic components. A distinct feature includes dark brown to black fluid within the cysts related to cholesterol crystal deposition; it is often described as having an appearance and consistency similar to motor oil (or "crank-case oil"). More often than the papillary subtype, these tumors also contain calcification and tend to be more adherent to neighboring structures. Microscopically, they demonstrate Rosenthal fiber formation, nodules of wet keratin, a palisading basal layer of cells and intense surrounding gliosis.[223] Animal models have demonstrated a distinct relationship between aberrant Wnt/β-catenin pathway signaling in the pathogenesis of adamantinomatous craniopharyngioma.[224] In humans, some patients with adamantinomatous craniopharyngiomas also present with alterations of the β-catenin gene, CTNNB1, which alters intracellular levels of β-catenin, leading to accumulation of its unphosphorylated form, which is subsequently translocated to the nucleus, where it binds with transcription factors such as c-myc and cyclin D1, leading to oncogenesis.[222] This knowledge may lead to targeted therapies for adamantinomatous histology.

Anatomy and Pathways of Spread

Craniopharyngiomas are typically suprasellar in location although other rare presentations have been documented. They can be divided into prechiasmal and retrochiasmal because these locations may dictate the presenting symptoms. They can appear well encapsulated on gross examination but can be locally aggressive causing an intense glial reaction on adjacent brain. As these tumor grow they can compress adjacent structures including the pituitary and hypothalamic region, chiasm, and third ventricle, and if large the surrounding cerebral hemispheres and posterior fossa. The formation of multiple cysts is characteristic of these tumors.

Clinical Manifestations, Patient Evaluation, and Staging

Patients present with symptoms related to the surrounding structures mentioned previously. These include headaches, visual field cuts, decline in visual acuity, and hormonal abnormalities (including antidiuretic and GH insufficiency, amenorrhea, impotence, and galactorrhea).

Imaging

Craniopharyngiomas are common tumors located in the suprasellar region. Contrast enhancement, cyst formation, and calcification are the three characteristic features of craniopharyngiomas on CT. More than 90% of suprasellar craniopharyngiomas exhibit at least two of these three features, thus providing easy radiologic detection.[225] Of note the squamous papillary subtype is less likely to demonstrate calcifications on imaging. MRI typically demonstrates a hyperintense abnormality on T1-weighted images, which differentiates craniopharyngioma from Rathke's cleft and tumor cysts. Upon contrast administration, both the solid and cystic components typically enhance. CT and MRI have complementary roles in achieving the diagnosis and understanding the extent of the craniopharyngioma.[226] In addition to obtaining baseline CT and MRI with and without contrast, patients should also undergo baseline endocrine and ophthalmologic evaluations.

In the PMH series, age (<53 or ≥53) was found to be prognostic factor for OS and CSS and multiple surgeries were associated with worse PFS. The timing of radiotherapy had no prognostic significance. New endocrinopathies and visual dysfunction were observed in 53% and 17% of patients after surgery, and in 11% and 6% after radiotherapy, respectively. Unfortunately, no prospective data evaluating the role of radiotherapy in adult patients with craniopharyngioma exists.

Prospective data from 28 pediatric patients treated with three-dimensional (3D) conformal radiotherapy using a 1-cm clinical tumor volume (CTV) margin at St Jude demonstrated a 3-year PFS rate of 90.3%.[229] Review of the available outcomes for pediatric patients treated with surgery and radiotherapy demonstrates poorer cognitive outcome for patients younger than 7.4 years, long duration of prediagnosis symptoms, more extensive surgery, multiple surgical procedures, and diabetes insipidus. The percentage of total brain, supratentorial brain, or left temporal lobe volumes receiving a dose in excess of 45 Gy had a significant impact on longitudinal IQ.

Irradiation Techniques and Tolerance

Surgical decompression should be considered before radiotherapy. Fractionated radiotherapy typically consists of doses of 54 Gy given at 1.8 Gy per fraction. Conformal radiotherapy including 3D-CRT or IMRT should be considered given the proximity of these tumors to critical normal structures. A range of CTV margins from 2 cm down to 5 mm have been used. Cyst expansion can occur during radiotherapy, and therefore the smaller CTV margin should be used in the setting of surveillance MRIs throughout therapy to ensure target coverage.[230]

SRS can be considered for these tumors. A retrospective report from Pakistan used SRS to treat 35 patients (17 children and 18 adults) with craniopharyngioma.[231] The prescription dose ranged from 8 Gy to 14 Gy resulting in 88.5% tumor control rate at a mean follow-up of 22 months. A multimodality treatment approach including stereotactic drainage and intracystic bleomycin followed by SRS with a mean dose of 10.8 Gy ± 8.7 Gy demonstrated good response for patients with monocystic and small tumors, but progression occurred in most patients with large multicystic targets.[232] A retrospective review of 222 benign skull-based tumors (including 7 with craniopharyngioma) treated with Gamma Knife SRS estimated the long-term risk (mean clinical follow-up of 83 months) of radiation-induced optic neuropathy (RION): the chance of RION according to the maximum radiation dose received by the anterior visual pathway was 0% for patients receiving ≤8 Gy, 8.1 Gy to 10.0 Gy, 10.1 Gy to 12.0 Gy, and 10% for those receiving >12 Gy.[233]

Proton therapy has been used for these tumors both as the only treatment and as an adjunct to photon therapy.[234-237] Dosimetric comparative studies demonstrate the possibility of reduced whole-brain and whole-body radiotherapy doses when compared to modern photon-IMRT.[238] When considering proton therapy, monitoring for changes in tumor, and especially cyst anatomy during treatment remains important with one report describing intervention needed in 6 out of 17 children because of changes in the tumor.[235] A retrospective evaluation of quality of life and executive function following surgery and proton therapy demonstrates a high incidence of depression and decline in executive function in this population.[234]

Cystic craniopharyngiomas may be treated with intracystic phosphorus-32 (^{32}P), which has been used for many decades.[239-241] To deliver ^{32}P, the cyst volume is estimated to determine the amount of P32 necessary to deliver 200 Gy to 250 Gy to the cyst wall. A cannula is placed into the cyst stereotactically and 1 cc of fluid is removed. ^{32}P is instilled thorough the cannula with 0.2 cc of saline to flush the cannula. Patients are typically admitted overnight for observation. This technique results in good control of the treated cyst with a reported 5-year freedom from progression of 86%.[242] However, the 5-year freedom from progression outside of the treated cyst was only 54.5%. Overall freedom from progression was 45.6% at 5 years. Ten percent of these patients developed permanent deterioration of vision, attributed to tumor progression. Hasegawa et al reported that 23% patients experienced worsened visual function after intracystic ^{32}P. Although some vision loss was felt to be as a result of tumor progression, a few of these patients were felt to be related to radiation.[241] Because ^{32}P only treats the cyst and not the entire tumor, the use of ^{32}P has been described in combination with EBRT and SRS.[243,244]

Conclusions

Craniopharyngioma, although histologically benign, can be difficult to treat because of location, which makes a GTR difficult without morbidities. Radiation can help control disease that is not completely resected, with outcomes that may be favorable to a GTR by limiting the toxicities of treatment. These toxicities have implications on vision, growth, and cognitive development and need to be factored when choosing primary treatment. SRS can be considered in select cases when there is good separation of the optic pathway and the tumor. Recurrence is difficult to treat because many of these patients have already received radiation. SRS, intracystic bleomycin, and intracystic ^{32}P may be considered for recurrence. Future directions include targeted therapies, particularly for lesions where specific targetable alterations can be identified.

CHAPTER

30 Spinal Cord Tumors

Malika L. Siker, Joseph Bovi, and Brian Alexander

INCIDENCE

The incidence of spinal cord tumors in the United States is approximately 0.63 per 100,000 population. Tumor origin is grouped by location: extradural or intradural and extramedullary or intramedullary.

BIOLOGIC CHARACTERISTICS

The tumor histologic type is an important prognostic factor in spinal cord tumors. Most intramedullary spinal tumors are tumors of glial origin such as astrocytoma and ependymoma. Most intradural, extramedullary tumors are either meningioma or schwannoma; chordoma and chondrosarcoma, as well as vascular lesions, account for most primary extradural tumors. For glial tumors, histology and grade predict outcome. Patients with ependymoma have longer survival than those with astrocytoma. Within the astrocytoma grouping, low-grade (versus high-grade) and pilocytic (versus diffuse fibrillary) subtypes have a more favorable prognosis.

STAGING EVALUATION

There is no Joint Committee on Cancer staging system for spinal cord tumors.

The clinical workup should include a full history and physical examination, with special attention given to a thorough neurologic assessment. Radiographic imaging of the tumor should be done by magnetic resonance imaging (MRI). Depending on the histology and clinical situation, laboratory tests may include a cerebrospinal fluid (CSF) evaluation, which should be performed after a complete neuraxis imaging study (preferably MRI) with and without contrast. A tissue diagnosis should be obtained, whenever feasible and safe.

PRIMARY THERAPY

If technically safe and achievable, complete surgical resection should be considered for all tumors, excluding spinal lymphomas. In general, if the tumor is completely resected, and is low-grade, postoperative adjuvant treatment may not be necessary. Definitive radiation therapy is considered in patients who cannot undergo resection. Radiation treatment is also recommended for patients with spinal lymphomas, who typically undergo biopsy only, followed by both chemotherapy and irradiation.

ADJUVANT THERAPY

Radiation therapy is frequently employed for tumors that are incompletely resected, for those with nerve root seeding, for high-grade tumors irrespective of the extent of resection, or for most recurrent tumors.

In adults, if there is a subtotal resection (STR) or the tumor is recurrent, postoperative irradiation is indicated for most histologic diagnoses. In pediatric patients, observation with close imaging follow-up after STR is an alternative option, which allows maximal opportunity for spinal growth to be completed. In these situations close observation is necessary and radiotherapy might have to be used if progression is noted. There is a limited role for chemotherapy.

LOCALLY ADVANCED DISEASE AND PALLIATION

Surgical resection may be indicated for symptoms because of spinal cord compromise in these settings. Noninvasive approaches such as radiation therapy may be preferred for palliation, particularly if there is no immediate cord compromise or if surgery is not feasible. For radiotherapeutic palliation, fractionation regimens are similar to those used for spinal column metastases.

Spinal cord tumors are a rare heterogeneous group of tumors with diverse clinical and biologic characteristics. These tumors are challenging to treat because of the functional morbidity associated with their location, which also imposes significant limitations on definitive treatment. The majority of these tumors are approached primarily with surgery, whereas irradiation is used for a significant proportion of tumors that are incompletely resected, recurrent, or located in areas in which surgery would result in unacceptable functional morbidity. Chemotherapy has a limited role.

EPIDEMIOLOGY AND ETIOLOGY

Primary spinal cord tumors comprise 3% of all primary central nervous system (CNS) tumors in adults.[1] Age-adjusted incidence rates are slightly higher for men than women, 0.67 compared with 0.59 per 100,000 population, respectively, and in non-Hispanic whites as compared to Hispanics or non-Hispanic blacks, 0.79 compared with 0.61 compared with 0.45 per 100,000 population, respectively.[1,2] Most of these tumors present as extramedullary masses (70%); intramedullary tumors are less common. Approximately 15% to 25% of spinal tumors involve the cervical spine, including the foramen magnum; 50% to 55% involve the thoracic spinal canal; and 25% to 30% involve the lumbosacral spine. The most common histologic subtypes in adults include meningeal tumors, nerve sheath tumors, and ependymal tumors as shown in Table 30-1.[1]

In the pediatric population, spinal cord tumors are slightly more common, representing 4% to 5% of all primary CNS tumors.[1] Ependymal tumors, gliomas, and nerve sheath tumors are the most common histologic subtypes in children.

TABLE 30-1 Distribution of Primary Spinal Cord Tumors by Histologic Type[1]

Histologic Type	Adult Distribution (%)	Pediatric Distribution (%)
Meningeal tumor	41	8.8
Glial origin		
Ependymoma	21.7	24.6
Pilocytic astrocytoma	0.8	12.6
Other glioma	2.3	11.6
Nerve sheath tumor	22.6	13.9
Hemangioma	3.2	1.9

Pilocytic astrocytomas, which are much more common in the pediatric population, comprise the majority of gliomas as listed in Tables 30-1.[1]

The etiology of spinal cord tumors is largely unknown. Prior exposure to radiation therapy may increase risk of developing secondary malignancies such as sarcomas and gliomas as well as benign tumors such as meningiomas, although the exact magnitude of risk has not been quantified. Depending on the histologic type, tumors may be associated with genetic syndromes such as neurofibromatosis (NF) 1 and 2 as well as von Hippel-Lindau (VHL) disease. Tumors of the spine can be detected in 40% of patients with NF1 on imaging, but they often have a long indolent natural history, causing neurologic symptoms in only 2% of patients.[3] However, in patients with NF2, spinal tumors can be found in 60% to 80% of patients, are more aggressive in terms of their growth, and often require resection with or without adjuvant radiotherapy.[4] Patients with VHL are at high risk for developing hemangioblastomas (60% to 80%), which arise in the spine half of the time.[5,6]

PREVENTION AND EARLY DETECTION

There is no known method for prevention of spinal cord tumors. Early detection relies on careful neurologic examination and consideration of the possibility of a spinal cord tumor in the differential diagnosis. Because of the rarity of these tumors, there are no recommendations for routine screening for the general public. Although routine screening with MRI of the spine has not been recommended by the Academy of Pediatrics for patients with NF1, there may be a role for surveillance of the spine with MRI for patients with NF2 and VHL.[4,5,7]

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

Like their intracranial counterparts, the diversity of primary spinal axis tumors partly results from the large spectrum of phenotypically distinct cells in the axis, which are capable of neoplastic transformation.[8] The genetic and molecular bases of spinal cord tumors are not yet well understood and vary depending on histologic findings and age at diagnosis.[9] Data regarding molecular characteristics of spinal cord tumors are limited both by the rarity of the diseases and the limited amount of tissue available for analysis. Even so, there have been studies describing various genetic aberrations and some evidence suggesting differential origins of spinal cord and intracranial tumors.

Specific genetic alterations that lead to the development of spinal cord tumors are suggested by the occurrence of these tumors in several genetic syndromes. For example, NF1 leads to the development of intramedullary astrocytomas, suggesting a role of the *NF1* gene. Similarly, NF2 is associated with the development of ependymomas and meningiomas and VHL predisposes to hemangioblastoma. In addition to specific genetic syndromes, it might be expected that spinal cord tumors share genetic and biologic characteristics with their related intracranial tumors, given their histopathologic similarities. Examples of this are *BRAF* aberrations, *CDKN2A* loss, and *PTEN* loss in low-grade spinal astrocytomas and losses on chromosome 22q in both spinal cord and intracranial meningioma.[10,11] In this manner, molecular data from studies of the more common intracranial tumors may still have value when applied to primary spinal cord tumors.

Conversely, there are molecular data suggesting some types of spinal tumors may be distinct from their intracranial counterparts. For example, gene expression clustering suggests a distinct pattern that is specific for extracranial ependymomas and genetic lesions involving *NF2* seem to be limited to spinal ependymomas.[12-14] This is certainly consistent with the spine-specific location for ependymoma development in patients with NF2. Further study of the potential molecular differences between spinal and intracranial variants of various tumors may be important to elucidate the mechanisms underlying tumor formation.

Most tumors are histologically benign but can cause significant morbidity by direct compression of important neural structures. Not surprisingly, histologic typing and grade are important prognostic factors in spinal cord tumors. Patients with ependymoma have a longer median survival time than those with astrocytoma. Additionally, low-grade (versus high-grade) and pilocytic (versus diffuse fibrillary) astrocytomas have more favorable prognoses.

ANATOMY, PATHOLOGY, AND PATHWAYS OF SPREAD

Anatomy

Enclosed in the bony vertebral column, the spinal cord extends from the *medulla oblongata* of the brainstem to approximately the level of L1or L2 at the *conus medullaris*. It measures approximately 43 cm to 45 cm. The periphery of the cord is composed of white matter, which contains sensory and motor tracts, and the central region contains the butterfly-shaped gray matter, which houses nerve cell bodies. Three layers of meninges, the innermost pia mater, arachnoid mater, and outer dura mater, cover the elliptically shaped spinal cord and are continuous with the brainstem and brain. The delicate pia mater envelops the spinal cord and blood vessels. From this layer extends the denticulate ligaments, which connect with the dense, protective dura mater to stabilize the cord within the spinal canal. The dura mater terminates beyond the conus medullaris at the *filum terminale*, which is a strand of fibrous tissue that attaches to the coccyx, providing longitudinal support to the cord. Between these two layers lies the arachnoid, which is filled with CSF.

The spinal cord is responsible for transmitting motor and sensory neural signals between the peripheral nervous system and the brain and contains its own independent pathways for coordinating certain reflexes (Figure 30-1). Functionally, the cord is divided into 31 segments. At each level, a pair of spinal nerves exits: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral pairs, and 1 coccygeal pair. In the cervical region, the spinal nerves exit above the corresponding vertebrae, whereas from the thoracic region and downward, the spinal nerves exit below the equivalent named vertebrae. Although the vertebral column continues to lengthen until adulthood, the canal and the cord are actually much shorter than the column because both

stop lengthening at approximately 4 years of age. This growth differential is responsible for the formation of the *cauda equina*, a collection of the lower lumbar, sacral, and coccygeal nerves that fills the lower spinal column beyond the conus medullaris.

Within the spinal canal, there exists a well-defined extradural space containing epidural fat and blood vessels. The extradural space communicates with adjacent extraspinal compartments via the intervertebral foramina. The blood supply comes from a single anterior spinal artery (75%) and two smaller posterior arteries (25%). The cervical region relies on the vertebral and inferior cerebellar arteries, whereas the thoracic and lumbar regions depend on the radicular arteries. Venous drainage occurs through a vast network of plexuses.

Tumors are classified based on their location (Figure 30-2). Intradural tumors include both intramedullary and extramedullary tumors. Intramedullary tumors develop from the cells that make up the spinal cord and cauda equina, and extramedullary tumors arise from the supportive tissues that lie outside the spinal cord and cauda equina, such as the meninges, vascular supply, and connective tissue. Extradural tumors arise from the vertebral canal itself or supportive tissues surrounding the dura.

Pathology and Pathways of Spread

The overall and anatomic distributions of histologic types are listed in Tables 30-1 and 30-2. Intradural extramedullary schwannoma (neurilemmoma) and meningioma are the most common intradural tumors, although occasionally they may present as extradural tumors. Other intradural extramedullary tumors include epidermoid and drop metastases of intracranial primary tumors such as medulloblastoma. The most common intramedullary tumors are those derived from glial precursors, most frequently, ependymomas and astrocytomas of low- to intermediate-grade. Nonneoplastic conditions may mimic spinal cord tumors (Figure 30-3), including acute transverse myelitis, *Angiostrongylus cantonensis* infection, infectious meningitis, intradural disc hernia, pseudotumor, sarcoidosis, and tuberculosis.[15-19]

The predominant mode of spread of primary tumors is by direct extension. Spread along the subarachnoid space with spinal or cranial involvement of the meninges may also occur. One should not always assume that a spinal cord tumor found on imaging is the primary lesion because the primary tumor could be intracranial in location. Although CSF seeding is uncommon, primary intracranial tumors that show a tendency toward leptomeningeal metastases include medulloblastoma and ependymoma, and rarely glioblastomas and anaplastic gliomas.[20-22] There is a paucity of lymphatics in the spinal cord and therefore nodal spread is rare. Hematogenous spread is also quite rare, and when encountered, is more often a consequence of metastatic disease from an extraneous source spreading through Batson's venous plexus (<1%).[23]

TABLE 30-2 Anatomic Distribution of Spinal Tumors by Histologic Type

Extradural	Intradural Extramedullary	Intradural Intramedullary
Chondroblastoma	Ependymoma, myxopapillary type	Astrocytoma
Chordoma	Epidermoid	Ependymoma
Chondrosarcoma	Lipoma	Ganglioglioma
Hemangioma	Meningioma	Hemangioblastoma
Lipoma	Neurofibroma	Hemangioma
Lymphoma	Paraganglioma	Lipoma
Meningioma	Schwannoma	Medulloblastoma
Metastasis		Neuroblastoma
Neuroblastoma		Neurofibroma
Neurofibroma		Oligodendroglioma
Osteoblastoma		Teratoma (mature)
Osteochondroma		
Osteosarcoma

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

The clinical presentation of tumors of the spinal axis is a function of the local anatomy (Figure 30-1). A spinal cord tumor produces local and distal symptoms and signs; the latter reflect involvement of motor and sensory long tracts within the spinal cord. These allow localization of the level of the lesion based on clinical findings. Localized pain from compression or stretching of the dura and bony periosteum can occur, as well as radicular pain from nerve root compression or involvement.

Clinical Workup

The diagnostic approach to primary spinal cord tumors is shown in Figure 30-4. In addition to focusing on neurologic symptoms, the history should include an evaluation of the patient's functional status and associated symptoms, which may suggest metastatic disease or nonmalignant causes of spinal cord tumors. It is also important to assess for family history and a detailed review of systems to investigate genetic disorders associated with spinal cord tumors.

Physical examination should involve an extensive neurologic assessment. Flaccid weakness, atrophy, fasciculations, and reduced deep tendon reflexes are seen in corresponding myotomes with involvement of the anterior horn cells and the ventral roots (lower motor neuron lesions). A tumor involving the lateral corticospinal tracts can cause weakness, spasticity, extensor plantar response (Babinski sign), and hyperreflexia (upper motor neuron lesion). Motor weakness and spasticity are seen with tumors above the conus medullaris. Weakness and flaccidity are seen with tumors below the conus because they compress the peripheral nerve roots of the cauda equina. A tumor restricted to the conus should not cause weakness, although one also involving the cauda equina or the lumbar enlargement of the spinal cord will do so.

Sensory impairment often helps to localize the level of the tumor based on loss of dermatomal function, although the upper level of impaired long-tract function may be several segments below the actual tumor (Figure 30-5). A lesion involving the lateral spinothalamic tract causes numbness, paresthesias, and decreased temperature sensation over the contralateral limb or trunk below the lesion. This produces the classic finding of a sensory level, which is best demonstrated with a pin or a large metal or cold object to test temperature sensation and with observation for absence of perspiration. A lesion in the posterior column causes an ataxic or tabetic gait. Standing posture is affected with the eyes closed (Romberg's sign). Paresthesias can occur below the level of the lesion.

Because pain and temperature pathways cross over in the spinal cord and proprioceptive and motor pathways do not, a unilateral spinal cord lesion can result in ipsilateral paralysis

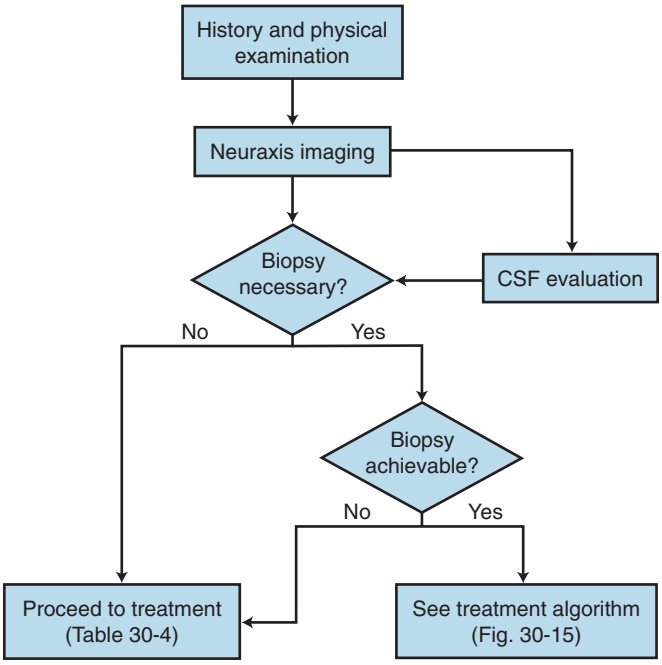

Figure 30-4 **Diagnostic algorithm for primary spinal cord tumors.** *CSF*, Cerebrospinal fluid.

(Adapted from Netter FH, Freidberg SR, Baker RA: Disorders of spinal cord, nerve root, and plexus. In Netter FH, Jones HR, Jr, Dingle RV, editors: The Ciba Collection of Medical Illustrations, Vol 1. Nervous System, Part II. West Caldwell, NJ, Ciba-Geigy, 1986, pp 181–189; Keegan JJ, Garrett FD: The segmental distribution of cutaneous nerves in the limbs of man. Anat Rec 102:409, 1948.)

and proprioceptive loss as well as contralateral pain and temperature loss below the level of the lesion. Because light touch travels in two pathways, one that crosses in the spinal cord (spinothalamic tract) and one that does not (posterior columns), it is usually spared in unilateral lesions. This combination of findings is known as the Brown-Séquard syndrome.

Both genitourinary and bowel symptoms can result from a spinal cord tumor. Bladder symptoms include hesitancy, dribbling, incontinence, urgency, or acute retention. Loss of bladder control is seen early in the presentation of tumors at or below the conus and later in tumors above the conus. Lesions above L1 can lead to impotence or reflex priapism. Lesions involving S2 to S4 may produce loss of erection and ejaculation ability. Decreased genital sensation can occur from lesions affecting the S2 nerve roots. If bowel control is affected, constipation occurs more frequently than incontinence.

The most common presenting symptom from spinal canal tumors is pain, caused by nerve root compression, bony destruction, or more subtly, pressure on the dura or deafferentation. The pain may be radicular, midline, or centrally located. Radicular pain is secondary to involvement of the posterior roots and is typically described as shooting pain in the dermatomal distribution. The nerve can be compressed inside of or outside of the dura. Midline spinal pain presents as discomfort localized to the area of the tumor and is thought to arise from pain-sensitive structures in the dura and extradural tissues. Characteristically, pain is more severe with extradural lesions. With spinal cord compression, a dull or burning pain, more widespread than segmental spinal or radicular pain, sometimes occurs. This type of pain, although relatively rare, has numerous designations, including central pain, causalgia, and deafferentation pain. It involves a limb or trunk below the lesion. Pain is the most common presenting symptom in patients with sacrococcygeal tumors. Headache may be caused by elevated intracranial pressure, which is unusual in patients with primary spinal cord tumors, with the exception of large tumors involving the foramen magnum. It can be caused by upward seeding of the tumor or by the development of carcinomatous meningitis from malignant tumors.

The clinical presentation of a spinal tumor rarely indicates whether it is extradural or intradural. However, intramedullary tumors can cause a characteristic neurologic syndrome. Early on, decreased temperature and pain sensation occurs in the dermatomes of the spinal segments occupied by the tumor and two or three segments caudal to the lesion. Other sensory modalities are not diminished while the tumor is confined to the central cord. This "dissociated" sensory loss is rarely seen with extramedullary tumors. Additionally, weakness and atrophy are early findings in the myotomes of the corresponding cord segments involved by tumor. As the tumor grows

transversely, reflexes produced at the level of the tumor disappear and spastic paralysis with hyperreflexia develops below the lesion. Eventually, all sensory modalities are affected. Cervical tumors can produce Horner's syndrome by interrupting unilateral autonomic pathways.

Lesions in the conus medullaris can produce several symptoms, including saddle anesthesia, acute urinary retention, incontinence of bowel and bladder, and impotence. If the lesion remains confined to the conus, it will not cause paralysis of the lower limbs and the ankle reflexes are preserved. More commonly, tumors originating in the conus are diagnosed when they have enlarged enough to cause signs characteristic of intramedullary tumors. These findings can also be mixed with those caused by growth of the tumor in the direction of the cauda equina, such as radicular pain.

Lesions of the cauda equina can cause radicular pain in the thigh, weakness, and atrophy of muscles, including the gluteus, hamstring, gastrocnemius, and anterior tibialis muscles. Saddle anesthesia, absent ankle reflexes, impotence, urinary urgency or acute retention, and constipation are also commonly seen. Depending on the location of the lesion, other reflexes may be affected.

Neuroimaging

Certain tumors may display characteristics on plain films such as the calcifications seen in meningiomas. Increased intracranial pressure can cause enlargement of the bony spinal canal, erosion of the pedicles, and scalloping of the posterior wall of the spinal canal. Computed tomography (CT) can be useful for evaluating the vertebral column in extradural tumors. Myelography has been replaced by more-advanced, less-invasive imaging but can be useful in patients who cannot tolerate MRI.

MRI with gadolinium contrast is the diagnostic study of choice in the evaluation of intramedullary and extramedullary spinal cord lesions. Advantages of MRI include the high soft-tissue contrast between the spinal cord and associated anatomic structures and tumor, ability to display the spine in multiple views, availability of multiple pulse sequences, lack of bony artifact, and capacity for three-dimensional (3D) visualization. Most spinal cord tumors enhance with contrast, the most common exception being World Health Organization (WHO) grade II gliomas. Edema appears as an area of low-signal intensity on T1-weighted MRI images and high-signal intensity on T2-weighted MRI images. Tumor infiltration may be differentiated from edema by suppression of CSF signal using fluid-attenuated inversion recovery (FLAIR) sequences. MR spectroscopy may help to differentiate tumor from spinal cord necrosis. MRI of the entire neuraxis is strongly recommended in the initial workup.

Cerebrospinal Fluid Examination

Examination of CSF may be indicated for diagnostic and staging purposes as well as for monitoring of therapeutic response in certain tumors. Because of the risk of herniation caused by increased intracranial pressure, neuroimaging studies should precede lumbar puncture. When obstruction of CSF flow occurs because of tumor expansion, patients can develop hydrocephalus. A lumbar puncture in a patient with a spinal cord tumor who presents with a headache should therefore be performed cautiously.

CSF examination is especially useful in the assessment of tumors that may seed the subarachnoid space and spread via the CSF. As such, CSF examination is routinely done at the time of diagnosis of ependymoma and primitive neuroectodermal tumors. The appearance of xanthochromic CSF, resulting from high protein content with an absence of erythrocytes, is characteristic of spinal cord tumors obstructing the subarachnoid space. CSF evaluation should include cytology for malignant cells, protein, and glucose. A high protein concentration with normal glucose levels and normal cytologic findings is seen in spinal cord tumors. However, if the tumor has seeded the meninges, the glucose level may be low and cytologic testing may reveal a malignant tumor.

Histologic Confirmation of Disease

The approach for histologic confirmation depends on the clinical presentation and suspected histologic type. The morbidity of potential biopsy should be weighed against the benefits of confirming the histologic type and whether it would change management. Image guidance can be used to improve safety and efficacy of biopsy. In patients presenting with acute spinal cord compression, surgical decompression should be considered to relieve progression of neurologic symptoms and establish a diagnosis.

Staging

There are no routine staging systems for the classification of spinal tumors.

PRIMARY THERAPY

General Principles of Surgery

Maximal surgical resection remains the primary treatment of choice for the majority of tumors.[24] As modern diagnostic and therapeutic techniques such as MRI, the operating microscope, microsurgical tools, and intraoperative neurophysiologic assessment have become available, more aggressive surgical intervention has become a more prevalent treatment strategy. This section will discuss general principles of surgery for CNS lesions, depending on anatomic location within the spinal cord. The outcome of surgery and its role in multidisciplinary management are described in the sections for each individual type of tumor. Table 30-3 shows an overview of the outcomes of the most common spinal cord tumors by treatment modality.

Surgical Planning

Neuroimaging is the basis for preoperative planning of the surgical approach. MRI obtained both before and after the administration of intravenous gadolinium-based contrast is the most sensitive modality for detecting tumor and delineating tumor from reactive changes such as a syrinx. CT scans are most useful for delineating the bony anatomy, acute blood and intratumoral calcifications. Spinal angiography is occasionally necessary to distinguish spinal cord tumors from vascular malformations such as dural arteriovenous malformations.

Surgical Techniques, Postoperative Management, and Complications

The use of the operating microscope is essential for spinal cord tumor surgery. The availability of other surgical adjuncts, including image-guided navigation systems, intraoperative ultrasound assessment, the carbon dioxide (CO_2) laser, and the ultrasonic aspirator (CUSA), are of value for selected tumors.[25] In addition, the use of 5-aminolevulinic acid fluorescence–guided surgery has been used to aid in the resection of spinal tumors; however, the benefits in spinal surgery have not been proven at this time.[26,27]

Multiple modalities are available for intraoperative monitoring of physiologic function. The most commonly used

techniques are somatosensory evoked potential (SSEP) and monitoring and electromyography (EMG). Motor-evoked potential (MEP) monitoring is more difficult to use reliably because it is more sensitive to the paralytic agents used in anesthesia. EMG is of particular use for cauda equina and foramen magnum tumors, where monitoring of the extremity musculature, the anal sphincter, and sometimes, the urinary sphincter can reduce the risk of postoperative deficits.[28]

Surgery for Intradural Extramedullary Tumors

Meningiomas and schwannomas (neurilemmomas) occur in the intradural extramedullary spinal compartment. Most of these tumors can be completely resected with curative intent because the normal spinal cord is not invaded by tumor.

Surgery for Intramedullary Tumors

The most common intramedullary tumors are ependymomas and astrocytomas. Modern series advocate maximum safe resection of intramedullary spinal tumors. The ability to resect these tumors completely varies widely, from less than 10% to as much as 86%, depending on the histologic type.[29-36] Complete resection is achieved more frequently for WHO grade I tumors; gliomas of higher grade tend to be infiltrative, and therefore are less often resected completely.[33,37-41] The gross total resection (GTR) rates for ependymomas range from 19% to 100%, whereas significantly less than 50% of astrocytomas are totally resectable.[42-45] For infiltrative astrocytomas, the role of surgery is most frequently limited to biopsy for diagnosis. Laminectomy offers limited functional benefit by decompressing the spinal cord in the case of bulky infiltrative tumors. Functional postoperative outcomes may be excellent in selected cases, with the majority of patients (more than 70%) experiencing either improvement or stabilization of their preoperative presenting symptoms, often after transient postsurgical worsening.[29,36,46,47] The incidence of total, permanent postoperative paralysis is reported at 1%.[48] Paralysis is often the result of unpredictable vascular events.

Intramedullary tumors are almost always approached through a laminectomy exposure with the patient in the prone position.[48] After the dura is opened, a longitudinal myelotomy is made over the widened region of the spinal cord, where imaging demonstrates the closest approximation of the tumor to the surface and the incision is deepened several millimeters until the tumor surface is reached. Infiltrative tumors with poorly defined dissection planes cannot be removed completely and, therefore, biopsy for diagnosis is often the safest course of action. When there is an exophytic component to the tumor, maximum safe debulking is typically performed.

Both intramedullary and extramedullary tumors can be associated with a CSF-filled syrinx dilating the central canal. The preferred treatment is tumor removal. If this is not possible, even modest shrinkage of the tumor by means of irradiation can stabilize or even reduce the size of a syrinx. Postoperatively, a syrinx can form from scarring in the central canal. A syrinx drainage procedure may not result in a significant improvement in neurologic function.

Postoperative Management

Corticosteroids are routinely administered before, during, and after surgery to minimize edema of the spinal cord. Intravenous or oral dexamethasone or high-dose intravenous methylprednisolone is most often the agent of choice. Once maximum symptom resolution has occurred, usually within a week of initiation of high-dose glucocorticoids, steroids should be tapered as rapidly as possible to minimize steroid-related side effects, as long as there is not associated worsening of symptoms.

Complications of Surgery

In patients who are neurologically intact before surgery, the incidence of significant acute morbidity is generally low, usually 5% or less.[48] Spinal deformities, including scoliosis and kyphosis, as well as infection and CSF leakage, can occur.[49,50] The development of postlaminectomy spinal deformities is a serious postoperative complication, occurring in up to 40% of pediatric and adolescent patients and may be observed as soon as 8 months postoperatively.[51]

General Principles of Radiation Therapy

The intent of radiation therapy in the treatment of spinal cord tumors is to improve local control and neurologic function while potentially increasing survival times. Radiation therapy is frequently used for tumors that are incompletely resected, at high risk of recurrence, located in areas where surgery would result in unacceptable functional morbidity, as well as for recurrent tumors. Outcomes of radiation therapy and its role in multidisciplinary management are described in a subsequent section for each individual type of tumor.

Because of the potential for growth and developmental side effects, the use of irradiation in children and infants with spinal cord tumors is controversial. Some authors do not recommend postoperative radiation therapy and suggest that observation with close follow-up and re-resection at the time of relapse is a safer approach, particularly for benign tumors or low-grade gliomas.[29] With this strategy, radiation therapy may be avoided, delayed or used only for children with multiply recurrent tumors.

General Principles of Chemotherapy

The efficacy of chemotherapy may be limited by the intact blood–nervous system barrier. Regional drug delivery may be in the form of intracerebrospinal fluid therapy, intraarterial infusion, and intratumoral therapy. Extramedullary spinal tumors gain their blood supply from meningeal blood vessels that are significantly more permeable than those of the brain, and chemotherapy may be of more use for these tumors. Drugs that have some efficacy in treating primary CNS malignant tumors and that are thought to cross the blood-brain barrier have been used in the treatment of malignant glial tumors of the spinal cord; however, no clear benefit from the use of chemotherapy has been demonstrated thus far.[40,52-55]

LOCALLY ADVANCED DISEASE AND PALLIATION

The principles of treatment are the same for patients with more locally advanced disease and palliation as for definitive treatment. Because of the severity of symptoms related to lack of control of spinal cord tumors, in most cases irradiation dose should not be substantially decreased, although this may be a consideration with large fields. Patients with end-stage disease requiring palliation of pain are typically treated based on the general principles of palliative management.

IRRADIATION TECHNIQUES AND TOLERANCE

Definition of Treatment Volumes

3D or intensity-modulated treatment planning based on International Commission on Radiation Units (ICRU) volume definitions is the norm.[56,57] The gross target volume (GTV)

TABLE 30-4 Suggested Definitions of ICRU Volumes Based on MRI and Dose Ranges Delivered to Volumes

	Initial Treatment Field			Final Treatment Field			
Diagnosis	**GTV1**	**Margin to CTV1**	**Dose (Gy)**	**GTV2**	**Margin to CTV2**	**Dose (Gy)**	**Dose to Craniospinal Axis (If Indicated)**
WHO grade I glioma	NA	NA	NA	Enhancing tumor (T1 + C)	1 cm	45-50.4	NA
WHO grade II glioma	Enhancing tumor (T1 + C) + Edema (T2/FLAIR)	2 cm	45	Enhancing tumor (T1 + C)	2 cm	50.4-54	NA
WHO grade III-IV glioma	Enhancing tumor (T1 + C) + Edema (T2/FLAIR)	2 cm	45-50.4	Enhancing tumor (T1 + C)	2 cm	55.8-61.2	Leptomeningeal spread on MRI: 30-39.6 Bulky disease: 55.8-61.2
Ependymoma	Enhancing tumor (T1 + C) + edema (T2/FLAIR)	2 cm	45	Enhancing tumor (T1 + C)	2 cm	50.4-55.8	Positive CSF: 36 Leptomeningeal spread on MRI: 39.6
Meningioma, benign/atypical	NA		NA	Enhancing tumor (T1 + C)	1 cm	45-55.8	NA
Meningioma, malignant	Enhancing tumor (T1 + C) + edema (T2/FLAIR)	2 cm	45-50.4	Enhancing tumor (T1 + C)	2 cm	54-61.2	NA
Chordoma	Enhancing tumor (T1 + C) + tumor bed	2 cm	50	Enhancing tumor (T1 + C)	2 cm	60-70	NA
Chondrosarcoma	Enhancing tumor (T1 + C) + tumor bed	2 cm	50	Enhancing tumor (T1 + C)	2 cm	60-70	NA
Sarcoma	Enhancing tumor (T1 + C) + tumor bed + surgical track, including scar	2 cm	50	Enhancing tumor (T1 + C)	2 cm	60-70	NA
Vertebral hemangioma	Enhancing vascular lesion + entire involved vertebral body	≥1 cm	NA	NA	NA	36-45	NA

represents the grossly visible disease burden. Typically, this is the T1-enhancing abnormality on MRI or the nonenhancing tumor seen on T2 or FLAIR images. If there is no residual abnormality after a surgical resection, the tumor resection cavity is defined to be the GTV. The clinical target volume (CTV) incorporates the GTV plus a margin for microscopic disease extension and includes areas at high suspicion for disease recurrence. Suggested definitions and doses to be delivered to the GTV and CTV are listed by histologic diagnosis in Table 30-4. The planning target volume (PTV) adds a dosimetric margin that takes into account uncertainties in daily treatment setup and physiologic variations that are difficult or impossible to control, such as (potential) fluctuations in the mass effect from cord edema that may occur over the course of treatment. Organs at risk typically include the thyroid, salivary glands, esophagus, lungs, heart, stomach, small bowel, liver, kidneys, bladders, ovaries, testicles, and uninvolved portions of the spinal cord itself.

Treatment Techniques

The most common approaches include a single posteroanterior (PA) field, opposed lateral fields, a PA field with opposed laterals, and oblique wedge-pair fields, which are typically designed to treat the PTV. For tumors in the cervicothoracic region, a split-beam approach is sometimes used. The central axis is placed just above the shoulders. Opposed lateral fields are used to treat the upper spine, whereas a PA field is used for the area of the spine below. Tumors in the thoracic region are often treated with a three-field approach using a PA field and opposed lateral beams. In the lumbar region, care must be taken to minimize the dose to the kidneys; a four-field approach using anteroposterior (AP)/PA and opposed lateral beams with the AP/PA beams preferentially weighted may be useful. In all sites, 3D conformal approaches are preferable, when feasible (Figure 30-6).

The advent of intensity-modulated radiation therapy (IMRT) techniques now allows for the development of sophisticated treatment plans, using several beam directions and treatment fields that may allow the dose to critical structures to be minimized.[58,59] The use of image guidance may also allow for reduced PTV margins. It is therefore important to compare different treatment field setups and techniques using dose-volume histograms to select the most appropriate option. In select centers, proton beam therapy is being used to decrease dose to organs at risk.

Certain neoplasms require treatment of the entire craniospinal axis. Several modifications of this approach are used in clinical practice (Figure 30-7). Patients may be treated either in the supine or prone position, often in an immobilization cast to ensure daily positional reproducibility.[60,61] The intracranial contents, including the upper segments of the cervical cord, are treated through opposed lateral fields. Customized blocks protect the normal head and neck tissues from the primary radiation beam. The spine is treated through one or two posterior fields, depending on the size of the patient. In one method, the collimator for the lateral cranial fields is angled to match the divergence of the upper border of the adjacent

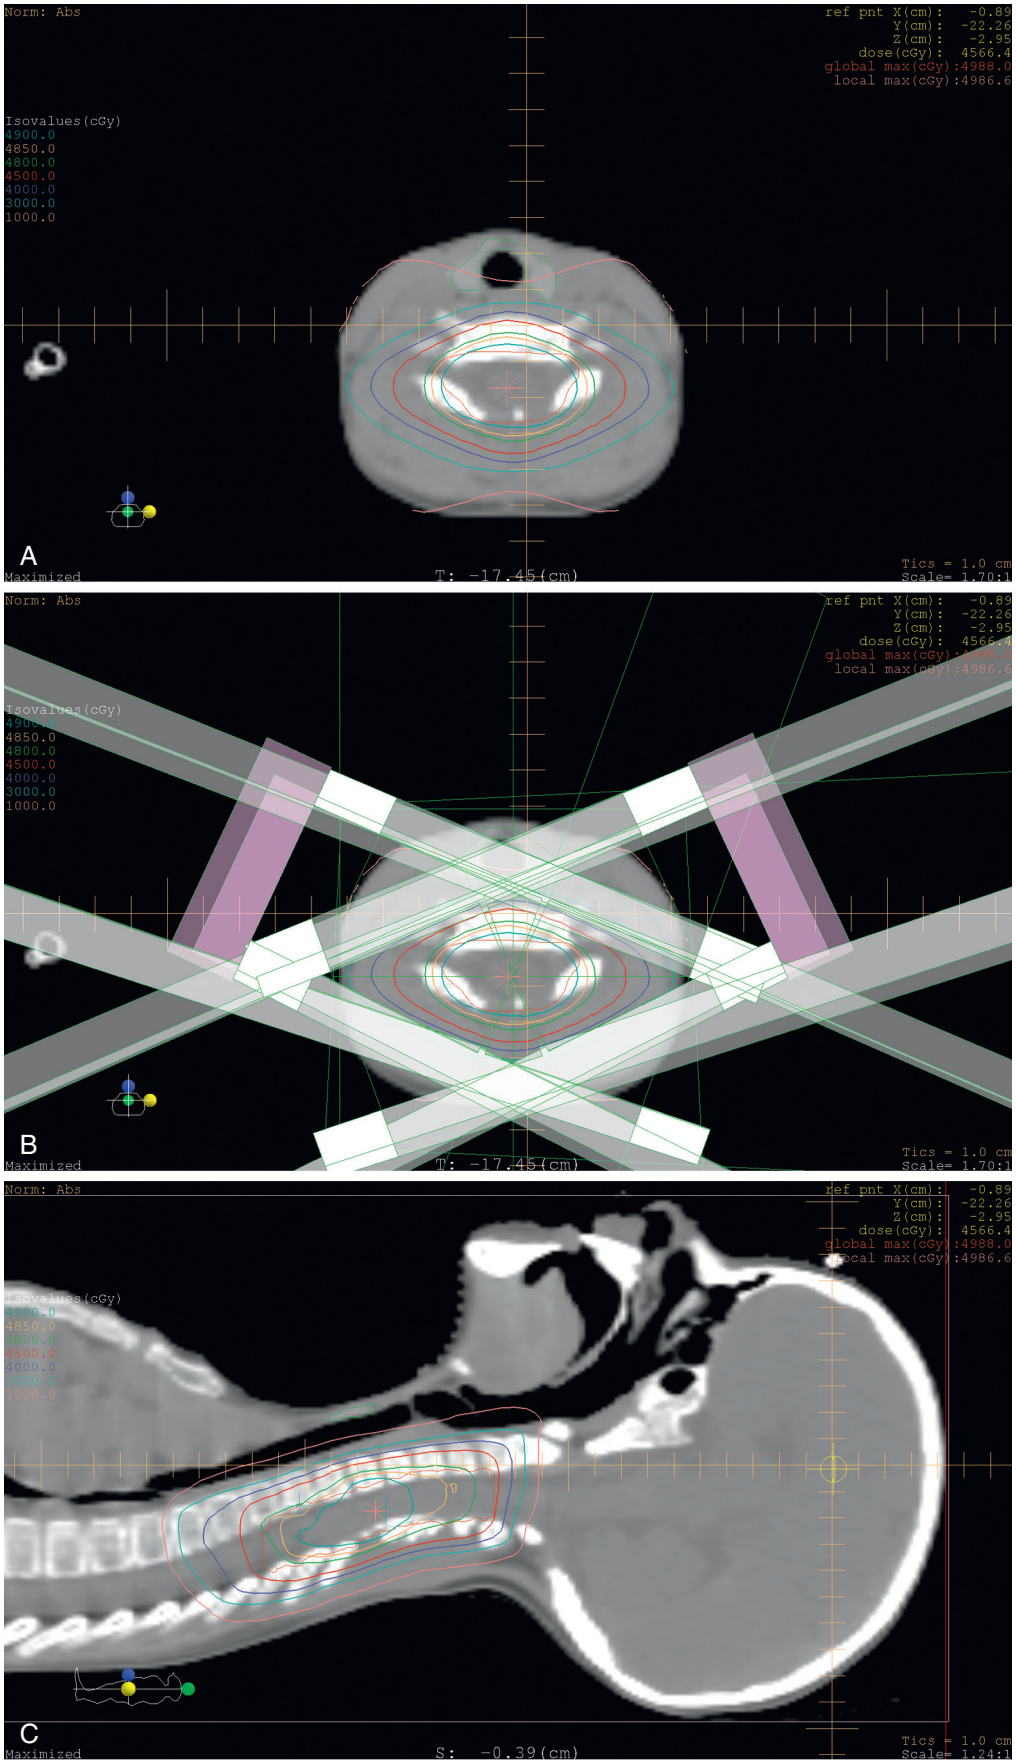

Figure 30-6 Patient is a 6 year-old boy with an atypical neurocytoma of the cervical and upper thoracic cord who underwent subtotal resection and was subsequently found to have radiographic evidence of disease progression. He received salvage radiation therapy with three-dimensional conformal technique to 48.5 Gy in 28 fractions. Images **A** and **B** represent the isodose distribution with and without beams respectively, whereas image **C** depicts a sagittal image with isodose distribution.

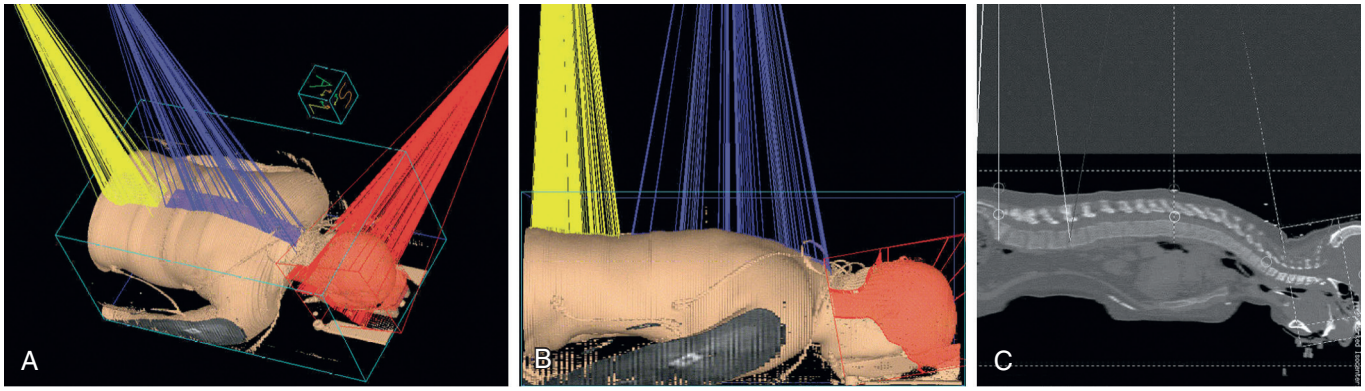

Figure 30-7 Two- and three-dimensional treatment planning images of craniospinal axis radiation therapy. Patients are treated in the supine or prone position, and an immobilization cast often is used to ensure positional reproducibility. Intracranial contents and the upper one or two segments of the cervical cord are treated through opposed lateral fields. Customized blocks protect the normal head and neck tissues from the primary radiation beam. The spine is treated through one or two posterior fields.

spinal field, and the treatment couch is angled so that the inferior border of the cranial field is parallel to the superior edge of the spinal field. Alternatively, one may dispense with collimator and couch angles by calculating appropriate gaps. The gap is calculated so that the 50% isodose lines meet at the level of the anterior spinal cord. All junction lines are moved 0.5 cm to 1 cm every 8 Gy to 10 Gy to avoid overdosing or underdosing segments of the cord. This is accomplished by shortening the inferior margin of the lateral cranial fields, symmetrically lengthening the superior and inferior margins of the posterior spinal field, and shortening the cranial margin of the caudal spinal field; a fixed block is placed at the inferior margin of the caudal spinal field to keep the lower margin of the irradiated volume at the same location. IMRT, volumetric modulated arc therapy (VMAT), or proton radiotherapy has been used to treat the craniospinal axis, especially in children, to better conform the target dose and allow improved sparing of critical structures.[62-67]

Proton radiation therapy may be considered in certain clinical situations (Figure 30-8). In patients with chordoma and chondrosarcoma, there is a well-defined role for proton therapy that allows for dose escalation with improved sparing of critical organs.[68-75] Proton therapy is also considered in pediatric patients to limit exposure to normal structures, and also in young adults, in which heart and breast sparing may reduce delayed second malignancies and cardiac complications.

Both single fraction and multifraction stereotactic radiosurgery (SRS) or stereotactic body radiotherapy (SBRT) deliver a highly conformal high dose of radiotherapy with stereotactic guidance (Figure 30-9). Advantages include patient convenience with a shorter treatment course and the steep dose gradient at the edge of the field, which may allow for greater tissue sparing. The use of image guidance before treatments is critical given the large doses and high conformality delivered with this technique. SRS has been used with clinical effectiveness for benign, malignant, and metastatic lesions in the spine and spinal cord, but its role remains limited, mainly because of technical and dosimetric considerations.[76-92]

Tolerance of the Spinal Cord and Lumbosacral Nerve Roots

A dose of 45 Gy to 50.4 Gy in 25 to 28 fractions over 5 to 5.5 weeks is usually considered to be safe. The risk of myelopathy is less than 1%, well below the steep portion of the dose-response curve.[93,94] It is estimated that with conventionally fractionated irradiation (1.8 Gy to 2 Gy per fraction in 5 fractions per week), the 5-year incidence of myelopathy is 5% for doses in the range of 57 Gy to 61 Gy (tolerance dose $TD_{5/5}$) and 50% for doses of 68 Gy to 73 Gy ($TD_{50/5}$).[94] There is no convincing evidence that the cervical and thoracic cord differ in their radiosensitivity, and there appears to be little change in tolerance with variations in the length of cord irradiated.[94] Table 30-5 shows a range of isomorbid fractionation schemes, all of which carry a 5% risk of radiation myelopathy. The use of chemotherapy may decrease the tolerance of the spinal cord.[95,96]

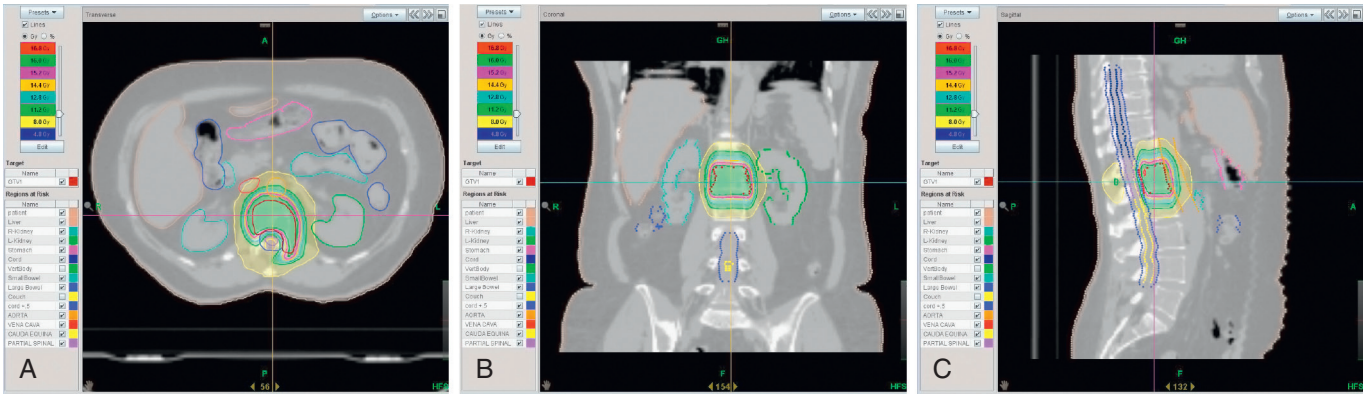

Figure 30-9 Patient is a 62-year-old woman with a biopsy-proven spine metastasis from a lung primary. She was treated with a single fraction of radiotherapy to 16 Gy prescribed to the 95% isodose line. Pain resolved within 24 hours. At 1 year, there was no progression of the spine disease.

Data from references 93, 97-105.

The tolerance of the lumbosacral nerve roots appears to be somewhat higher than that of the spinal cord. Most series report a 0% complication rate if patients are treated to doses of 70 Gy (or equivalent) as long as fraction sizes are kept at or below 2 Gy.[106,107]

The Quantitative Analysis of Normal Tissue Effects in the Clinic (QUANTEC) workgroup reviewed data from preclinical, conventional, reirradiation, and SBRT studies to refine normal tissue dose and volume tolerance guidelines.[108] Based on this, a total dose of 54 Gy, 60 Gy, or 69 Gy with conventional 2-Gy once-daily fractionation was associated with a myelopathy rate of less than 1%, 6%, and 50%, with a calculated strong dependence on dose/fraction ($\alpha/\beta = 0.87$ Gy). For partial cord irradiation as part of spinal SRS/SBRT, a maximum cord dose of 13 Gy in a single fraction or 20 Gy in three fractions appeared to have a minimal (<1%) risk of injury.[109] However, emerging data from Stanford University suggest that spinal cord tolerance may be higher.[110]

PRIMARY THERAPY BY TUMOR TYPE

Astrocytoma

Astrocytomas represent 3% of adult and 24% of pediatric spinal canal tumors.[1] They are one of the most common intramedullary spinal cord tumors and comprise 35% to 45% of all reported cases of intramedullary tumors in adults. In children, 75% to 90% of intramedullary spinal cord tumors are astrocytomas, the majority of which are low-grade or juvenile pilocytic astrocytomas (Figure 30-10). Fewer than 20% of pediatric and 25% of adult spinal cord astrocytomas are malignant.[111-115]

Back pain and motor deficits are the most common presenting symptom in astrocytomas, occurring in up to 87% of patients. The median time from onset of symptoms to diagnosis ranges from 6 months to 2 years. In general, high-grade astrocytomas tend to have a shorter prodrome (median duration, 1.6 months to 7 months) than low-grade tumors (median duration, 2 years). Tumor dissemination by spread along the subarachnoid space is reported in up to 58% of patients with high-grade astrocytomas. Approximately 1% of WHO grades III to IV spinal cord astrocytomas have multifocal disease at presentation.[115]

Prognostic Factors

The most significant prognostic factors in patients with primary spinal cord astrocytoma are tumor histology, tumor grade, age, and performance status. High histopathologic grade is typically associated with a high risk of mortality and short median survival time.[112-114,116-119] In a Mayo Clinic review, median survival of patients with pilocytic tumors was significantly longer than those with infiltrative astrocytomas (39.9 years versus 1.85 years, $p < 0.001$).[114] Similar findings were reported from another retrospective review from M. D.

Anderson Cancer Center (MDACC) where the 5-year overall survival (OS) for pilocytic tumors was 85% compared to 36% for infiltrative tumors. When looking more specifically at grade of infiltrative tumors in this study, higher grade conferred worse median survival which was 7.6, 2.8, and 1.4 years for WHO grades II, III, and IV, respectively.[112] According to a Surveillance, Epidemiology, and End Results (SEER) database review, 5-year OS for grades I, II, III, and IV was 82%, 70%, 28%, and 14% respectively.[113] Because of the rare nature of this disease, almost all data are based on retrospective reviews fraught with selection bias. Therefore, neither the extent of resection nor treatment with adjuvant irradiation appears to be prognostic, although this is controversial.[112-117,120-124]

Treatment and Outcomes

The treatment of choice for intramedullary astrocytomas is complete excision of the tumor, when it can be safely accomplished without neurologic compromise.[122] Otherwise, an incomplete excision is typically performed for grade I lesions, and biopsy alone is the surgical strategy for the nonexophytic component of an infiltrative glioma.[114,116,118,120-124] GTR is typically extremely difficult to achieve because of the infiltrative nature of all but the pilocytic lesions, with most authors reporting a 0% to 50% likelihood of GTR for spinal cord astrocytoma.[34,41,114,116,118,122,124,125] A series from Japan suggests that complete excision with favorable outcomes was achieved in 50% of patients with low-grade tumors, suggesting that complete excision should be attempted in this population, whereas total excision was difficult and functional outcomes were poor among patients with high-grade tumors.[116] In patients with favorable prognostic factors (low-grade histologic findings, good performance status, and young age), observation with serial imaging studies, reserving irradiation for local recurrence, is an appropriate management option, particularly for young children.[48,111-114,125-127] In the remainder of patients, adjuvant irradiation (RT) is usually recommended because progression of tumor in the spinal cord may lead to significant neurologic impairment.[29,34,111-114,117,121,126,128] Doses have traditionally been based on the experience with cerebral tumors, with lower grade tumors typically receiving 45 Gy to 54 Gy and high-grade tumors receiving higher doses.[111,114,117,121,125,126,129,130]

The overall outcomes are similar for patients with low-grade gliomas of the spinal cord treated either by GTR or STR or biopsy followed by external beam irradiation (EBRT), with most series reporting OS at 5 and 10 years in the ranges of 55% to 100% and 39% to 83%, respectively, and disease-free survival (DFS) of 38% to 93% and 26% to 80% at 5 and 10 years, respectively. Overall long-term local control rates for gliomas range from 31% to 100%, with grade being the strongest predictor.[111-114,116-119,121,126,127,131] A retrospective review from the Mayo Clinic suggests that postoperative EBRT may improve OS in infiltrative gliomas but not with pilocytic tumors, while a mulitiinstitutional retrospective review shows postoperative EBRT prolongs progression-free survival (PFS).[114,117] However, there are multiple series showing that the use of postoperative EBRT does not influence outcome.[112,113,126] A comparison of survival and local control rates is shown in Table 30-3.

With high-grade tumors in adults and children, the median survival time is quite poor (4 months to 10 months) despite surgery and EBRT. Almost all patients die of local or disseminated disease.[38,41,111-114,116,120,123-125,128] In regard to treatment, multiple retrospective series have failed to consistently improvements in outcome with the administration of radiation therapy, although the Mayo Clinic series described previously did show a survival benefit with the addition of postoperative EBRT for infiltrative tumors.[112-114,116,119,120,123-125,128] Nevertheless, radiation therapy remains the standard of care for these patients.

Data specific to adjuvant chemotherapy (after surgery or radiation therapy) for spinal cord astrocytomas are scant and composed mostly of small retrospective series.[52,54,111,112,132-139] In a retrospective series from MDACC, the use of chemotherapy at diagnosis was associated significantly with improved PFS but not OS in patients with infiltrative astrocytomas.[112] In two small trials, children with high-grade spinal astrocytoma had a 5-year PFS of 46% to 50% and a 5-year OS of 54% to 88% when chemotherapy was given either in the adjuvant setting or at the time of relapse.[54,132] Extrapolating from the results of Stupp et al for intracranial glioblastoma, temozolomide has emerged as a treatment strategy in high-grade tumors in upfront treatment as well as recurrent disease.[133,137,140,141] Overall, although there is no clear evidence of a difference in outcomes with or without chemotherapy for spinal cord tumors, chemotherapy is usually given for patients with malignant astrocytoma.[133-135,140]

Ependymoma

Ependymomas, which are glial tumors, are approximately equal in incidence to astrocytomas, although some studies suggest that they are more common.[118,122,142,143] The mean age at presentation is 30 years to 39 years. These tumors are more common in adults than in children and in males than in females.[144,145] The median duration of symptoms before presentation is 2 years to 4 years and pain is the most common presenting symptom.[144,146-148] Two thirds occur in the lumbosacral region and 40% arise from the filum terminale (Figure 30-11).[45,149] Because of the propensity of these tumors for seeding the craniospinal axis, CSF evaluation and craniospinal MRI are strongly recommended. It is also important to note that 11% of patients with intracranial ependymomas have documented spinal metastases, so imaging of the brain may be indicated to rule out a primary brain tumor (Figure 30-12).[150]

Pathology

Ependymomas arise from ependymal cells and typically occur in the central canal of the spinal cord, the filum terminale, and the white matter adjacent to a ventricular surface. They are either low-grade tumors or anaplastic tumors, the latter being more likely to disseminate via the CSF. The majority of tumors are low grade. Myxopapillary ependymomas are low-grade tumors that typically occur in the lumbosacral region (filum terminale), are well-differentiated, and are often encapsulated but can seed the CSF, typically with "drop metastases" at the thecal sac. Myxopapillary ependymomas often progress slowly and cause milder-than-expected neurologic deficits for their size. Some published series have included ependymoblastomas; however, these are primitive neuroectodermal tumors (PNETs), which have a high propensity to disseminate throughout the CNS and therefore should be considered in the medulloblastoma-PNET family of tumors.

Prognostic Factors

Multiple factors have been reviewed in the literature as being prognostic for local recurrence and survival. Factors prognostic for a favorable outcome include patient age younger than 40 years; tumors with a lumbosacral location, myxopapillary histologic findings, or a grade of WHO grade I; tumors amenable to GTR or STR; and good preoperative function of the patient.[43,116-118,122,144,149,151,152] Some authors believe that the volume of residual disease appears to correlate with a worse outcome after EBRT, whereas other authors have found no differences in outcomes when comparing complete excision with STR followed by EBRT.[44,117,149,153-155]

Myxopapillary subtypes appear to be associated with a favorable prognosis, potentially because of ease of resection

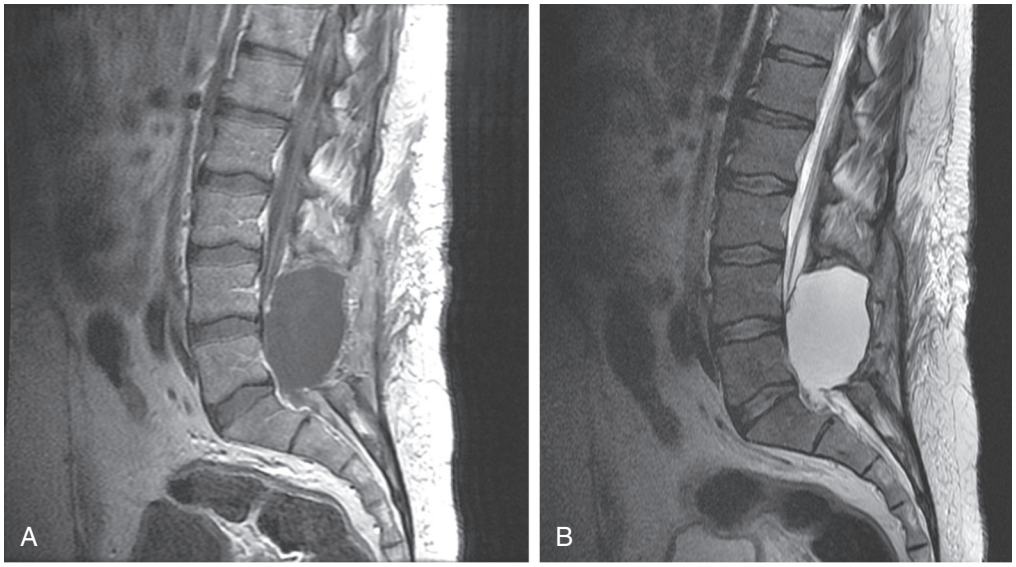

Figure 30-11 MRI of a sacral ependymoma. Shown are T1-weighted image with contrast medium **(A)** and T2-weighted sagittal image **(B)**.

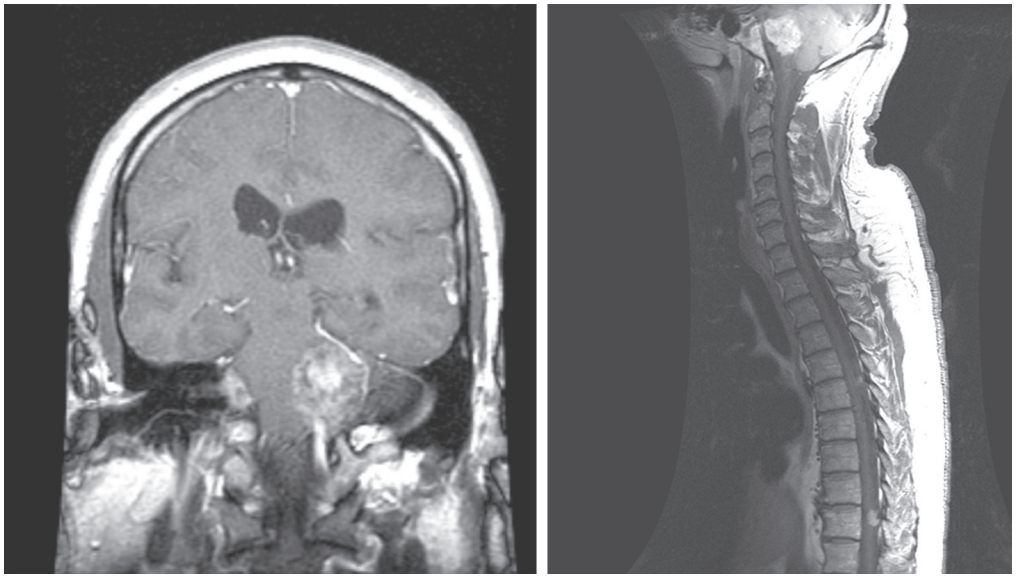

Figure 30-12 MRI of a myxopapillary ependymoma with drop metastases. Shown are T1-weighted, coronal-view image **(A)** and sagittal-view image **(B)**, both with contrast enhancement.

because of their anatomic location. Five-year OS for the myxopapillary subtype and for WHO grade I tumors are 97% to 100%, respectively, and the 5-year disease-specific survival (DSS) is 97%.[153,156] Patients who are able to achieve GTR have improved outcomes and the upfront addition of radiation therapy is of questionable benefit.[146,152,157-159] However, one study suggests that pediatric patients with this tumor had higher recurrence rates, even in the setting of GTR, and appeared to benefit from postoperative irradiation.[157] A retrospective review from the Rare Cancer Network suggests that higher postoperative radiation dose (>50.4 Gy) for the myxopapillary subtype may be associated with improved PFS.[158]

Treatment and Outcomes

Most intradural extramedullary ependymomas are myxopapillary and are often amenable to complete surgical resection if they are not multifocal.[26,148,159] The goal of surgery is GTR. Every attempt should be made to remove tumors as a whole as opposed to piecemeal removal, because of the risk of seeding, including upward seeding to the cranial nerves. The potential for cure may increase the severity of a hopefully transient deficit that surgeon and patient may be willing to incur and illustrates the importance of prospective multidisciplinary management of these tumors. Typically, complete resection is achievable in 79% to 100% of modern series.[36,37,42,43,116,118,143,148,159] Five- and 10-year OS for all spinal cord ependymomas is 67% to 100% and 68% to 100%, respectively.[43,44,116-118,122,143,148,149,153] DSS at 5 and 10 years is 69% to 96% and 62% to 93%, respectively.[33,117,122,160] Local control rates after GTR are 95% to 100%.[31,43,116,118,146,157,161] Late failures may occur more than 4 years after curative surgery, particularly with the myxopapillary subtype, warranting long-term follow-up.[159]

Postoperative EBRT appears to improve local control in patients with STR ependymomas and also for patients with high-grade lesions and those with neuraxis dissemination.[117,144,149,157-160,162,163] In most but not all series, the outcome

for STR followed by EBRT appears to be similar to that of complete resection. Typically, the dose given to the tumor bed is 49 Gy to 56 Gy, whereas the craniospinal axis (if indicated) receives 30 Gy to 36 Gy, and in selected instances, up to 45 Gy.[44,121,146,152,156,158,161,164] Low-grade lesions with a low risk of seeding are typically treated with limited fields to 50.4 Gy to 55.8 Gy in 1.8-Gy daily fractions. In patients with tumors at high risk of seeding, when pretreatment CSF cytologic studies reveal malignant cells, or if the spinal MRI scan shows evidence of leptomeningeal disease, the craniospinal axis should be treated to 36 Gy in 1.5-Gy to 1.8-Gy daily fractions. Subsequently, the primary tumor site is boosted to a total dose of 50.4 Gy to 55.8 Gy. If gross leptomeningeal spread is evident, the craniospinal axis dose should be 39.6 Gy (1.8 Gy/fraction) or 40.5 Gy (1.5 Gy/fraction), with the same boost dose to the primary tumor as previously discussed. For patients with anaplastic ependymoma, if neuraxis radiation is to be employed, some have advocated total doses as high as 45 Gy.

In patients undergoing EBRT following incomplete resection, OS at 5 years, 10 years, and 15 years is 67% to 100%, 67% to 100%, and 75%, respectively.[43,44,117,153,156,159] Cause-specific survival (CSS) at 5 years, 10 years, and 15 years for all tumors is 74% to 93%, 50% to 93%, and 35% to 46%, respectively.[117,160,165] CSS at 5 years is 87% to 97% for myxopapillary and low-grade lesions and 27% to 71% for high-grade tumors.[153,156] DFS at 5 years and 10 years is 59 and 59%, respectively.[160] Local control rates are 72% to 100%.[44,118,153,157,159,161,166]

There is no strong body of evidence thus far demonstrating that the addition of chemotherapy to EBRT improves the outcome.[53,55,167] A single trial of etoposide for recurrent spinal ependymoma has shown a median response duration of 15 months, with a median survival time of 16 months.[55] Responders had a median survival time of 20 months, whereas those who did not respond lived only 4 months; the results approached statistical significance. Pediatric patients with anaplastic ependymoma or ependymoblastoma are routinely given chemotherapy.[168-170] Further trials are ongoing evaluating the use of chemotherapy following surgery and radiotherapy in newly diagnosed ependymoma.

Meningioma

Spinal meningiomas make up only 8% of all meningiomas but account for 25% to 46% of all spinal neoplasms.[171-173] They tend to occur in females three to seven times more commonly than in males.[49,171-175] Most patients are older than the age of 40 years, with a mean age at diagnosis of 49 years to 63 years.[174,175] The incidence appears to be bimodal, the first peak being in the third decade of life, with a second larger peak seen after age 50.[174,175] In younger patients, 13% have NF2.[175] Younger patients (younger than 50 years of age) have a recurrence rate of 23% compared with 5% in older patients, though not all authors agree that young age in and of itself carries a worse prognosis.[171,175]

The most common site is the thoracic region, where 55% to 80% of meningiomas of the spine occur, whereas cervical lesions make up approximately one third of all lesions.[171,172,174-176] The incidence by location varies with age: younger than age 50 years, 39%, 56%, and 5% of lesions occur in the cervical, thoracic, or lumbar spine, respectively; in patients older than age 50 years, the distribution is 16%, 80%, and 5% in the cervical, thoracic, or lumbar spine, respectively.[175]

Treatment and Outcomes

The mainstay of treatment of spinal meningiomas is surgical resection.[142,177] Meningiomas in most patients can be removed through a posterior (laminectomy) approach because they are commonly situated in a lateral or anterolateral location, and even the more anteriorly placed tumors cause enough lateral displacement of the spinal cord to allow access for resection without traction on the spinal cord. If the tumor is located anterior to the spinal cord, it may require an anterior approach, including corpectomy with arthrodesis. Anteriorly situated meningiomas are sometimes unresectable because of their encasement of the anterior spinal cord or because they lie at the foramen magnum encasing a vertebral artery.

Functional improvement of neurologic deficits is seen in 66% to 100% of patients.[49,142,174,176,177] Complete resection is achievable in 82% to 100% of cases, with a 1% to 6% late local failure rate.[142,172,176,177] With STR, late local recurrence rates range from 17% to 100%.[49,142,172,177] Because local failures can take place even decades after surgery, the actual late failure rate may be even higher, similar to that seen in patients with intracranial meningiomas. In one large series, after complete resection, relapse-free rates at 5 years, 10 years, and 15 years were 93%, 80%, and 68%, respectively, and after STR, relapse-free rates at 5 years, 10 years, and 15 years were 63%, 45%, and 9%, respectively.[171] Because local failure rates in the spine are higher with STR, some authors recommend radiation therapy.

The role of irradiation is not well understood because of the small number of cases reported in the literature; most clinicians extrapolate from the data on irradiation of intracranial meningiomas.[171,174,176,178] The expected outcome of radiation therapy is long-term stabilization of disease.[179] Patients who undergo complete resection should be observed. When patients are irradiated, the dose delivered is typically 50.4 Gy to 54 Gy, based on the data from the treatment of intracranial meningioma.[179]

The use of SRS in the treatment of spinal meningioma has been reported.[81,89,91,180] After a mean follow up of 33 months, 91% of meningiomas had shown a treatment response with only one patient developing a transient myelopathy 9 months after treatment. The mean prescription dose was 19.4 Gy (range 14 Gy to 30 Gy) delivered in one to five sessions (median, two).[91]

Chemotherapy has a limited role in this disease. It is sometimes considered for patients who cannot receive further surgery or radiation therapy or for those with diffuse multifocal disease. Hydroxyurea and somatostatin have been used.[181,182]

Chordoma

Chordomas are slow-growing neoplasms thought to arise from remnants of the embryonic notochord that are present in the vertebral bodies and axial skeleton. Expression of the transcription factor *brachyury*, a gene important in notochord development, is characteristic of these tumors and helpful in diagnosis. Chordomas make up approximately 4% of spinal tumors and primarily involve the skull base and sacrococcygeal regions.[68,183,184] A SEER-based analysis suggests, however, that chordomas may be more equally distributed between cranial sites (mostly skull base), the mobile spine, and the sacrum and coccyx.[185] Most chordomas occur during the fourth decade of life, with a male to female ratio of 2 to 1, though sacrococcygeal chordomas tend to arise in the fifth and sixth decades.[186-191]

Prognostic Factors

Several prognostic factors have been identified. Location is prognostic for survival, with a 5-year OS of 66% for sacrococcygeal tumors and 50% for vertebral lesions.[69] Overall, 14% to 39% of patients develop metastases at a median of 5 years, most commonly to the lungs.[98,183,184,186,192,193] The incidence of metastases varies by location of the primary tumor: 26% to 44% of patients with sacrococcygeal lesions develop metastatic disease (usually to the thecal sac), whereas 61% of those

with vertebral primaries can metastasize, typically in a caudal direction. In some series, skull-base lesions have rarely been reported to metastasize.[186,189] Gender may also be prognostic: 5-year and 8-year local control rates are 81% and 75% for men and 65% and 17% for women, respectively.[194,195] The prognostic importance of age is controversial; in some series, children have a higher incidence of metastases, but in other series, patients older than the age of 52 years have a worse local control rate.[68,196,197] Finally, residual microscopic disease after resection (either tumor spillage or positive margins) increases the risk of local relapse to 60% to 64% from 25% to 28% after GTR.[191,198] Primary tumor size less than 8 cm has also been suggested as a good prognostic factor.[197]

Treatment and Outcomes

Although en bloc GTR has traditionally been advocated for these lesions, it is rarely possible. As such, most patients undergo STR or biopsy followed by EBRT. However, surgery is an important component of treatment despite potential morbidity; a recent large database review showed that patients who had undergone more radical resection had significantly prolonged survival times.[197] In most series, patients have been treated with conventional photon radiotherapy, typically to doses of 55 Gy to 70 Gy in 2-Gy fractions, with 5-year OS of 38% to 58%.[184,186,187,189,199-201] Although EBRT prolongs the disease-free interval, most tumors recur unless they have been completely resected; local progression is the most common cause of death.[187] In one older series, the local control rate of sacrococcygeal tumors was 0% with either surgery or EBRT as monotherapy but was 40% when the two were combined.[184]

Some treatment series using conventional photon irradiation suggest that local control rates improve with increasing radiation dose. With doses of less than 40 Gy, more than 48 Gy, more than 50 Gy, and more than 55 Gy, 5-year DFS is approximately 0%, 13%, 31%, and 41%, respectively.[186,200] However, not all authors have found that increased dose improves outcome.[202]

Most experts now advocate charged particle therapy, typically with protons, as the modality of choice, alone or in combination with photons.[68-75,203,204] When patients are treated either immediately after maximum resection or at the time of recurrence, with median doses of 65 Gy to 76 Gy equivalent using charged particle radiation therapy, local control rates at 3 years, 5 years, and 10 years are 67% to 71%, 40% to 75%, and 54%, respectively, with OS at 3 years, 5 years, and 10 years of 88% to 97%, 75% to 80%, and 54%, respectively.[68,71,72,107,205] There is some suggestion that radiation is more effective in controlling chordomas after initial resection rather than at recurrence.[70,206]

SRS/SBRT has also been used in the treatment of residual and recurrent cervical spine chordoma. A mean dose of 19 Gy in a single fraction prescribed at the tumor margin resulted in a 4-year local control rate of 80% without neurologic sequelae in one series.[207]

The experience with interstitial irradiation is minimal. This modality has fallen out of favor with the advent of charged particle therapy and SRS.[208-210]

Chondrosarcoma

Primary chondrosarcoma of the spine is a rare, slowly growing tumor thought to originate from primitive mesenchymal cells or from the embryonal rests of the cranial cartilaginous matrix. Spinal chondrosarcomas are slightly more common in men than in women and the median age of presentation is 51.[211-213] Of the axial skeleton chondrosarcomas, 33% occur in the mobile spine, most often in the thoracic region, whereas another 33% arise in the sacrum.[212-214]

Patients with spinal chondrosarcomas typically have a long-term OS of 25% to 54%.[211-213,215] Adverse prognostic factors include positive surgical margins, high tumor grade, and older patient age.[214,215] Twelve percent to 19% of lesions are grade 4 tumors, which carry a poor prognosis (3-year OS of only 14%; median survival time of 2.7 years; 75% to 86% incidence of metastases).[214,215]

Treatment and Outcomes

Surgical resection is the mainstay of treatment of these lesions with en bloc resection consistently showing significantly better local control and survival rates.[216] OS after any degree of resection is 55% to 72%, 67%, and 63% at 5 years, 10 years, and 15 years, respectively.[213,214] The median survival time is typically 6 years, with local control rates ranging from 36% to 72%.[212,214,215] Patients with GTR have a better outcome than those with STR. After complete resection, the local control rate is 97%, with a 90% 10-year OS and an 84% DFS.[214] Many chondrosarcomas have indolent courses, but others behave more aggressively. Radiation therapy after incomplete resection has been shown to lengthen the disease-free interval from 16 months to 44 months in one series.[212] The use of adjuvant radiation with doses exceeding 60 Gy to 65 Gy is associated with a high rate of local control, although the quality of the supporting evidence is low.[216] Chemotherapy has not been shown to improve outcomes.[212]

Miscellaneous Primary Spinal Tumors

Chloroma

Spinal canal chloroma (also known as granulocytic sarcoma) is defined as an extramedullary localized tumor mass of blasts of granulocytic lineage. This tumor can arise during the course of acute myeloid leukemia (AML) or myelodysplastic syndrome (MDS), either at the same time as the initial tumor or at relapse, but also as an isolated tumor without any signs of medullary involvement. Spinal chloromas occasionally precede the development of systemic disease by weeks to years.

Spinal complications of chloromas, such as cord compression secondary to epidural tumor or cauda equina syndrome, have been described but are uncommon. The median age at presentation is 22 years, with a 7.8:1 male-to-female ratio. The thoracic spine is most commonly involved (73%), followed by the lumbar region (34%), sacral region (23%), and cervical region (5%). Multiple noncontiguous areas of involvement are found in 18% of patients.

The most effective treatment appears to be multimodality therapy coupled with early diagnosis. Options include surgical decompression, intravenous or intrathecal chemotherapy, radiation therapy at doses of 20 Gy to 30 Gy, or any combination of these treatments. Patient survival times range from 18 days to 9.5 years after diagnosis. In a review of the literature, no clear relationship could be found between the specific treatment modality used and the length of survival. Those receiving systemic therapy soon after diagnosis experienced the longest disease-free episodes, however.[217]

Epidermoid Tumor

Epidermoid tumors are benign congenital lesions derived from ectodermal tissue thought to arise because of errors in neural tube closure. These tumors account for approximately 1% of all intracranial tumors but are even rarer in the spine.

Given their benign nature and indolent drown pattern, complete surgical excision is usually curative though many asymptomatic tumors may be observed. Incompletely excised tumors may recur, but because of their slow growth, this may take several years. Radiation does not have a role in the management of these benign lesions but has been used as adjuvant

Epidermoid tumors have male preponderance and are most commonly found in the lumbosacral region. They can be differentiated from arachnoid cysts using diffusion-weighted or FLAIR images given the high degree of restricted diffusion in epidermoids.

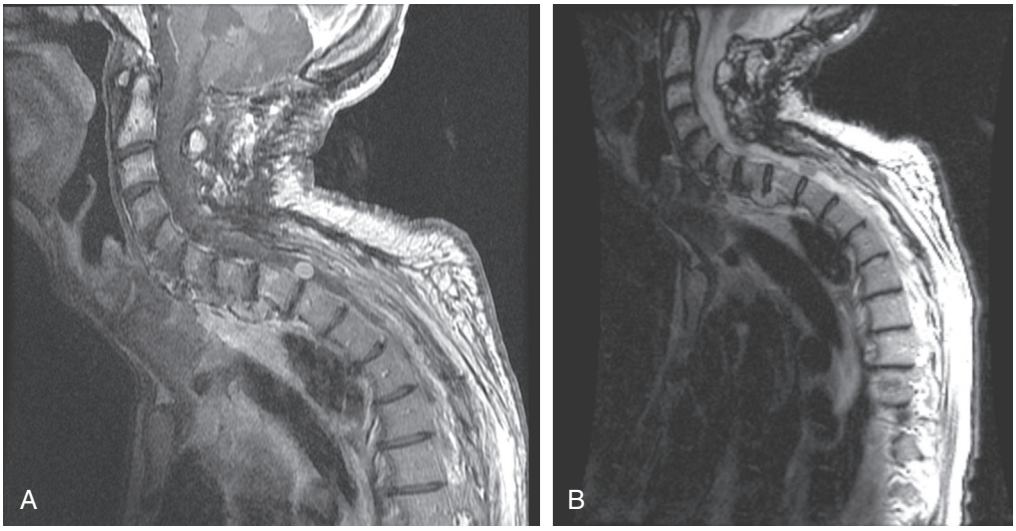

Figure 30-13 MRI of a spinal hemangioblastoma with an associated syrinx in the setting of von Hippel-Lindau syndrome. Shown are a T1-weighted image with contrast enhancement **(A)** and a T2-weighted sagittal-view image **(B)**.

therapy for intracranial epidermoids that have exhibited malignant transformation.[218]

Hemangioblastoma

Intramedullary hemangioblastomas are slowly growing vascular tumors composed of endothelial and stromal components and account for 3% to 13% of intramedullary spinal tumors.

Multiple CNS hemangioblastomas are diagnostic of VHL. Multiply recurrent hemangioblastoma may also raise the suspicion of VHL. Patients with isolated spinal hemangioblastoma should be screened for other manifestations of VHL by ophthalmologic evaluation, brain MRI, and abdominal CT scanning to rule out retinal and cranial hemangioblastoma and renal tumors, respectively. In patients with VHL, 51% of neuraxis lesions are located in the spinal cord and only 29% are completely intramedullary, with the remainder having an extramedullary component (Figure 30-13).[220]

Factors prognostic for favorable outcome (defined as improvement or stabilization of neurologic function) are minimal or no preoperative neurologic deficits, lesions smaller than 0.5 cm^2, dorsally located lesions, and total surgical removal of the lesion.[220,221] Progressive syringomyelia is a negative prognostic factor with respect to preservation of neurologic function and is often recalcitrant to treatment attempts.

Surgical resection is the mainstay of treatment for symptomatic lesions. Hemangioblastomas are extremely vascular tumors occurring in the spinal intramedullary compartment. The dorsal location of most of these lesions and the commonly associated cyst help to simplify the removal somewhat because the cyst provides a safe route for approaching the tumor. Removal of the enhancing tumor is satisfactory to prevent reaccumulation of the cyst, and the remainder of the cyst wall may, therefore, be left intact. Tumor margins are addressed first and feeding arteries are coagulated. Then the tumor is dissected and removed en bloc. After surgical resection, 41% to 68% of patients experience improvement of neurologic function and another 32% to 84% have stabilization of their preoperative function.[219,220,222]

Although SRS is an option for cerebellar hemangioblastoma, it has not been properly evaluated for spinal hemangioblastoma because of concerns regarding the radiation tolerance of the spinal cord.[131] A few small series suggest safety and efficacy.[80,110,223]

Lipoma

Primary spinal lipomas are benign, congenital, intradural-extramedullary lesions located in the cervicothoracic region. These tumors account for approximately 1% of spinal cord tumors. The classic presentation is that of a slow ascending spastic monoparesis or paraparesis with rapid late deterioration.

Early surgical decompression is mandatory for preservation of existing neurologic function, but complete surgical debulking is almost impossible due to the infiltrative nature of the tumors.[224-226] There is no known role for radiation therapy or chemotherapy.

Lymphoma

Primary spinal cord lymphomas are uncommon lesions. Only 4% of lymphomas are primary epidural tumors of which 90% are of B-cell origin (Figure 30-14).[227-229] Typically, lymphomas involving the spinal cord are seen in the context of primary CNS non-Hodgkin's lymphoma, with 27% having positive CSF findings and 16% eventually developing leptomeningeal disease involving the spine.[228]

If the initial presentation is one of spinal cord compression, management is similar to that of other metastatic tumors described, although rapid responses may be seen with steroids, chemotherapy, and irradiation to a median dose of 38 Gy.[227] Lengthy administration of preoperative steroids may result in disappearance of the tumor by the time of surgery (ghost-tumor effect). Otherwise, management is similar to that of cerebral non-Hodgkin's lymphoma. After decompressive laminectomy, STR, and spinal irradiation, the local control rate is 60%, with a median duration of survival of 42 months.[227]

Neurocytoma

Central neurocytoma has been reported to arise in the spine.[230,231] Staining for synaptophysin and neurospecific enolase allows these tumors to be reliably distinguished. As in the brain, their behavior is variable. Because this tumor arises centrally in the spinal cord, observation or irradiation may be the primary management strategy, with resection reserved for tumors with progressive neurologic deficits.

Sarcoma

Primary soft-tissue sarcomas of the spinal cord are exceedingly rare, accounting for 0.7% of CNS malignant tumors of

The male-to-female ratio is 1.8 to 1.[219] The median age at presentation is 36 years for sporadic lesions, whereas patients with VHL typically present a decade earlier and have multiple tumors.

Figure 30-14 MRI of a lymphoma involving the bone and spinal cord. Shown is a sagittal-view, T1-weighted image with contrast enhancement.

which 5.6% of these are found in the spinal canal.[232] Malignant fibrous histiocytoma represents the most common histologic diagnosis and may display a more aggressive biology that frequently recurs locally and distantly.[233] Tumors arise from the nerve roots of the cauda equina, the spinal cord, or the spinal blood vessels.[232,234] Surgical debulking and postoperative EBRT to approximately 60 Gy in 1.8-Gy to 2-Gy fractions represents the typical treatment approach described in the literature.[232,234] The 5-year OS of patients with high-grade lesions is significantly worse at 28% than the 83% reported with low-grade lesions. The role of chemotherapy is not known. Other sarcomas that may arise in the spine include Ewing sarcoma, rhabdomyosarcoma, and osteosarcoma.

Schwannoma

Spinal schwannoma may present simultaneously in both the spinal canal and the thoracic cavity. These dumbbell-shaped tumors are typically benign and may involve the spinal cord and spinal nerves via the neural foramina. Surgical resection is the treatment of choice.[50,235,236] Schwannomas arise from spinal rootlets (most often, the dorsal rootlets) and may grow along the nerve root in a dumbbell fashion through a neural foramen. Therefore, resection requires removal of sections of the involved rootlets. Only 3% of these tumors are malignant; adjuvant EBRT has been used in such cases with mixed outcomes.[235,236] Although surgery is the mainstay of treatment for spinal schwannomas, SRS and hypofractionated SBRT have also been used.[81,91,237]

Teratoma

True intramedullary teratoma is an extremely rare tumor, with only nine cases reported in the literature.[238] Early surgical resection is recommended to preserve neurologic status. Because teratomas may adhere to the functional neural tissue of the spinal cord in such a way that no dissection plane is available, complete resection is often not possible. A low-grade histopathologic status predominates, so the symptomatic recurrence of incompletely resected mature teratomas is often slow and may eventually require a second surgical procedure.[239] Radiation therapy is generally reserved for multiply recurrent, subtotally resected disease.

Vertebral Hemangioma

Vertebral hemangiomas are benign growths of endothelial origin typically located in the thoracic and upper lumbar spine. They are the most common benign spinal column tumors, with an incidence of approximately 11%. Because vertebral body hemangiomas are most frequently stable over long periods of time, some authors consider them to be nonneoplastic. Growth causing progressive symptoms has been documented. Only 1% to 2% of patients develop clinically significant pain. New onset of back pain followed by subacute progression of a thoracic myelopathy, typically over a period of 4 months to 5 months, is the most common presentation for patients with neurologic deficit.[240] These tumors also occasionally cause root and cord compression syndromes. A preoperative diagnosis of compressive vertebral hemangioma can often be made on imaging studies.[241]

Treatment is initiated only when progressive symptoms, including focal pain or progressive neurologic deficit, develop. Historically, standard treatment consisted of surgical removal of the lesion. Endovascular embolization of these vascular growths with or without surgical decompression may also provide pain control.[242] Vertebroplasty has high reported rates of success. More extensive resections are used for aggressive lesions.[243] The local control rate at 3 years is 70%. Of lesions that regrow, 90% recur within the first 2 years.[244]

Irradiation is an effective treatment alternative. A meta-analysis demonstrated that a total dose of 30 Gy given in 2-Gy fractions resulted in a 57% complete amelioration of pain in 57% of patients and 32% experienced partial improvement of pain.[245] A second, smaller analysis showed an apparent dose-response effect. Patients treated with the biologic equivalent of 36 Gy to 44 Gy in 2-Gy fractions had significantly better complete pain relief than those treated with 20 Gy to 34 Gy (82 versus 39%, respectively).[246]

Treatment-Related Complications

Radiation myelopathy may present as a transient early delayed or late delayed reaction. Transient radiation myelopathy is clinically manifested by momentary, electrical shock-like paresthesias or numbness radiating from the neck to the extremities, precipitated by neck flexion (Lhermitte's sign).[247] The syndrome typically develops 3 months to 4 months after treatment and spontaneously resolves over the following 3 months to 6 months without therapy. It is attributed to transient demyelination caused by radiation-induced inhibition of myelin-producing oligodendroglial cells in the irradiated spinal cord segment.[247-249]

Irreversible radiation myelopathy usually is not seen earlier than 6 months to 12 months after completion of treatment. Typically, half of the patients who develop radiation-induced myelopathy in the cervical or thoracic cord region will do so within 20 months of treatment and 75% of cases will occur within 30 months.[250] The signs and symptoms are typically progressive over several months, but acute onset of plegia over several hours or a few days is possible. It is thought to be multifactorial in origin, involving demyelination and white matter necrosis ultimately resulting from oligodendroglial cell depletion and microvascular injury. The diagnosis of radiation myelopathy is one of exclusion with the following characteristics: (1) a history of radiation therapy in doses sufficient to result in injury must be present; (2) the region of the irradiated cord must lie slightly above the dermatome level of expression of the lesion; (3) the latent period from the completion of

treatment to the onset of injury must be consistent with that observed in radiation myelopathy; and (4) local tumor progression must be ruled out.

There are no pathognomonic laboratory tests or imaging studies that conclusively diagnose radiation myelopathy. MRI findings include swelling of the spinal cord with hyperintensity on the T2-weighted images with or without areas of contrast enhancement.[248-251] There is no known consistently effective treatment for radiation myelitis.[252,253] The probability of dying from radiation myelopathy is approximately 70% with cervical lesions and 30% with thoracic spinal cord injury.[254]

Radiation side effects in children include growth abnormalities such as decreased vertebral height, kyphosis, and scoliosis.[255] Secondary malignant disease, including bone or soft-tissue sarcomas and glioblastoma, has been reported after irradiation of spinal cord tumors.[256-258]

TREATMENT ALGORITHM, CHALLENGES, AND FUTURE POSSIBILITIES

Treatment Algorithm

Primary tumors of the spinal cord are uncommon. Much of the literature groups these tumors together by location (intramedullary vs. extramedullary) when reporting outcomes. However, spinal cord tumors clearly behave differently depending on the histologic type, and this needs to be taken into account when making management decisions. The primary treatment for most spinal cord tumors continues to be surgical resection, with irradiation recommended for patients in whom a complete resection cannot be achieved, for those at high risk of recurrence, and for those with tumors involved in areas where resection would cause unacceptable functional morbidity. The role of chemotherapy in the management of spinal cord tumors remains unclear. A general simplified treatment algorithm is shown in Figure 30-15.

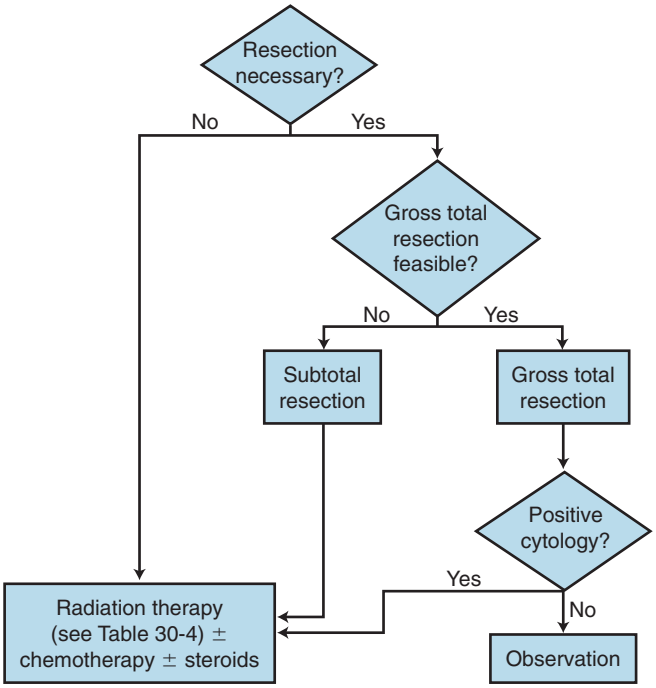

Figure 30-15 Treatment algorithm for the general management of primary spinal tumors. Details about the histologic diagnosis and radiation therapy are provided in the text and Table 30-4.

Challenges and Future Possibilities

Future directions in the management of spinal cord tumors include continued evolution in how these diseases are diagnosed and treated. Advances in imaging may ultimately assist in noninvasively obtaining an accurate tissue diagnosis of a suspicious spinal cord lesion and accurately measuring treatment response. To this extent, novel MRI contrast agents could serve as biochemical reporters of various cellular functions.[259] These newer contrast agents could be tailored to report on the physiologic status or metabolic activity of biologic systems. For example, enzyme-activated agents may correlate developmental biologic events with gene expression. Calcium-activated agents can measure intracellular signal transduction, whereas pH-activated agents provide a blood oxygen level-dependent (BOLD) signal that might be used for noninvasive mapping of human nervous system function. Furthermore, T2-activated agents can detect specific oligonucleotide sequences. Graded functional diffusion map imaging and apparent diffusion coefficient characteristics have shown promise as a potential imaging biomarker in glioblastoma.[260] Relative cerebral blood volume imaging may also be useful in diagnosing tumors and assessing response.[261-263] These areas of interest are currently under investigation in the setting of primary brain tumor treatment, and it remains to be seen how the results will be applied to spinal cord therapy.

Intraoperative fluorescence-guided resection with 5-aminolevulinic acid–induced porphyrins has been suggested to improve outcomes in patients with brain tumors. This method potentially enhances diagnostic accuracy and extent of tumor resection as compared to neuro navigation-guided approaches.[264] This technique has been found to be feasible in the spine and additional studies are needed to better define its role in the management of CNS tumors.[27]

Continued advances in radiation therapy will allow for improved treatment accuracy and precision. The validation and incorporation of functional imaging may improve our ability to define our targets.[265] Fractionated EBRT techniques with photons such as IMRT, VMAT, and helical tomotherapy provide much improved conformality over 3D approaches, which enables increased dose to targeted tissues while minimizing dose to organs at risk. Because most spinal cord tumors typically recur locally, IMRT should allow the exploration of anatomic/biologic treatment planning and delivery to optimize different doses to different cell populations within heterogeneous volumes. To better understand and predict toxicity, better refinements in dose and volume tolerance are necessary, with improvements presented in the recent QUANTEC study.[108,109]

Additional useful radiation therapy techniques include charged particle therapy and hypofractionated regimens/SBRT. Although the role of charged particle therapy with protons has been defined for chordoma and chondrosarcoma, the use of protons is being explored in other histologies of spinal cord tumors.[164] As our experience with patients treated hypofractionated regimens and SBRT grows, long-term data are needed to best assess efficacy and safety.[265]

As we maximize our capacity to conform high doses of radiation therapy to our target, we must also rely on image-guidance to ensure optimal delivery. CT-based image-guided radiation therapy has permitted improved treatment precision. Moreover, further advances are under way with the development of MR-guided linear accelerators. This technology may deliver even better daily targeting for spinal tumors, given the high soft tissue contrast afforded by MRI.

CHAPTER

31 Orbital, Ocular, and Optic Nerve Tumors

John T. Lucas, Jr., Craig M. Greven, and Kathryn McConnell Greven

INCIDENCE
There are 2800 estimated cases of primary ocular tumors annually. The most frequent intraocular primary tumor is ocular melanoma; the second most frequent primary tumor is retinoblastoma seen primarily in children.

BIOLOGIC CHARACTERISTICS
Clinical behavior varies with specific histological and genetic subtype.

STAGING EVALUATION
For melanoma, Collaborative Ocular Melanoma Study (COMS) size criteria are used, and for orbital lymphoma, Ann Arbor staging criteria are used. Ocular rhabdomyosarcomas are discussed in Chapter 68 and retinoblastomas in Chapter 71.

PRIMARY THERAPY
Primary therapy differs by lesion site and histology. For melanoma, iodine-125 (^{125}I) plaque irradiation is used for small and intermediate-size lesions, and enucleation is used for large lesions or eyes with poor vision. Proton beam therapy is also effective for ocular melanoma. For lymphoma, orbital irradiation is used for low-grade lesions and chemotherapy with or without irradiation is used for high-grade lesions. For optic nerve sheath meningioma, orbital irradiation allows for vision preservation and reduction of cranial nerve deficits. For optic pathway gliomas, chemotherapy can be used to delay radiotherapy in children, whereas radiotherapy offers high rates of progression-free survival.

ADJUVANT THERAPY
Adjuvant therapy and outcomes vary with tumor type and extension.

LOCALLY ADVANCED DISEASE
Treatment approach and outcomes vary with specific tumor type.

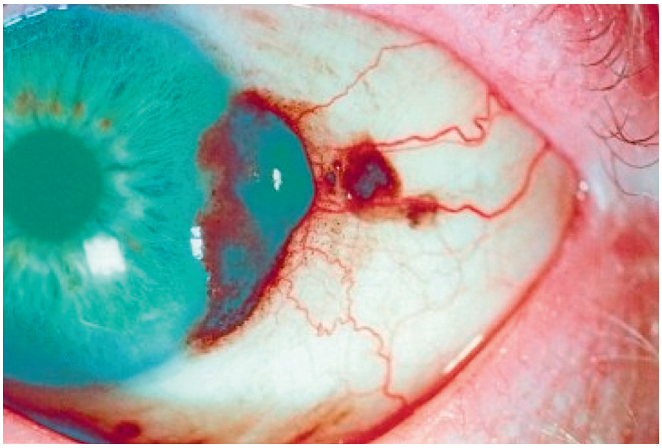
PALLIATION
Irradiation is effective treatment for advanced primary or metastatic disease and offers symptomatic relief and vision preservation in patients with choroidal metastases. Chemotherapy or hormonal treatment is used for some metastatic tumors.

Based on the incidence rates from the Surveillance, Epidemiology, and End Results Program of the National Cancer Institute, the American Cancer Society estimated that approximately 2800 new cases of all types of primary ocular and orbital malignant tumors were diagnosed in the United States in 2013.[1] Uveal melanoma is the single-most common malignant tumor of the eye and orbit and makes up nearly 70% of all cancers of these tissues.[1] Irradiation is used in the management of many ocular and orbital cancers, as well as in the management of several benign ocular processes. Understanding the pathophysiologic processes of ocular cancers and the results of radiation treatment can guide treatment recommendations.

Complicating the assessment of ocular cancer treatment is the real possibility that therapy itself may result in loss of vision or loss of the treated eye. A thorough understanding of radiation tolerances and treatment sequelae is vital for maximizing overall and vision-related quality of life following treatment.

ETIOLOGY AND EPIDEMIOLOGY

Eyelid Skin Cancers



Basal cell cancers make up 90% of eyelid skin cancers; the other 10% is composed of squamous cell cancers. Basal and squamous cell carcinomas of the periorbital skin (nasal bridge, medial canthus, and eyelid) most frequently occur on the lower eyelid and medial canthus. Patients with sun exposure and those who are immunosuppressed have an increased incidence of these cancers.[2,3]

Uveal Melanoma

Uveal melanoma is the most common primary malignant intraocular neoplasm.[1] It is thought to arise from melanocytes of the uveal tract. The incidence in the United States has remained relatively unchanged and is estimated to be 5.1 per million patients per year.[1,4] Uveal melanomas are more common in lightly pigmented persons and are infrequent in nonwhite races[4]; the average age at diagnosis is 62 years.[4-6] Although the disease occurs with equal frequency among men and women, there is significant variation in age-adjusted incidence between sexes (male = 5.58, 95% CI, 5.5-6.2; female = 4.4, 95% CI, 4.2-4.7 per million).[4,7] The tumors are *rarely* bilateral.[4] Factors proposed as increasing the risk for the development of uveal melanoma are prolonged sustained sunlight exposure[7] and lighter-colored irises.[8] Certain diseases may predispose to melanoma, including xeroderma pigmentosum,[9] which is an inherited disorder of DNA repair; oculodermal melanocytosis,[10] in which the ocular surface and the uveal tract are hyperpigmented; and dysplastic nevus syndrome.[11] There are some reports implying a possible rare genetic predisposition, although most melanomas occur as sporadic tumors.

Conjunctival Melanoma

Conjunctival melanomas are rare (5% of ocular melanomas), although the incidence is believed to be increasing.[12] Lesions most commonly arise from primary acquired melanosis (60%) or conjunctival nevus (eFigure 31-1). The lack of atypia on biopsy of the nevus connotes a low likelihood of transformation

eFigure 31-1 Primary conjunctival melanoma. Conjunctival melanoma including a small, additional lesion peripheral to the main juxtalimbal tumor.
Courtesy Seregard S: Conjunctival melanoma. Surv Ophthalmol 42(4):321–350, 1998. Review.[16]

to melanoma.[13] Similar to uveal melanoma, conjunctival melanoma has no particular gender predilection and occurs almost exclusively in Caucasians. Its incidence increases with age and seems to plateau at ages older than 60 years.[14-16]

Retinal Tumors

Retinoblastomas are discussed in Chapter 71.

Optic Nerve Tumors

Meningioma

Optic nerve sheath meningiomas arise from the meningothelial cap cells of arachnoid villi and can develop anywhere along the optic nerve, from the globe to the prechiasmal intracisternal optic nerve. They may be unilateral, bilateral, or multifocal. Patients with type 2 neurofibromatosis are predisposed to bilateral or multifocal lesions.[17] Meningiomas from other locations can also extend to involve the optic nerve. Optic nerve sheath meningiomas are more common in women (61% versus 39%) and present commonly at age 40.[18] Bilateral cases appear to have an earlier age of onset.

Glioma

Optic pathway gliomas account for 1% to 5% of intracranial gliomas and 4% of orbital tumors. They occur most frequently in children, with 75% in the first decade and 90% in the first two decades of life.[19] In pediatric patients with optic pathway glioma, 10% to 38% have type 1 neurofibromatosis, and 15% to 40% of children with neurofibromatosis 1 have an optic glioma.[20] When bilateral, the lesions are pathognomonic for neurofibromatosis 1.

These tumors are increasingly being seen as markers of enhanced risk in patients and their families for the subsequent development of central nervous system (CNS) tumors. Up to 30% to 40% of such patients have a second primary CNS tumor.[21,22]

Orbital Tumors

In a recent report of 1264 consecutive patients with orbital masses, 33% of patients had malignant lesions. Rhabdomyosarcoma was the most common malignant tumor in children, representing 3% of all orbital masses, and lymphoma was the most common malignant tumor in older patients, representing 10% of cases.[23] In one large series, metastatic breast cancer comprised 4% of these lesions.

Rhabdomyosarcoma

Rhabdomyosarcomas are discussed in Chapter 68.

Lacrimal Gland Tumors

Lacrimal gland tumors are rare. The gender distributions are equal and patient age ranges from 10 years to 73 years (mean of 46 years). Most of these lesions are malignant and are typically either adenoid cystic carcinoma or mucoepidermoid carcinoma histology.[23,24] Benign pleomorphic adenomas represent the majority of benign lacrimal masses, although the overall incidence is exceedingly low.

Orbital Lymphoma

Primary orbital lymphomas are rare and account for less than 1% of all lymphomas. The incidence of these tumors has tripled in the United States over the last two decades, as a result of the increase in the primary intraocular lymphoma associated with primary CNS lymphoma. Lymphomas in the orbit can occur anteriorly in the conjunctival tissues or in the retrobulbar region. Patients who are immunocompetent tend to present in the late 50s to 60s, whereas patients who are immunodeficient present at an earlier age, similar to primary CNS lymphoma. Primary orbital lymphoma is slightly more common in men than in women.

Primary adnexal lymphoma (conjunctival, lacrimal gland, orbit, and eyelids) is a distinct clinical and biological disease entity relative to the primary uveal (intraocular)/primary CNS manifestation and has a different natural history. Adnexal lymphomas are most commonly the low-grade subtype of non-Hodgkin's lymphoma (NHL) known as mucosa-associated lymphoid tissue (MALT)-type lymphoma. The median age at diagnosis is about 65 years[25] and unlike all other subtypes of NHL, the male-to-female ratio favors females.[26] Unlike its CNS counterpart, primary adnexal lymphoma is not associated with HIV infection[27] but does have a strong etiological association with *Chlamydia psittaci* infection, similar to the association of *Helicobacter pylori* with primary gastric MALT lymphoma.

Primary intraocular lymphoma may present with malignant lymphoid cells involving the retina, vitreous, or optic nerve head with or without concomitant CNS involvement; it represents a variant of primary CNS lymphoma. The age distribution is bimodal and exhibits two peaks at approximately 31 years and 60 years. The rise in incidence in this subtype is thought to be linked to the greater numbers of patients who are pharmacologically and virally immunosuppressed.[28]

Metastatic Tumors

The most common primary tumor to metastasize to the orbit is breast cancer followed in incidence by lung cancer.[29] Other orbital metastases have been reported to occur from neuroblastoma, renal cell cancer, and prostate cancer. Similarly, choroidal metastases are most frequently of breast cancer origin, followed by lung cancer.[30] In one report of 420 patients, uveal metastasis arose from a primary cancer of the breast in 196 patients (47%), the lung in 90 patients (21%), the gastrointestinal tract in 18 patients (4%), the kidney in 9 patients (2%), the skin in 9 patients (2%), the prostate in 9 patients (2%), and other cancers in 16 patients (4%).

Benign Ocular Conditions

Pterygium

A pterygium is a benign growth of fibrovascular tissue on the cornea. These lesions may become red and inflamed, ultimately encroaching on the visual axis. In addition to functional impairment, these may be viewed as cosmetic nuisances for patients.

Most pterygia are located nasally and occur in patients aged 20 years to 50 years; men and women are equally affected.[31] They are more commonly encountered in warm, dry climates or in patients who are chronically exposed to outdoor elements or smoky and dusty environments. Ultraviolet light exposure appears to be the most significant factor in the development of pterygia,[32] whereas hereditary contributions are considered rare.

Orbital Inflammatory Syndrome or Pseudotumor

Orbital pseudotumor, or idiopathic orbital inflammatory syndrome, is a nonspecific inflammatory process of unknown etiology that may mimic orbital lymphoma and comprises some 10% of all orbital mass lesions.[23] The diagnosis of pseudotumor is vague and remains one of exclusion.[33] Because the disease mimics infectious or neoplastic processes, these must be ruled out. Autoimmune disease, endocrinopathies, and granulomatous processes also must be excluded, as well as local infection with secondary involvement of the orbit, such as sinusitis and subperiosteal abscess.

Secondary lymphomatous involvement of the orbit is also not infrequent and patients with lymphoma at other sites can also present with eye involvement at any point in the course of their disease.

The term *pseudolymphoma* has been advocated to describe a diagnosis of reactive lymphoid hyperplasia. In general, lymphoid hyperplasia arises in the anterior ocular structures, and pseudotumor arises more posteriorly in the bony orbit. However, the literature includes reports of patients with biopsied and unbiopsied lesions, as well as reactive lymphoid hyperplasia and the more nonspecific inflammatory lesions. For this reason, the term *pseudotumor* refers to any idiopathic inflammatory lesion of the orbit.

Although the precise etiology is unknown, several theories have been proposed.[34] The response to steroids and immunosuppressive drugs suggests an autoimmune disorder.[35] Similarly, a fibroproliferative disorder and aberrant wound healing provoked by infection or autoimmune disease have also been postulated as causes of reactive lymphoid hyperplasia.

Graves's Ophthalmopathy

The pathogenesis of Graves's ophthalmopathy is thought to be autoimmune, triggered by an autoantigen which, once encountered, triggers T lymphocytes to invade the orbit and stimulate glycosaminoglycan production in fibroblasts, which undergo a phenotypic change as a result of surrounding cytokine influences, resulting in tissue edema, lymphocyte infiltration, and marked enlargement of the extraocular muscles.[36] The ophthalmopathy typically goes through three phases: progression, followed by stabilization, and perhaps some improvement. Because lymphocytes and fibroblasts are sensitive to radiation, retrobulbar irradiation has been advocated as a treatment. Residual signs of ophthalmopathy after the disease has reached a plateau are thought likely to be the result of fibrosis and other tissue changes rather than persistent inflammation.

Macular Degeneration

Age-related macular degeneration (AMD) is the leading cause of blindness in patients older than 65 years.[37] The progressive loss of central vision is usually consequential to an atrophic process involving the retinal epithelium and choriocapillaris in the macula, which is classified as dry AMD.[38] The wet form of AMD is an exudative process with subretinal neovascularization. Wet AMD generally progresses to destructive disciform scarring of the macula, with fibrovascular scars involving the choroid and sensory retina. Poor visual acuity is the result.

PREVENTION AND EARLY DETECTION

Because of the rarity of all ocular tumors, no prevention or early detection methods have been developed for most tumor types. However, in children born into a family with known retinoblastoma, early and careful ophthalmologic evaluation is warranted. Genetic counseling and evaluation of the siblings of patients with retinoblastoma is important, given the high hereditary likelihood.[39] After the diagnosis of unilateral retinoblastoma, routine evaluation of the uninvolved eye is indicated because of the increased risk of contralateral disease (see Chapter 71). Similarly, physicians caring for patients with neurofibromatosis 1 and optic pathway gliomas should be wary of additional intracranial lesions because a second primary CNS tumor will develop in approximately 30% to 40% of those patients.[22] Early detection may provide the best opportunity for interventions that optimize patients' quality of life.

MOLECULAR BIOLOGY AND BIOLOGIC CHARACTERISTICS

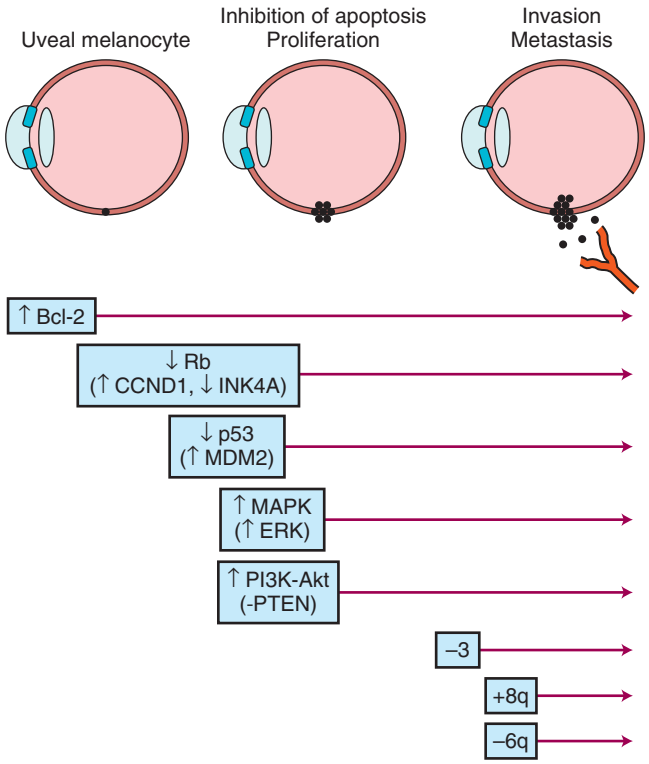
Ocular Melanoma

Ocular melanoma is a biologically distinct malignancy relative to its cutaneous counterpart. Recent data suggest that specific chromosomal aberrations within the tumor may be associated with clinical outcomes. Kilic et al conducted a cytogenetic analysis of 74 primary uveal melanomas, which led to the identification of common cytogenetic chromosomal losses, including 1p (24%), 3p (41%), and 3q (42%), and 6q (28%). Common chromosomal gains include 6p (18%) and 8q (53%). The degree to which each chromosomal aberration impacted disease-free survival varied, although monosomy of chromosome 3 seemed to have the largest impact when correcting for other confounding factors. It is detected in more than 70% of metastasizing and 20% of nonmetastasizing uveal melanomas; by contrast, the loss of 1p occurred only in the metastasized uveal melanomas.[40,41] Concomitant loss of 1p and monosomy of chromosome 3 were strongly predictive of decreased survival.[42] Recent efforts to classify uveal melanomas with biomarker-based assays to predict distant disease-free survival have focused on gene expression profiling and have resulted in the classification of tumors into two classes: class 1 or low-grade tumors (with a reduced propensity for distant spread) and class 2 or high-grade tumors, which have a higher level of aneuploidy, proliferation rate, and much reduced survival relative to class 1 tumors (95% in class 1 versus 31% in class 2 at 7 years).[43-46] Such information can be gleaned from fine-needle aspiration biopsy in patients likely to be treated with local, conservative modalities such as proton therapy or episcleral plaque radiotherapy.[47]

Orbital Lymphoma

The biology and natural history of these tumors varies with the histological classification within the Revised European-American Lymphoma system or the Working Formulation.[61,62] Stage and histological type play the most significant roles in outcome for orbital lesions.

Primary adnexal/conjunctival lymphoma is predominantly comprised of MALT type lymphoma and thus is dissimilar to the CNS manifestation, which is most frequently the diffuse large B-cell subtype of NHL. Clonality is easily demonstrated in the vast majority of cases because heavy chain immunoglobulin (IgH) rearrangement occurs in 80% of patients.[63] Despite multiple cytogenetic, mutation, and comparative genomic hybridization studies, a keystone mutation found in more than 50% of cases has not been identified. Although chromosomal losses and gains are relatively common, the frequencies are nonuniformly distributed between reports. At present, the most frequent translocation identified (15% to 40% of patients) includes t(11:18)(q21:q21) and results in the juxtaposition of the API2 (apoptosis inhibitor 2) gene and the MALT1 gene.[64-66] The translated fusion product of the aforementioned translocation leads to the constitutive activation of IK protein kinase, which degrades I-kB, and the subsequent translocation of the NF-kB complex to the nucleus, which in turn affects genes involved in inflammation, apoptosis, and immunity.[67,68]



Primary intraocular lymphoma is believed to be a subset of primary central nervous system lymphoma. Roughly 90% of cases are of the diffuse large B-cell NHL subtype, and roughly 10% are either Burkitt's or T-cell lymphoma. Because pathologic diagnosis can be difficult, flow cytometry is often done to document the presence of monoclonal populations of B lymphocytes derived from immunoblasts or centroblasts. These probably arise from late germinal center or postgerminal center lymphoid cells with a predilection for clustering around cerebral blood vessels secondary to an incompletely understood neurotropism. Expression profiling has resulted in the description of three characteristic transcriptomic profiles, known as germinal center B cell, activated B-cell, and type 3 B-cell lymphoma.[69] Further gene expression profiling studies

Although the genetic mutations characteristic to cutaneous melanomas have been better characterized (i.e., BRAF, NRAS), the mutations characteristic to choroidal melanomas are only now being appreciated (eTable 31-1). For instance, BRAF, which is among the more common mutations in cutaneous melanoma, occurs at a low frequency in uveal melanomas; however, its incidence in iris (~50%) and conjunctival (22.7%) melanomas is much higher.[48,49] The most common genetic mutations in uveal melanomas are uncommon in cutaneous melanoma (eFigure 31-2). Those mutations more common in the posterior uvea are distinct from iris and conjunctival melanomas, and include GNAQ, GNA11, and BAP1.[50,51] Eighty percent of all uveal lesions harbor mutations in either GNAQ (~50%) or GNA11 (~30%). These are heterotrimeric GTP-binding protein alpha-subunits that couple G-protein signaling to MAPK activation. MAPK is commonly activated in cutaneous melanomas under the direction of BRAF or NRAS.[52-55] The high incidence of these mutations in nearly all uveal lesions and some blue nevi have led some to believe that these mutations are early oncogenic events in the development of melanoma.[56] Late oncogenic mutations include decreased PTEN and BAP1 mutations, or their complete absence. Somatic mutations in BAP1 (BRCA1 associated protein-1) are common among class 2 uveal melanomas (84%), but not class 1 melanomas.[51] This protein facilitates the transformation to a class 2 melanoma by unknown means and results in a highly metastatic phenotype.[57] The sequential mutation of BAP1 in uveal melanoma is thought to be a late oncogenic event relative to other insults like GNAQ mutations.[51] PTEN loss, similar to BAP1 mutations, occurs in a high proportion of class 2 uveal melanomas and results in unfettered PI3K-Akt signaling, leading to resistance to apoptosis, increased growth potential, and reduced disease-free survival.[58,59]

eTABLE 31-1 Genotypic Differences between Cutaneous and Uveal Melanoma

Gene	Cutaneous	Uveal
BRAF	50%-70% (mut)	<5%
NRAS	15%-30% (mut)	<5%
AKT3	40%-67% (amp)	—
GNAQ	83% (blue nevi)	45% (mut)
GNA11	—	32% (mut)
BAP1	5%	47% (mut)
KIT	11%-21%	<5%
CDKN2A	30%-70% (del/mut/silenced)	<5%
PTEN	5%-20% (del/mut)	15%-58.7%
APAF1	(40% silenced)	—
TP53	(10% loss/mut)	<5% (mut)
CCND1	6%-44% (amp)	65% (amp)
MITF	10%-16% (amp)	>75% (amp)

have been heterogeneous and have drawn limited conclusions (largely because of tissue availability and small numbers). Several key translocations are being investigated further: TTF (70%), PAX5 (60%), CMYC (60%), PIM1 (50%), IG loci (38%), BCL6 (23%), CD95 (20%), and PRDM1 (19%).[70-72]

Orbital Pseudotumor

The histopathologic types of orbital pseudotumor vary, and attempts to refine and subdivide them have been advocated. The histopathologic spectrum of idiopathic orbital inflammation is typically nondiagnostic and diverse, ranging from the typical diffuse polymorphous infiltrate to the atypical granulomatous inflammation, tissue eosinophilia, and infiltrative sclerosis. One report suggested dividing this condition into three principal types: lymphoid, granulomatous, and sclerosing types.[73] Several authors have endorsed the exclusion of reactive lymphoid hyperplasia and defined pseudotumor as a mixed inflammatory infiltrate with fibrosis of varying degrees.[74]

Pterygium

Pterygia represent a degeneration of the conjunctival stroma with replacement by thickened, tortuous elastotic fibers.[75] Activated fibroblasts in the leading edge of the pterygium invade and fragment Bowman's layer. Pterygium development resembles actinic degeneration of the skin.

PATHOLOGY AND PATHWAYS OF SPREAD

Skin Cancers

Squamous cell cancers have regional lymph node involvement in 5% to 24% of patients, whereas nodal involvement in basal cell carcinoma is rare.[76-78] Lymph node involvement is more common for larger tumors, recurrent tumors, and those with perineural invasion.[79] Patients with recurrent lesions or perineural invasion may have tumor cells spread more peripherally than is clinically apparent, and advanced imaging approaches may be needed to adequately describe the extent of spread.[80,81] Standard hematoxylin and eosin staining detects approximately half of cases with perineural invasion; the addition of $p75^{NGFR}$ and S-100 may enhance the detection rate, although the prognostic significance is unclear.[82] Tumors located in the embryologic fusion planes of the face are more deeply infiltrating.[81] The area around the medial canthus may affect the depth of treatment necessary for a successful outcome.[83]

Ocular Melanoma

Uveal melanomas arise from melanocytes of neuroectodermal origin and have a large nuclear to cytoplasmic ratio, prominent or multiple nucleoli, and frequent mitotic figures. Tumors are generally classified as composed of either spindle cells or epithelioid cells.[84] Spindle cells have a fusiform shape and less pronounced atypia, whereas epithelioid cells are larger and more ovoid in shape and have more anaplastic characteristics. Uveal melanomas are classified as spindle cell melanomas if they are composed of only spindle cells, mixed cell melanomas if they contain both spindle cells and epithelioid cells, and epithelioid cell melanomas if they contain predominantly or exclusively epithelioid cells. Occasionally, the cells within the melanoma undergo necrosis, and these tumors are classified as necrotic melanomas. Melanomas tend to be slow-growing tumors, but the rate of growth can be quite variable and more rapidly growing tumors tend to be anaplastic and composed of epithelioid cells.

At the time of diagnosis, most posterior uveal melanomas are confined inside the sclera of the eye. Extraocular extension of the melanoma can occur through emissary canals, through which normal ocular structures such as vessels and nerves enter and exit the sclera, and generally not by atrophy or thinning of the sclera. Extraocular extension is classified as microscopic or gross (visible on gross inspection), occurs in 8% to 14% of eyes harboring a melanoma, and is associated with a worse prognosis[85,86] as reflected by the seventh edition AJCC staging system.

Despite the relatively small size and location, ocular melanoma has a high rate of distant failure, which drives patient mortality, although identifiable metastatic disease occurs in less than 3% of patients at the time of initial diagnosis. In the COMS report, sites of metastasis from melanoma included liver (91%), lung (28%), and bone (18%) (eFigure 31-3). Melanomas of the iris rarely metastasize. More unusual sites of spread include skin and subcutaneous tissue, brain, and spinal cord tissue. The brain is an infrequent site of metastasis; in the COMS report, brain metastases were discovered in only 4% of patients at the time of death.[87] Lymph node involvement was noted in 10% of patients who died from metastatic disease within the COMS.[87]

Choroidal Metastasis

The most common pathologic type is adenocarcinoma from the breast or non–small cell lung cancer. Most patients have other sites of metastatic disease. Disease extent can be localized to the choroid or infiltrative. The average number of lesions seen in the choroid in one large series was two and in about 25% of cases, multiple or bilateral tumors are present.[30,88,89] Orbital metastases can also occur but are typically less common and are unilateral; however, patients with breast cancer may have an increased incidence of bilateral globe involvement.[90]

Orbital and Ocular Lymphoma

A wide range of NHLs have been described involving the orbit and globe. In patients with orbital lymphomas, most of the lesions are of B-cell origin and classified as low or intermediate grade according to the World Health Organization (WHO) classification.[91] The most common subtype of ocular adnexal lymphoma which is generally referred to as "extranodal marginal zone B-cell lymphomas (EMZL)" is a MALT type lymphoma.[92] Primary uveal lymphomas involving the iris or choroid are usually of the aggressive, diffuse, large B-cell type.[25,93,94]

The pattern of spread in low-grade lymphomas associated with lacrimal and conjunctival sites is similar to that of its counterparts in the rest of the body. Risk of involvement of distant sites ranges from 15% to 20% at 5 years, although there is some suggestion that lacrimal and soft-tissue lesions may have rates of distant relapse as high as 50%.[95] Primary uveal lymphomas tend to disseminate into or be a component of disease within the CNS, with 60% to 80% of these ultimately being diagnosed as intracranial primary CNS lymphoma.[96]

Optic Nerve Sheath Meningioma

Meningiomas spread along the path of least resistance, remaining confined to the subarachnoid or intradural space of the intraorbital optic nerve. The tumor may invade the dura, adjacent orbital tissue, muscle, bone, and globe. These tumors may traverse the optic canal and affect the intracranial segment of the optic nerve or adjacent structures. Optic nerve sheath meningiomas have histological features similar to those of

Immunologic cytochemical staining, polymerase chain reaction testing, and flow cytometry are all helpful for demonstrating surface membrane or cytoplasmic markers that correspond to a lymphoma. Polyclonal distributions are associated with pseudolymphoma.

eFigure 31-3 Natural history of ocular melanoma. Massive distant failure in the liver three years from a patient treated for ocular melanoma.

intracranial meningiomas and are graded according to WHO criteria on the basis of sheeting, number of mitoses, cellularity, nucleoli, nuclear-to-cytoplasmic ratio, necrosis, frank anaplasia, subtype, and brain invasion.[97] Most lesions demonstrate concentric formations of spindle cells or ovoid meningothelial cells, with sheets of polygonal cells separated by vascular trabeculae, and are of the meningothelial or transitional subtypes.[98,99]

Lacrimal Gland Tumors

Pathologic findings are typically those of adenoid cystic cancer, followed by mucoepidermoid cancer and adenocarcinoma. Outcome seems to be related to the presence of necrosis, hemorrhage, perineural invasion, and high mitotic count.[100,101]

Optic Pathway Glioma

In the pediatric form of the disease, the cell of origin for optic nerve gliomas is unknown. Optic nerve gliomas are classified as grade-1 astrocytomas and are frequently either of the pilocytic or fibrillary subtype in the WHO classification of gliomas. Optic nerve gliomas develop in stages, from generalized hyperplasia of glial cells in the nerve to complete disorganization with loss of neural landmarks within the nerve and nerve sheath. A reactive meningeal hyperplasia may be incited, making it difficult to distinguish a glioma from a perioptic meningioma. Histologically, the WHO grade-1 variant consists of a population of cells that are biphasic and have compacted bipolar cells and less dense multipolar cells. The biphasic component often consists of spindle-shaped cells with elongated or ovoid nuclei and is frequently associated with "Rosenthal fibers." These fibers are representative of degenerating astrocytes and contain eosinophilic, spherical, cylindrical granular aggregates composed of degenerated glial filaments.[102] These lesions may appear cystic.[103]

Similar to intracranial low-grade gliomas, these lesions grow slowly, and bony constraints determine the route of extension.[104] Intracranial extension is common for more advanced lesions, which may result in enlargement of the optic canal. In the diffuse type, the optic nerve appears enlarged and thickened, and it effaces the arachnoid space; whereas in the extrinsic/peripheral subtype, the tumor fills the subarachnoid space and minimally enlarges the diameter of the optic nerve. Except for the neurofibromatosis 1 variety, optic nerve gliomas are nearly always unilateral. Chiasmal involvement and extension beyond the optic pathways are less common, and cystic enlargement is more common (10%) in patients with neurofibromatosis 1.[105] Resultant hydrocephalus is uncommon in patients with neurofibromatosis 1.

In the adult form of the disease, optic nerve gliomas are more likely to be diffusely infiltrative, including astrocytoma (WHO grade II), anaplastic astrocytoma (WHO grade III), or glioblastoma (WHO grade IV).[106] Spread beyond the original site may occur anywhere along the optic tracts as far back as the lateral geniculate bodies in the optic radiations, although this is rare. Histologically, adult lesions may display more nuclear atypia, mitoses, endothelial proliferation, and necrosis because the lower-grade subtypes are less common.

Orbital Pseudotumors

Pseudotumors are rarely infiltrative. One review documented infiltration of the retrobulbar fat in 76% of patients, enlargement of the extraocular muscles in 57%, thickening of the optic nerve/sheath complex in 38%, contrast enhancement in 95%, and proptosis in 71%.[107] Intracranial extension is unusual but has been documented in up to 8.8% of patients.[108]

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

The diagnostic algorithm for ocular, orbital, and lid tumors is given in Figure 31-1.

Skin Cancers

Patients should be evaluated for lymph node involvement with physical examination of the parotid, facial, and neck node areas. Symptoms of pain, formication, or other sensory changes may indicate perineural invasion.[109,110] The role of sentinel lymph node biopsy is unclear and should not be considered standard practice.[111] In some cases, it may be necessary to biopsy the distal branch of the suspected involved cranial nerve, although this approach confers morbidity and is prone to false-negative determinations because perineural invasion perineural invasion (PNI) may skip locations along the nerve.[112] Magnetic resonance imaging (MRI) of the face and orbits is the most sensitive modality for determining the clinical extent of perineural invasion because it may detect enlargement of the affected nerves[113] and should be considered in cases in which either clinical symptoms or documented histological features are suggestion of PNI.

Ocular Melanoma

At the time of presentation, 30% of patients with ocular melanomas may be asymptomatic. Symptomatic patients often complain of visual symptoms such as flashes of light, floaters, decreased visual acuity, or scotoma. Those who have visual symptoms typically have a more posteriorly located tumor, a large tumor, or an associated retinal detachment leading to a visual field deficit (Figure 31-2). Rarely, pain and redness are presenting symptoms, occurring in large or necrotic tumors

that have associated inflammation. Tumors of the ciliary body often appear silhouetted against the red reflex and are detected late because of the lack of direct impact on vision until there is significant mass effect. Iris melanomas are typically detected early and are often visible on standard ophthalmologic examination.

The diagnosis of melanoma is based primarily on ophthalmoscopic appearance and ancillary testing. The tumor typically appears as a unilateral, solitary, elevated, dark brown or gray, variably pigmented, dome-shaped mass (Figure 31-2). Orange pigment (lipofuscin) is often found on the surface of the tumor and is thought to represent increased metabolic activity.[115] The presence of lipofuscin can help differentiate these lesions from uveal nevi. Retinal detachment may be present and is more likely in larger tumors.

The initial ophthalmologic workup includes fundus photography, fluorescein angiography, and ultrasonography of the globe (Figure 31-3). These tests facilitate making a correct diagnosis and are also useful in following the lesions for growth or regression after treatment. Ocular melanoma exhibits a central hypoechoic area referred to as the acoustic quiet zone; metastases often have higher internal reflectivity. Ocular melanomas display a double circulation pattern and fluorescein leakage on fluorescein angiography. Standard indirect ophthalmoscopy and MRI may be useful in determining ciliary body involvement and extrascleral extension. In a large prospective trial, 645 of 647 patients who underwent enucleation for melanoma had that diagnosis confirmed at pathologic evaluation. Two of the patients had adenocarcinoma.[116] In eyes with opaque media secondary to cataract or vitreous hemorrhage, ultrasonography of the globe and MRI of the orbits can allow an accurate diagnosis. Optical coherence tomography is useful for estimating macular edema and determining whether there is retinal detachment overlying the tumor.[117] Biopsy of a lesion suspicious for an ocular melanoma is used in cases of diagnostic uncertainty and to determine cytogenetic characteristics for prognostic information. In patients requiring biopsy, histopathologic and immunohistochemical assessments can be useful in confirming the diagnosis and determining the presence of druggable mutations. Although this additional information may be useful at the time of presentation with metastatic disease, its role is still poorly defined when the disease is clinically localized. Fine-needle aspiration may result in vitreous hemorrhage and so in the setting where a characteristic gross appearance is present, biopsy may be avoided.

To assess disease extent, care providers should obtain a general history and perform a physical examination with attention directed to skin lesions, weight loss, the lungs, and the liver. History of a prior cancer would indicate the possibility of a metastatic lesion in the eye rather than a primary melanoma. Because the most frequent site of metastasis is the liver, the workup generally includes liver enzyme levels, which often prompt radiographic imaging. This approach was recently reported to have low sensitivity but high specificity and predictive value.[119] MRI has the highest sensitivity for detecting liver metastases, but its role in the initial evaluation is poorly defined. A recent prospective study of patients at high risk for uveal melanoma based on stage, histologic grade, and genetic subtype used serial MRIs for surveillance. They identified hepatic metastases in 48% of patients with a median of 18 months following treatment; most patients (92%) were asymptomatic, and 49% had less than five lesions, all less than 2 cm in diameter.[120] Other sites of metastatic disease include the lung. In such cases, imaging with chest computed tomography (CT) scanning is most accurate for early detection of disease.

Negative prognostic indicators include largest basal diameter, tumor thickness, ciliary body involvement, extraocular extension, and location of the anterior tumor margin. For each millimeter increase in tumor diameter, risk of cancer-related death increases (HR 1.08, $p = 0.0012$).[121] In a retrospective review of 289 patients in Finland, extraocular growth (HR 2.27, $p = 0.0076$) and ciliary body involvement (HR 1.89, $p = 0.0011$) conferred a similar hazard for cancer-related death (after accounting for competing risks). The 7th edition of the AJCC staging manual has been revised to reflect this and has been subsequently evaluated and validated by the European Ophthalmic Oncology Group (Table 31-1).[122]

Prognosis and duration of vision preservation and patient's quality of life outcomes after local therapies (not including enucleation) are affected by tumor-related factors such as tumor cell type, tumor size, tumor location relative to other intraocular structures, extension of the tumor outside the sclera[123,124] and the location of the anterior tumor margin. Tumors located anterior to the equator of the eye in the anterior choroid or ciliary body have a worse prognosis than those

located more posteriorly.[124] Conversely, lesions more posterior, which approximate the macula, have a higher probability of developing visual acuity loss at 1 and 3 years.[125] Patients with spindle cell tumors having a better survival rate than those with epithelioid cell tumors.[126,127] The prognosis is more favorable in spindle cell melanoma, intermediate in mixed cell tumors, and poorest in epithelioid or necrotic melanoma. Survival rates are adversely affected by increased size of the uveal melanoma. Although the previous literature had various size classifications, the COMS has established a standard size classification.[85,128,129] Small melanomas are 1 mm to 3 mm thick and less than 16 mm in largest dimension. Medium-sized melanomas are 2.5 mm to 10 mm thick (8 if close to optic disc) and less than 16 mm in basal diameter, and large melanomas are more than 10 mm thick or more than 16 mm in largest dimension (Table 31-1).

Ocular Metastasis

In 93% of cases, patients with uveal metastasis from breast cancer presented to ophthalmologists with visual symptoms. Of 264 patients with uveal metastasis, 225 (85%) had choroidal metastasis, 8 (3%) had iris metastasis, 2 (<1%) had ciliary body metastasis, and 29 (11%) had metastasis in multiple uveal sites. Asymptomatic metastases were detected in 56% of patients in the opposite eye.[130] CT and MRI often demonstrate a space filling enhancing mass which is hyperintense on T1 and hypointense on T2 (eFigure 31-4).

Patients with orbital tumors more often present with diplopia, ocular motility disorder, and proptosis. Lesions are usually unilateral.[131] Metastatic disease may be detected in a high proportion of the patients who present with this entity.

Orbital Lymphoma

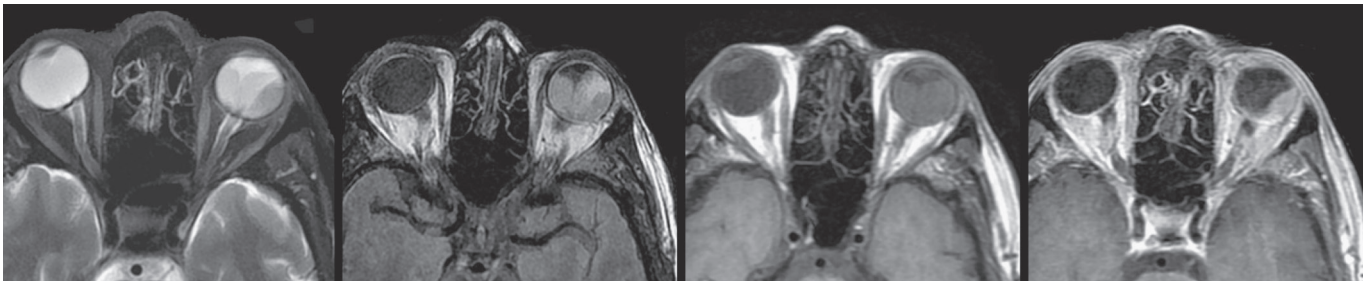
Orbital lymphoma can involve the soft tissues and present as a palpable mass. The most common ocular complaints are floaters and blurred vision, although proptosis, diplopia, and inflammation can also be present.[132-134] Conjunctival lymphomas are erythematous and present as a visible and palpable mass that is sometimes referred to as salmon colored. Patients should be evaluated for systemic disease with routine staging for a lymphoma workup, including complete blood count, liver function tests, chemistries, lactic dehydrogenase, bone marrow biopsy, and imaging of the chest, abdomen, and pelvis. Full nodal examination with assessment of symptoms, including weight loss, fevers, and night sweats should be included. Bone marrow examination should be performed for stages 3 to 4 disease or any patient with bulky disease. CT or MRI scans of the orbit can be used to delineate the extent of retrobulbar and soft-tissue involvement (eFigure 31-5).

Primary intraocular lymphoma is one of the most challenging intraocular tumors to diagnose. Cytologic examination of vitreal aspirates remains the gold standard for exclusion of neoplastic disease in patients with chronic idiopathic uveitis.[135-137] Patients with primary vitreous involvement should also have cerebrospinal fluid (CSF) examination and MRI of the brain and meninges.[138] Sixty percent to 80% of patients with primary vitreous involvement have bilateral involvement.[139-141]

Staging and prognosis is determined by the Ann Arbor staging system and International Prognostic Index.[142,143] A localized orbital lymphoma would be stage IeA.

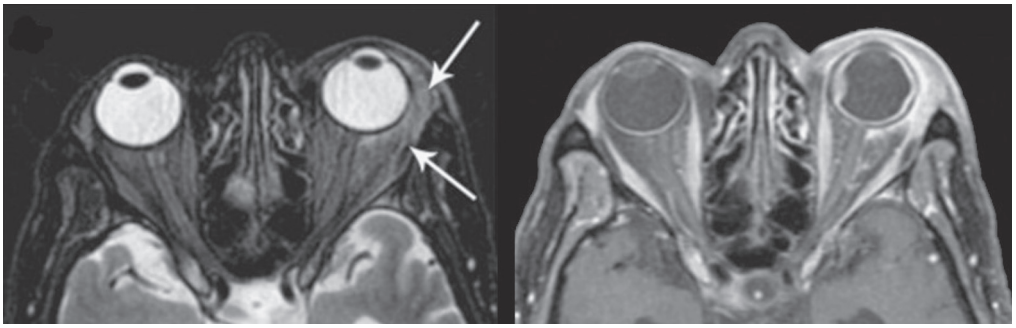
Optic Nerve Sheath Meningioma

Patients typically have painless progressive visual acuity loss or visual field defect.[144] Afferent papillary defect, dyschromatopsia, scotomas, altitudinal defects, and spontaneous or gaze-evoked transient visual obscurations usually associated with edema and swelling of the optic disc may also be present. Proptosis, lid edema, chemosis, and limited motion of extraocular muscles are often secondary to mass effect. Approximately 45% of patients present with vision of 20/40 or better; about 25% have poor vision (minimal light perception, count fingers).[145] Ophthalmoscopic examination may reveal optic nerve head or disc swelling, macular edema, nerve pallor, or choroidal folds.



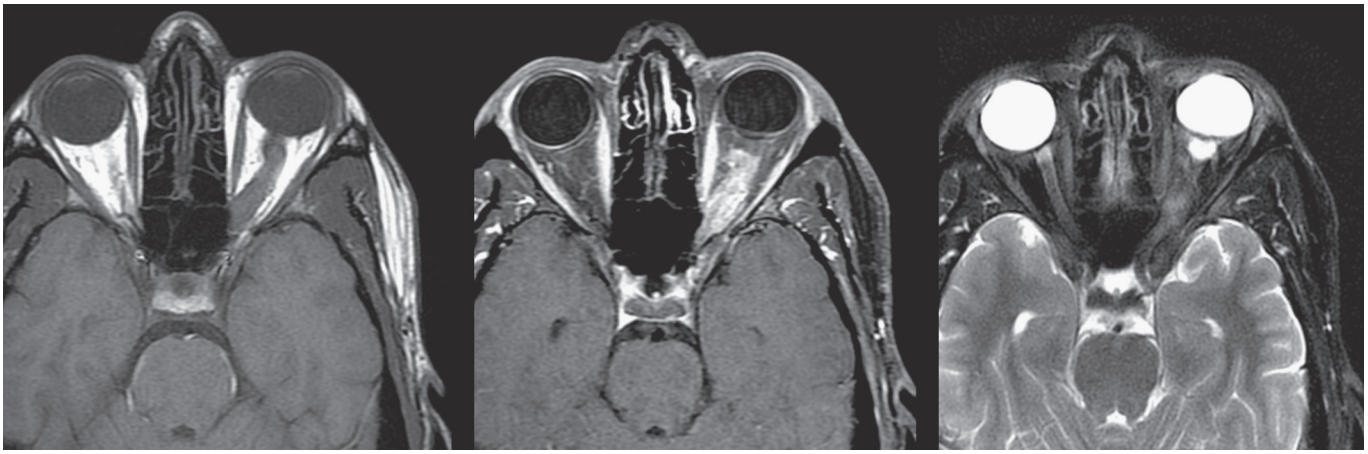
MRI is the procedure of choice for diagnosis of these lesions.[146] Lesions appear slightly hypointense to brain and optic nerve tissue on T1-weighted images and may be either diffuse, tubular enlargements, or localized eccentric expansion of the optic nerve (eFigure 31-6). They are homogenously enhanced following administration of gadolinium. Modern techniques may illustrate vascular changes and differentiate between alternative causes of optic neuropathy.[147] Thin CT scans may reveal regular or irregular thickening of the nerve sheath meninges. The nerve may appear normal in size or smaller as the result of circumferential compression or atrophy. Calcification has been described in 30% of patients and is associated with slower growth.[148] Differential diagnosis includes sarcoid, demyelinating optic neuritis, orbital inflammatory disease, schwannoma, lymphoma, hemangiopericytoma, and optic nerve metastasis.

Visual loss will generally occur in untreated eyes over 5 to 10 years.[149,150] Rapid growth has been observed during pregnancy, which may be mediated by hormone receptors.[151,152] Other tumors have demonstrated rapid visual loss even without radiographic enlargement, possibly as a result of microvasculature changes. Similar to other meningiomas, many will remain stable over a lifetime, but those that present with unilateral visual decline will likely continue to adversely impact vision.[153]



Optic Pathway Gliomas

Patients may be asymptomatic depending on the location of the mass. Typically, lesions within the orbit present with proptosis, visual loss, and strabismus, whereas individuals with extraorbital/intracranial lesions exhibit visual loss, spasmus nutans, obstructive hydrocephalus, and endocrine/hypothalamic disturbances. Patients with neurofibromatosis 1 are more likely to present with hydrocephalus, nystagmus, and proptosis.



Between 10% and 20% of optic pathway gliomas are confined to the orbit, with the remainder involving the intracranial compartment.[154,155] Children with isolated optic nerve tumors have a better prognosis than those whose lesions involve the chiasm or that extend along the visual pathway.[156-159] Children with neurofibromatosis type 1 also have a better prognosis, especially when the tumor is found in asymptomatic patients at the time of screening.[157,160] MRI is the preferred method for evaluation of optic pathway glioma[161] because both the intraorbital and intracranial component can be effectively characterized with this modality. In the intracranial region, MRI provides superior evaluation of the optic nerve, chiasm, tracts, and geniculate body and of optic irradiation compared with CT scanning. When evaluating the orbit, gadolinium-enhanced T1-weighted images with fat saturation are effective at defining the extent of adult optic glioma. Typically these lesions are hypo- to isointense on T1-weighted images, hyperintense on T2-weighted sequences, and enhanced with gadolinium administration (eFigure 31-7). Patients with neurofibromatosis 1 have characteristic features including the double intensity/pseudo-CSF signal and extension to the lateral geniculate ganglia and temporal lobes.[162]

Orbital Pseudotumors

Patients have proptosis, decreased ocular motility, soft-tissue edema, decreased visual acuity, or pain. Typical presentations include unilateral or bilateral anterior pseudotumor or unilateral or bilateral retrobulbar disease.[34] Orbital imaging is important to verify the extent of involvement. CT scanning may reveal a unilateral focal or more diffuse mass. Biopsy is recommended whenever possible to ensure accuracy of diagnosis.[34] Lymphoma, metastatic carcinoma, and sarcomas may be ruled out by a biopsy.

Lacrimal Gland Tumors

Most patients have an orbital mass that is frequently appreciated on examination and pain. Fine-needle aspiration is preferred for obtaining histologic diagnosis. CT scanning of the orbit should be performed to determine the extent of the mass.

Graves's Ophthalmopathy

Signs and symptoms of Graves's ophthalmopathy vary widely and range from mild periorbital soft-tissue fullness with no significant functional impairment to diplopia and visual loss. Visual loss is usually secondary to dysthyroid optic neuropathy and keratopathy. Other prominent symptoms include bilateral exophthalmia, extraocular muscle dysfunction, diplopia, blurred vision, eyelid and periorbital edema, chemosis, lid lag and retraction, and compressive optic neuropathy. Imaging with MRI may distinguish between acute inflammatory active and fibrotic, inactive end-stage disease.[163] CT scanning of the orbit will demonstrate changes consistent with enlargement of extraocular muscles, which are usually symmetric.[164]

PRIMARY AND ADJUVANT THERAPY

Periocular Skin Cancers

In general, surgical excision is the preferred treatment. In a large group of patients treated with Mohs's surgery for basal cell cancer, there was a 0% recurrence rate following treatment for a newly diagnosed basal cell cancer, but a 7% recurrence rate for those treated for recurrent basal cell cancer.[165] Incomplete excision rates can be high (25.4%) and are more common in morpheaform-type basal cell carcinoma and medial canthus lesions.[166] Incomplete excision results in increased recurrence rates relative to complete excisions (8.4% versus 4.6%). Another report of patients with squamous cell cancer demonstrated a recurrence rate of 3% at 5 years following Mohs's surgery.[167]

If surgery is not feasible because of associated functional and cosmetic problems, treatment with radiation has been successful for patients with either histologic type.[168-170] In more than 1000 patients with eyelid tumors treated with radiation, Fitzpatrick et al[171] noted a 5-year local control rate of 95% and 93% in basal cell and squamous cell carcinoma primary cancers, respectively. Similar results have been observed in more recent series using high-dose-rate brachytherapy and surface molds (99% local control among primary tumors and 87% for recurrent lesions).[172] The presence of pathologic or clinical perineural invasion may require wider radiation fields.[80,173,174] Clinically apparent perineural invasion or grossly involved nerves may prompt consideration of coverage of the infraorbital nerve as well as the trigeminal ganglion.[80,173,174]

Ocular Melanoma

The primary therapy of posterior uveal melanomas depends on many factors. Ocular factors involved in the selection of the treatment modality include tumor size, location, the presence or absence of extraocular extension, and visual function in the involved and uninvolved eye. Systemic factors important in management decisions include patient age, presence or absence of metastatic disease, and general health of the patient. The treatment algorithm is shown in Figure 31-4. Observation without treatment is used for asymptomatic small melanomas with dormant characteristics or elderly patients with severe systemic health problems or with short life expectancy. In these situations, the treating physician and patient must weigh the risks of treatment (loss of vision and possible tumor dissemination) against the risks of withholding treatment with growth of the tumor and subsequent increased risk of metastatic disease. The COMS group reported that at 2 and 5 years, 21% and 31%, respectively, of small melanomas managed initially by observation had grown.[129] Factors associated with growth after observation in COMS report No. 4 included orange pigmentation, the absence of drusen, thickness of greater than 2 mm, basal diameter of greater than 12 mm at diagnosis, and lack of adjacent retinal pigment changes.

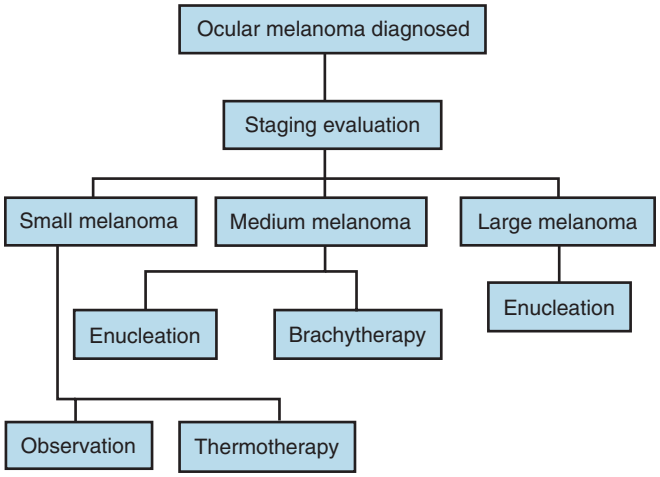

Figure 31-4 Treatment algorithm—Choroidal melanoma.

Enucleation has been the standard of care for the treatment of choroidal melanoma since the 19th century. Enucleation requires disinsertion of the extraocular muscles from the sclera, with removal of the entire globe with a long segment of optic nerve. It is the treatment of choice for large tumors, when the eye is blind, when there is pain from mass effect or invasion, or where the tumor has invaded or is contiguous with the optic nerve. An increase in the death rate at 2 years following enucleation has been reported; putatively supporting the hypothesis that enucleation may induce dissemination of tumor cells (Zimmerman-McLean hypothesis). However, this hypothesis remains controversial, with no strong evidence to support it.[175] Although all eyes with uveal melanoma can be treated by enucleation, the obvious morbidity of immediate and permanent loss of the eye and vision prompted the development of other techniques to treat these neoplasms.

Photocoagulation, transpupillary thermotherapy, and local resection have been used for treating selected patients. Transpupillary thermotherapy is probably the most common management for small melanomas and has produced excellent control (81% local control at 5 years) in selected patients.[176,177] Local resection has a high morbidity and is thus used rarely. It may be considered for anterior tumors involving the ciliary body or iris. Appropriate use of these techniques in the treatment of choroidal melanomas remains investigational.

TABLE 31-2 Eye Plaque Prescription Dose by Local Control and Vision Preservation

Dose	5-yr LC	>20/200	Loss >6 lines	Inst./Org/Au.
85 Gy	90%	3 yr 57%	49%	COMS[85,87,123,180,181]

70 Gy	82%	5 yr 58%	—	Quivey et al[183]
63 Gy	90%	5 yr 78%	10%	WFU[184]

Radiotherapy Options

Radiation therapy in the management of uveal melanomas has revolutionized the treatment of this ocular cancer. The principal advantage of irradiation in the management of these tumors is that the globe is spared, salvaging the eye and useful vision in many patients. Two main modalities of treatment are used: episcleral plaque radiotherapy and charged particle therapy (Video 31-1). In episcleral plaque therapy, tumors up to 18 mm in diameter and 8 mm to 10 mm thick may be treated, whereas with charged particle therapy tumors up to 24.4 mm in diameter and 14 mm in height have been treated.[178,179]

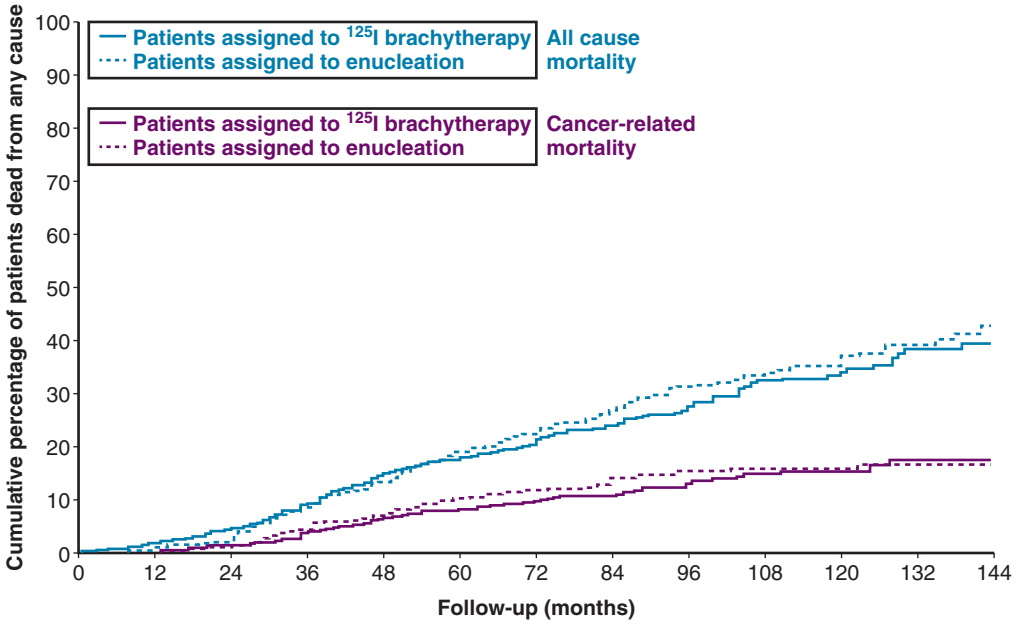
A randomized multicenter trial (COMS) enrolled 1317 patients with medium-size melanomas to treatment with enucleation or with brachytherapy with ^{125}I plaques. This study demonstrated equivalent 5-year overall survival rates of 81% in both arms[85] (eFigure 31-8). Visual acuity decreased over time in a proportion of patients treated with brachytherapy, with a 5-year cumulative rate of visual acuity of 20/200 or worse in the study eye at two consecutive examinations of 63% (95% CI, 59% to 68%).[116] The risk of vision loss was associated with a history of diabetes, thick tumors, tumors close to or beneath the macula, tumors with secondary retinal detachments, and tumors that were not dome-shaped.[180] Five years after plaque therapy, enucleation was necessary in 10% of patients because of tumor growth and in 3% of patients secondary to complications such as radiation-induced ischemia, pain, or loss of visual acuity[85] (Table 31-2).[181] Risk factors for treatment failure were older age, greater tumor thickness, and proximity of the tumor to the foveal avascular zone.[116]

Charged particle radiotherapy, primarily proton beam therapy, is a less common technique for treating uveal melanoma largely because of patient access. With this technique, tantalum rings are sutured to the external sclera at the margins of the tumor for localization, and charged particles (either protons or helium ions) are delivered in four or five fractions over a 7-day period. The standard target dose is 50 Gy to 70 Gy.[179,185,186] An advantage of charged particle therapy is the relatively uniform dose of radiation delivered to the entire tumor and the sharp reduction in dose outside the treated area.[187] Visual acuity following charged particle therapy is less thoroughly characterized relative to episcleral plaque therapy. However, a report from the Curie Institut-Orsay Proton Therapy Center of patients with ≥20/40 vision before treatment showed acuity at 5 years was stable in 19.6%, reduced to 20/200 to <20/40 in 10.9%, and significantly declined to < 20/200 in 18.6% after treatment.[179]

Ocular Metastasis

Choroidal metastases are sensitive to radiation, but overall survival rates are poor. In one study, external beam radiotherapy (EBRT) was used in 137 patients with uveal metastasis (52%), providing tumor control in 116 patients (85%) at a mean follow-up of 21 months. Using Kaplan-Meier estimates, the overall survival of all patients with uveal metastasis from breast cancer was 65% at 1-year, 34% at 3-year, and 24% at 5-year follow-ups.[130]

Ocular Lymphoma



With systemic disease, chemotherapy is the preferred definitive therapy; radiotherapy should be reserved for palliation. Patients with solitary low-grade lymphoma can be successfully treated with local irradiation to the orbit with doses greater than 25 Gy.[199] Patients who have intermediate-grade lymphoma may be treated with a combination of systemic chemotherapy and irradiation. Radiation therapy should be considered if a less than complete response in the orbit is observed following chemotherapy.[200-202] Doses to the orbit or conjunctiva range from 20 Gy to 36 Gy (1.8 Gy to 2 Gy per fraction in most series) and result in 89% to 100% local control rates. Follicular lymphomas are controlled with doses in the mid 20-Gy range, whereas data suggest that MALT lymphoma should receive 30 Gy to 36 Gy with 1.8 Gy/fraction to 2 Gy/fraction.[203,204] A trial of antibiotics before radiotherapy may be appropriate in a selected subset of patients with an indolent history of biopsy-proven primary conjunctival MALT lymphoma.[205] Complication rates are acceptably low with doses in the range of 20 Gy to 30 Gy.[203,206-209] Cataract formation is common without lens shielding although with extended times, even low doses (<5 Gy) may result in cataracts.[210-212] A recent publication suggested inferior results when only partial orbital irradiation was given compared with entire orbital irradiation, with control rates of 66% and 100%, respectively.[213]

Primary Intraocular Lymphoma

Currently, most primary intraocular lymphomas are treated with systemic high-dose methotrexate-based chemotherapy.[214] Ferrari advocates for upfront chemotherapy in patients with primary intraocular lymphoma followed by whole brain radiotherapy with fields that encompass both orbits. However, treatment-related factors such as cumulative dose of methotrexate, response to chemotherapy, and age at presentation should be considered.[215-217] Orbit directed radiotherapy should always include both globes and whole brain because from 60% to80% of cases may have bilateral ocular involvement and as many as 70% to 80% will go on to develop primary CNS lymphoma. Complications of EBRT are common and patients older than 60 are at increased risk for severe delayed neurotoxicity following combined methotrexate and whole brain radiotherapy.[216] Additional toxicities can include cataracts (50%), dry eyes (40%), punctate keratopathy (20%), radiation retinopathy (20%), and optic atrophy (10%). Doses for primary CNS and intraocular lymphoma are controversial and range from 23.4 Gy in the consolidation setting following systemic methotrexate to 45 Gy.[216] Ocular recurrences are often treated with EBRT and increasingly with intraocular methotrexate.

Optic Nerve Sheath Meningiomas

For most patients, stereotactic fractionated EBRT is preferred as the definitive therapy because it offers both excellent local control and long-term preservation of visual function.[218-225] Turbin et al[219] studied 59 patients with visual loss at presentation. These patients were divided into four groups: observation, surgery, radiation therapy, or surgery and radiation therapy. Only the group treated with radiation alone did not have significant visual loss at the last follow-up. Other series with shorter durations of follow-up have reported stable or improved vision in most patients treated with more modern radiation therapy delivery techniques.[220-224] More precise delivery of EBRT to smaller volumes reduces the amount of

eFigure 31-8 **All-cause and cancer-related mortality.**
Courtesy Diener-West M, Earle JD, Fine SL, et al: Collaborative Ocular Melanoma Study Group: The COMS randomized trial of iodine 125 brachytherapy for choroidal melanoma, III: Initial mortality findings. COMS Report No. 18. Arch Ophthalmol 119(7):969–982, 2001.[85]

A systematic review found that as of 2012, three randomized controlled trials and 16 uncontrolled and 9 controlled cohort studies had reported using charged particle therapy for ocular melanoma. One randomized trial compared helium ions to ^{125}I plaque radiotherapy and found similar local control rates across radiotherapy modalities, although there were more anterior segment complications in the helium ion group.[183] An additional study from the Curie Institute found that the combination of transpupillary thermotherapy and proton beam irradiation (60 GyE) resulted in a higher response rate (greater reduction of tumor thickness), less retinal detachment, and a lower secondary enucleation rate, although the former two findings were not statistically significant.[188] The other two trials compared proton beam therapy (50 GyE). The final randomized study was a dose-seeking trial, which found no significant difference between complication rates between 50 Gy and 70 Gy.[189] The case series suggested favorable survival rates, but with significant complication rates including (but not limited to) optic neuropathy, compromised visual acuity, and anterior segment complications. Although the aforementioned systematic review by Wang suggested that local control rates may be more favorable with charged particle therapy relative to brachytherapy, there have been no randomized controlled studies designed to answer this question.[190] Trials focused on delineating appropriate patient selection for either technique are needed to elucidate the role of charged particle therapy.

Newer techniques such as stereotactic radiosurgery are being used at some centers.[191] However, no long-term data are available on efficacy or complication rates. Early 3- and 5-year local control rates have been reported to be 88.8% and 81.9%, respectively. Visual acuity is short-lived; in one series, many patients had near-complete loss as assessed with a Snellen eye chart.[192]

In 1994, the German Cancer Society began a prospective study to examine the results of standardized EBRT for choroidal metastases with 40 Gy in 20 fractions.[193] With a median follow-up of 5.8 months (range 1 months to 44 months), 41 of 50 patients were dead. The median survival time of all patients was 7 months, and for patients with breast cancer, 10 months. Of the 50 symptomatic eyes, visual acuity increased greater than or equal to two lines in 36% (18 of 50 eyes), was stabilized in 50% (25 of 50 eyes), and decreased in 14% (7 of 50 eyes). No patient with asymptomatic metastasis ($n = 15$ eyes) developed ocular symptoms during follow-up. No patient with unilateral tumor and unilateral irradiation developed contralateral metastasis. Severe side effects, possibly related to tumor progression, occurred in three eyes (5%). More recent series are limited, although improvements in systemic therapy in subsets of patients with breast cancer (Her 2/Neu positive) may favor more prolonged fractionation to preserve optic structures.[194-197]

Nonbreast cancer metastases to the orbit also carry a poor prognostic outcome, with metastatic lung cancer demonstrating a shorter survival rate than metastatic breast cancer. Patients should be assessed for systemic extent of disease, confirmation of histology, and determination of available salvage systemic therapy options to decide on fractionation pattern and shielding. Patients with limited extraorbital disease may have improved prognoses and potential quality of life gains relative to those with widely progressive systemic disease. If the primary tumor is chemosensitive, the use of systemic therapy and localized EBRT may be indicated. Doses of radiation are typically 30 Gy to 40 Gy in 2-Gy to 2.5-Gy fractions. Consideration should be given to sparing the cornea or lens if possible.[198]

normal tissue exposed to radiation. These techniques require better immobilization for reproducibility of treatment, CT treatment planning for better tumor localization, image guidance, and conformal beam arrangements for optimizing treatment planning.[225]

Treatment is usually initiated as soon as a decline in visual acuity or fields is documented (20/40 vision) or with progressive tumor enlargement without loss of vision. It is advisable to treat these lesions with tight margins. Dose per fraction should be no more than 1.8 Gy to 2 Gy, with total doses of 50 Gy to 54 Gy. The risk of radiation-related toxicity to the optic structures rises from 2% at doses of 45 Gy to 50 Gy to about 5% at doses of 54 Gy.[226-228] Similarly, at fraction sizes of more than 2 Gy per fraction and total doses higher than 60 Gy radiation optic neuropathy occurs in about 47% of patients, whereas at doses of 1.9 Gy per fraction to a similar total dose, the risk is 11%.[229,230] Complications can include radiation retinopathy, optic neuropathy, cataract formation, or dry eye, depending on the volume of normal tissue and dose gradients. Some authors have expressed concerns when treating a patient with diabetes because of potential vascular complications associated with irradiation.[231]

Optic Pathway Glioma

The goals of treatment include improvement in progression-free survival (PFS) and stabilization of visual function. Optimal management should weigh the age at diagnosis, visual function, and the presence of progression. Observation is an option for young patients with neurofibromatosis as these tumors rarely progress before age 6.[232] Spontaneous regressions have been reported in low-grade gliomas in children (although uncommon) but may be related to telomere length.[233-235] For children with isolated optic nerve lesions and progressive symptoms, local radiation therapy is preferred and may result in prolonged progression-free survival.[236-238] Surgical resection is usually not preferred as the first-line approach because the rate of vision deficits postoperatively is high.[239]

One report detailed outcomes of 24 patients treated with radiation therapy only if there was evidence of visual deterioration or other clinical or radiographic evidence of disease progression. Radiation doses ranged from 45 Gy to 56.6 Gy (median, 54 Gy) in 1.8 Gy/fraction with up to a 17-year follow-up period (median, 6 years). The 6-year actuarial rates of freedom from disease progression and overall survival were 88% and 100%, respectively. Visual improvement or stabilization was seen in 21 patients (91%) after radiation therapy. A high incidence of endocrine abnormalities was reported, and 15 of 18 patients evaluated after treatment had growth hormone deficiency.[236]

In young patients who are still at risk for neurocognitive sequelae from radiotherapy, chemotherapy may be a viable option. Response rates approximating 50% to 75% have been noted in multiple studies; typical drugs include carboplatin and vincristine or temozolomide.[240-242] One study treated 50 patients with progressive gliomas with carboplatin on a phase II Pediatric Oncology Group (POG) study. Objective responses were found in 30% of patients.[243] Durable responses may be seen in adults with 1p19q codeletion; however, this mutation is uncommon in children relative to adults.[244,245] Similarly, the changing landscape of mutation analysis has shown a high incidence of BRAF-KIAA1549 fusion gene aberrations (61%) among patients with non-NF1 optic pathway gliomas, suggesting a potential therapeutic target that has not been explored.[246] There is a slight predominance of the BRAF-KIAA1549 fusion gene aberration in children relative to adults (64% versus 56%).[246] The implications of the changing understanding of the genetics of the disease are unknown.

Orbital Pseudotumor

Treatment for orbital pseudotumor is usually recommended in the setting of progression symptoms or declining visual function, although the condition can occasionally resolve without treatment. An oral dose of prednisone (80 mg/day for 1 week followed by a taper) is generally considered the first-line treatment.[247] Additional options may include nonsteroidal antiinflammatory steroids, although reports demonstrate improved responses with steroids. Immunosuppressive drugs such as cyclosporine and chemotherapy (cyclophosphamide, azathioprine, or methotrexate) have been employed with modest efficacy and should be limited to aggressive or refractory lesions.[248]

Local therapy is generally reserved for patients who fail the preceding and can either consist of radiation therapy at doses between 20 Gy and 30 Gy at conventional fractionation or surgery.[249-251] Surgery is typically only indicated when the lesion is burned out and the patient requires decompression. These lesions are radioresponsive. Irradiation is typically used for patients who fail to respond to medical management, patients who are intolerant of steroids, or those who have a rapidly aggressive course. Patients with the focal persistent sclerotic subtype of pseudotumor may benefit, especially when orbital decompression is required.[252]

The EBRT treatment technique varies based on the anatomic extent of the lesion (Figure 31-5). Patients with anterior lesions may be treated with an anterior direct electron beam that includes the lesion with a margin that is determined by the beam penumbra. Central lens shielding may be accomplished with either a lead-mounted contact lens or a hanging lens block. Low-energy electrons have significant skin sparing, and a bolus may be necessary to increase the surface dose. When pursuing this technique, particular attention must be paid to the scleral dose, and the recognition that if bolus material is used, the eyelids should be closed, to reduce trauma and irritation to the scleral surface. Even with closed eyelids, it is useful to instruct the patients to "look straight up" at a constant imaginary point, to minimize ocular motion and positional variability.

Total EBRT doses are typically 20 Gy delivered in 2-Gy fractions. One report of nine patients treated with initial total doses of 3 Gy noted that five of these patients required further irradiation for durable control of orbital disease.[251] Local control rates range from 74% to 100% for doses of 3.8 Gy to 36 Gy.[34,250,251,253]

Lacrimal Gland Tumors

Primary therapy is surgical resection with adjuvant EBRT as needed for close surgical margins, perineural invasion, or adenoid cystic histology.[254] Even with aggressive treatment, local recurrence rates were high following surgery and EBRT for adenoid cystic histologic types.[101,255] Eye-sparing surgery may be possible in limited cases with small tumors and favorable features although adjuvant radiotherapy is uniformly recommended regardless of resection extent.[256]

Graves's Disease

Peterson and others reported results in 311 patients treated with orbital irradiation, with 80% showing improvement of soft-tissue symptoms, 75% showing improvement in corneal signs, 61% and 52% having improved extraocular dysfunction and proptosis, and 41% to 71% having improved visual acuity.[257] After irradiation, 76% were able to discontinue corticosteroid therapy.

An older randomized controlled double-blinded trial treated 42 patients with EBRT to one eye and sham therapy to the other eye.[258] Six months later, the therapies were reversed.

Patients with unilateral retrobulbar lesions are usually treated with a photon wedged-pair technique. Donaldson et al suggested treatment with a central eye bar to shield the lens in each field.[253] However, low-dose regions in the retrobulbar area do result from this technique. Bilateral retrobulbar lesions are treated with opposed lateral fields with a half-beam block used to spare the anterior segment of the eye if it is uninvolved (see Figure 31-5).

Rec., *Recurrent.*

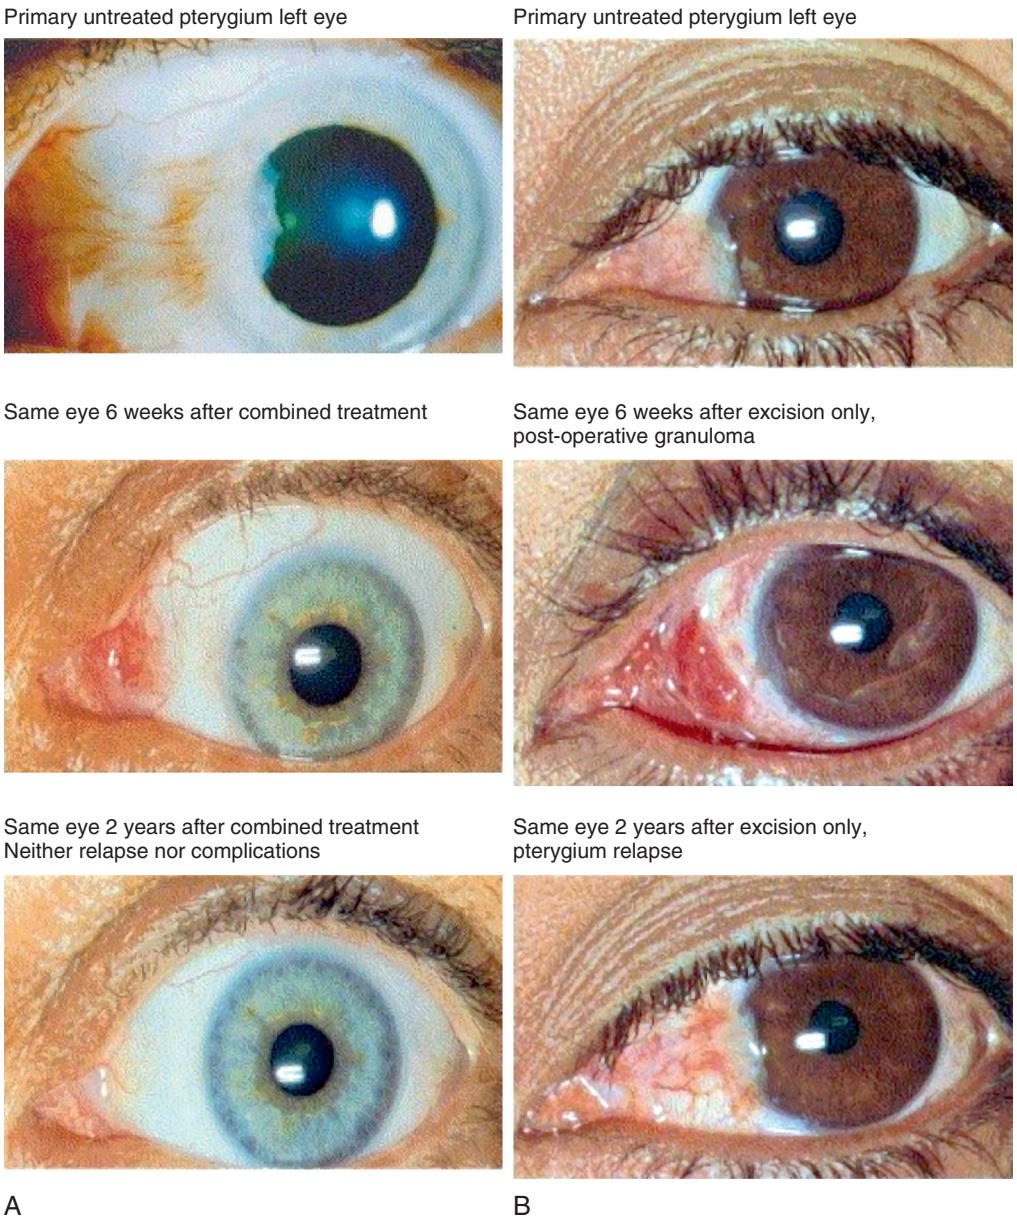
There was no apparent benefit for the orbit that received initial irradiation. This study has been criticized because it included patients whose onset of symptoms ranged from 0.2 to 16 years and may have included patients who had a more fibrotic reaction (i.e., more stable) compared with an active inflammatory process. A more recent controlled trial randomized 44 patients to orbital EBRT and 44 to sham irradiation. After 12 months, 52% of the patients who were irradiated had improvement compared with 27% of the patients who were sham-irradiated ($p = 0.02$).[259] Similarly, a meta-analysis of the use of multiple modalities for Graves's disease-related ophthalmopathy found a significant benefit of combined steroids and irradiation over corticosteroids alone, although the benefit of radiotherapy as monotherapy was limited.[260] In light of the controversy, the American Society of Ophthalmic Plastic and Reconstructive Surgery recommend a trial of steroids and radiation for patients with progressive symptoms.

Long-term follow-up suggests that orbital irradiation is safe, with a similar incidence of cataract formation to the corticosteroid group but with a possibly increased risk of retinopathy for patients with diabetes.[261] Thus, orbital irradiation is typically used in the setting of symptomatic Graves's ophthalmopathy that is difficult to control with steroids, for patients with poor tolerance to steroids, or for patients for whom surgical orbital decompression has failed.

Pterygia

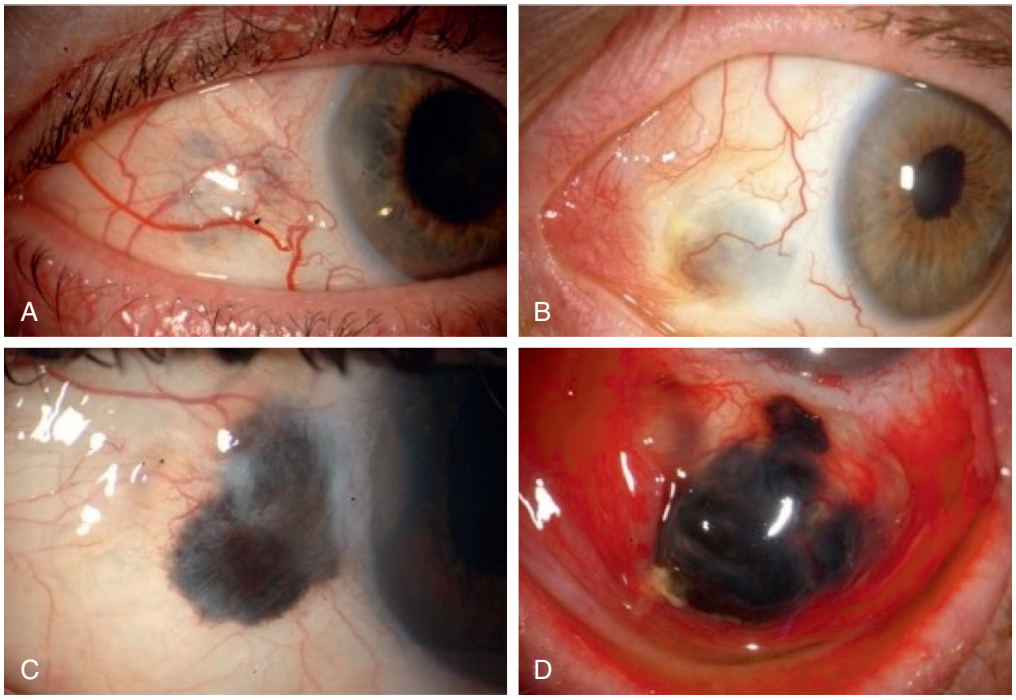
Treatment for pterygia involves surgical excision with removal of the fibrous tissue down to the level of Tenon's capsule. Free conjunctival flaps may be grafted over the bare sclera; autografting has markedly reduced recurrence rates with the adoption of this technique. Recurrence rates have varied, with rates of 20% to 68% with surgery alone, although more recent series have rates of recurrence of 12% for primary, 21.4% for recurrent lesions.[262-265] Topical Mitomycin-C was found to be equivalent to conjunctival autografts.[266] Postoperative adjuvant therapy with irradiation, topical thiotepa, mitomycin, or other antimetabolic agents may diminish the chance of recurrence and have been used in multiple institutional series (see Table 31-3).[267,268]

A randomized trial treated 96 patients with a single dose of 25 Gy using a strontium-90 (^{90}Sr) ophthalmic applicator or sham irradiation within 24 hours of surgery showed crude local control rates of 93 versus 33% in the treated and sham group, respectively, with no serious complications being observed in either group ($p = 0.004$).[274]



Macular Degeneration

The advent over the past 5 years of intravitreal injection of vascular endothelial growth factor (VEGF) blockers for management of exudative macular degeneration has greatly improved the visual prognosis of patients with macular degeneration.



In the 1990s there was interest in using ionizing irradiation as a treatment for macular degeneration, because it can destroy vascular tissue and prevent neovascularization. The rationale for using local irradiation for choroidal neovascular membrane is based on the radiosensitivity of proliferating endothelial cells, reduction in the inflammatory response, and possible occlusion of aberrant vessels. Various dose schedules and techniques have been used; 3DCRT (10 Gy to 24 Gy, in 2-Gy to 4-Gy fractions), proton radiotherapy (8 CGE to 24 CGE, single fraction), stereotactic low-voltage radiotherapy (16 Gy to 24 Gy in one fraction or 20 Gy to 40 Gy in 2-Gy fractions), and macular brachytherapy (12.5 Gy to 32.4 Gy in one application ^{90}Sr or ^{103}Pd).[276]

Early studies with three-dimensional conformal radiotherapy suggested stabilization of vision and even improvement

Multiple retrospective studies have used irradiation with beta emitters started within 24 hours of surgery (Table 31-3 and eFigure 31-9). Doses range from 10 Gy to 60 Gy and are given in one to six fractions.[269-274] There does not appear to be a dose-response relationship. Recurrence rates are more common for pterygia that are recurrent after initial surgery. Complication rates are low, but instances of scleral necrosis (eFigure 31-10), cataract induction, corneal thinning, symblepharon, cataract, and corneal ulceration have been described. These are much more common in patients who have been reirradiated.[273] Treatment with multiple fields with possible dose overlap may be responsible for some of these complications.

in vision.[277,278] A randomized controlled trial from the Netherlands treated 34 patients with 24 Gy in four fractions compared with a control group. The time until vision decreased by at least three lines was prolonged.[279] However, the results from other studies have been mixed.[280-284] The rise of anti-VEGF therapeutics has limited further application of conventional EBRT and directed development to more targeted techniques such as epimacular brachytherapy, stereotactic radiation, and proton radiotherapy.[285] The therapeutic ratio and utility of conventional EBRT has largely been limited by adjacent normal tissue tolerance.

More recent techniques such as epimacular brachytherapy (EMB) have been attractive because the lens is essentially spared and little to no radiation retinopathy events have been observed. Angiography and optical coherence tomography in several studies have shown a marked reduction in choroidal neovascularization at 12, 24, and 36 months.[286] This technique however requires a pars plana vitrectomy with subsequent placement of the ^{90}Sr source adjacent the fovea. Prospective evaluations of the safety and efficacy showed stable visual acuity and suggested potential reduction in the frequency of anti-VEGF injections. The recently reported CABERNET study, which assessed vision outcomes and frequency of anti-VEGF injections over time in patients receiving anti-VEGF monotherapy with or without EMB showed that patients in the monotherapy arm required 1.5 times more anti-VEGF injections over 12-months.[287] There was a high rate of cataracts secondary to vitrectomy.[288] Although the efficacy did not meet the prespecified 10% noninferiority margin (primary endpoint of the trial) for occult lesions, it did result in the reduced visual acuity loss of fewer than 15 letters in classic and minimally classic lesions. The benefit of anti-VEGF monotherapy versus anti-VEGF therapy plus EMB in patients pretreated with anti-VEGF therapy is being evaluated in the MERLOT trial, which is ongoing.

Altogether newer treatment delivery methods with stereotactic therapy show promise in that the low energy photons are less likely to cause damage to deep adjacent ocular structures, is less invasive than EMB, and sharper penumbra (less low dose spillage) can facilitate dose escalation.[289] This technique requires eye immobilization with a suction-enabled contact lens for an approximate 5-minute exposure to deliver the required single fraction dose. Estimated dosimetry suggests minimal dose to adjacent organs at risk (lens, optic nerve) on the order of 199 mGy to 1200 mGy.[290] The accuracy and precision of the delivered dose is estimated to be submillimeter at 0.4 mm to 0.6 mm.[291] The results of the recently reported INTREPID study demonstrated reduced ranibizumab retreatment relative to the sham arm (mean 3.74 versus mean 2.64) with only modest improvement in acuity at 52 weeks in the loss of fewer than 15 letters.[292] Further studies examining the utility of newer radiotherapy techniques in addition to anti-VEGF therapeutics are ongoing.

LOCALLY ADVANCED DISEASE AND PALLIATION

Ocular Melanoma

Patients with large choroidal melanoma are usually treated with enucleation, although proton beam radiotherapy and plaque brachytherapy have been used in selected circumstances. Plaque brachytherapy is often avoided in large tumors because of increased complication rates associated with treatment, higher incidence of transcleral extension (contraindication), lower vision preservation rates, and technical considerations, which limit adequate dosimetric coverage.[293] Certain situations may favor an approach that preserves vision with plaque brachytherapy even in large tumors. Such situations include poor vision in the contralateral eye, or individuals not felt to be able to tolerate the psychological effects of loss of their eye as a result of poor mental health. In the largest reported experience with large tumors treated with plaque radiotherapy, the enucleation rate following treatment was 34% at 10 years.[294] Factors that resulted in a short time to enucleation following plaque brachytherapy include >50% ciliary body involvement, thickness greater than 8 mm and tumor proximity to the fovea.[294]

The COMS enrolled 1003 patients to a study that randomized them to either enucleation or enucleation preceded by EBRT (20 Gy).[128] Patients receiving preoperative radiotherapy had no significant difference in 5-year overall survival. The 5-year all-cause mortality rate for large melanomas was 40%. There was no difference in local control between the two groups.

More recent single-institution series such as the one from the French Ocular Oncology Center demonstrated clinically equivalent survival estimates for patients with large choroidal melanoma following either enucleation or proton beam therapy, although the enucleation group had a slight predominance of tumors with greater thickness (12.0 ± 2.8 versus 9.8 ± 1.6).[295] Eye retention and best-corrected visual acuity of 0.1 (20/200) or better was 74% at 1 year and 32% at 5 years in the proton therapy group. Despite the former, early reports on the application of proton beam radiotherapy should still be considered investigational for COMS large choroidal melanoma.

Orbital Lymphoma

Irradiation to the orbit can provide effective palliation for patients with widespread systemic disease or locally advanced disease. Even in patients who have received prior radiation therapy, reirradiation for local disease progression that is resulting in progressive visual loss or symptoms can be considered.[296,297]

IRRADIATION TECHNIQUES AND TOLERANCE

Plaque Irradiation

Multiple different isotopes have been used for plaque therapy, including cesium-131 (^{131}Cs), cobalt-60 (^{60}Co), gold-198 (^{198}Au), palladium-103 (^{103}Pd), ruthenium-106 (^{106}Ru), iodine-125 (^{125}I), and iridium-192 (^{192}Ir).[298-301] The most commonly used isotope is ^{125}I as it was mandated by the COMS medium study. This isotope carries the advantage of low-energy gamma rays and therefore decreased shielding and dose to distant structures. Ruthenium-106 is a beta emitter that has few shielding concerns, but it has a penetration of only a short distance, which may limit its application.

A variety of plaque applicators have been used for ocular melanomas, but the most commonly used ones are those developed for the COMS (Figure 31-6). These plaques allow shielding of the posterior and lateral structures with a 0.5-mm thick gold alloy shield (77% gold, 14% silver, 8% copper, and 1% palladium). The overall design includes a circumferential collimating lip and incorporates a 1-mm Silastic carrier for seeds, which allows for different prescription depths. However, not all plaque designs incorporate Silastic carriers, and this should be taken into account with the use of other plaques and isotopes.[302] Originally, COMS dosimetry ignored the contributions of source anisotropy, and backscatter from the gold allowed plaque and Silastic attenuation (density is actually greater than assumed water equivalent sclera (eFigure 31-11). Recent studies that have studied the incorporation of these

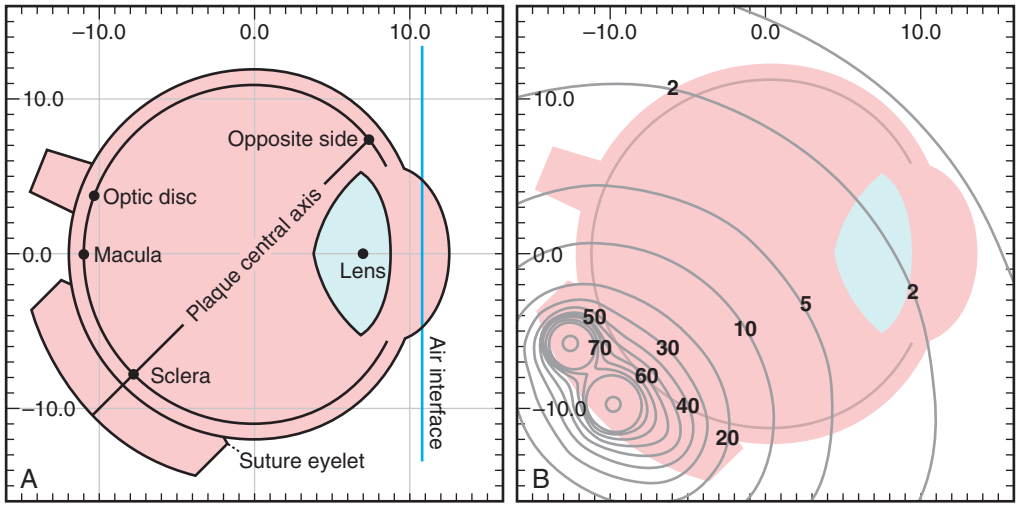
factors into treatment planning have shown that these adjustments may result in reduction of the calculated doses to critical structures within the globe such as the macula, sclera, optic disc, lens, and opposite retina.[303] Although hypothesized to be significant, this has yet to be demonstrated in a patient data set.

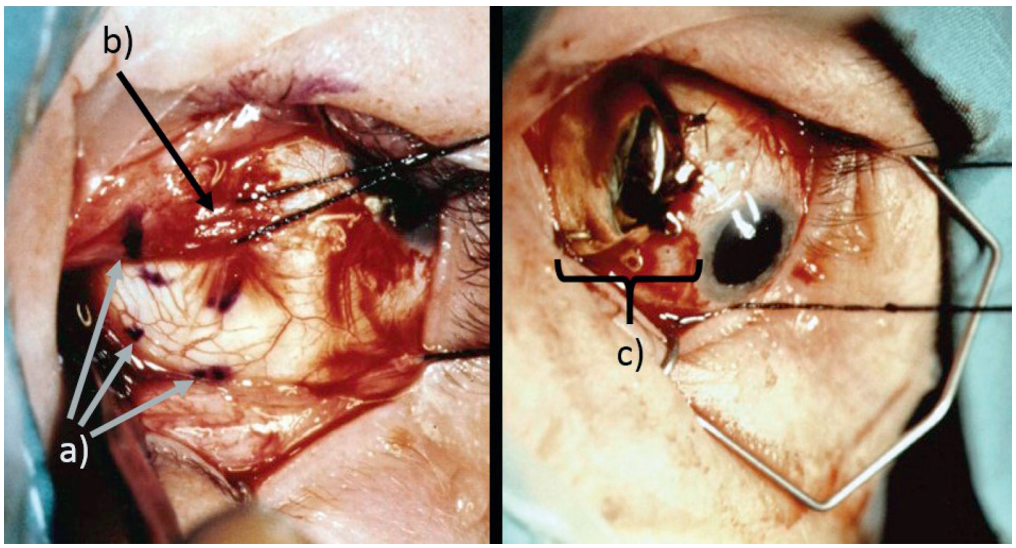
Plaque selection should incorporate the largest basal tumor diameter plus an additional 2-mm margin circumferentially around the tumor. Placement of the seeds within the applicator varies, depending on the height of the tumor. The prescription point should be the apex of the tumor or 5 mm, whichever is greater, as prescribing to heights of 3 mm or less can result in dosimetric uncertainty.[302] The prescription point is calculated by taking into account the tumor height in mm based on ultrasound plus 1 mm to account for scleral thickness and 1.4 mm to take into account the thickness of the Silastic carrier.

In the COMS, a total dose of 85 Gy was used and delivered to the apex of the tumor at a dose rate between 0.5 Gy/hour and 1.25 Gy/hour. The optimal dose of radiation therapy for treatment of choroidal melanoma is controversial. Equivalent local control, survival, and disease-free survival rates with less ocular morbidity and vision loss have been reported with lower radiation therapy doses.[184]



Principal complications of radiotherapy to the eye include cataract formation, radiation retinopathy, macular edema, and optic neuropathy.[305] Anti-angiogenic therapeutics such as intravitreal bevacizumab may be useful in treating radiation retinopathy (eFigure 31-13). Radiation effects on the retina and optic nerve may be potentiated by the presence of systemic vascular diseases such as hypertension and diabetes mellitus and often result in loss of useful vision. The proximity of the tumor to critical visual structures such as the optic nerve and macula is predictive of the long-term visual prognosis. Although no radiation tolerance has been ascribed to the macula itself, at doses of 50.5 Gy (IQR 18.6 to 97.3) delivered using plaque brachytherapy, the median visual acuity at 3 years was less than 20/50, whereas vision was a median of less than 20/200 at a median dose of 61.5 Gy (IQR 25.7 to 110.9).[306] Previous estimates of optic nerve tolerance were likely overly conservative as subsequent series have observed that a radiation dose per fraction threshold for radiation induced optic neuropathy approximates zero at fractions less than 2 Gy per fraction, whereas doses greater than or equal to 2 Gy per fraction increases the risk of radiation-induced optic neuropathy from 3% to 7%, from a total dose of 55 Gy to 60 Gy and then escalates at doses greater than 60 Gy to a risk of greater than 7% to 20%.[211,307]

Skin Lesions



Treatment of skin lesions close to the eye can be difficult. The close proximity of normal structures must be balanced with the dosimetric constraints that are present with electrons. Most of the data supporting the use of radiation therapy came from series using kilovoltage x-ray beams. However, this type of x-ray equipment is no longer widely available. Electrons have a larger penumbra and area of beam constriction laterally, necessitating larger treatment fields than kilovoltage beams. One report demonstrated higher corneal doses with electrons compared with kilovoltage beams (doses were two to four times higher). Also, the 95% isodose area was 32% wider with kilovoltage beams than with 6-MeV electrons.[83] A minimum recommended field size of 4×4 cm is required for reliable electron dosimetry. Treatment fields may be made smaller with the use of skin surface lead shielding for collimation of the beam to the clinically relevant volume. Lower energy electrons are skin sparing at superficial depths. Institutional data tables should be referenced regarding optimal bolus thickness if the dose at the superficial skin is to be therapeutic. Verification of the superficial skin dose with solid state dosimeters (such as thermoluminescent dosimeters), silicon diodes, or film is recommended in each instance.[309-311]

Unilateral Eye Lesions

Treatment of one eye may be necessary for patients with choroidal or orbital metastasis or orbital lymphomas. Pretreatment imaging is essential in deciding on the need for the extent of the orbit and orbital contents to be included in the field. Typically, a wedged-pair technique is used if the entire orbit needs to be treated. This field arrangement is designed to limit the irradiation to the opposite eye. Reduced exit dose to the temporal lobe and brainstem can be minimized by placing the isocenter just deep to the apex and half beam blocking each of the wedged fields to minimize divergence beyond the treatment field and limiting the total volume of normal brain treated. CT planning can assist with location of the normal optic structures and the tumor volume that is to be included in the field (Figure 31-7). Three-dimensional treatment planning may enable more treatment conformity around the structure to be treated and decrease normal tissue sequelae. A single anteroposterior photon field can be considered that permits the use of a hanging block to spare the lens dose (Figures 31-8 and 31-9). Eye drops (such as 5% proparacaine hydrochloride) may be required in the case of lens shielding as repeated shield insertions can cause eye irritation. Patients

eFigure 31-12 Episcleral plaque insertion. A, Sites of transilluminated tumor markings over the surface of the sclera on the immobilized globe. **B,** Insertion of the rectus muscle with corresponding suture for immobilization. **C,** Inserted plaque against the lateral portion of the globe once sewn into place with three to four eyelets.

The plaque is placed by the ophthalmologist by marking the boundary of the tumor base with a surgical marking pencil or light cautery that can be seen when the tumor is transilluminated intraoperatively after mobilization of the globe (see Video 31-1). The plaque is then centered over the marks. Appropriate plaque placement and/or transillumination may require detachment of the ocular rectus muscles. The plaque is then sutured to the sclera (eFigure 31-12). Good placement can be confirmed with ultrasonic evaluation of the eye. Occasionally, the melanoma is located adjacent to the optic nerve (peripapillary tumors), in which case the use of a notched plaque may allow better dosimetry and coverage of the tumor in this situation.[304]

After the patient is immobilized, the tumor volume should be outlined, followed by design of the treatment field based on the margin felt necessary to encompass the tumor, beam penumbra, and setup uncertainties. The distance of microscopic tumor beyond the gross clinical volume is a mean of 5 mm, but this distance may vary with extent of perineural invasion and grade.[312] At least an additional 0.5 cm should be provided beyond that which would be used for orthovoltage equipment. For instance, for a tumor less than 2 cm in size, the penumbra would include a horizontal margin of 0.5 cm to 1 cm for an orthovoltage field, whereas electrons require an additional 0.5 cm—a total of 1 cm to 1.5 cm for a tumor ~2 cm in size. Depth of treatment should be determined with attention to perineural invasion, location near an embryologic fusion plane, and size of the lesion, but in general should include a bolus of varying thickness depending on beam energy if superficial dose is intended. If perineural invasion is present, reviewing the relevant path of the involved nerve and additional imaging is often required.[313-318] Tungsten eye shields may provide better shielding of anterior eye structures than lead for 9-MeV electrons.[319,320]

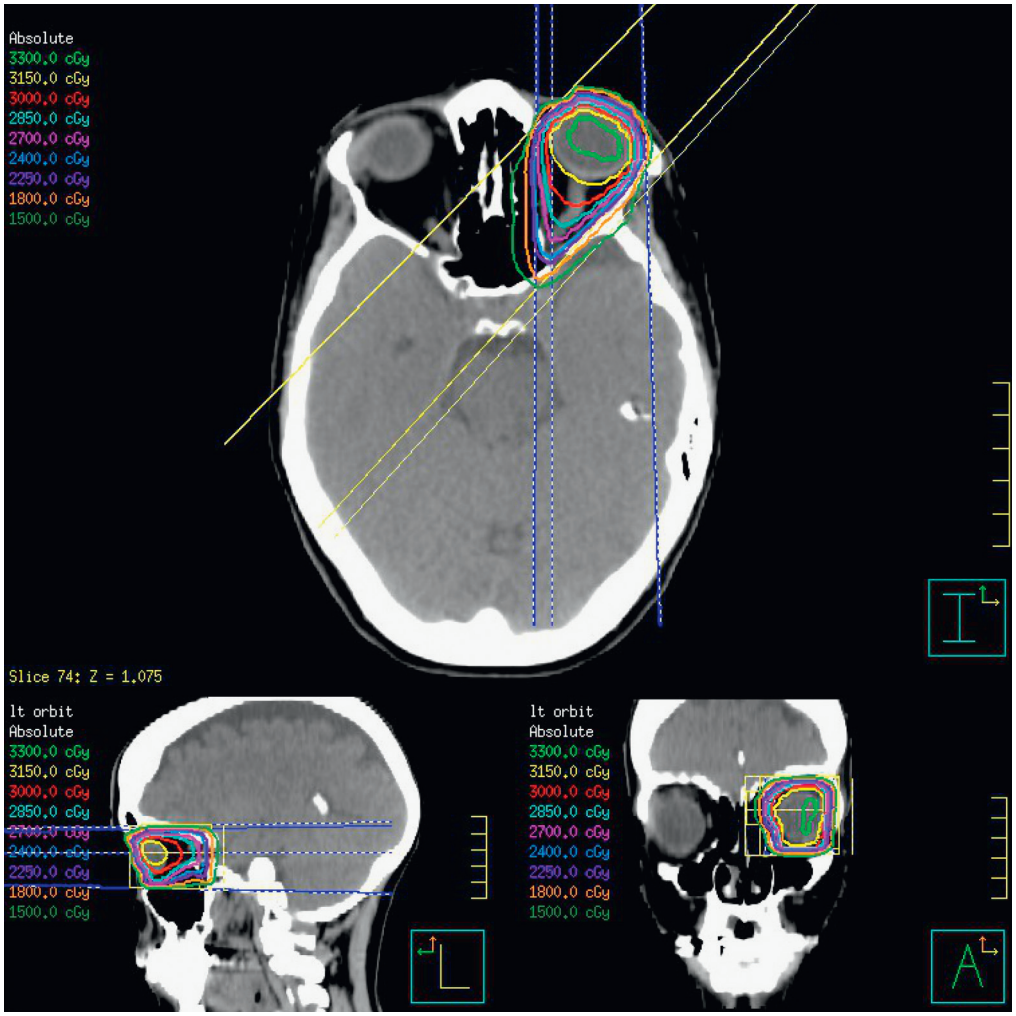

Figure 31-7 Treatment planning—Orbital metastasis. Axial, sagittal, and coronal noncontrasted CT slices of a three-dimensional conformal radiotherapy plan for a patient with a metastasis of the globe treated to a total dose of 30 Gy in three Gy fractions.

should be discouraged from using numbing medications outside of daily shield insertion because it may numb them to self-induced trauma during the excessive tearing often seen following and at later time points during therapy.[321]

Bilateral Eye Lesions

Treatment of both eyes is usually done with opposed lateral fields. If it is possible to spare the lens (i.e., Graves's ophthalmopathy), then the central axis of the beam should be placed just posterior to the lens (5 mm behind the most anterior aspect of the globe). A split-beam technique is used to block the anterior structures if possible. Graves's disease, bilateral choroidal metastasis, and bilateral lymphomas are treated in this manner. Some have proposed a mixed photon electron field technique for the treatment of bilateral orbital disease to maximize homogeneity of the periorbital and retro-orbital tissues while minimizing the dose to the lens, although this technique requires the use of a wax compensator and a sunken lead alloy eye block to prevent dose to the anterior segment of the eye.[323]

Anterior Lesions

Involvement of the conjunctiva may require treatment of the anterior structures alone. This can be accomplished with electron fields directed en face to the globe. Central lens shielding can be accomplished with a hanging block at which the patient is instructed to look (see Figure 31-8). En face electrons can be used with a lead contact lens if electrons of not more than 6 MeV and tungsten if 9-MeV electrons are used.[319] In the case of a unilateral superficial conjunctival orbital lymphoma, the aforementioned technique can be considered, although caution should be employed as any involvement of the retrobulbar tissues will receive less than a therapeutic dose and treatment of the partial relative to the complete orbit has resulted in treatment failures.[213]

Intensity-Modulated Radiation Therapy

Techniques using three-dimensional treatment planning and intensity-modulated radiation therapy may be advantageous for treating optic nerve meningiomas or gliomas (Figures 31-10 and 31-11). All critical structures of the eye should be identified at the time of CT simulation and volume delineation and appropriate planning dose constraints applied. Patient immobilization is crucial, and the use of a stereotactic setup should be considered.[324]

Tolerance Issues

Sequelae from radiation exposure to the eye vary by type of radiation therapy (photon, electron, or brachytherapy), total

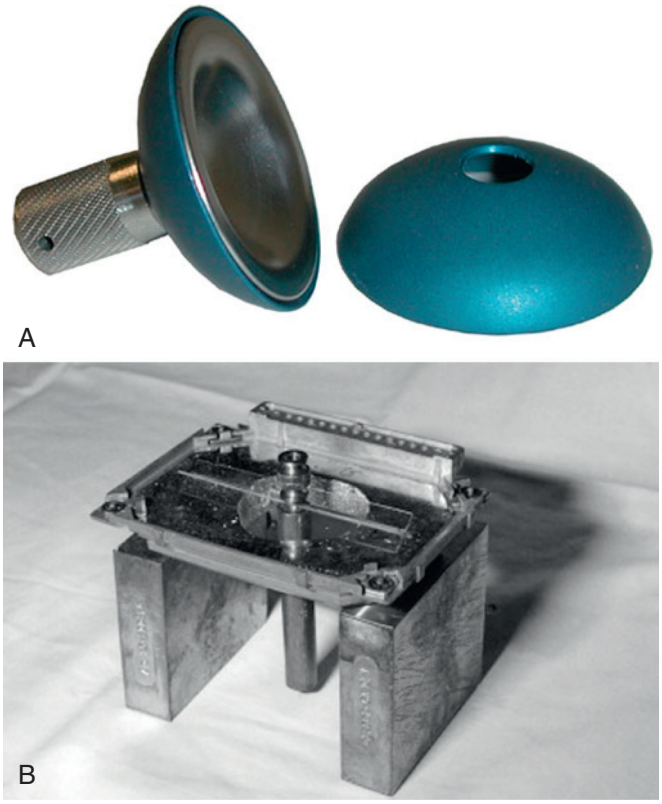

Figure 31-8 **Treatment setup. (A)** Representative tungsten lens shields used for reducing anterior radiotherapy dose to the lens. **(B)** Hanging block apparatus.

dose, radiotherapeutic fraction size, and part of the eye included in the radiation exposure. Unrelated medical conditions such as diabetes, hypertension, and collagen vascular diseases can affect the radiation tolerance of structures in the eye. Systemic chemotherapy or steroids can enhance radiation toxicity or contribute to additional symptoms.

The most sensitive structure in the eye is the lens, which is located directly behind the pupil. The germinal layer of the lens located at the equator is the layer most sensitive to radiation. These cells undergo mitotic division, elongate, lose their nuclei, and migrate posteriorly to the center of the lens. This posterior migration and proliferation of the lens's epithelial cells reduce lens clarity, causing a cataract, and often some degree of visual loss. A radiation cataract usually presents first as a posterior, central subcapsular opacification. The latency and frequency of lens opacities are a function of radiation therapy dose and fractionation.

In most human studies, total fractionated doses under 5 Gy have not produced visually significant lens opacities. Merriam and Focht[325] reported cataract formation with EBRT fractions of 1.5 Gy to 2 Gy, to a total dose of 12 Gy. When single-dose, total body irradiation was used, cataracts developed in 80% of survivors; the incidence decreased to 20% when fractionated EBRT was given to a total dose of 13 Gy.[325] Reduction of dose to the lens may be possible with customized lens shields, pencil-beam lead blocks, or more complex treatment planning with IMRT. Lens extraction for cataract development can correct the vision in an otherwise functioning eye following irradiation.

Other anterior structures in the globe include the cornea and conjunctiva. The conjunctiva is a mucous membrane of nonkeratinized squamous epithelium with goblet cells overlying a thin substantia propria.[326] It covers the inner surface of the eyelid and outer surface of the eye, extending to the peripheral cornea. The cornea is composed of nonkeratinized stratified squamous epithelium. Its outermost surface is composed of irregular microvilli made optically smooth by the precorneal tear film. The basal cells are attached to Bowman's layer, which is made up of randomly dispersed collagen fibrils that may become opacified by scar tissue. The stroma, which makes up 90% of the total corneal thickness, is composed of fibroblasts and collagen lamellae.

Acute effects of fractionated radiotherapy include injection and erythema of the conjunctiva with irritation that is usually self-limited. Fractionated doses of radiation to a total dose above 40 Gy to 50 Gy to the cornea can produce edema with punctate keratitis.[327] Management consists of aggressive lubrication, patching, and antibiotic drops. Recurrent corneal erosions may progress to ulceration and infection leading, to either opacification or perforation. Ulcerations of the cornea have been reported with fractionated radiation therapy to doses above 40 Gy.[207,328] Similarly, ulceration, telangiectasias, and keratinization can develop in the conjunctiva.

The eyelid skin is the thinnest in the body. The lids contain sebaceous, serous, and apocrine glands, which contribute to the tear film. There are puncta on the medial lid margins that form the opening to the nasolacrimal drainage system. Transient effects of eyelash loss and erythema occur at 30 Gy to 40 Gy with conventional fractionation, whereas permanent lash loss occurs at doses above 50 Gy.[167,171] Scarring and fibrosis can develop at doses above 50 Gy, which can result in ectropion or entropion of the lid as well as stenosis of the eyelid puncta.

There are several structures necessary for adequate tear film production, which include the lacrimal gland, goblet cells, meibomian glands, and accessory lacrimal glands. Dry eye syndrome can result from injury to any component of the tear film. Symptoms include burning, decreased vision, excessive tearing, and a foreign body sensation. Examination reveals corneal changes ranging from keratitis to corneal scarring and opacification. One report described 19% of patients who received doses less than or equal to 45 Gy in 25 fractions developing a dry eye syndrome compared with 100% for doses above or equal to 57 Gy in 30 fractions.[230] Severe keratitis sicca can lead to corneal ulceration and perforation of the globe. Prevention of lacrimal damage requires consideration of the location of the lacrimal gland when designing fields for radiation therapy delivery.[329]

The sclera covers the posterior 80% of the globe. It is largely avascular and consists of collagen fibrils, fibroblast, and ground substance. It is resistant to radiation and can withstand doses of more than 150 Gy that are delivered with plaque radiotherapy used to treat choroidal melanomas. Scleral thinning, necrosis, and ulceration are unusual complications of high doses of radiation therapy.[275,330]

The retina consists of an extensive network of neural, glial, and vascular elements. The blood supply to the outer layers of the retina is via the choriocapillaris. The inner retinal layers are supplied by the branches of the central retinal artery, of which the largest branches are the temporal and nasal arcades. Pathology involving the region within the temporal arcades is more visually significant than that occurring elsewhere. Radiation retinopathy is caused by occlusive microangiopathy manifest by cotton wool spots, microaneurysms, telangiectasias, hemorrhages, macular edema, exudates, neovascularization, vitreous hemorrhage, and pigment changes. Visual symptoms

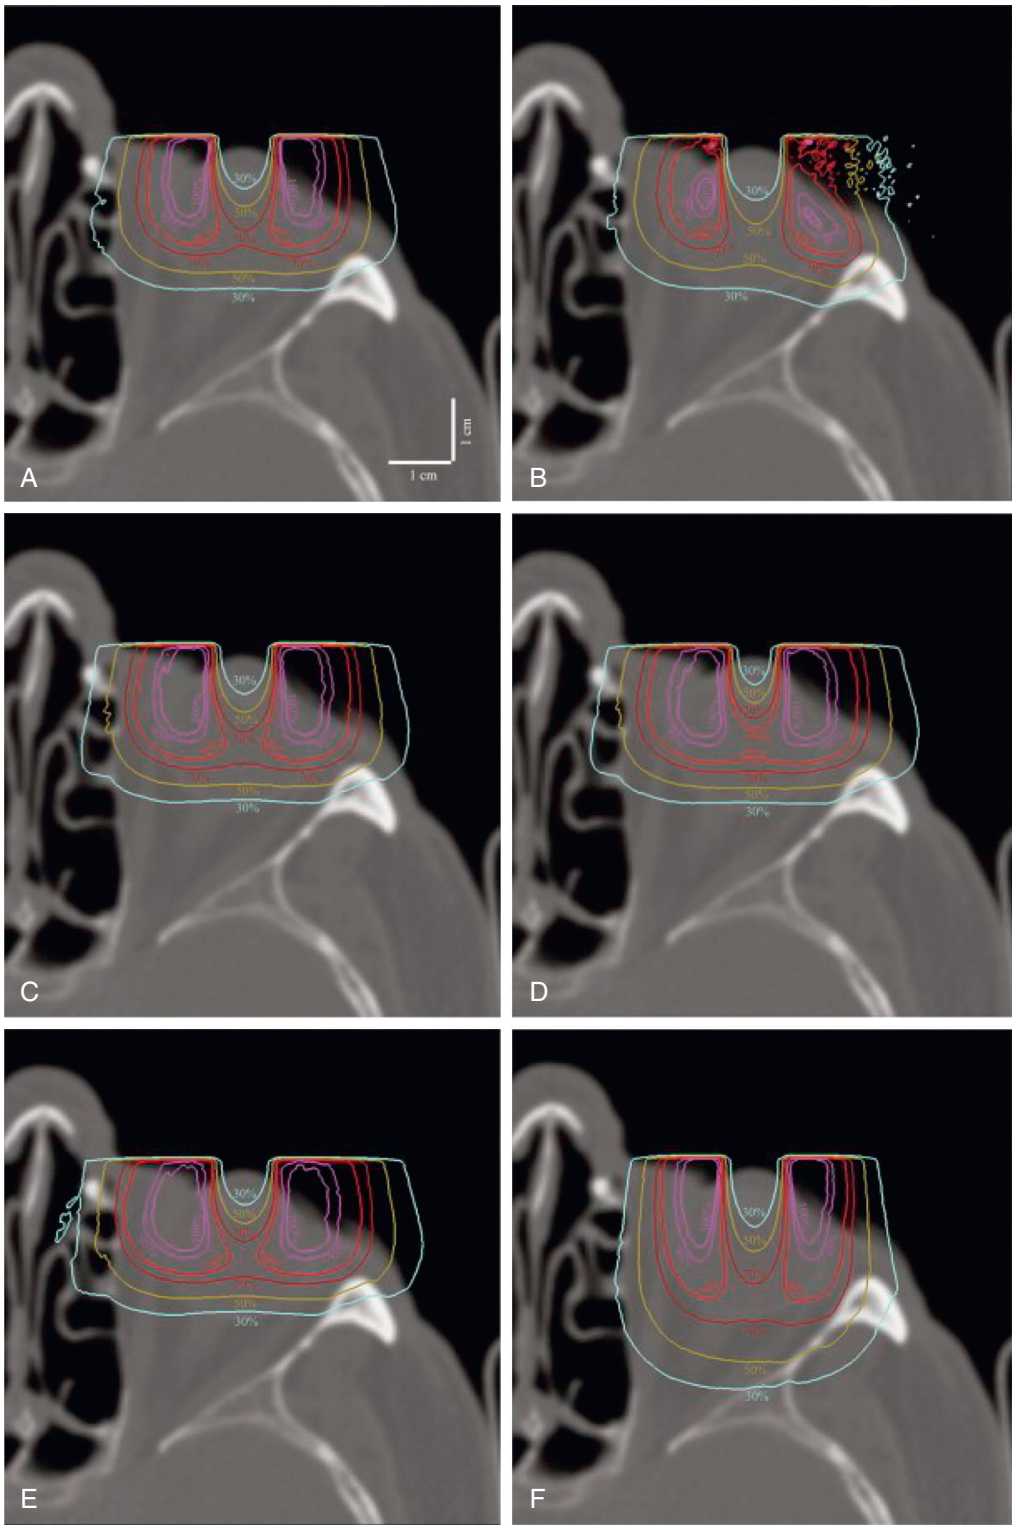

Figure 31-9 Hanging block dosimetry. Isodose lines at the isocenter slice for the following treatment setups: **A,** 6-MeV, hole diameter *(h)* = 3.0 cm, rod diameter *(r)* = 1.0 cm, with bolus; **B,** 6 MeV, *h* = 3.0 cm, *r* = 1.0 cm, no bolus; **C,** 6 MeV, *h* = 3.5 cm, *r* = 1.0 cm, with bolus; **D,** 6 MeV, *h* = 3.5 cm, *r* = 0.8 cm, with bolus; **E,** 6 MeV, *h* = 4.0 cm, *r* = 1.0 cm, with bolus; and **F,** 9 MeV, *h* = 3.0 cm, *r* = 1.0 cm, with bolus. All plotted cases have used the 15 × 15 cm^2 electron applicator. Inner to outer relative isodose lines correspond to 100%, 95%, 80%, 70%, 50%, and 30% of the maximum absorbed dose of each case.

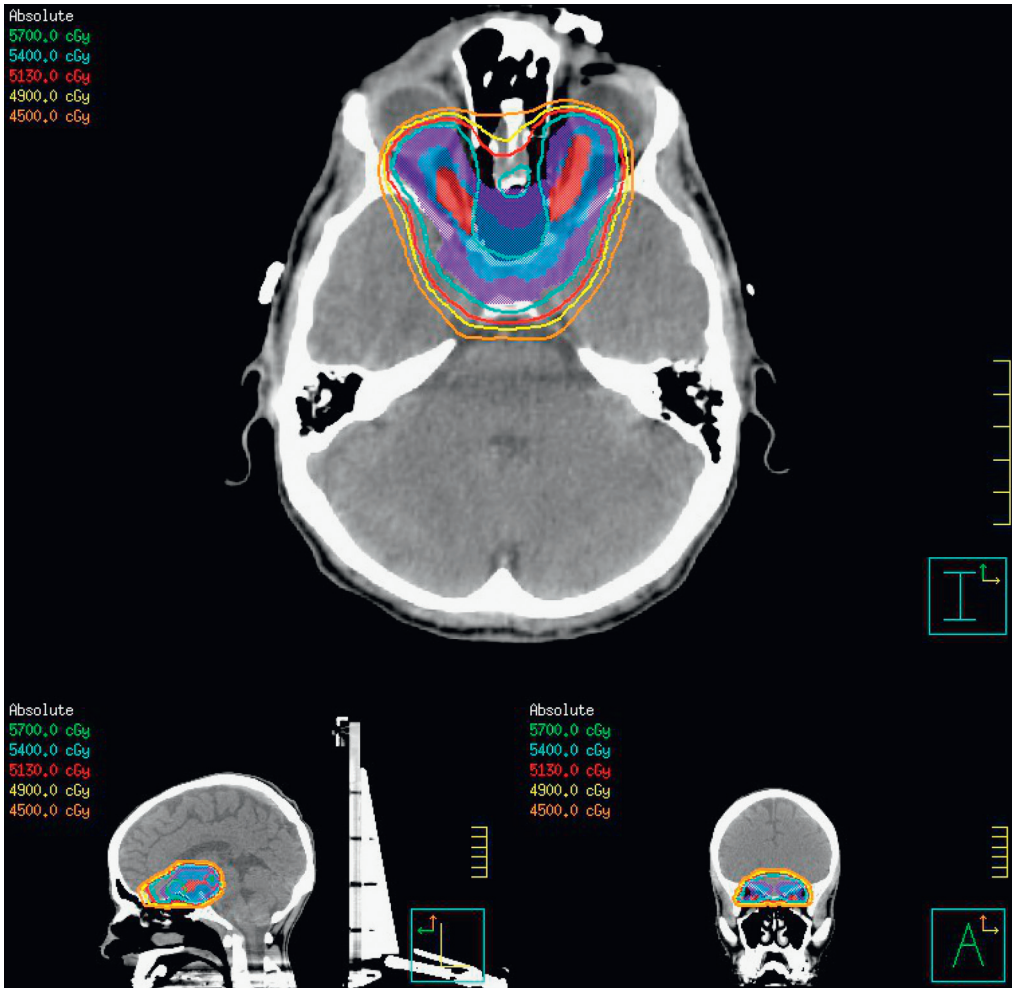

Figure 31-10 Treatment planning—Optic pathway glioma. Axial, sagittal and coronal noncontrasted CT slices of an IMRT radiotherapy plan for a patient with a chiasmal low grade glioma treated to a total dose of 54 Gy in two Gy fractions.

secondary to radiation retinopathy depend on the area of the retina that is affected. A history of diabetes, collagen vascular disease, hypertension, and treatment with chemotherapy predisposes patients to radiation-induced injury.[230] In one report, radiation retinopathy was not observed at doses below 45 Gy in 25 fractions but increased steadily above this dose.[230] Patients also seemed to be at increased risk if they were treated with doses per fraction greater than or equal to 1.9 Gy.[230] Although the estimated tolerance dose with a 5% risk at 5 years ($TD_{5/5}$) is 45 Gy and the $TD_{50/5}$ is 65 Gy, the threshold dose for the retina is thought to be between 30 Gy and 35 Gy.[211] A meta-analysis of radiotherapy as it relates to retinopathy in macular degeneration found no damage in patients treated up to 24 Gy although it appears this risk rises sharply after 45 Gy to 50 Gy.[331]

Optic nerve injury is secondary to ischemia and generally presents with painless monocular loss of vision. Damage begins with perivascular lymphocyte cuffing, loss of endothelial cells, and hyalinization, with fibrosis, thrombosis, and infarction of neural tissue. Fractionation plays a key role in modulating the development of optic nerve injury. Of patients who were treated to a total dose of 45 Gy to 50 Gy and received a daily fraction size of more than 2.5 Gy, 18% developed visually significant changes, whereas those patients who received fractions below 2.5 Gy did not develop optic neuropathy.[332] Stereotactic radiosurgery that delivers large fraction sizes can cause optic neuropathy with single doses of 8 Gy, although tiny volumes to high doses have been given without toxicity.[333] With conventional fractionation, the $TD_{5/5}$ of the optic nerve is considered to be 60 Gy.[230]

CONCLUSIONS AND FUTURE POSSIBILITIES

The COMS has made a significant contribution to the understanding of and treatment of choroidal melanoma, which is the most common primary intraocular malignant tumor. Future investigations may shed light on the role of charged particle therapy and optimize patient selection for additional therapy. By understanding and incorporating ocular anatomy and physiology with more directed treatment techniques, a better therapeutic ratio may be expected with the use of irradiation for patients with ocular pathology. Finally, advances in molecular biology and immunohistochemistry may lead to better insight into disease processes and patient selection for treatment.

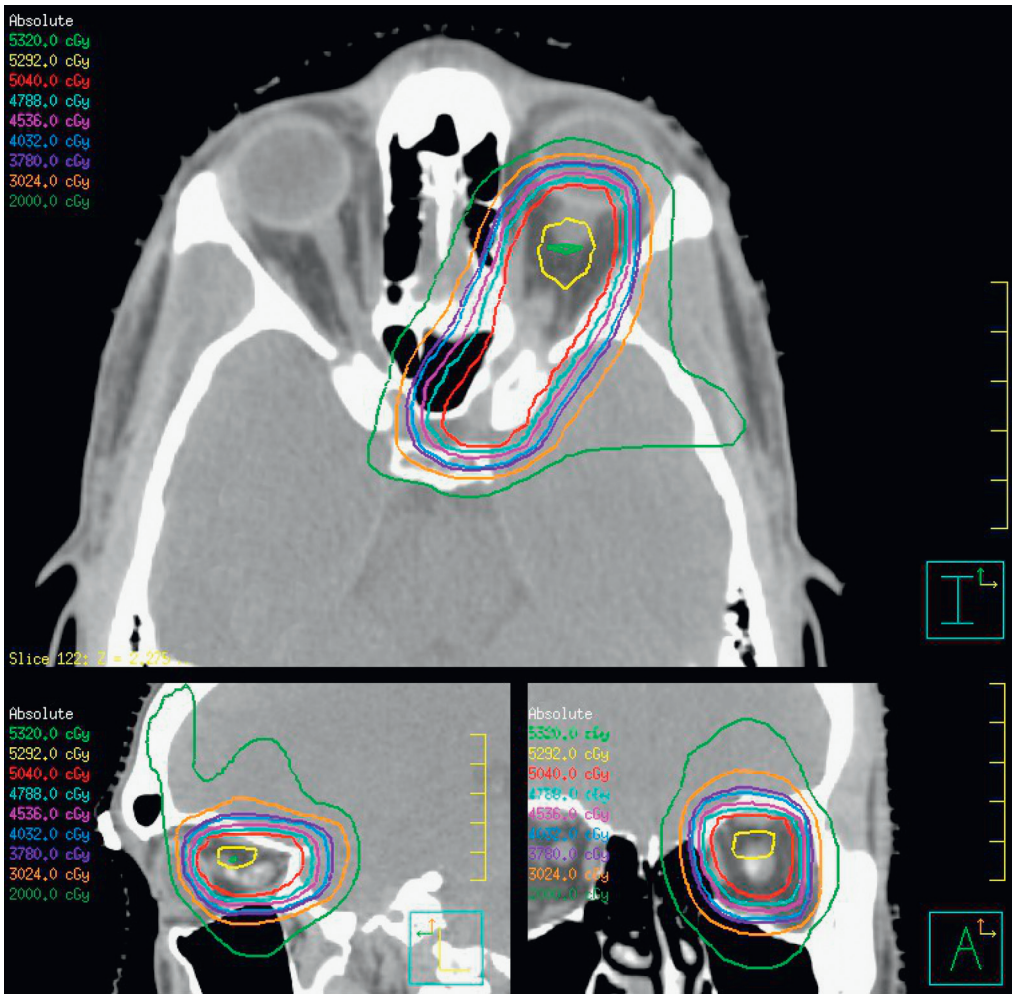

Figure 31-11 Treatment planning—optic nerve sheath meningioma. Axial, sagittal and coronal noncontrasted CT slices of a three-dimensional conformal radiotherapy plan treated with a fractionated stereotactic setup with reduced margins to a total dose of 50.4 Gy in 1.8 Gy fractions.

Overview

Robert L. Foote and K. Kian Ang

Although representing about 4% of cancers, a variety of neoplasms with diverging natural histories arise in the relatively small body region of the head and neck. Essential basic physiologic functions that are critical for one's expression, respiration, nutrition, and social interactions are all located within the head and neck region, including one's personal appearance. Depending on the site, size, and pattern of spread, head and neck cancers can cause various degrees of structural deformities and functional handicaps, compromising comfort and social integration. Treatments used in the management of head and neck tumors can induce additional mutilations and malfunctions, worsening the quality of life. Consequently, optimizing outcomes in terms of survival, tumor control, function, and quality of life is challenging.

Knowledge of the basic principles of oncology and expertise in patient assessment and in individual specialties are essential for the optimal staging workup of patients and for appropriate treatment selection. Integrated interdisciplinary collaborations among surgical, radiation, medical, and dental oncologists as well as interactions among oncologists and pathologists, radiologists, reconstructive surgeons, physical medicine and rehabilitation physicians, psychiatrists, nurses, speech and swallowing therapists, dieticians, social workers, chaplains, and other health and spiritual care personnel are essential for optimal management and rehabilitation of patients with head and neck cancer. Well-functioning, integrated, and coordinated care is essential to yield the highest complication-free cure rate with maximal functional and cosmetic outcome. Close collaborations among radiation oncologists, dosimetrists, medical physicists, radiotherapists, and oncology nurses are important to deliver quality radiotherapy.

Long-term investment in cancer research has come to fruition for certain cancers. The mortality rate for most cancers in the United States increased for decades, but since 1975 the rate has decreased.[1] Many advances have been achieved in the understanding of the biology, natural history, and treatment of head and neck cancers.

This summary highlights a few interesting and evolving concepts and recent findings of clinical interest in the carcinogenesis, biology, and treatment of head and neck cancers. Site-specific issues are discussed in the subsequent chapters.

MOLECULAR BIOLOGY AND ECOGENETICS

The molecular tumor progression model was initially proposed by Fearon and Vogelstein.[2] This model states that tumors progress by activation of oncogenes and inactivation of tumor suppressor genes (TSGs), with each process producing a growth advantage for a clonal population of cells, and that specific genetic events usually occur in a distinct order (i.e., multistep carcinogenesis) that is not necessarily the same for each tumor.

For head and neck carcinomas, Califano et al[3] described a preliminary tumor progression model using allelic loss or imbalance as a molecular marker for oncogene amplification TSG inactivation. They identified *CDKN2A* (formerly designated *p16*; 9p21), *TP53* (17p), and *RB1* (13q) as candidate TSGs, and *CCND1* (cyclin D1 gene; 11q13) as a candidate proto-oncogene. The results of this work support the initial observations of the colorectal molecular progression model in that clonal genetic changes occur early in the histopathologic continuum of tumor progression. About one third of histopathologically benign squamous hyperplasias contain a clonal population of cells with shared genetic anomalies characterizing head and neck cancers. Identification of such early events facilitates discovery of genetic alterations associated with further transformation and aggressive clinical behavior. Genetic mutations of the PI3K/Akt/mTOR pathway have been reported in most head and neck squamous cell carcinomas (HNSCCs).[4] Mutation rates are low in human papillomavirus (HPV)-positive squamous cell carcinomas of the head and neck when compared to HPV-negative cancers. PIK3CA is the most commonly mutated oncogene pathway in HPV-positive cancers.[5] With further validation, this knowledge will contribute greatly to the development of screening strategies, focusing on previous steps of the estimated 10 or more genetic alterations required to generate an invasive tumor phenotype and to the conception of early pharmacologic or genetic therapy approaches.

Tobacco and alcohol exposure has long been recognized as the dominant risk factor in head and neck carcinogenesis. Although the use of these substances was estimated to account for approximately three fourths of oral and pharyngeal carcinomas,[6] neoplasms develop in only a small fraction of exposed individuals. This intriguing information raised the notion of the contribution of genetic susceptibility or predisposition and other cofactors (e.g., viral infection) to carcinogenesis. The potential pathways are thought to include genetic polymorphism influencing environmental carcinogen absorption and detoxification, individual sensitivity to carcinogen-induced genotypic alterations, and so on. These ideas can now be tested properly because of progress in molecular biology concepts and assay methodology. The ability to identify smokers at high risk for the development of cancer, for example, has important practical clinical implications, such as in selecting individuals for more aggressive screening programs or for enrollment in intensive chemoprevention trials (discussed later).

RECEPTOR TYROSINE KINASES

Intensive research efforts sparked by the characterization of epidermal growth factor receptor (EGFR, also known as HER1 or ERBB1) in the late 1970s generated insights into the structures and functions of receptor tyrosine kinases (RTKs) and their roles in the ligand-mediated signaling pathways governing proliferation, differentiation, survival, and other key cellular processes.

More than two decades after the initial characterization of the EGFR, it is known that receptor tyrosine kinases are highly related in structure and domain arrangements despite their unique biologic roles. This class of receptors comprises 58 members distributed among 20 subfamilies (reviewed by Gschwind et al[7]). EGFR-mediated signaling and its deregulation in pathogenesis and as the target of therapeutic intervention of human tumors have also been reviewed.[8,9] Its value as a prognostic-predictive biomarker and as a target of therapeutic intervention in head and neck carcinoma is addressed in the section on "Biomarkers and Molecular Targeting."

Deregulation of the *RET* gene-encoded transmembrane receptor tyrosine kinase plays an important role in the pathogenesis of papillary and medullary thyroid cancer (reviewed by Santoro et al[10]). The *RET* gene is located in the pericentromeric region of the short arm of chromosome 10. Alternative splicing of the RET product results in two protein isoforms: RET9 and RET51. RET shows that a single gene can induce different types of cancer, depending on the mutation. The genetic characteristics of papillary thyroid carcinoma (PTC), the most common thyroid neoplasm, are chromosomal inversions or translocations leading to several types of combinations of intracellular kinase-coding RET domain with heterologous genes, producing the *RET*/PTC chimeric oncogenes. In vitro and in vivo irradiation was found to induce the formation of a RET/PTC1 rearrangement,[11] and RET/PTC rearrangements have been found in more than 60% of post-Chernobyl accident papillary thyroid carcinomas.[12] These findings contribute to the understanding of the pathogenesis of radiation-induced thyroid carcinoma.

In contrast to the rearrangement observed in papillary thyroid carcinoma, germline point mutations in *RET* cause three types of related dominantly inherited cancer syndromes: multiple endocrine neoplasia type 2A (MEN2A), MEN2B, and familial medullary thyroid carcinoma (FMTC).[13-15] Most RET mutations in MEN2A and FMTC affect cysteine in the extracellular cysteine-rich domain (i.e., codon 634 [particularly, C634R] in MEN2A) or are evenly distributed among various cysteines in FMTC. Mutations in the kinase domain have also been observed. The most common mutation in MEN2B is M918T in the kinase domain. Somatic mutations of V804, M918, and E768 occur in about one half of sporadic medullary thyroid carcinomas (MTCs).[13-16] Functionally, RET cysteine mutants form covalent dimers leading to constitutive kinase activity, whereas the M918T mutation causes a change in the substrate specificity.[17]

VIRAL CAUSES

Nasopharyngeal carcinoma (NPC) has been an excellent model for studying viral causes of human cancer. Although the association between Epstein-Barr virus (EBV) and NPC has been recognized for about four decades, significant progress in this field has been made only more recently. For example, the EBV genome was characterized (reviewed by Liebowitz[18]) and found to consist of a linear, 172-kb, double-stranded DNA having five unique sequences, separated by four internal repeats along with two terminal repeats. The DNA circularizes by homologous recombination at random locations within terminal repeats in the nucleus of infected cells. The length of terminal repeat is therefore specific for each infected cell, and this is the basis for clonality assay, which may be useful in determining the putative primary tumor in patients presenting with nodal metastasis from an unknown source. The genome encodes several families of proteins, such as early antigens (EAs), EB nuclear antigens (EBNAs), and latency membrane proteins (LMPs). Many of these proteins control viral behavior and affect cell proliferation regulatory mechanisms, and they are thought to play a role in transformation and carcinogenesis and to influence the tumor response to therapy. EBNA-1 regulates viral genome replication during cell division and was found to induce growth and dedifferentiation of an EBV(–) NPC cell line.[19] LMP-1 seems to alter growth of epithelial cells, induce well-differentiated squamous carcinomas from human epithelial cell-line transfectants, and is associated with BCL2 expression in tumors.[20,21]

More work has been done on the molecular genetics of NPC. Many NPCs were found to have deletions of the short arm or some regions of the short arm of chromosomes 3 and 9, suggesting the possibility of the existence of TSGs in these regions.[22,23] For example, some studies[24,25] revealed that the combined frequency for chromosome 3p and 9p (bearing *CDKN2A* and *RASSF1A*) losses in the normal nasopharyngeal epithelium among southern Chinese individuals in Hong Kong, a population at high risk for NPC, was 82.6%, compared with 20% in the low-risk populations. In contrast, latent EBV infection was detected only in high-grade nasopharyngeal dysplasia or NPC. Consequently, it was postulated that the abnormal genetic changes in chromosomes 3p and 9p predispose nasopharyngeal cells to sustain latent EBV infection, and this combination promotes a cascade of events leading to malignancy. One study revealed that in patients with nonmetastatic NPC, the plasma level of EBV DNA, particularly when assayed after completion of therapy, is a robust prognostic biomarker (see section "Biomarkers and Molecular Targeting").

The causal relationship between HPVs and some human neoplasms has been established, particularly for carcinoma of the uterine cervix. Most cervical cancers contain integrated HPV DNA, most commonly of high-risk types HPV-16 and HPV-18.[26] Cell culture studies clearly demonstrated that the high-risk HPVs can transform and immortalize epithelial cells from the cervix, foreskin, and oral cavity.[27-29] In contrast, HPV-6 and HPV-11, associated more often with benign lesions, do not possess this capability.[30,31] Expression of E6 and E7 open reading frames of the HPV-16 or HPV-18 genome is sufficient for immortalization.[32,33]

The potential role of HPV in head and neck carcinogenesis has attracted attention (reviewed by Blitzer[34]). Carcinomas of the tonsil, oral tongue, and floor of the mouth were found to have a relatively high prevalence of HPV DNA.[35-37] A high proportion of verrucous carcinomas, rare locally invasive carcinomas with papillomatous morphology, are associated with HPV.[38,39] Verrucous carcinomas of the larynx predominantly contain HPV-6, HPV-11, HPV-16, or related DNA.[40] The evidence for the role of HPVs in carcinogenesis of tonsillar carcinomas is increasing because these tumors contain HPV DNA in most of the cells and express readily detectable levels of HPV RNA.[41] In a series of 253 patients, Gillison et al[42] detected HPV in 25% of tumors, with HPV-16 present in 90% of the positive neoplasms. HPV presence was most common in oropharyngeal carcinoma, occurring in individuals with no history of smoking and alcohol consumption, and having a basaloid subtype without *TP53* mutation. Laboratory data showing that transcriptionally active, integrated HPV-16 DNA persisted in an oral carcinoma cell line having features indistinguishable from those of the primary tumor[43] provide strong evidence for an active role of HPV in carcinogenesis.

Ang et al[44] reported that tumor HPV status is a strong and independent prognostic factor for survival among patients with oropharyngeal cancer. They performed a retrospective analysis of the association between tumor HPV status and survival among patients with stage III or IV oropharyngeal squamous cell carcinoma who were enrolled in a randomized trial comparing accelerated fractionation radiotherapy with standard fractionation radiotherapy, each combined with cisplatin (Radiation Therapy Oncology Group [RTOG] 0129). Proportional hazards models were used to compare the risk of death among patients with HPV-positive cancer and those with HPV-negative cancer. With a median follow-up of 4.8 years, patients with HPV-positive tumors had significantly better 3-year rates of overall survival (OS). After adjustment for age, race, tumor and nodal stage, tobacco exposure, and treatment assignment, patients with HPV-positive tumors had a 58% reduction in the risk of death. These results have been confirmed by others.[45]

Understanding HPV infection and the mechanisms of HPV-induced malignant conversion is essential for developing strategies for preventing HPV infection and virus-associated carcinogenesis, such as blocking expression of its E6 and E7 proteins.

TREATMENT OF RELATIVELY LOCALLY ADVANCED CANCERS

Refinement in surgical resection and reconstructive techniques and advances in radiotherapy planning and delivery technology have produced good outcomes for most patients with early-stage head and neck cancers. Unfortunately, for more locally advanced cancers, the current standard therapy consisting of surgical resection and preoperative or postoperative irradiation achieves poor results in terms of disease control, preservation of organ function, or both. Consequently, there has been a continuous search for better treatment approaches. This quest plus the simplicity of clinical evaluation and a well-characterized pattern of relapse make head and neck carcinomas ideal models for testing the relative efficacy of novel therapy concepts and modalities. For example, most clinical radiobiologic investigations have been conducted in patients with head and neck cancers.

Clinical Radiobiology: Fractionation Schedules

Radiobiologic concepts derived from more than two decades of integrated laboratory and clinical investigations led to the conception of two classes of new fractionation schedules for the treatment of head and neck cancers. These altered fractionation regimens are referred to as *hyperfractionation* and *accelerated fractionation schedules*. Hyperfractionation exploits the difference in fractionation sensitivity between tumors and normal tissues manifesting late morbidity. In contrast, accelerated fractionation attempts to reduce tumor proliferation as a major cause of radiotherapy failure. Although there are many permutations in accelerating radiation treatment, the existing schedules can be conceptually grouped into two categories: pure and hybrid accelerated fractionation regimens, depicting the absence and presence of concurrent changes in other fractionation parameters, respectively.

These radiobiologically sound fractionation regimens have been extensively tested in patients with intermediate and more locally advanced head and neck carcinomas, mainly of the oropharynx. This line of clinical research has concluded. Results of the completed phase III clinical trials have been reviewed,[46,47] and the results and conclusions are briefly reviewed here.

Hyperfractionation

The clinical trial results, most notably those of the European Organization for Research on Treatment of Cancer (EORTC), show a moderate (10% to 15%) but consistent improvement in the local control of T2 to T3, N0 to N1 oropharyngeal carcinomas.[48] The incidence of late toxicity with a 10% to 15% total dose increment delivered twice daily in smaller than standard fraction sizes was within the range observed with conventional fractionation schedules, although none of the studies was designed to test the equivalency of late morbidity.

Accelerated Fractionation

The trial results indicate that mucosal toxicity limits the magnitude of overall time reduction to at most 2 weeks without decreasing the total dose. With *pure accelerated fractionation* (no or minimal change in the total dose and fraction size relative to a conventional schedule), delivery of 10 fractions per week (Vancouver trial[49]) induced severe acute mucositis. Administration of continuous daily irradiation without a weekend break (CAIR trial[50]) caused severe late effects, which were thought to be consequential.

With *hybrid accelerated fractionation*, delivery of three fractions of 1.6 Gy per day, separated by an interval of approximately 6 hours, without reduction of the total dose (EORTC trial[51]) increased late complications such as soft-tissue fibrosis, peripheral neuropathy, and myelopathy. Based on the repair kinetic data obtained from experimental spinal cord and skin models and from human skin, these late morbidities can be ascribed in part to the occurrence of compounding incomplete cellular repair of sublethal injury. A 12-Gy total dose reduction (as in continuous hyperfractionated accelerated radiation therapy [CHART][52]) seemed more than sufficient to offset the compounding incomplete repair associated with the delivery of three fractions per day and thereby resulted in lesser severity of a number of late complications, including skin telangiectasia, mucosal ulceration, and laryngeal edema. However, CHART did not improve tumor control in patients with a variety of locally advanced head and neck carcinomas. This study showed that it is possible to substitute radiation dose by overall time reduction and thereby provide indirect evidence for the importance of tumor clonogenic proliferation in determining local cure by irradiation. Theoretically, this regimen should benefit a subset of patients with rapidly proliferating tumors. Based on subset analyses, the investigators postulated that this subgroup might be those with T3 to T4, well-differentiated carcinomas of the larynx. This study warrants further analysis.

A pure accelerated fractionation regimen delivering six fractions per week (Danish trial[53]) and a hybrid variant by concomitant boost (RTOG trial[54]) yielded improved local control rates for locally advanced head and neck cancers without increasing the morbidity. The Danish trial (DAHANCA 7) randomized a total of 1485 patients eligible for primary irradiation alone to receive 66 Gy to 68 Gy in 33 to 34 fractions given in 5 or 6 fractions per week. The compliance rate to both regimens was high. The incidence of acute severe mucositis and dysphagia was higher in patients receiving 6 fractions per week, but there was no difference in the incidence of late edema or fibrosis. The 5-year actuarial locoregional control rates in 1476 evaluable patients were 70% and 60% for accelerated and conventional regimens, respectively ($p = 0.0005$). The benefit for acceleration resulted primarily from improvement in primary tumor control.

The RTOG randomized trial 90-03 compared the relative efficacy of three altered fractionation regimens with the standard dose of 70 Gy in 35 fractions over 7 weeks.[54] The test

radiation schedules were hyperfractionation (81.6 Gy in 68 fractions over 7 weeks, with 1.2 Gy given twice daily), split-course accelerated fractionation (67.2 Gy in 42 fractions of 1.6 Gy twice daily over 6 weeks, including a 2-week break), and a concomitant boost regimen (72 Gy in 42 fractions over 6 weeks, with 1.8 Gy daily for the first 3.6 weeks and 1.8 Gy [large field] plus 1.5 Gy [boost field], 6 hours apart, for the last 2.4 weeks). Analysis of results for the 1073 patients enrolled showed that the concomitant boost and hyperfractionation regimens yielded significantly higher locoregional control than standard fractionation. The split-course accelerated regimen did not improve locoregional control rates over the standard fractionation regimen. The acute mucosal reactions were more severe in patients receiving altered fractionation regimens, but there was no difference in the complication rates at 6, 12, 18, and 24 months after therapy. With long-term follow up (5 years), only patients treated with hyperfractionation had improved locoregional tumor control and improved OS, without an increase in late toxicity, when compared to standard fractionation.[55]

Conclusions

More than two decades of intensive clinical investigations of altered fractionation schedules have produced conceptually interesting and clinically important findings. Trials addressing hyperfractionation show that this biologically sound regimen yields a moderate but consistent improvement in locoregional control and OS of moderate or more locally advanced HNSCC, with no observed increase in late toxicity.

The results of accelerated fractionation indicate that acute mucosal toxicity limits the magnitude of overall time reduction to at most 2 weeks and that late complications resulting from compounding incomplete repair compromise delivery of three fractions of 1.6 Gy per day without a reduction in total dose. Acceleration by concomitant boost also appears to be associated with a higher rate of late complications. However, acceleration of radiotherapy by delivering six fractions per week yielded significantly improved local tumor control rates relative to standard fractionation without increasing the morbidity in the treatment of predominantly locally advanced carcinomas.

All in all, well-organized clinical trials enrolling more than 6000 patients to test the relative efficacy of various altered fractionation regimens have generated important data. In terms of radiobiological findings, the trial results demonstrated the existence of differential fractionation sensitivity between head and neck carcinomas and late-responding normal tissues and firm evidence that tumor clonogenic proliferation is a major obstacle to curing advanced head and neck cancers with fractionated radiotherapy. Clinically, the results of these trials call for changing radiotherapy practice for the treatment of moderate or advanced head and neck carcinomas. Because of the magnitude of therapeutic gain achieved with six fractions per week, economic and logistic considerations determine the choice of the new standard treatment. For reasons of cost, resource utilization, and patient convenience, many centers have adopted the relatively simple six-fractions-per-week regimen as the standard radiotherapy for patients with intermediate-stage head and neck carcinomas and those with locally advanced cancers either not eligible for protocol studies (having contraindications to chemotherapy or biologically targeted agents) or choosing to receive irradiation alone.

The data open the challenge for conceiving creative approaches to integrate altered fractionation regimens with cytotoxic or biologic agents to further improve the therapeutic outcome. Several concepts have been tested or are undergoing preclinical and clinical testing.

Combination of Radiation with Chemotherapy

Sequential versus Concurrent Radiation and Chemotherapy

Most combined irradiation-chemotherapy regimens tested have evolved empirically by administering drugs found to have some activity against tumors of interest in a dose and time sequence known to be tolerated in a single-modality therapy setting. Meta-analyses of available data of randomized trials in head and neck cancer undertaken a few years ago showed that despite a high initial response rate, multiagent chemotherapy given before radiation treatment (neoadjuvant setting) has a small impact on the locoregional control and survival rates.[56] Concurrent irradiation and chemotherapy yielded an almost 10% higher survival rate relative to irradiation alone.[57] Unfortunately, the complication rates of combined regimens are also higher than those of radiotherapy only.[57]

The Meta-Analysis of Chemotherapy in Head and Neck Cancer (MACH-NC) Collaborative Group undertook an extensive meta-analysis. The project investigators obtained updated patient data of 93 randomized trials enrolling a total of 17,346 patients. This study revealed tremendous heterogeneity in eligibility criteria and results between studies exploring chemotherapy for patients with nonmetastatic head and neck carcinoma, which made a simple conclusion on the role of chemotherapy difficult. Nonetheless, the analysis revealed a small statistically significant benefit with the addition of chemotherapy to locoregional therapy, which consists of a 4.5% improvement in survival at 5 years. The benefit primarily reflected the favorable effect of concurrent irradiation and chemotherapy, resulting in a 6.5% overall improvement in the survival rate. The study authors conclude that the benefit of concomitant chemotherapy is confirmed and is greater than the benefit of induction chemotherapy. They suggest that future clinical trials should compare concurrent chemotherapy with induction and concurrent chemotherapy to see if the reduction in distant metastasis seen with induction chemotherapy will further improve survival and to determine if induction chemotherapy adversely affects the compliance to concomitant chemoradiation, the most important component of sequential therapy.[58] Unfortunately, to date, in the patient populations studied and with the cytotoxic agents administered in three Phase III clinical trials, there has been no improvement in survival when induction chemotherapy was added to concurrent chemoradiotherapy.[59-61]

Results of many published Phase III trials[62-68] confirm the finding of meta-analyses that chemotherapy given concurrently with irradiation yields better locoregional control and survival rates than irradiation alone in patients with locally advanced HNSCC. Two trials have also shown the benefit of concurrent irradiation and chemotherapy given in the postoperative adjuvant setting.[69,70]

The combined irradiation-chemotherapy regimen most extensively tested is the combination of conventionally fractionated irradiation (70 Gy in 35 fractions over 7 weeks) with cisplatin. In previous trials, cisplatin was given in a dose of 100 mg/m^2, administered during weeks 1, 4, and 7 of radiotherapy (approximately one third of patients were not able to tolerate the last dose). The systemic and mucosal toxicities of such a high-dose, intermittent cisplatin regimen are rather severe. There are four trials showing locoregional control or survival benefit of alternative cisplatin regimens, such as five doses of 20 mg/m^2 over 5 consecutive days or four doses of 25 mg/m^2 over 4 sequential days during weeks 1, 4, and 7[71,72]; weekly fixed doses of 50 mg during the 7- to 9-week course of postoperative radiotherapy[73]; or 6 mg/m^2/day for 5 days each week during the 7-week course of radiotherapy.[68]

Unfortunately, recording and reporting of the late morbidity of combined irradiation and chemotherapy have not been sufficiently consistent and systematic.[74] A thorough report of the long-term results of a French cooperative group (GORTEC) trial reveals that the late complication rate of the combination of irradiation with concurrent carboplatin and fluorouracil was significantly higher than that of irradiation alone.[65] Because of the lack of adequate reporting, controversy still exists about whether the late toxicity of the combination of standard irradiation with 100 mg/m^2 of cisplatin given every 3 weeks may be higher than irradiation alone. It is hoped that longer and more complete follow-up data on late morbidities will be reported in the future. Despite this uncertainty, many oncologists consider 100 mg/m^2 of cisplatin given during weeks 1, 4, and 7 of conventionally fractionated irradiation as the standard of care for patients with locally advanced head and neck carcinomas who are found to be medically fit to receive chemotherapy. The majority of current ECOG and RTOG clinical trials are using 40 mg/m^2 cisplatin given weekly during radiotherapy.

Principles for Optimizing Combined Radiotherapy and Systemic Therapy

A clear understanding of the therapy objective is essential for designing a logical combined-therapy regimen. The purpose of combining irradiation and systemic therapy in the treatment of neoplastic diseases can be to eliminate hematogenous micrometastases that have occurred before initiation of locoregional therapy or to improve the probability of eradicating primary tumors and involved regional nodes. Depending on the pattern of failure, one or both objectives may be desirable in given clinical settings. The primary objective determines the choice of the agents and the timing of drug administration relative to irradiation. If the main aim is to reduce the probability of metastatic relapse, it is logical to select the least toxic agents with proven antitumor activity and administer irradiation and systemic therapy sequentially, rather than concurrently, to minimize direct drug-irradiation interactions that may increase normal tissue toxicity within the radiation treatment volumes. If the major purpose is to increase local tumor control, it is logical to select drugs based on mechanisms of action and administer systemic therapy concurrently with irradiation to maximize drug-radiation interactions. In the latter scenario, therapeutic benefit occurs only when the combined therapy enhances tumor response more than it increases normal-tissue toxicity.

Analysis of the data from the randomized trial RTOG 90-03 on altered fractionations for locally advanced head and neck carcinomas enrolling more than 1000 patients, 60% of whom had stage IV disease, revealed that locoregional relapse is the predominant pattern of failure. Overall, the actuarial locoregional tumor recurrence rate was close to 50%, compared with less than 20% for distant metastasis.[54] Consequently, for the time being, effort should preferentially focus on developing combined therapy aiming at improving locoregional control for patients with locally advanced HNSCC, especially in patients with a more than a 10-pack a year smoking history, HPV-negative cancer, or an oral cavity, hypopharynx, or larynx primary cancer. The finding that concurrent irradiation and systemic therapy improved outcome but that sequential combined therapy did not improve outcome is consistent with this first principle. Such confirmation should be taken into account in the design of future trials.

Despite three decades of clinical research, many scientific questions related to combinations of irradiation and chemotherapy are still not answered. Newer cytotoxic agents with higher efficacy are needed. Factors to be taken into account in selecting agents for combination with irradiation include mechanisms of drug-radiation interaction, pharmacodynamic characteristics, and clinical activity in inducing tumor response in a single-modality therapy setting. A large number of laboratory studies have been undertaken to optimize the combination of irradiation with chemotherapy, particularly using newer cytotoxic and biologic agents such as taxanes, inhibitors of growth factor receptor signaling pathways, and so on.

HIGH-PRECISION RADIOTHERAPY

Advances in computerized radiotherapy planning and delivery technology offered the possibility of conforming irradiation to an irregular tumor target volume (i.e., conformal radiotherapy).[75] It is feasible to reduce the radiation dose to more of the critical normal tissues surrounding the tumor without compromising dose delivery to the intended target volume, resulting in a reduction in morbidity. Reduced toxicity permits escalation of the radiation dose or combining of irradiation with intensive chemotherapy, each of which has the prospect of improving HNSCC control. Basic expertise in anatomy, imaging, and patterns of tumor spread are vital for clinical application of precision radiotherapy.

Precision radiotherapy can be accomplished by the use of an array of x-ray beams individually shaped to conform to the projection of the target, which is referred to as three-dimensional conformal radiation therapy (3DCRT). Technology is also available to modify the intensity of the beams across the irradiated field as an added degree of freedom to enhance the capability of conforming dose distributions in three dimensions. This irradiation technique is called *intensity-modulated radiation therapy* (IMRT). Proton beams offer an even higher magnitude of normal tissue sparing, which is desirable for the treatment of head and neck tumors. Carbon ion beams may offer enhanced normal tissue sparing compared to proton beams, with the added benefit of being biologically more effective, particularly for malignant tumors considered to be resistant to photon and proton irradiation (i.e., hypoxic tumors, inoperable melanoma and salivary gland cancers).

The roles of 3DCRT and, particularly, IMRT in reducing morbidity and perhaps improving the control of squamous cell carcinoma through radiation dose escalation are being tested in a number of medical centers. Results already reveal that these modalities are effective in sparing the parotid glands from receiving a high radiation dose and, thereby, they diminish radiation-induced permanent xerostomia in selected patients.[76-79] Improved OS has also been reported with the use of IMRT.[80]

Single-institution studies testing the role of IMRT in the management of NPC and oropharyngeal cancers have yielded exciting results. In patients with NPC, IMRT was given alone or, for locally advanced stages, in combination with chemotherapy consisting of concurrent cisplatin and adjuvant cisplatin plus 5-fluorouracil.[81] In a series of 67 patients with a median follow-up of 31 months, the 4-year estimates of local progression-free, locoregional progression-free, distant metastasis-free, and OS rates were 98%, 97%, 66%, and 88%, respectively. The worst acute toxicity was grades 1 to 2 in 51 patients (76%), grade 3 in 15 patients (22%), and grade 4 in 1 patient (2%). The worst late morbidity was grade 1 in 20 patients (30%), grade 2 in 15 patients (22%), grade 3 in 7 patients (10%), and grade 4 in 1 patient (2%). Xerostomia was less pronounced than after 3DCRT and decreased with time. At 3 months after IMRT, 8% of patients had no dry mouth, 28% had grade 1 xerostomia, and 64% had grade 2 xerostomia. Of the 41 patients evaluated at 2 years, 66% had no dry mouth and 32% had grade 1 xerostomia, and only 1 patient had grade 2 xerostomia.

In a series of 74 patients with oropharyngeal carcinoma reported by Chao et al,[82] 14 received IMRT alone, 17 had IMRT combined with cisplatin-based chemotherapy, and 43 underwent surgery followed by postoperative IMRT. With a median follow-up of 33 months, the 4-year estimates of locoregional control, distant metastasis-free, disease-free survival (DFS), and OS rates were 87%, 90%, 81%, and 87%, respectively. Grades 1 and 2 cases of late xerostomia were reported for 32 and 9 patients, respectively. Late skin toxicity occurred in three patients (two had grade 1 toxicity, and one had grade 2 toxicity), mucositis in three patients (all had grade 1 toxicity), and trismus in three patients.

Inspired by encouraging single-institution data, a number of prospective multiinstitutional trials addressing the role of IMRT in the treatment of head and neck carcinomas were completed. RTOG 0022 evaluated the efficacy of IMRT in the treatment of 69 patients with T1 to T2, N0 to N1, M0 oropharyngeal cancer. The patients underwent bilateral neck irradiation without concurrent chemotherapy. A dose of 66 Gy in 30 fractions of 2.2 Gy each was administered to the gross tumor planning target volume (PTV), 60 Gy in 30 fractions of 2 Gy each to the intermediate-risk PTV, and 54 Gy in 30 fractions of 1.8 Gy each to the low-risk elective lymph node region PTVs. With a median follow up of 2.8 years, the 2-year estimated locoregional failure rate was 9% (and only 6% in the 49 patients without a major underdose deviation). The maximal late grade 2 or greater toxicity was skin 12%, mucosa 24%, salivary 67%, esophagus 19%, and osteoradionecrosis 6%. The incidence of grade 2 or higher xerostomia was 55% at 6 months, 25% at 12 months, and 16% at 24 months. The authors concluded that IMRT for early-stage oropharyngeal cancer results in high local and regional tumor control rates with lower salivary toxicity when compared with patients treated in previous RTOG clinical trials.[83]

RTOG 0225 evaluated IMRT in the treatment of 68 patients with stage I to IVB NPC (94% were World Health Organization [WHO] type 2 or 3). The PTV for the gross tumor at the primary tumor site and within involved lymph nodes received 70 Gy in 33 fractions of 2.12 Gy each. Regions at risk for subclinical disease and electively treated lymph nodes received 59.4 Gy in 33 fractions of 1.8 Gy each to the PTV. Patients with T2 to T4 primary tumors or with nodal disease beyond N1 category received concurrent cisplatin chemotherapy and adjuvant cisplatin and 5-fluorouracil chemotherapy. The estimated 2-year local progression-free survival (PFS) was 92.6%, regional PFS was 90.8%, local and regional PFS was 89.3%, and the distant metastasis-free survival was 84.7%. The estimated 2-year PFS was 72.7%, and 2-yr OS was 80.2%. Late grade 3 toxicity included esophageal toxicity in 4.7% of patients, mucous membrane toxicity in 3.1%, and xerostomia in 3.1%. The incidence of grade 2 xerostomia at 1 year was 13.5%. Only two patients developed grade 3 xerostomia. No patient developed grade 4 xerostomia. The authors concluded that it is feasible to administer IMRT with or without chemotherapy to patients with NPC and that such treatment is effective with 90% locoregional PFS and minimal grade 3 xerostomia.[84]

Proton beam therapy is being evaluated for patients with locally advanced head and neck cancers.[85-104] Liebsch et al[105] at Massachusetts General Hospital have used proton beam therapy with or without chemotherapy in the treatment of 17 patients with NPC. They escalated the dose to 73.6 Gy by taking advantage of the Bragg peak physical characteristics of the proton beam. With a median follow-up of 43 months, they reported a 3-year relapse-free and OS rate of 91%, which is quite encouraging. Slater et al[106] from Loma Linda University Medical Center treated 29 patients with oropharyngeal carcinoma with proton beam therapy. They were able to escalate the dose to 75.9 Gy in 45 fractions over 5.5 weeks (concomitant boost). With a median follow-up of 28 months, they reported a 2-year locoregional control rate of 92%, DFS rate of 81%, and grade 3 or higher late toxicity of 11%. Proton beam therapy has also been shown to be safe and effective in the treatment of a variety of head and neck malignant tumors located in the region of the skull base adjacent to critical normal tissues, including the eyes, optic nerves, brainstem, and brain. Promising reports are emerging for neuroendocrine tumors of the sinonasal tract, skull base adenoid cystic carcinoma, olfactory neuroblastoma, and sphenoid sinus malignant disease.[107-110] Prospective studies in well-defined patient cohorts are ongoing to determine the outcomes, cost, and value of proton therapy.

Carbon ion therapy holds promise in the treatment of selected head and neck malignant disease. Potential advantages of carbon ion therapy include improved tumor control resulting from even more conformal and precise tumor targeting than photons and protons, thus allowing for dose escalation to the tumor, reduction of dose to normal tissues, and greater radiobiologic effectiveness because of high linear energy transfer (LET), and completion of therapy with at least 50% fewer treatments. Examples include the treatment of inoperable salivary gland malignant tumors and mucosal melanomas. Mizoe et al[111] from the National Institute of Radiological Sciences (NIRS) in Chiba, Japan, treated 8 patients with advanced inoperable salivary gland cancers with carbon ion therapy (64 GyE to 70.2 GyE in 16 to 18 fractions over 4 to 6 weeks). With a median follow-up of 90 months, they report 100% tumor control and no grade 3 or higher late morbidity. Similarly, Castro et al[112] from Lawrence Berkeley Laboratory treated 9 patients with inoperable salivary gland tumors with neon ions (8 patients) or helium ions (1 patient) (52 GyE to 70 GyE, 2 GyE per fraction, four fractions per week). With a median follow-up of 17 months, they reported a 78% tumor control rate, with no grade 3 or higher late effects. These results appear to be better when compared with the RTOG/MRC randomized trial comparing photons with neutrons,[113] but the series are small. Finally, Yanagi et al[114] from NIRS have treated 72 patients with mucosal malignant melanoma of the head and neck with carbon ions (52.8 GyE to 64 GyE in 16 fractions over 4 weeks). With a median follow-up of 49.2 months, they reported no grade 3 or higher late effects and a 5-year local control rate of 84.1%. The 5-year OS and cause-specific survival rates were 27% and 39.6%, respectively.

More developments are needed to fully benefit from these new sophisticated technologies. Challenges to treating the head and neck region with charged particle therapy include the presence of air cavities and dental restorations. Current treatment planning is limited by field size and the need to patch and match scattered proton or carbon ion beams. Full development of intensity-modulated proton and carbon ion pencil beam scanning is well under way, has been found to be feasible, and has been instituted in the clinic. Prospective clinical trials evaluating larger numbers of patients with long-term follow-up are needed to compare the outcomes of photons, protons, and carbon ions. Areas needing improvement to refine margins of coverage include immobilization devices, topographic and biologic tumor imaging to better define target volumes, and quantification of day-to-day anatomic variations occurring during the course of radiotherapy as a result of motion and changes in tumor and normal tissue volume.

Although results of IMRT and proton beam therapy are encouraging, the observation that most recurrences originate from the high-dose region indicates that radiation dose escalation with low LET irradiation alone will improve the tumor control outcome only for a subset of patients. Further advances in the treatment of solid tumors will likely come through application of newer knowledge about tumor biology, as

exemplified by translational research addressing the role of EGFR in tumor progression and as a target for therapeutic intervention and high LET irradiation.

BIOMARKERS AND MOLECULAR TARGETING

Progress in searching for useful markers for early detection of tumor, estimation of tumor burden, prediction of response to therapy, and monitoring of disease progression has been slow. However, some studies of head and neck carcinomas have generated optimism.

A review of the literature data up to a few years ago identified TP53, EGFR and one of its ligands, transforming growth factor-alpha (TGF-α), and cyclin D1 as promising prognostic biomarkers for HNSCC.[115-117] A few studies[118-120] corroborated the prognostic value of EGFR. A study using HNSCC specimens of patients enrolled in a Phase III trial of the RTOG[54] and randomized to receive standard irradiation,[120] for example, revealed no correlation between EGFR expression and T category, N category, American Joint Committee on Cancer (AJCC) stage grouping, and recursive partitioning analysis (RPA) classes[121] (r = –0.07 to 0.17). However, patients with more than median EGFR-expressing tumors, as measured using an image analysis-based immunohistochemical (IA-IHC) assay, were found to have significantly lower OS and PFS rates because of a significantly higher locoregional relapse rate. Multivariate analysis showed that EGFR expression was a strong, independent predictor of survival and of locoregional relapse.

A completed follow-up study, using a validation set of patients enrolled in the same trial, revealed high reproducibility of the IA-IHC assay and confirmed the absence of correlation between EGFR expression and tumor stage and other clinical prognostic variables (r = –0.20 to 0.18). The results validated previous findings that higher tumor EGFR expression predicted worse rates of OS, PFS, and locoregional relapse, with hazard ratios of 1.97, 2.15, and 3.12, respectively. However, the questions of whether EGFR predicts for the risk for metastasis and whether EGFR is a marker for tumor clonogen proliferation have not been resolved.

Recognition of the importance of the ERBB family of tyrosine kinase receptors in coregulating cell proliferation, death, and angiogenesis led to development of several strategies targeting the EGFR signaling pathway for cancer treatment. Two of these strategies, a monoclonal antibody (e.g., cetuximab) and small-molecule kinase inhibitors (e.g., gefitinib, erlotinib) have gone through various stages of preclinical and clinical development for several types of cancers. Several reviews summarize the status of these clinical investigations.[8,9,120,122] Randomized trials of treatment for colorectal adenocarcinoma[123] and HNSCC[124] showed that cetuximab given in combination with irinotecan or cisplatin yielded higher objective response rates (23% and 26%, respectively) than chemotherapy alone. However, the higher response rates for combined therapies have not translated into improved OS rates relative to monotherapy. Two Phase III trials enrolling patients with non–small cell lung cancer showed that gefitinib did not improve the response rate or survival rate when it was added to cisplatin-gemcitabine or carboplatin-paclitaxel doublets.[125,126]

In contrast to the results of combinations of EGFR antagonists with chemotherapy, data regarding the combination of cetuximab with radiotherapy in patients with locally advanced HNSCC are impressive. A completed international Phase III trial (IMCL CP02-9815) revealed that compared with irradiation alone, adding cetuximab to irradiation resulted in a significant improvement in OS and locoregional control rates without increasing mucositis or dysphagia.[127] These findings validate the notion that selective enhancement of the tumor response leading to durable locoregional control can be achieved by "designer drugs" targeting a specific molecular pathway.

Progress has been made in identifying prognostic markers in patients with NPC. The study of Chan et al[128] showed in a series of 170 patients that the posttreatment plasma level of Epstein-Barr virus (EBV) DNA was strongly correlated with PFS and OS rates, more so than the pretreatment titer. For example, the relative risk for NPC recurrence was 11.9% (95% CI, 5.53 to 25.43) for patients with a posttreatment EBV DNA titer, compared with 2.5% (95% CI, 1.14 to 5.7) for patients with higher pretreatment titers of EBV DNA. The positive and negative predictive values for recurrence for higher posttherapy EBV DNA were 83% (58% to 98%) and 98% (76% to 89%), respectively. NRG Oncology (NRG HN001) is evaluating this marker to see if it is useful in identifying high-risk patients for testing more aggressive therapy and monitoring their response to treatment. Eligible patients include those with detectable plasma EBV DNA before treatment. All patients will be treated with 69.96 Gy in 33 fractions with 6 weekly doses of cisplatin 40 mg/m^2. Plasma EBV DNA will be determined again 1 week after completion of treatment. Patients with undetectable plasma EBV DNA will undergo Phase III randomization to either observation or three cycles of cisplatin (80 mg/m^2) and 5-FU (1000 mg/m^2/d) for 4 days by intravenous continuous infusion every 28 days starting 4 weeks after completion of radiation therapy. Patients with detectable plasma EBV DNA will undergo Phase II randomization to either three cycles of cisplatin (80 mg/m^2) and 5-FU (1000 mg/m^2/d) for 4 days by intravenous continuous infusion or four cycles of gemcitabine (1000 mg/m^2) days 1 and 8 and paclitaxel (80 mg/m^2) days 1 and 8 every 21 days starting 4 weeks after completion of radiation therapy.

Tumor HPV status (HPV DNA and p16 expression) as a strong and independent prognostic factor for survival among patients with oropharyngeal cancer has been discussed.[44,45] This appears to be independent of treatment by radiotherapy alone or combined with concurrent chemotherapy.[129] It is possible that patients with HPV-positive tumors are being overtreated with concurrent irradiation and chemotherapy and are experiencing excessive toxicity despite an excellent prognosis. Current studies are evaluating dose de-escalation by reducing the radiotherapy dose, decreasing the cisplatin dose, or replacing cisplatin with cetuximab or some other biologically targeted agent. In the RTOG 1016 clinical trial, patients with HPV-related oropharynx cancer are randomly assigned to either accelerated RT to 70 Gy administered over 6 weeks with concurrent high dose cisplatin (100 mg/m^2) days 1 and 22 or the same IMRT with cetuximab (400 mg/m^2 loading dose pre-IMRT, then 250 mg/m^2 weekly during IMRT and for 1 week after IMRT). In the ECOG 3311 clinical trial, patients with HPV-related oropharynx cancer undergo transoral resection and neck dissection for T1-T2, N0-N2 disease. Low-risk patients (T1-T2, N0-N1, 0-1 positive nodes, negative margins) then undergo observation. Intermediate-risk patients (close margins [<3 mm], <1 mm extracapsular extension, and two to four positive nodes) are randomly assigned to receive either IMRT to 50 Gy in 25 treatments or IMRT to 60 Gy in 30 treatments. High-risk patients (positive margins, >1 mm extracapsular extension, or 5 or more positive nodes) receive IMRT to 66 Gy in 33 treatments with concurrent weekly cisplatin (40 mg/m^2). In the ADEPT clinical trial, coordinated by Washington University School of Medicine, patients with HPV-related oropharynx cancer undergo complete resection with negative margins by transoral surgery and neck dissection. Patients with positive nodes with extracapsular extension are

randomized to 60 Gy in 30 fractions either alone or with concurrent weekly cisplatin 40 mg/m^2.

PREVENTION OF HEAD AND NECK CANCERS

The concept of *field cancerization* was first described by Slaughter et al[130] in 1953 and has long been validated by clinical data. This evolving notion describes diffuse subcellular injury to the epithelium, resulting from interactions between prolonged carcinogen exposure and individuals' genetic profiles, rendering the whole anatomic field at risk for developing invasive cancers through stepwise, progressive accumulation of genetic alterations. It follows that an individual who develops and survives an upper aerodigestive cancer is at a higher risk (i.e., susceptible) for forming a second primary tumor in the same anatomic field during the ensuing years. The field cancerization and multistep carcinogenesis concepts form the basis for research on cancer chemoprevention.

Results of relatively large series revealed that patients cured of their first head and neck cancer had a more than 20% projected lifetime risk of development of a secondary primary tumor. The estimated annual secondary primary tumor development rate ranged from 4% to 6% for at least 8 years after the diagnosis of the first cancer.[131,132] A secondary primary tumor is the leading cause of death in patients with early head and neck cancers.[133]

This patient population has served as a model for addressing the efficacy of *adjuvant chemoprevention* regimens. An initial trial testing the role of *cis*-retinoic acid in preventing secondary primary tumors had yielded encouraging results.[134] Unfortunately, two large, multiinstitutional, randomized trials did not confirm its benefit.[135,136]

Leukoplakia and erythroplakia carry increased risk for transformation into squamous carcinomas. This patient subset has been used as a model to test *chemoprevention of malignant transformation*. The weaknesses of this model are that the natural history of leukoplakia is rather variable, with spontaneous improvement occurring in many cases, and that the malignant transformation rate at 8 years may vary from 18% to 36%, depending on the degree of dysplasia observed histologically.[137] Consequently, large series and prolonged follow-up studies are required to properly test the efficacy of a given primary chemoprevention strategy.

Identification of key genetic changes resulting in development of malignant clones and markers of multistep carcinogenesis will aid in selecting patients with the highest risk for enrollment into chemoprevention trials and thereby in reducing the required sample size. Markers can also serve as intermediate, surrogate endpoints for assessing the efficacy of chemoprevention regimens, and thereby, shorten the length of the required follow-up. Physicians can counsel their patients regarding healthy lifestyle choices, such as abstaining from using tobacco products and alcohol or from engaging in early-age sexual activity with multiple partners (including oral sex practices) and receiving the HPV vaccine. They can also advise them to practice good oral hygiene and eat a diet rich in fresh fruits and vegetables.

SUMMARY

The past two decades have been an exciting era for participation in clinical trials and laboratory research that have produced gratifying progress in understanding and treating head and neck cancer. Advances in molecular biology techniques opened new research avenues yielding new concepts and knowledge, such as the multistep tumor progression model, genetic susceptibility to environmental carcinogen-induced tumorigenesis, processes of virus-induced changes in cellular behavior, and factors and mechanisms governing the radiation response of cells and tissues. Some of the wisdom gained has already found applications in developing novel therapy strategies that have completed or are undergoing preclinical and clinical testing. Examples include altered photon fractionation regimens, charged particle therapy, mechanism- or molecular-oriented combined-therapy modalities, and conformal radiotherapy with photons and charged particles. The basic and translational research efforts have paid off in that the head and neck cancer mortality rate in the United States has declined since the inception of record keeping. For example, the annual death rate for men because of oral cavity and pharyngeal cancers in the United States decreased by an average of 1.9%, 3%, and 1.2% between 1975 and 1993, between 1993 and 2001, and between 2001 and 2010, respectively.[1]

It is likely that the pace of discovery will increase in the coming years. Sensitive methods for detecting occult tumor foci for screening and staging purposes will be developed, and new approaches in characterizing the genetic profile of cancers will accurately depict their individual virulence, predict the therapy response, and guide treatment selection. Optimism about developing rational novel therapy strategies aimed at specific molecular targets to prevent malignant transformation or reverse malignant phenotyping is also increasing. The insights and new technologies gained from further research should have a sizable impact in reducing the mortality rate caused by head and neck cancers.

The accelerated pace of new discoveries and the large number of research directions make it increasingly complex to determine what constitutes the standard therapy for a variety of patient subsets. When several treatment options can yield approximately the same locoregional tumor control rate, other determinants to be taken into account in selecting the treatment of choice include cosmetic and functional outcome, acute and long-term morbidity (quality of life), resource utilization (cost), physician expertise, patient convenience, out-of-pocket costs (transportation, time off work for the patient, family members, and friends, indirect medical costs), and patient preference.

CHAPTER

32 Oral Cavity

William M. Mendenhall, Robert L. Foote, Pamela L. Sandow, and Rui P. Fernandes

INCIDENCE

For 2015, there were 30,260 estimated new cases and 5990 estimated deaths.

BIOLOGIC CHARACTERISTICS

The natural history of oral cavity carcinoma depends on its anatomical site, histologic type, and stage of the tumor.

STAGING EVALUATION

A physical examination should be performed to determine the location and extent of the primary tumor and to assess for presence and extent of nodal involvement.

Computed tomography (CT) scanning will help to determine the extent of the tumor (particularly, deep invasion), detect bone invasion (CT plus panoramic x-ray film [Panorex] view) and to assess regional lymph nodes; for retromolar trigone lesions, magnetic resonance imaging (MRI) is useful to assess muscle invasion; and chest radiograph to detect pulmonary metastases. The routine use of positron emission tomography (PET) is not recommended.

PRIMARY THERAPY

For early disease (T1 to early T2 lesions), single modality surgery or radiotherapy (RT) can achieve excellent local control and survival in most oral cavity sites (85% to 90%). The treatment choice is predicated on function and treatment side effects.

Moderately advanced (large T2-early T3) lesions are treated with RT alone or surgery plus irradiation with moderate local control (60% to 80%).

LOCALLY ADVANCED DISEASE

Locally advanced disease (large T3 to T4 lesions), combined RT plus surgery is indicated in most sites because single modality disease control is poor (≤30%). RT alone or combined with concomitant chemotherapy likely results in a lower probability of cure.

For locally recurrent cancers seen after the primary tumor has been treated with surgery alone, salvage with surgery is appropriate, followed by postoperative RT, RT with or without chemotherapy, or palliative RT. Reirradiation may be considered if a recurrence is low volume, unifocal, or as a result of low dose or a marginal miss. It may also be considered for a T1-T2N0 metachronous second primary that is not amenable to surgery.

Locally recurrent cancers that occur after definitive RT alone or combined with chemotherapy can be managed with surgical salvage, palliative chemotherapy, or supportive care.

PALLIATION

Moderate dose palliative RT can be given as 30 Gy in 10 fractions over 2 weeks or 20 Gy in 2 fractions with a 1 week interfraction interval.

The estimated number of newly diagnosed oral cancers in 2015 is 30,260.[1] The estimated number of deaths is 5990.

The oral cavity consists of the lip, floor of mouth, oral tongue (the anterior two thirds of the tongue), buccal mucosa, upper and lower gingiva, hard palate, and retromolar trigone. The frequency of involvement of various locations is shown in Table 32-1.[2] After a general discussion of etiology and epidemiology, issues relative to the various subsites will be presented separately. A discussion of preradiotherapy and postradiotherapy dental care is included.

ETIOLOGY AND EPIDEMIOLOGY

Oral cavity cancer is predominately a disease of middle-aged men who use tobacco and alcohol. Approximately 95% of carcinomas appear after age 45 with an average age of 60 years.[2] The use of tobacco in any form is associated with an increased risk of oral cancer.[3-5] Some evidence suggests that patients with oral cavity cancer who continue to smoke during RT have poorer outcomes.[6] The risk of tobacco-related cancers of the upper aerodigestive tracts declines among former smokers after 5 years and after 10 years of abstention the risk may approach that of nonsmokers.[7] Although the effects of alcohol and tobacco in inducing cancers of the upper aerodigestive tract seem to be additive, the risk of alcohol consumption without tobacco use is unclear. Some studies indicate a slightly increased risk with alcohol use in the absence of tobacco, whereas others show no apparent increased risk.[8,9]

Human papillomavirus (HPV) infection, marijuana smoking, betel quid use, and drinking the beverage "mate" have also been implicated as causative agents in the formation of squamous cell carcinomas of the upper aerodigestive tract.[10-13] In recent years, oral cancers have increased among relatively young females who have never consumed alcohol or smoked. The reason for this is unclear.[14]

Smokeless tobacco (snuff) can promote carcinomas of the buccal gingival sulcus, which are diagnosed most often in older, white women living in the southeastern United States. Carcinoma of the buccal mucosa is also associated with chewing tobacco. It is commonly seen in the southeastern United States, with a male to female ratio of 3 or 4 to 1.[15] Leukoplakia is seen with oral carcinoma in approximately 15% of cases.[16]

Persons with a "Scotch-Irish" complexion (red hair and blue eyes) or prolonged exposure to sunlight are most susceptible to lip carcinoma.[17] In one series, 82% were previous or present tobacco smokers.[18] Pipe smoking is an alleged risk factor, but this has not been substantiated by most studies. Lip cancer is often associated with poor dental hygiene or edentulous patients.[18,19] Lip trauma and a history of alcohol abuse

TABLE 32-1 Distribution of Oral Cavity Cancer: 14,253 Cases

Site	Percentage
Lower lip	38
Tongue	22
Floor of mouth	17
Gingiva	6
Palate	6
Retromolar trigone	5
Upper lip	4
Buccal mucosa	2

are also related factors.[18] Most cases appear after age 40 years, but approximately 10% occur before age 40 and a few before age 30 years. This disease is uncommon in blacks.

PREVENTION AND EARLY DETECTION

This information on prevention and early detection is of major importance for patients with oral cavity cancers. It is covered in the Part B Overview, "Head and Neck Tumors," by Robert L Foote and K. Kian Ang; it will not be reiterated here.

ORAL CARE

A complete dental examination should be performed on all patients, whether dentate or edentulous, before irradiating any portion of the mandible or maxilla. The radiation oncologist should inform the patient's dentist of the anticipated RT treatment plan, including dose and location of the RT fields. To make appropriate pretherapy recommendations, the dentist should be familiar with possible post-RT complications, such as caries and osteoradionecrosis. There is a lifelong risk of impaired healing that can lead to osteoradionecrosis, especially when teeth are extracted from hypovascularized and hypocellular bone.[20] Therefore, one objective of the pretherapy oral evaluation is to determine whether teeth in the proposed irradiated area can be reasonably maintained in a healthy state for the remainder of the patient's life.

Medical, dental, and psychosocial issues that affect a person's future dental health should be assessed at the pretherapy evaluation. The patient's compliance, motivation for daily oral hygiene procedures, dental awareness, and access to dental care are predictors of dental health. A panoramic radiograph, intraoral radiographs, and hard and soft-tissue examinations should be performed to identify high-risk dental factors such as deep caries, nonrestorable teeth, root tips, bony pathology, endodontically treated teeth, periapical and pulpal pathology, and nonfunctional teeth. Teeth exhibiting periodontal disease should be evaluated to determine their long-term prognosis. Some prognostic factors for poor periodontal health include probing depths more than 6 mm, gingival recession, furcation involvement, or mobility.[21,22] Because of the numerous reported cases of progression of gingival recession and periodontal disease after RT, it may be difficult to assess the longevity of each tooth.

To reduce the future risk of osteoradionecrosis, teeth with high-risk dental factors should be removed before the patient receives doses of more than 55 Gy.[21] Whether extraction of teeth with moderate disease is indicated remains controversial. If the patient has poor resistance to dental disease or an unwillingness to perform routine dental care or fluoride applications, pretherapy extraction of moderately diseased teeth may be justified. A healing time of 14 to 21 days is recommended after extraction, before initiating of RT.[20] Extraction should be accomplished as atraumatically as possible, with alveoloplasty to remove sharp, bony projections. The dentist should coordinate dental appointments with the radiation oncologist to minimize the delay in cancer therapy. However, extraction of healthy teeth does not reduce the risk of osteradionecrosis and should be avoided.[23]

Denture adjustments, smoothing edges of sharp teeth, dental cleaning, and oral hygiene instruction can be accomplished at the pretherapy dental visit. Ill-fitting dentures that irritate mucosal surfaces should be worn with caution during RT. Daily disinfection of dental prostheses is recommended.

Impressions for custom fluoride trays can be made before or within the first 2 weeks of RT. Patients who receive RT to major salivary glands are at lifelong risk for rampant caries. Daily use of 0.4% stannous fluoride or 1.1% sodium fluoride gel for 5 minutes each evening before sleep, in custom trays, is imperative as long as natural teeth remain. Patients should be advised to refrain from rinsing, eating, or drinking for 30 minutes after fluoride application. The dentist and radiation oncologist should consistently promote proper oral hygiene and use of fluoride throughout the posttreatment years.

Clinical practice guidelines for the treatment of cancer therapy-induced oral mucositis have been published.[24] RT-induced mucositis cannot be prevented; however, excellent oral hygiene can reduce the risk of oral infections. Supersoft toothbrushes and mild toothpastes are available for patients to facilitate proper oral hygiene during and after RT.

Consultation with the radiation oncologist is required before postirradiation extraction of teeth or invasive procedures that involve the exposure of irradiated bone. Preextraction and postextraction hyperbaric oxygen therapy may be indicated to promote healing of extraction or surgical sites.

Patients should be closely monitored for possible late effects of RT to oropharyngeal regions. Trismus, xerostomia, caries, and oral candidiasis can persist or occur at any time after treatment is completed.

MOLECULAR BIOLOGY

A discussion of the molecular biology of head and neck cancers is found in the Part B Overview, "Head and Neck Tumors" preceding this chapter.

LIP CANCER

Anatomy

The lips are composed of the orbicularis oris muscle that surrounds the mouth and is covered externally by skin and internally by mucous membrane. The upper and lower lips are attached to the gingiva by raised folds of mucous membrane called the *labial frenula*. The vascular supply is from the superior and inferior labial branches of the facial arteries. The sensory nerve of the upper lip is the infraorbital nerve; the mental nerve provides sensory innervation for the lower lip.

Lymph vessels from both lips drain into the submandibular lymph nodes (level Ib). In addition, lymph from the central part of the lower lip drains into the submental lymph nodes (level Ia). The submental nodes (level Ia) drain either to the submandibular lymph nodes (level Ib) or to the jugulo-omohyoid node (level II). The submandibular lymph nodes drain to the deep cervical chain of lymph nodes (levels II to IV).[25]

Pathology and Patterns of Spread

The most common neoplasms are moderately to well differentiated squamous cell carcinomas; approximately 5% are poorly differentiated.[26] Basal cell carcinomas usually arise on the skin above or below the lip and invade the vermilion border but rarely arise from the vermilion border. Squamous cell carcinomas start on the vermilion of the lower lip and less commonly on the upper lip. The commissure is rarely the site of origin. Leukoplakia is a common problem on the lower lip and may precede carcinoma by many years.[16]

Early lesions can initially invade adjacent skin and the orbicularis oris muscle. Advanced lesions can invade the adjacent commissures of the lip and buccal mucosa, the skin and wet mucosa of the lip, the adjacent mandible, and eventually the mental nerve. The incidence of perineural invasion is approximately 2%.[27] Lymph node involvement at presentation occurs in approximately 5% to 10% of patients. An additional 5% to 10% of patients with a clinically negative neck subsequently develop lymph node metastases. The risk of lymph node involvement increases with depth of invasion, poor differentiation, larger lesions, invasion of the commissure, and recurrence after prior treatment.[19]

Hendricks et al[28] from the Mayo Clinic reported the following incidence of positive cervical lymph nodes by T stage: T1, 2%; T2, 9%; and T3, 30%. The overall incidence of adenopathy was 19% when the commissure was involved.[26] De Visscher et al[29] reported a nodal recurrence rate of 5.4% after primary surgical resection in 184 patients with squamous cell carcinoma of the lower lip. Ninety-three percent of lesions were stage I at presentation.

Clinical Manifestations and Staging

Carcinoma of the lip usually presents as a slowly enlarging exophytic lesion with an elevated border. Occasionally there is minor bleeding. Erythema of the adjacent skin may suggest dermal lymphatic invasion. Anesthesia or paresthesia of the skin indicates perineural invasion.[30]

The American Joint Committee on Cancer (AJCC) staging for lip cancer applies to lesions arising from the vermilion surface (Table 32-2).[31]

TABLE 32-2 American Joint Committee on Cancer: Oral Cavity Primary Tumor Staging

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor 2 cm or less in greatest dimension
T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension
T3	Tumor more than 4 cm in greatest dimension
T4 (lip)	Tumor invades through cortical bone, inferior alveolar nerve, floor of mouth, or skin of face (i.e., chin or nose)
T4 (oral cavity)	Tumor invades through cortical bone into deep (extrinsic) muscle of tongue (genioglossus, hyoglossus, palatoglossus, and styloglossus), maxillary sinus, or skin of face
T4b	Tumor involves masticator space, pterygoid plate, or skull base or encases internal carotid artery

Reprinted from the American Joint Committee on Cancer: Lip and oral cavity. In Edge SB, Byrd D, Compton CC, et al, editors: AJCC cancer staging handbook, ed 7, Chicago, 2010, Springer, pp 49–61.

Early lip cancers rarely require diagnostic imaging. Locally advanced, deeply infiltrating, or recurrent carcinomas may benefit from a CT scan or panoramic x-ray film to evaluate possible bony invasion and regional nodal spread.

Treatment

Early Lesions (<2 cm)

The majority of these lesions can be surgically excised with primary closure as an outpatient procedure. Surgery is satisfactory if the lip commissure does not need to be resected, and if the resulting aperture of the oral cavity permits the insertion of dentures. Postoperative RT is recommended for positive margins or perineural invasion.[27,33,34]

Tumors that should be treated with RT include those involving a commissure to obtain better cosmesis and improved local control.[35] The uncommon, poorly differentiated lesions are also preferably treated by RT to cover a more generous treatment volume and the first echelon lymph nodes. An algorithm for treatment planning is shown in Figure 32-1.

Moderately Advanced Lesions (2 cm to 4 cm)

The length of the lower lip is approximately 7 cm. Removal of more than half of the lower lip with simple closure produces a poor cosmetic and functional result so that a reconstructive procedure is usually necessary. In these cases, RT has the advantage of a better functional and cosmetic result. Traditionally, the reconstructed lip may look normal in a photograph, but it may lack sensory and motor innervation as well as elasticity. However, there have been recent improvements in the functional and cosmetic results of various reconstructive surgical procedures.[36-38]

Stranc et al[35] studied lip function in 37 patients after surgery (19 cases) or RT (18 cases) and compared them to normal controls. Compared with surgery, RT produced better preservation of lip sensation, intercommissural distance, and elasticity. Inadequate lip seal was observed in 2 of 18 patients (11%) after RT compared with 8 of 19 patients (42%) treated surgically.

Teichgraeber and Larson reviewed the M. D. Anderson Hospital experience for patients with lip cancer involving the commissure.[39] Of the 22 patients with T2 lesions who were treated with surgery, 10 patients (45%) had recurrence. There are no data for commissure involvement treated with RT, but the relative ease of RT and the cosmetic and functional results lead us to recommend RT for lesions exhibiting this pattern of spread.

Locally Advanced Lesions (>4 cm)

Large lesions are managed by resection and postoperative RT.[34] Erythema of the skin adjacent to the lesion may indicate dermal lymphatic involvement; wide-field irradiation is recommended followed by consideration of surgical resection depending on the response to RT. Management by definitive radiotherapy and concomitant chemotherapy is generally preferred in patients who are not surgical candidates.

Management of the Neck

Regional lymphatics are not electively treated for T1 and T2 lesions unless perineural invasion or commissure involvement is present. Patients with advanced (>4 cm), poorly differentiated, or recurrent tumors often require elective neck treatment. Other factors associated with an increased risk of nodal spread include perineural invasion, maximal thickness more than 6 mm, or low p27Kip1 protein expression.[40] The decision to employ elective neck irradiation or elective neck dissection depends on the modality selected for treatment of the primary tumor.

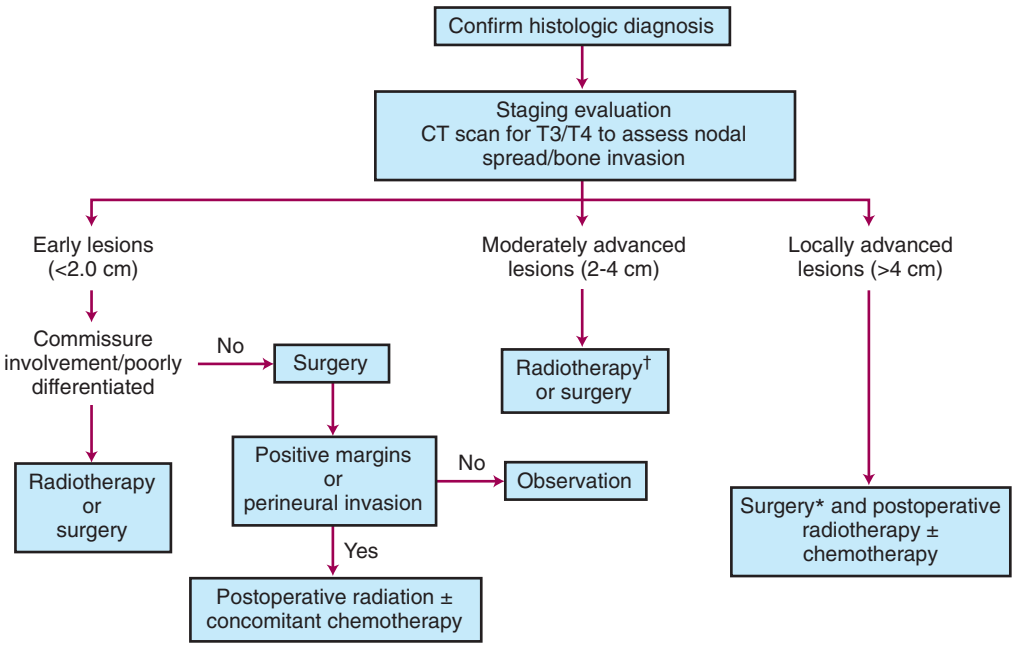

Figure 32-1 Treatment algorithm for de novo lip cancer. *Treat neck (neck dissection or radiotherapy).[28] †If poorly differentiated, dermal or commissure involvement.[26]

TABLE 32-3 Lip Carcinoma Treated with Interstitial Radiotherapy (N = 869 Patients)

Category	Local Recurrence Rate (5-year, %)	Survival Rate (5-year, %)
T1	7.4	99.5
T2	12.7	97.4
T3	26.4	81.4

Data from Jorgensen K, Elbrond O, Andersen AP: Carcinoma of the lip. A series of 869 patients. Acta Otolaryngol (Stockh) 75:312–313, 1973.

Results

T1 to T3 Lesions

Interstitial Irradiation with or without External Beam Irradiation (EBRT)

Jorgensen et al[41] reviewed 869 patients with squamous cell carcinoma who were treated with an interstitial radium implant alone; 90% of the lesions were less than 2 cm in size. The local recurrence and survival rates are shown in Table 32-3; 99% of the primary tumors were ultimately controlled with RT alone or combined with salvage surgery. Thirty-eight percent of patients with T3 tumors who developed a local recurrence developed lymph node metastases. Only 4% of patients died of lip cancer. Twenty-nine complications arose, of which two were bone necrosis.

Pierquin et al[42] reported on 50 patients with carcinoma of the lower lip treated with brachytherapy. Only one local recurrence (2%) was observed.

McKay and Sellers[26] reviewed 2854 patients; 92% of whom were initially treated with brachytherapy and EBRT. The primary lesion was controlled in 84% of the cases; 8% were salvaged later for an overall local control rate of 92%. Regional control was achieved in 58% of patients who presented with positive nodes. However, the ultimate rate of neck control was only 35% when neck nodes appeared at a later date. The cause-specific and absolute 5-year survival rates were 89% and 65%, respectively.

Tombolini et al[43] reported on 57 patients with squamous cell carcinoma of the lower lip treated with low-dose rate brachytherapy alone. Patients with clinically positive neck nodes received EBRT to the involved side of the neck. International Union Against Cancer (UICC) T stages were T1 in 27 cases (47%), T2 in 20 cases (35%), and T3 in 10 cases (18%). The 5-year local control rate was 90%.

Orrechia et al[44] treated 47 patients with T1 (n = 21) and T2 (n = 26) lip cancers with iridium-192 (^{192}Ir) brachytherapy. The 5-year and 10-year disease-free survival (DFS) rates were 92% and 85%, respectively.

Guinot et al[45] treated 39 patients with lip carcinoma using high dose rate brachytherapy twice daily to total doses ranging from 40.5 Gy to 45 Gy and observed a 3-year local control rate of 88%. Acute and chronic reactions were similar to those observed after low-dose rate brachytherapy.

Petrovich et al[46] reported on 250 patients with lip cancer treated with RT; half were treated with brachytherapy and the remainder with EBRT. Two hundred forty-seven patients (99%) had squamous cell carcinomas and 240 patients (96%) had lower lip carcinomas. The incidence of lymph node metastasis was 9%. Eleven percent experienced recurrences after RT and half were salvaged; 18 patients (7%) died of lip cancer. Moderately advanced tumors and tumors near the commissures were best treated with EBRT.

EBRT or Surgery

Babington et al[34] reported on 130 patients with lip carcinoma; 75% had T1 tumors. Initial treatment consisted of surgery (39%), RT (48%), or both (13%). Close (≤2 mm) or positive margins were observed in 27% of those treated surgically. The 2-year relapse-free survival rates were 82% and 54% after RT and surgery, respectively ($p < 0.001$). The recurrence rate after surgery was significantly higher for those with close or positive margins.

Baker and Krause[18] reported on 279 patients treated with either RT (47%) or surgery (53%) at the University of Michigan

TABLE 32-4 Carcinoma of the Lip—University of Michigan (*N* = 279 Patients)*

Extent of Primary Lesion	Patients	Local Recurrence (%)	5-Year Survival (%)	
			Cause-Specific	Absolute
<1 cm	85	10.6	100	76
1 to 3 cm	154	9.1	92	71
>3 cm	29	20.7	71	52
Bone invasion	11	90.9	50	45

Modified from Baker SR, Krause CJ: Carcinoma of the lip. Laryngoscope 90:19–27, 1980.
**Treated by radiotherapy, 47%; treated by surgery, 53%.*

(Table 32-4). There was no difference in the 5-year cause-specific survival (CSS) rates between the two groups. Patients with positive regional nodal metastases had a 5-year CSS of 29%. Regional lymph node metastases developed in 31% of those treated for locally recurrent lesions, indicating the need for elective neck treatment for this subset of patients.

De Visscher et al[29] treated 184 patients with squamous cell carcinoma of the lower lip surgically; 93% had stage I cancers. The local and regional recurrence rates were 4.9% and 5.4%, respectively.

Mohs's Surgery

Mohs and Snow[47] reported on 1148 patients with squamous cell carcinomas of the lower lip treated with microscopically controlled surgery. The 5-year local control rates were 94.2% for those with T1 lesions and 59.6% for patients operated on for T2 lesions. The 5-year local control rates were 96.3% for well to moderately differentiated tumors compared with 66.7% for those with poorly differentiated cancers.

Holmkvist and Roenigk[48] reported on 50 consecutive patients with of squamous cell carcinoma of the lip treated with Mohs micrographic surgery (MMS). Four patients (8%) experienced a recurrence; all were successfully salvaged with additional MMS. The average time to recurrence after the initial MMS was 2.5 years. Hruza[49] also reported a relatively long interval between MMS and initial recurrence, with 20% of recurrences developing after 5 years.

T4 Lesions

Cancers that present with bone or nerve involvement are usually treated with a combination of surgery and EBRT. There are limited data pertaining to the local control rates after RT or surgery alone, ranging from 0% to 74%[26,45]; therefore, combined treatment is usually recommended. Byers et al[27] observed that 80% of patients with histologically proven perineural invasion developed cervical node metastases. Eight of 25 patients (32%) in their series who presented with either perineural invasion, tumors larger than 3 cm, or regional metastases died of disease.

The postoperative EBRT portals should include the primary site as well as the regional lymphatics (levels IA, IB, and II). The low neck is usually treated to doses sufficient for subclinical disease, and doses are frequently higher in patients with positive nodes. The total dose ranges from 60 Gy to 70 Gy, at 2.0 Gy per once-daily fraction to the primary site, depending on the pathologic findings. Higher doses with altered fractionation schemes (e.g., 74.4 Gy at 1.2 Gy per fraction twice daily), as well as concomitant chemotherapy should be considered in patients with positive margins or other high-risk factors such as extracapsular extension.[50-55]

Recurrent Lesions

Cross et al[19] reported on 563 patients treated with surgery for recurrent lip cancer. The prognosis was particularly poor for those with high-grade tumors of whom 16.7% were salvaged compared with 31.8% and 42.9% for those with well and moderately differentiated cancers, respectively. Holmkvist and Roenigk[48] reported on four patients treated with MMS; all four were salvaged.

Techniques of Irradiation

EBRT is usually delivered with either orthovoltage x-rays or electron beam. The electron beam energy depends on the tumor thickness. Lead shields are placed behind the lip to limit the dose to the oral cavity and mandible. Orthovoltage fractionation schedules range from 40 Gy to 45 Gy in 3 to 4 weeks for smaller lesions, and 50 Gy to 63 Gy in 4 to 7 weeks for moderately advanced lesions. The dose is increased 10% to 15% for electron beam RT to account for differences in the relative biological effectiveness. Orthovoltage x-rays are preferred, if available, because the maximum dose is at the surface and there is less beam constriction compared with electron beam.

An appositional field with a margin of 1 to 1.5 cm is sufficient for most small to moderately advanced lesions if orthovoltage irradiation is used. The field borders are determined by bimanual palpation. Because of beam constriction, 2.0-cm to 2.5-cm margins are necessary if an electron beam is employed. A lead shield is used to collimate the beam at the skin/lip surface.

Brachytherapy may be used as the sole treatment or in conjunction with EBRT. Implantation is usually performed under local anesthesia using ^{192}Ir sources and a single-plane plastic tube technique. The sources are arranged horizontally 10 mm to 12 mm apart with crossing sources on the lateral aspects of the implant. Three to five horizontal sources are used depending on the size of the lesion. The advantage of the plastic tube technique is that the volume of the implant is more easily adapted to the extent of the tumor and the commissure is readily included, if necessary. A gauze roll is placed between the lip and gum to increase the distance between the radioactive sources and the alveolar ridge. The recommended dose is 60 Gy to 70 Gy at a dose rate of 0.4 Gy to 0.5 Gy per hour for an implant alone. Large infiltrative lesions may be first treated with EBRT, 30 Gy at 2.5 Gy per fraction to shrink the tumor, followed by interstitial brachytherapy boost to deliver an additional 35 Gy to 40 Gy. Treatment of lip cancer with high-dose rate (HDR) interstitial needles is advocated by some.[45]

T3 and T4

Low-volume T3 cancers may be treated with primary RT, preferably combining EBRT to the primary lesion and neck followed by a brachytherapy boost. EBRT is administered with parallel-opposed fields, including the lip lesion and the level I and II lymph nodes (Figure 32-2).[56] A cork is placed in the mouth to displace the maxilla and upper lip and reduce the volume of normal tissues included in the fields. A separate anterior field is used to treat the levels III and IV lymph nodes with a tapered midline block over the larynx. The supraclavicular lymph nodes are at low risk and are not included in

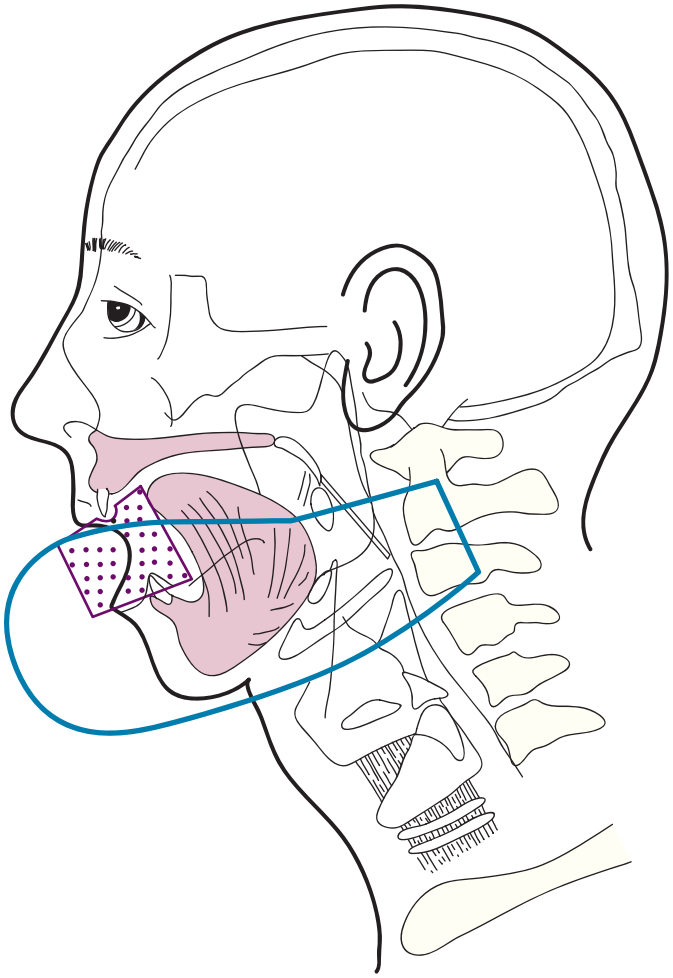

Figure 32-2 Parallel-opposed fields used to treat a carcinoma of the lower lip in conjunction with the levels I and II lymph nodes. *(From Mendenhall WM: Radiotherapy for cancer of the lip: treatment technique. In Werning JW, editor: Oral cancer, New York, 2005, Thieme Medical Publishers Inc.)*

the fields. Both sides of the neck are treated with RT because it is unlikely that T3 and T4 primary lesions would be well lateralized.

The junction between the parallel-opposed fields and the low-neck field is at the thyroid notch. The dose fractionation schedule used varies from 38.4 Gy at 1.6 Gy twice daily to 50 Gy at 2 Gy per fraction once daily, followed by a brachytherapy boost. Low-energy photons such as 4 MV or 6 MV beams are recommended.

High-volume T3 and T4 cancers are unlikely to be cured with RT alone and are better treated with surgery and postoperative RT. RT fields are similar to those used to treat patients with RT alone. A petroleum jelly gauze bolus is placed over incisions to ensure the surface dose is adequate. The fields are extended to the skull base along the course of the third division of the fifth cranial nerve if perineural invasion is present. The dose depends on the surgical margins: negative (R0), 60 Gy; microscopically positive (R1), 66 Gy; and gross residual disease (R2), 70 Gy. Patients are treated once daily at 2 Gy per fraction, 5 days a week, in a continuous course. Intensity modulated radiotherapy (IMRT) may be employed to limit the dose to one or both parotid glands to a mean dose of ≤26 Gy to reduce long-term xerostomia if this can be done without jeopardizing target coverage.

Complications

After RT, there is gradual atrophy of the irradiated tissues. The irradiated lip must be protected from sun exposure by use of hats and ultraviolet protectants. Because the anterior teeth and gingiva are protected by lead shields when radiation is given by EBRT, radiation caries, bone exposure, and osteoradionecrosis are uncommon.

Fitzpatrick[57] reported a 3.3% incidence of late complications that required surgical intervention. Orrechia et al[44] observed a 10.6% incidence of mucosal necrosis after RT for 47 T1 and T2 lip cancers treated with ^{192}Ir brachytherapy. The risk of late complications increased with dose, dose per fraction, and volume.

FLOOR OF MOUTH

Anatomy

The floor of the mouth is a semilunar space overlying the mylohyoid and hyoglossus muscles, extending from the inner surfaces of the mandibular alveolar ridge to the ventral surface of the oral tongue. Its posterior boundary is the base of the anterior tonsillar pillar; it is bisected anteriorly by the frenulum of the tongue. The mylohyoid muscle arises from the mylohyoid ridge of the mandible and is the muscular floor of the oral cavity. The posterior insertion is at the level of the third molars.

The submandibular glands lie along the body of the mandible. The inferior aspect of the gland extends below the inferior edge of the mandibular arch; part of the gland is superficial to the mylohyoid muscle. The submandibular gland is palpable as a soft mass over the posterior portion of the mylohyoid muscle when the muscle is tensed by forcing the tip of the tongue against the maxillary incisor teeth.

The submandibular duct (Wharton's duct) is approximately 5 cm long and arises from the portion of the gland that lies between the mylohyoid and hyoglossus muscles. The duct passes deep and then superficial to the lingual nerve and exits in the anterior floor of the mouth near the midline.

The sublingual glands are the smallest of the major salivary glands and are the most deeply situated. Each lies in the floor of the mouth between the mandible and the genioglossus muscle.

The first echelon nodes for the floor of mouth are the submandibular lymph nodes (level IB), which may be stratified into preglandular, intraglandular, and postglandular groups. Lymph may also drain into the submental (level IA) nodes. These lymph nodes eventually drain to the jugulo-omohyoid (level II) nodes.[25]

The lingual nerve is a branch of the mandibular nerve and provides the sensory innervation to the floor of the mouth. It enters the mouth between the medial pterygoid muscle and the ramus of the mandible and passes anteriorly under the oral mucosa medial to the third mandibular molar.

The hypoglossal nerve (cranial nerve XII) is the motor nerve of the tongue. It passes anterior to the inferior aspect of the hyoglossus muscle and then to the lateral aspect of the genioglossus muscle. Injury to the hypoglossal nerve results in paralysis and atrophy of the ipsilateral oral tongue. The tongue deviates to the paralyzed side on protrusion because of the unopposed contralateral genioglossus muscle.

Pathology and Patterns of Spread

Most floor-of-mouth neoplasms are squamous cell carcinomas; most are moderately differentiated. Adenoid cystic and mucoepidermoid carcinomas arise from the minor

salivary glands and account for 2% to 3% of floor-of-mouth tumors.

Most floor-of-mouth carcinomas are located in the anterior midline adjacent to Wharton's ducts. Extension toward the gingiva and periosteum occurs early and frequently.

Small to moderate size (stage T1 and T2) lesions are associated with metastases to the ipsilateral regional lymph nodes in 15% to 38% of cases, depending on the size and depth of invasion of the primary tumor.[58-60]

Mohit-Tabatabai et al[61] reviewed 84 patients with squamous cell carcinoma of the floor of the mouth and concluded that lesion thickness was related to the probability of subclinical cervical metastases in clinically node negative (N0) patients (Table 32-5). Patients with a primary lesion more than 1.5 mm thick had a 20% or higher risk of lymph node metastases.[61] Histologic grade and configuration of the primary lesion did not have a statistically significant correlation with subsequent development of neck node metastases. O'Brien et al analyzed the impact of tumor thickness on the incidence of regional lymph node metastases and found that the risk increased significantly for lesions 4 mm or more in thickness.[59] The reported incidence of recurrence in the untreated clinically negative neck varies from 20% to 35%.[60,62] Histologic grade and extent of vascular and perineural invasion have been implicated as predictors of lymph node spread.[63]

The distribution of clinically positive neck nodes at diagnosis is shown in Figure 32-3,[64] and the distribution of pathologically positive nodes after elective neck dissection in 62 patients with carcinoma of the floor of the mouth is shown in Figure 32-4.[65] The incidence of positive lymph nodes was 19% for those with T1 or T2 lesions and 26% for patients with T3 or T4 cancers.

TABLE 32-5 Floor-of-Mouth Carcinomas: Correlation of Primary Tumor Thickness with Neck Failure*

Thickness (mm)	T1N0	T2N0
0.1 to 1.5	1/38 (3%)	0/19
1.6 to 3.5	1/5 (20%)	3/7 (43%)
≥3.6	7/11 (64%)	2/4 (50%)

Clinical Manifestations, Patient Evaluation, and Staging

Floor-of-mouth carcinomas usually present as slightly elevated mucosal lesions with well-defined borders. A background of leukoplakia may be present. The lesions are often diagnosed by a dentist or physician during a routine physical examination.

T1 and T2 tumors may be noted initially when the patient feels a lump in the floor of the mouth with the tip of the tongue. Advanced lesions tend to produce pain, bleeding, foul breath, loose teeth, and change in speech due to fixation of the tongue.

Bimanual palpation is necessary to accurately determine the extent of induration and degree of fixation to the periosteum. Extensive lesions may exhibit invasion into the soft tissues of the neck or skin.

The AJCC staging system[32] (Table 32-2) is based on tumor size and invasion of adjacent structures such as bone or soft

tissue of the neck. Radiographic studies may facilitate staging with reference to (1) the status of the mandible and teeth, (2) the deep extent of the tumor, and (3) the evaluation of the regional lymph nodes. CT scans should be obtained in essentially all patients. The mandible may be evaluated by panoramic x-ray films, dental films, and CT scanning. MRI is useful to evaluate marrow space and muscle invasion and perineural involvement.[66]

The role of PET scanning as part of the initial staging workup for oral cavity cancers has not gained widespread acceptance. It may, however, be useful in early detection of recurrences and in prediction of which patients may benefit from elective neck dissection after chemoradiation.[67-69]

Treatment

Early Lesions (T1 and Superficial T2)

Surgery and RT produce equal cure rates for T1 and superficial T2 lesions. The risk of RT induced bone and soft-tissue necrosis is significant. Therefore, surgery is usually the treatment of choice. The neck is also treated with an elective neck dissection,[70] although some advocate observation of the neck in select patients with clinically negative nodes (cN0).[71] A treatment algorithm is shown in Figure 32-5.

Sentinel lymph node biopsy is being investigated for possible use in oral cavity cancers.[73,74] However, a recent study showed that this procedure was less sensitive for floor-of-mouth cancers (80%) compared with other oral sites (100%).[75]

Some patients present after excisional biopsy of the primary tumor. If the margins are either close or involved and there is no evidence of visible or palpable residual tumor, an interstitial implant alone to the primary site is a good alternative provided that the depth of invasion is less than 1.5 mm. Reexcision may not be feasible because the surgeon does not know exactly what to remove. An additional advantage of RT is the ability to treat a larger area. Six patients were treated in this manner at M.D. Anderson Hospital[76] and seven patients at the University of Florida.[77] All had disease locally controlled and none of the patients developed regional lymph node metastases. Conversely, Sessions et al[71] have recommended reexcision rather than RT if close or positive margins are found on permanent sections.

Moderately Advanced Lesions (Large T2 and Exophytic T3 Lesions)

Infiltrative lesions with fixation or tethering to inner tables of the mandible are best treated by excision with resection of the periosteum with or without a rim of mandible. Postoperative RT is indicated for patients with close (≤5 mm) or positive margins, perineural invasion, or lymphatic space invasion.

One common indication for adjuvant RT is the inability of the surgeon to obtain adequate margins of resection, because this often leads to local recurrence,[78] even if immediate reexcision is performed.[79] Jacobs et al[80] and Laramore et al[81] reported a large intergroup study where adjuvant postoperative EBRT (60 Gy) was administered for locally advanced cancers. They found that the relapse rate was 11% in patients with satisfactory margins and 26% in those with unsatisfactory margins. Unsatisfactory margins tend to reflect a higher residual tumor burden; therefore, it may be prudent to deliver a higher dose of postoperative RT. At the University of Florida, patients with involved margins receive hyperfractionated RT to increase the dose given to the primary site while minimizing the potential late morbidity.[53] An alternative is 70 Gy in 35 fractions over 6 weeks treating once-daily, 4 days weekly and twice daily, one day per week during the last 5 weeks of irradiation.

Lapeyre et al[82] reported on 36 patients with oral tongue or floor-of-mouth carcinomas treated with brachytherapy after resection with close or positive margins. The local control was 88.5% at 2 years. Grades 2 to 3 chronic sequelae were seen in 3 of 19 patients (16%) with floor of mouth cancers.

The neck should be electively dissected if it is clinically negative. If there are multiple positive nodes or extracapsular extension, postoperative RT is indicated.[33,53] Based on the latest results of the European Organization for Research and Treatment of Cancer (EORTC) and Radiation Therapy

Oncology Group (RTOG) trials, concomitant chemotherapy is generally recommended as well in high-risk postoperative settings such as positive margins or extracapsular extension.[50,52]

Locally Advanced Lesions (Endophytic T3 and T4)

Patients with locally advanced floor-of-mouth cancers are treated with surgery followed by postoperative RT. In some cases, preoperative RT can be used for unresectable tumors. Patients with extensive tongue invasion with fixation or extension into the soft tissues of the neck, as well as those with massive neck disease can be treated with palliative RT (30 Gy in 10 fractions or 20 Gy in 2 fractions with a 1 week interfraction interval).

Concomitant Postoperative Chemoradiation

The issue of whether concomitant chemotherapy is beneficial when administered with postoperative RT for head and neck cancer was recently addressed by two randomized trials (RTOG 9501 and EORTC 22931).[50,52] Each of these showed an improvement in local regional control and DFS when cisplatin (100 mg/m^2) was given on days 1, 22, and 43 of the RT regimen.[50,52] Severe acute effects are seen more frequently with chemoradiation compared with postoperative RT alone.

Results

Outcomes after RT alone vary with the stage of disease and treatment technique. The RT schedules used at the University of Florida are shown in Table 32-6.[83] EBRT alone results in lower local control rates compared with brachytherapy alone or combined with EBRT.[84] The M. D. Anderson experience with RT alone is depicted in Table 32-7.[85] The failure rates range from 2% for T1 lesions to 23% and 79% for T3 and T4 lesions, respectively. For T2 and T3 lesions, brachytherapy with or without EBRT appears to result in better local control than EBRT alone.

Sessions et al[71] reported on 280 patients who were treated with surgery alone, RT alone, or combined surgery and RT. Tumor categories were: T1, 106 patients; T2, 107 patients; T3, 40 patients; and T4, 27 patients. The local recurrence rate was 41%. The 5-year CSS rates by treatment modality are shown in Table 32-8.

One hundred sixty patients with T1 (79 patients) and T2 (81 patients) floor-of-mouth cancers were treated at the Institute Gustave-Roussy with low-dose rate ^{192}Ir brachytherapy.[86] One hundred twenty-seven patients had a clinically negative neck and 33 patients (21%) had N1 neck disease. Patients with T2 and/or N1 lesions underwent a neck dissection. With a minimum follow-up of 9 years, local control rates were 93% for T1 cancers and 88% for T2 tumors.

Pernot et al[87] reported 207 patients with floor-of-mouth carcinomas treated with EBRT and ^{192}Ir brachytherapy (105 patients) or brachytherapy alone (102 patients). Tumor categories were 41%, Tl; 48%, T2; 8%, T3; 2%, T4; and 1% TX. Neck categories were 83%, N0; 12%, Nl; 3%, N2; 2%, N3. The 5-year local control rates were 97%, 72%, and 51% for Tl, T2, and T3 tumors, respectively. The 5-year CSS were: T1, 88%; T2, 47%; and T3, 36%.

Rodgers et al[88] reviewed 194 patients treated at the University of Florida. Patients with advanced lesions (T3, T4) had lower control rates when treated with RT or surgery alone compared with those treated with combined surgery and RT (Table 32-9). The 5-year CSS were: stage I, 96%; stage II, 70%; stage III, 67%; and stage IVA, 44%.

Techniques of Irradiation

Because of the proximity of the gingival ridge, which is vulnerable to high-dose RT-induced soft-tissue injury or osteoradionecrosis, the floor of the mouth has a lower RT tolerance than other portions of the oral cavity. Therefore, preirradiation and postirradiation oral care is critical.

TABLE 32-6 Carcinoma of the Floor of Mouth: RT Schedules Currently Prescribed at the University of Florida

	Interstitial Only (Gy)	Intraoral Cone Only (Gy)	EBRT ± Interstitial (Gy)	Intraoral Cone Plus EBRT (Gy)
TX—No visible or palpable tumor	55	45 over 3 wk	Not recommended	Not recommended
TX—Palpable induration or positive margins	65	55 over 4 wk	45 plus 25	15 to 18 in 10 fractions plus 50
Early superficial	60 to 65	45 over 3 wk	Not recommended	Not recommended
Early, 1 to 3 cm, induration	Not recommended	Not recommended	45 plus 25 to 30	15 to 24 in 10 fractions plus 45

T1 and T2 Cancers

Patients with superficial (≤4 mm thick), well-differentiated squamous cell carcinoma of the floor of mouth may be treated either with brachytherapy alone or, when accessible, with intraoral cone RT. Brachytherapy is not feasible if the tumor abuts or extends onto the mandibular alveolar ridge because of the risk of bone exposure. Brachytherapy may be performed with iridium using the plastic tube technique.

Intraoral cone RT is administered with either orthovoltage x-rays or electrons. Orthovoltage x-rays are preferred because there is less beam constriction and the surface dose is higher. Before each treatment, it is necessary for the radiation oncologist to verify the position of the tumor relative to the intraoral cone. Because a small volume of tissue is included in the intraoral cone field, the dose per fraction may be increased to 2.5 Gy to 3.0 Gy once daily.

Cancers thicker than 4 mm and those that are poorly differentiated have an increased risk of subclinical disease in the regional nodes. The first echelon nodes for the floor of mouth are the level I and II nodes. EBRT is delivered with either 4-MV or 6-MV x-rays using parallel-opposed fields that encompass the primary tumor as well as the first echelon nodes. An intraoral stent is placed in the mouth to displace the maxilla and upper lip out of the fields (Figure 32-6).[56] The EBRT fields are treated to 46 Gy in 23 fractions once daily or 38.4 Gy at 1.6 Gy per fraction twice daily. Brachytherapy follows the EBRT if that is the technique selected to boost the tumor. If intraoral cone RT is selected to boost the tumor, it precedes the EBRT so the extent of the tumor can be optimally defined and because it may be difficult to place the cone after EBRT because of patient discomfort. The total dose ranges from 65 Gy to 70 Gy.

The low neck (levels III and IV nodes) is irradiated with an anterior field, using 4-MV or 6-MV x-rays to 50 Gy in 25 fractions or 40.5 Gy in 15 fractions specified a D-max. The latter schedule is preferred if treatment to the upper neck will be completed in less than 25 fractions. A tapered midline block is used to shield the larynx. The junction between the parallel-opposed fields and the low neck field is at the thyroid notch (Figure 32-7).[89]

T3 and T4 Cancers

The likelihood of cure without a major complication after primary RT is low. Therefore, if patients are treated with curative intent, postoperative RT is combined with resection of the primary tumor and a neck dissection. The fields are similar to those described for patients treated with RT alone. The superior border of the field is extended to the skull base if there are multiple positive nodes or extracapsular extension. The portals are reduced off of the spinal cord at 44 Gy to 46 Gy and, if necessary, the neck posterior to the reduced fields may be irradiated with 8-MeV to 10-MeV electrons. Patients with ipsilateral positive nodes may be treated with IMRT to reduce the dose to the contralateral parotid gland and, thus, the risk of long-term xerostomia.[90,91] Patients with bilateral positive nodes are treated with parallel opposed field because parotid-sparing IMRT may result in an increased risk of a marginal recurrence. Those with negative nodes may be treated with parallel opposed fields excluding most of the parotid glands. A petroleum jelly gauze bolus is placed on the incision to ensure an adequate surface dose. Patients with negative margins generally receive 60 Gy at 2 Gy per fraction. Altered fractionation should be considered for patients with positive margins and for those with an interval of more than 6 weeks between surgery and initiation of postoperative RT. The preferred schedule at the University of Florida is 74.4 Gy at 1.2 Gy per fraction administered twice daily in a continuous course over 6.5 weeks, usually with concomitant cisplatin.

An occasional patient may present with an incompletely resectable tumor, usually because of fixed neck disease. In this event, RT precedes surgery in an effort to render the tumor

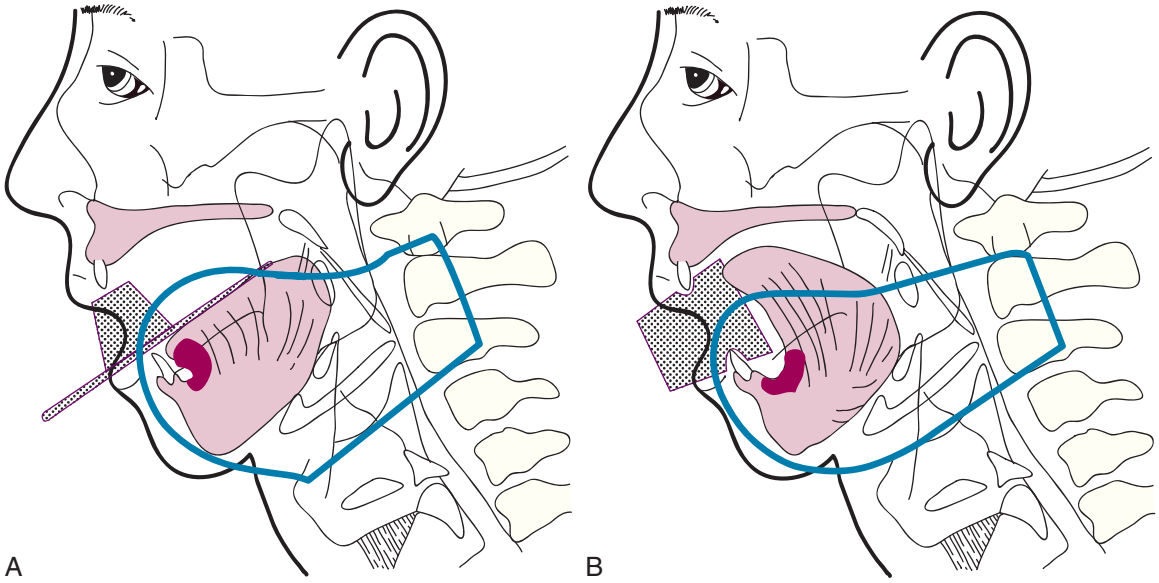

Figure 32-6 **A,** Portal for treatment of carcinoma of the floor of the mouth with tongue invasion; the tongue is depressed into the floor of the mouth with a tongue blade and cork. **B,** Portal for irradiation of limited anterior floor of mouth carcinoma without tongue invasion. Two notches are cut on a cork so it can be held in the same position between the patient's upper and lower incisors during every treatment session; the tip of the tongue is displaced from the treatment field. The anterior border of the field covers the full thickness of the mandibular arch. The lower field edge is at the thyroid cartilage, ensuring adequate coverage of the submandibular lymph nodes. The superior border is shaped so that much of the oral cavity, oropharynx, and parotid glands are out of the portal. The minimum tumor dose to the planning target volume (PTV) is specified at the primary site (i.e., not along the central axis of the portal) with the aid of computer dosimetry.
(From Parsons JT, Mendenhall WM, Moore GJ, et al: Radiotherapy of tumors of the oral cavity. In Thawley SE, Panje WR, Batsakis JG, et al, editors: Comprehensive management of head and neck tumors, ed 2, Philadelphia, 1999, W.B. Saunders Company, pp 695–719). [Figures 35-8 and 35-9, p 704].

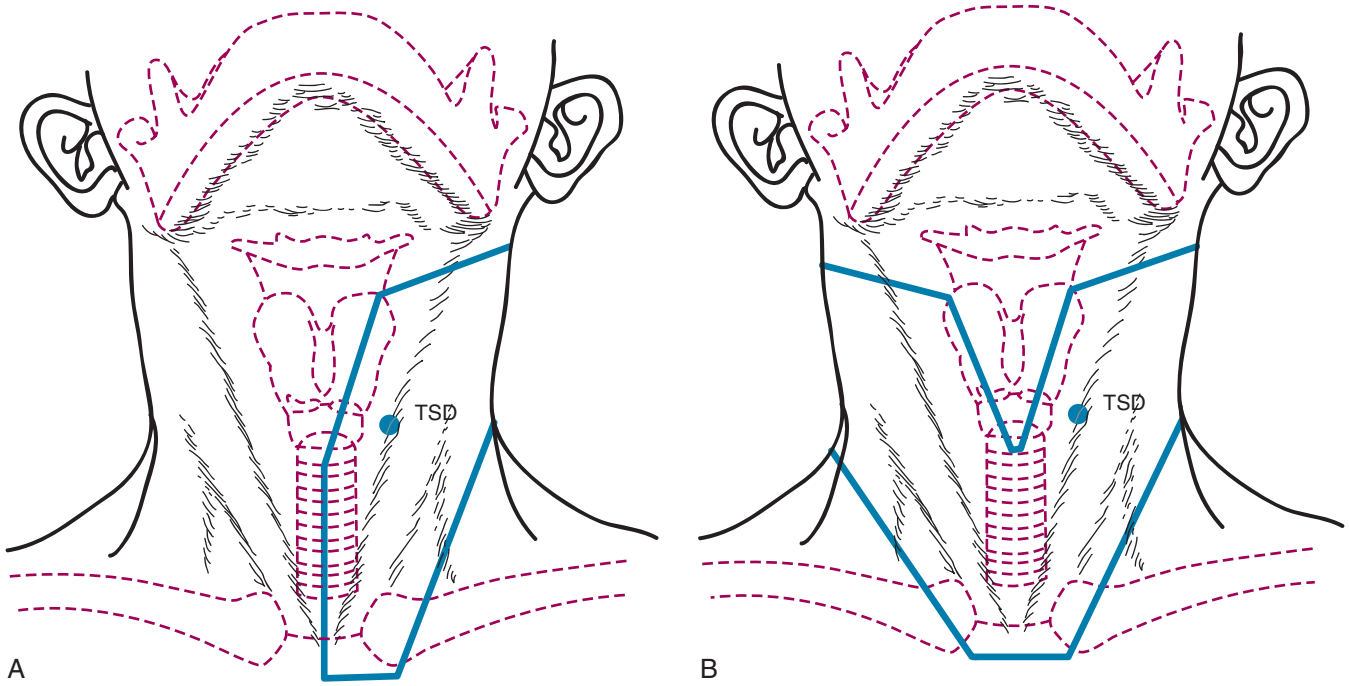

Figure 32-7 **A,** Portal used to irradiate the ipsilateral neck. In patients with N0 disease, the nodes in the lateral supraclavicular fossa are at low risk and are not irradiated electively. **B,** Fields for bilateral lower neck RT of the N0 neck. The larynx shield should be carefully designed. Because the internal jugular vein lymph nodes lie adjacent to the posterolateral margin of the thyroid cartilage, the shield cannot cover the entire cartilage without producing a low-dose area in these nodes. A common error in the treatment of the lower neck is to extend the low neck portal laterally out to the shoulders encompassing lateral supraclavicular lymph nodes that are at negligible risk while partially shielding the high-risk midjugular lymph nodes with a large rectangular laryngeal block. The inferior extent of the shield is at the cricoid cartilage or first or second tracheal ring; the shield must be tapered because the nodes tend to lie closer to the midline as the lower neck is approached.

resectable. Approximately 46 Gy to 50 Gy is delivered to the primary tumor and both sides of the neck followed by a reduction and a boost to the area limiting resection to 60 Gy to 70 Gy.

Patients with advanced disease and a remote chance of cure are treated with palliative intent. The dose fractionation schedules employed at the University of Florida are 20 Gy in 2 fractions with a 1-week interfraction interval or 30 Gy in 10 fractions over 2 weeks.

Complications

A limited soft-tissue necrosis may develop in the floor of the mouth, usually at the site of the original lesion. These ulcers are painful and usually respond to local anesthetic measures (viscous lidocaine or tetracaine lollipops), antibiotics, and time. If the ulceration develops on the gingiva, the underlying mandible may be exposed. It is recommended to discontinue wearing of dentures, apply a local anesthetic and administer antibiotics. Recent data suggests that pentoxifylline, 400 mg three or four times daily, may be beneficial in this setting, and may also reduce late RT-induced fibrosis.[92] If the soft-tissue or bone necrosis progresses, hyperbaric oxygen and surgical debridement may be necessary.[93,94] Eighteen of 194 patients (9%) treated at the University of Florida developed severe complications (Table 32-10).[88]

Sessions et al[71] reported on 280 patients treated with surgery alone or RT. They observed late RT complications in 41% of patients treated by EBRT and brachytherapy, most of which appeared within 1 year of treatment. Surgical complications included infection (5%), wound slough (9.6%), orocutaneous fistula (6.1%), carotid artery exposure/blowout (1.1%), and delayed fatality (1.4%). Fifty-eight percent of these complications were related to the use of combined surgery and external RT.

Bone necrosis was seen in 18% of patients treated with brachytherapy for T1-T2 floor-of-mouth cancers at the Institut Gustave-Roussy; 2.5% were severe.[86]

ORAL TONGUE CANCERS

Anatomy

The tongue is located in the floor of the mouth, and at rest, fills most of the oral cavity. It is involved with mastication, taste, and oral cleansing; but its main functions are propelling food into the pharynx when swallowing, and forming words when speaking.

The sulcus terminalis divides the tongue into the oral and pharyngeal portions; the oral portion consists of the anterior two thirds of the tongue. The tongue is attached to the floor of the mouth by the frenulum. The circumvallate papillae are the largest taste buds; they are 1 mm to 2 mm in diameter and lie anterior to the sulcus terminalis.

The oral tongue consists of four muscles: the genioglossus, hyoglossus, styloglossus, and palatoglossus. They all originate outside the tongue and insert into it and their function is to move the tongue. There are four intrinsic muscles of the tongue that alter the shape of the tongue.

The muscles and mucous membranes of the tongue have separate nerve supplies. The hypoglossal nerve (cranial nerve XII) is the motor nerve of the tongue. It descends from the medulla and exits through the hypoglossal canal from whence it passes laterally between the internal jugular vein and internal and external carotid arteries to curve anteriorly and enter the tongue. It passes anteriorly on the inferior aspect of the hyoglossus muscle and then to the lateral aspect of the genioglossus muscle. Injury of the hypoglossal nerve results in paralysis and eventual atrophy of the ipsilateral tongue.

The lingual nerve, which is a branch of the mandibular division of cranial nerve V, is the sensory nerve for the oral tongue. For special sensation such as taste, the anterior two thirds of the tongue is supplied by the chorda tympani branch of the facial nerve (cranial nerve VII). The chorda tympani joins the lingual nerve and runs anteriorly in its sheath. The blood supply to the tongue is from the lingual artery; two lingual veins accompany the lingual artery. The deep lingual vein begins at the tip of the tongue and runs posteriorly in the median plane.

The tongue has a submucosal plexus of lymph vessels. There are three routes of lymphatic drainage from the oral tongue: the tip of the tongue drains to the submental lymph nodes (level Ia); lymph from the lateral aspects of the tongue drains to the submandibular lymph nodes (level Ib) and from there into the deep cervical lymph nodes (level II-IV); and lymph from the medial tongue drains directly to the inferior deep cervical lymph nodes (levels III and IV). Approximately 15% of patients have lymphatic metastases that bypass level II and present in levels III and IV.[95] Lymphatic drainage is unilateral; drainage to the contralateral lymphatics is unlikely.

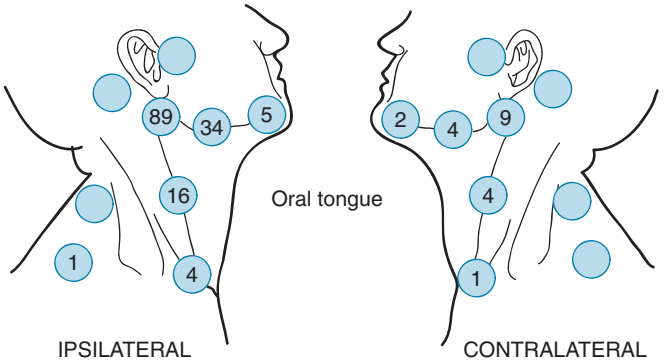
Pathology and Patterns of Spread

Ninety-five percent of oral tongue cancers are squamous cell carcinomas. Leukoplakia is also common.[96] Verrucous carcinoma and minor salivary gland tumors occur infrequently.

Nearly all squamous cell carcinomas occur on the lateral and ventral surfaces of the tongue. Anterior-third (tip) lesions are usually diagnosed early. Middle-third lesions often invade the musculature of the tongue and subsequently extend into the lateral floor of mouth. Posterior-third lesions grow into the musculature of tongue, floor of mouth, anterior tonsillar pillar, base of tongue, glossotonsillar sulcus, and the mandible.

The distribution of clinically positive neck node metastases on presentation is shown in Figure 32-8.[64] Forty-five percent of patients with cancers of the oral tongue have clinically positive nodes at diagnosis; 5% are bilateral. Byers et al[65] reported a 19% incidence of subclinical disease for T1N0 and T2N0 lesions, and 32% for T3N0 to T4N0 cancers after elective neck dissection. Ozeki et al[97] have reported three cases with metastases to the lingual lymph nodes.

Clinical Manifestations, Patient Evaluation, and Staging



Patients with oral tongue carcinomas usually present with a sense of tongue irritation or of a mass in the tongue. Deep

infiltration may affect speech and swallowing. Advanced ulcerative lesions are often associated with a foul odor and pain.

Palpation of the tongue and floor of mouth, visual examination, and assessment of tongue mobility will help define the extent of the primary tumor. CT and, to a lesser extent MRI, is useful for defining the deep extent of larger primary tumors and to assess the neck. The staging system is depicted in Table 32-2.[31]

Treatment

A treatment algorithm is shown in Figure 32-9.

N_0	N_1	N_{2A}	N_{2B}	N_{3A}	N_{3B}	N_1–N_3 / Total
197	40	9	32	8	16	105 / 302 = 35%

Early Lesions (T1 and Superficial T2)

Surgery and RT are equally effective in controlling small oral tongue cancers. Superficial well-defined lesions can be cured using resection alone with good functional results.[98,99] Postoperative RT is recommended for close or positive margins,[78,100] extensive nodal disease (large or multiple positive neck nodes), vascular space invasion, extracapsular extension, or perineural invasion.[33,53] Although the risk of a significant RT complication is low, surgery is the preferred treatment in the authors' institution because of a lower risk of bone exposure or soft-tissue necrosis that may persist for months or years after RT.

Patients are treated with definitive RT if they decline surgery or are at high risk for operative complications.[101] RT for early stage oral tongue carcinoma can be given with EBRT combined with an interstitial implant or an intraoral cone boost, or with an interstitial implant alone.[85,102] The results of EBRT alone are suboptimal.

Moderately Advanced Lesions (Large T2 and T3)

Moderately advanced primary cancers are managed by partial glossectomy followed by postoperative RT. Preoperative RT is rarely used because it is easier for the surgeon to define the extent of the tumor in the patient who is unirradiated and because the risk of postoperative complications is higher.

Advanced Lesions (T4)

The likelihood of cure for T4 tongue cancers is low. Early T4 cancer may be suitable for partial glossectomy and adjuvant RT. More advanced lesions require a total glossectomy either with or without a total laryngectomy (to prevent aspiration) and reconstruction. Preoperative RT alone or plus concurrent chemotherapy can be given to patients with unresectable tumors, giving at least 50 Gy in 25 fractions to attempt to render the tumor operable or allow the surgeon to perform a more complete resection. Patients who are in poor health or

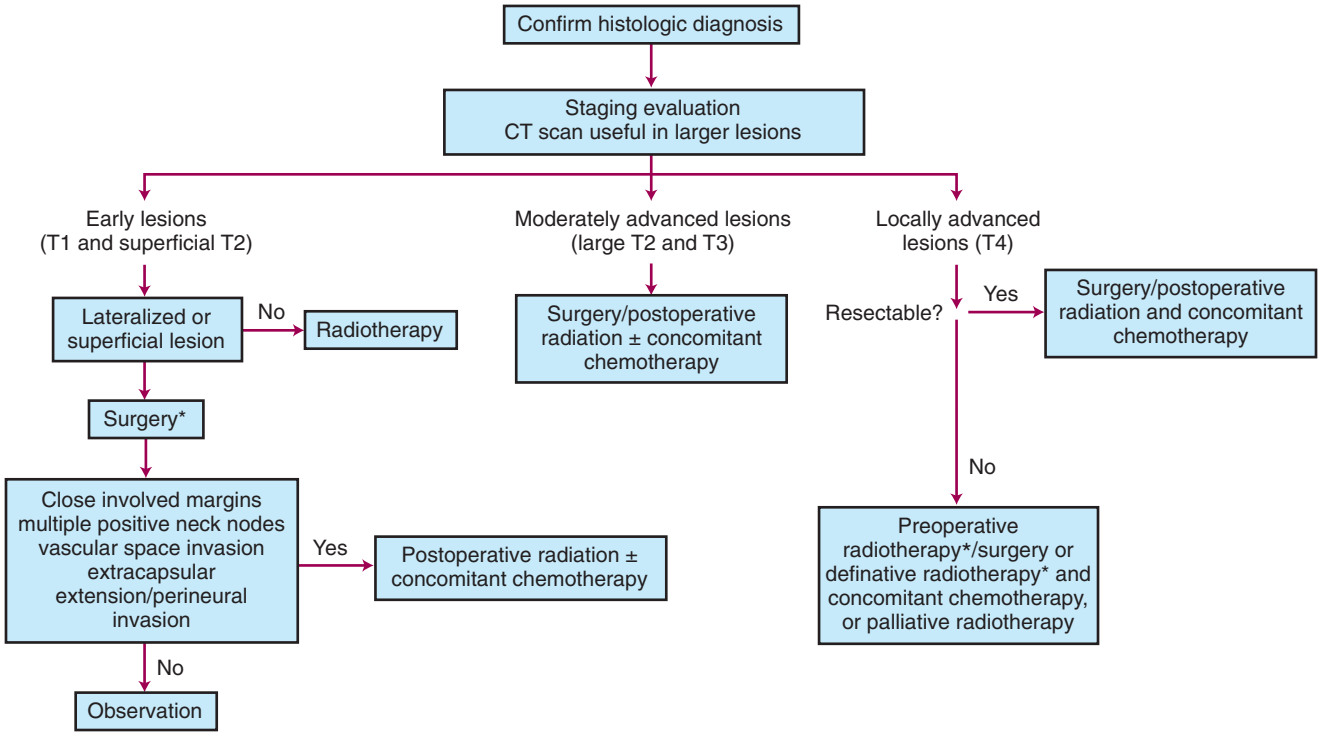

Figure 32-9 Treatment algorithm for de novo oral tongue cancer. *Treat neck (neck dissection or radiotherapy) for primary tumors >2 mm thick.[98] †May use concomitant chemotherapy.[72]

who also have advanced neck disease are treated with palliative RT.

Results

Wang et al[103] evaluated results of various boost techniques combined with EBRT for patients with T1 and T2 oral tongue lesions and observed a 5-year actuarial local control rate of 54% after an interstitial implant, 50% after intraoral cone orthovoltage RT, and 86% after intraoral cone electron beam therapy. The reason that local control was better after electron beam intraoral cone boost compared with orthovoltage intraoral cone is unclear. Compared with interstitial implantation, intraoral cone RT is associated with a lower dose to the mandible and does not require anesthesia or hospitalization. It may also be associated with fewer complications. Wang et al at Massachusetts General Hospital gave 3.0 Gy per fraction for eight to nine daily fractions with intraoral electron beam RT (five fractions per week) followed immediately by EBRT with 1.6 Gy twice daily for 12 days.[103] The patient was given a 1.5 to 2 week split and resumed RT to a total EBRT dose of 51.4 Gy; the total dose is approximately 75 Gy.

Intraoral cone RT with orthovoltage x-rays is preferred at the University of Florida.[104] Patients usually receive 3.0 Gy per fraction with intraoral cone treatment for 7 to 9 days for a total of 21 Gy to 27 Gy followed by EBRT to 30 Gy in 10 once-daily fractions or 32 Gy at 1.6 per fraction twice daily over 2 weeks to the primary site and neck.

Brachytherapy may also be combined with EBRT to treat oral tongue cancer.[99,102,105] Patients treated at the University of Florida with EBRT followed by an interstitial implant had a local control rate of 83%.[101] Wendt et al[105] reported on the M. D. Anderson experience with T1N0 and T2N0 oral tongue carcinomas in which patients underwent either brachytherapy alone or combined with EBRT. Of 8 patients who were treated with EBRT alone, 5 (63%) developed a local recurrence. Six of 18 patients (33%) treated with interstitial therapy failed at the primary site. In those patients treated with a combination of EBRT and brachytherapy, the 2-year local control rate was 92% for those treated with EBRT doses less than 40 Gy combined with a moderately high brachytherapy dose, compared with 65% for patients who received EBRT doses of 40 Gy or more with a lower brachytherapy dose.[105] A review of the pertinent literature supports the efficacy of brachytherapy (Table 32-11).[84]

Subclinical disease in the neck nodes is common in patients with oral tongue cancer. Matsuura et al stressed the importance of elective treatment to the neck, especially as tumor thickness increases.[108] In their experience, patients with tumor thickness 8 mm or more were at an increased risk of nodal failure in the clinically negative neck. Wendt et al[105] also showed the importance of elective therapy to the clinically negative neck. Failure in the neck occurred in 44% of patients receiving no elective neck RT; 27% of the failures were in patients receiving less than 40 Gy compared to an 11% failure rate for those who received 40 Gy or more. Byers et al[109] recommended elective treatment to the clinically negative neck in patients with T2 to T4 primary tumors. Haddadin et al[110] observed that patients with T2 tongue carcinomas had a significantly better outcome after an elective neck dissection compared with those who were followed with salvage reserved until development of a regional failure (75% versus 39% 5-year survival rates, respectively). Based on a review of the Memorial Sloan-Kettering Cancer Center (MSKCC) experience, Spiro et al[98] recommended that elective neck therapy be given for primary tumors exceeding 2 mm in thickness because the risk of cervical metastasis approached 40% in this cohort of patients. O-Charoenrat et al[111] found that increasing tumor thickness predicted for occult cervical node metastasis and poor outcomes in patients with stages I and II oral tongue squamous cell carcinoma treated at the Royal Marsden Hospital. Univariate analysis of DFS showed poorer outcomes for patients older than 60 years ($p = 0.0423$) and with tumors thicker than 5 mm ($p = 0.0067$). The impact of tumor thickness on outcome ($p = 0.005$) was also appreciated in a multivariate analysis. They recommended elective neck treatment for tumors more than 5 mm thick.

The use of sentinel lymph node biopsy and PET scanning may alter the treatment paradigm as more experience is gained in their use for oral cavity cancers.[112]

Bourgier et al reported on 279 patients treated with exclusive low-dose rate brachytherapy with or without an elective neck dissection for T2N0 squamous cell carcinoma of the oral tongue.[113] The incidence of subclinical cervical node metastases was 45%. The 2-year local and regional control rates were 79% and 76%, respectively. The incidence of grade 3 complications was 3%.

Fein et al[101] compared the results and complications of treatment with RT or surgery for squamous cell carcinoma of the oral tongue. The control rates for RT alone or surgery alone or in combination with RT were the same for stage T1 and T2 lesions; combined modality treatment resulted in higher cure rates for T3 and T4 tumors (Table 32-12). In an analysis of patients with T1 and T2 lesions, those receiving less than 30 Gy of EBRT plus an interstitial implant had a better outcome than those receiving surgery plus or minus postoperative RT.[101] Currently, for patients receiving RT alone, a dose of 1.6 Gy per fraction is given twice daily to 32 Gy followed immediately by an interstitial implant for an additional 35 Gy to 40 Gy. This technique decreases the overall treatment time and avoids the large dose per fraction associated with 30 Gy in 10 fractions over 2 weeks.[101]

Chao et al[100] reported on 55 patients with stage T1 and T2 lesions treated with surgery and postoperative RT. Thirty-nine patients received EBRT alone and 16 patients had an interstitial implant as part of the treatment. By adding an interstitial implant for patients with positive margins, the local control was equivalent to that observed for patients with negative margins treated with EBRT alone.

Sessions et al[99] reported on 332 patients with oral tongue cancer treated with surgery or RT at Washington University. Tumor stages at presentation were T1 116 patients; T2, 128 patients; T3, 71 patients; and T4, 17 patients. Local recurrences

occurred in 34% and 31% suffered a neck recurrence. The 5-year CSS versus treatment group for 279 of the 332 patients are shown in Table 32-13.

Techniques of Irradiation

T1 and T2 Cancers

Reduction of overall treatment time is vital to the successful treatment of oral tongue carcinomas with RT alone. Patients with well-differentiated carcinomas that are 4 mm or less are optimally treated with brachytherapy alone. Interstitial implantation may be accomplished with iridium using the plastic tube technique. The total dose varies from 65 Gy to 70 Gy over 5 to 7 days.

Although intraoral cone RT has been used successfully to treat oral tongue cancers, it is often difficult to immobilize the lesion so that setup reproducibility may be problematic. If treatment with an intraoral cone is chosen, then the cone is positioned so that the tumor is treated with a 1-cm margin. The intraoral cone therapy should be done before EBRT because of better tolerance and because the lesion can be clearly defined. Orthovoltage x-rays or electron beam may be used. If electrons are used, a beam spoiler or bolus is necessary to ensure an adequate surface dose. Additionally, a larger margin is necessary because of beam constriction compared with orthovoltage RT.

Patients who have poorly differentiated carcinomas, as well as those with 5 mm or more depth of invasion, should be treated with a combination of EBRT and brachytherapy. Parallel-opposed fields include the primary tumor as well as the levels I and II lymph nodes. A cork-and-tongue block displaces the tongue inferiorly and the maxilla superiorly to minimize the amount of normal tissue included in the treatment volume (Figure 32-10). The fields are weighted 3:2 to the side of the tumor and either 30 Gy in 10 fractions once daily or 32 to 38.4 Gy at 1.6 Gy per fraction twice daily is delivered over 2 to 2.5 weeks with 4-MV or 6-MV x-rays. Although ^{60}Co is an ideal beam for treatment of patients with oral cavity

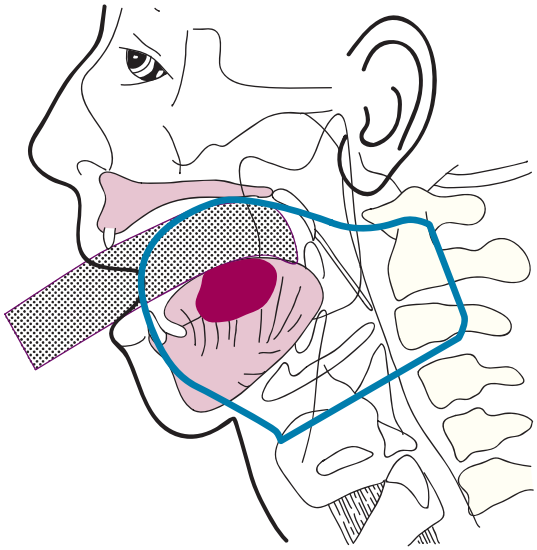

Figure 32-10 Well lateralized squamous cell carcinoma of the oral tongue (neck stage N0). A single ipsilateral field is used. The field encompasses the submaxillary (level Ib) and subdigastric (level II) lymph nodes; the entire width of the vertebral body is included to ensure adequate posterior coverage of the subdigastric lymph nodes (level II). Stainless steel pins are usually inserted into the anterior most and posterior most aspects of the lesion to the aid in localizing the cancer on the treatment planning (simulation) roentgenogram or CT scan and to confirm coverage by the interstitial implant. For lesions smaller than 2.0 cm in diameter, the low neck is not irradiated (unless the histology is poorly differentiated squamous cell carcinoma). The larynx is excluded from the radiation field. The anterior submental skin and subcutaneous tissues are shielded, when possible, to reduce submental edema and late development of fibrosis. The upper border is shaped to exclude most of the parotid gland. An intraoral lead block (stippled area) shields the contralateral mucosa. The block is coated with beeswax to prevent a high-dose effect on the adjacent mucosa resulting from scattered low-energy electrons from the metal surface. The usual preinterstitial tumor dose is 32 Gy using 1.6 Gy per fraction, twice-a-day fractionation. For larger lesions, which extend near the midline, treatment is applied by means of parallel opposed portals with no intraoral lead block.

cancers, it is not available in most clinics. The levels III and IV nodes are included in an anterior field as previously described. After EBRT, 35 Gy to 40 Gy is added with an interstitial implant.

T3 and T4 Cancers

Patients with T3 and T4 oral tongue carcinomas are difficult to cure with RT alone. The ability to adequately encompass the primary tumor with an interstitial implant is difficult for all but the occasional patient with a favorable low volume T3 cancer. The risk of a major complication, such as a soft-tissue necrosis or bone necrosis, is high after successful RT. Therefore, most patients are treated with surgery and postoperative RT. As for other sites, dose depends on margin status: Patients with negative margins generally receive 60 Gy at 2 Gy per fraction. Altered fractionation should be considered for patients with positive margins or for those with multiple risk factors or an interval of more than 6 weeks between surgery and initiation of postoperative RT. At our institution, the preferred schedule is 74.4 Gy at 1.2 Gy per fraction administered twice daily in a continuous course over 6.5 weeks. Concomitant cisplatin is also recommended for high-risk situations (close or positive margins or extracapsular nodal extension).[53]

Radiotherapy portals are designed to include the primary tumor and both sides of the neck (levels I to IV). The initial fields extend to the skull base to include the retropharyngeal nodes if the cervical nodes are involved. A petroleum jelly gauze bolus is placed on the incisions to ensure an adequate surface dose. IMRT may be employed to spare the contralateral parotid gland unless bilateral positive nodes are present.

Patients with incompletely resected T3 and T4 carcinomas have a poor prognosis and are treated with EBRT from 74.4 Gy to 76.8 Gy at 1.2 Gy per fraction twice daily over 6.5 weeks with concomitant chemotherapy. Thereafter, patients are evaluated for resection of residual primary tumor (nidusectomy) versus an interstitial implant. Nidusectomy is preferred because of the high risk of necrosis associated with the addition of brachytherapy. Patients who have advanced, unfavorable oral tongue cancers and who are unsuitable for aggressive treatment are treated with palliative RT consisting of either 30 Gy in 10 fractions over 2 weeks or 20 Gy in 2 fractions with a 1-week interfraction interval.

Complications

After RT, patients may complain of a sensitive tongue, even after the mucosa appears to have healed. Taste tends to reappear from 1 to 3 months after treatment; however, because of xerostomia, post-RT taste perception is less sensitive.

Small, self-limited soft-tissue necroses are fairly common. If these occur, recurrent cancer must be ruled out. If the lesion is thought to be necrotic, conservative treatment is instituted. The patient is examined frequently and broad-spectrum antibiotics such as tetracycline are initiated as well as pentoxifylline.[92] Viscous lidocaine or a tetracaine lollipop can be applied to the ulcer for local analgesia. Hyperbaric oxygen treatment is indicated for larger progressive necroses that do not respond to conservative management. Surgery is employed as a last resort for large persistent necroses that are often associated with bone necrosis.

Osteoradionecrosis occurs infrequently; the onset varies from one month to many years after RT.[114] It is more common in patients receiving higher doses per fraction or with tumor invading the bone.[115] If a patient has dentures, the dentures must be removed or altered by the dentist to avoid trauma to areas of exposed bone; healing may require many months. Management is similar to that for soft-tissue necroses.

TABLE 32-14 Oral Tongue Carcinoma: Severe Complications (N = 170 Patients)

**Radiation alone or followed by planned neck dissection.*

RT-induced xerostomia is common and is related to the volume of salivary tissue irradiated and the radiation dose. Patients who are treated with brachytherapy or intraoral cone RT without EBRT usually retain salivary function.

Oral pilocarpine has been advocated by some for xerostomia. Pilocarpine exercises a broad spectrum of pharmacologic effects, including increasing the secretions of exocrine glands, most notably the salivary glands. In a multicenter, randomized, double-blind, placebo-controlled trial published in 1993, pilocarpine produced a clinically significant benefit.[116] However, its efficacy has been questioned by the outcomes of recent randomized trials.[117,118] The recommended dose is 5 mg, three to four times a day. The time interval necessary to achieve optimal results is 8 to 12 weeks.

Amifostine has been used more recently in an effort to lessen the untoward effects of RT. It can be administered either intravenously or subcutaneously.[119,120] The latter is generally felt to be more convenient and associated with less toxicity.[121] A full course of treatment with amifostine is quite expensive. This fact, coupled with its potential to cause nausea and skin reactions, has limited its acceptance in some centers.

At the University of Florida, the severe complication rate for 170 patients treated with surgery alone or in combination with RT for oral tongue cancer was compared with the severe complication rate for patients treated with RT alone; the findings are presented in Table 32-14.[101]

Sessions et al[99] reported major treatment complications in 21 of 270 patients (12.8%), most of which occurred in those receiving composite resection and RT. Complications associated with RT included orocutaneous fistula (6/224 [2.7%]), flap necrosis (1/224 [0.4%]), carotid hemorrhage (1/224 [0.4%]), xerostomia (7/224 [3.1%]), trismus (5/224 [2.2%]), radiation caries (3.1%), soft-tissue ulcer (22/224 [9.8%]), bone necrosis (14/224 [6.2%]), and dysphagia (3/224 [1.3%]).[99]

BUCCAL MUCOSA

Anatomy

The lateral walls of the oral cavity are formed by the cheeks. The buccal mucosa is composed of the inner lining of the cheeks. It is contiguous with the lips and has the same structure.

The muscle of the cheek is the buccinator. The buccal fat pad is superficial to the fascia covering the buccinator muscle and gives the cheeks a rounded contour.

Branches of the maxillary and mandibular nerves (cranial nerves V2 and V3) provide sensory innervation to the skin, cheek, and the mucous membranes lining the cheeks. The

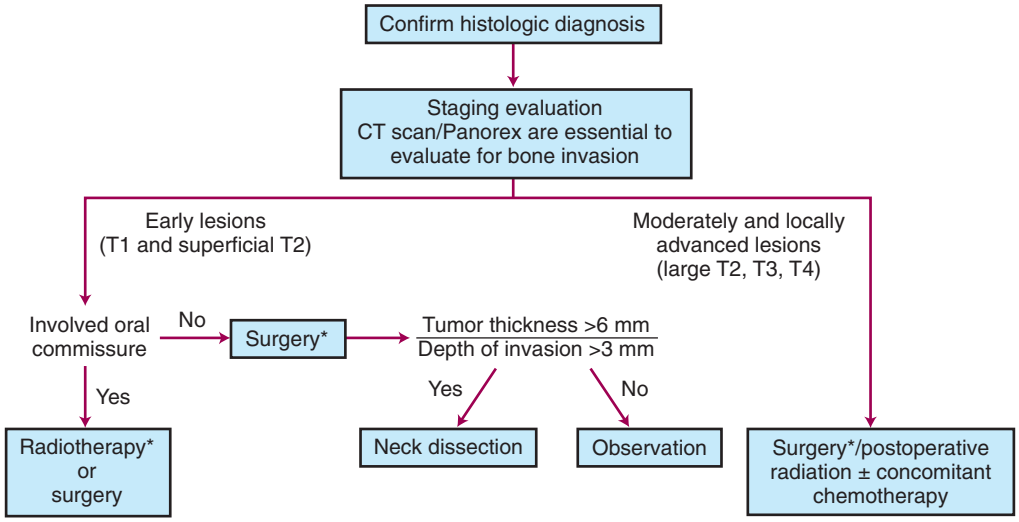

Figure 32-11 Treatment algorithm for de novo buccal mucosa cancer. *Treat neck (radiotherapy or neck dissection) for T2 to T4 tumors.[122,123]

facial nerve (cranial nerve VII) provides motor innervation to the muscles of the cheeks and lips. The lips and cheeks function together as an oral sphincter propelling food into the oral cavity. If the facial nerve is paralyzed, food tends to accumulate within the cheek along the affected side so that saliva and food dribble out of the corner of the mouth.

Pathology and Patterns of Spread

The majority of tumors originating from the buccal mucosa are low-grade squamous cell carcinomas that are frequently associated with leukoplakia. Verrucous carcinomas are observed more frequently in the buccal mucosa than in other parts of the oral cavity.[122]

Early lesions tend to be discrete, exophytic, mucosal growths. Advanced tumors tend to be ulcerated and are often associated with muscle invasion. Lesions that involve the lower gum may invade the mandible. Advanced lesions may extend to the soft tissues of the cheek.

The first echelon lymphatics are the submandibular (level Ib) and subdigastric (level II) lymph nodes. The incidence of positive nodes at diagnosis ranges from 9% to 31%; the risk of subclinical disease is 16%.[123] Bilateral cervical node metastases are unusual. Advanced cancers have a higher propensity (60%) for lymph node metastases.[122]

Clinical Manifestations and Staging

Although pain tends to be minimal, even when the lesion is large, posterior extension may result in involvement of the lingual or dental nerves which may cause ear pain. Extension behind the pterygomandibular raphe into the pterygoid muscles or into the buccinator and masseter muscles may cause trismus. Intermittent bleeding may occur when the lesions are irritated by chewing.

CT imaging can be used to evaluate the deep extension of the lesion, to detect bone invasion, and to assess the parotid and facial nodes.[66] The AJCC staging system is depicted in Table 32-2.[31]

Treatment

Early Lesions (T1 and Superficial T2 Lesions)

The preferred treatment for patients with carcinoma of the buccal mucosa is surgery. RT alone is used to treat patients by default in the uncommon situation where surgery is not feasible. Patients with T1 and T2 cancers may be treated with a combination of EBRT and an interstitial implant.[122] A treatment algorithm is shown in Figure 32-11.

Moderate to Locally Advanced Cancers (Large T2, T3, and T4)

Superficial T2 and T3 cancers may be treated with RT; however, if there is deep muscle invasion, the cure rates after RT are poor.[124,125] The preferred treatment for patients with large T3 and T4 cancers is resection of the primary tumor in conjunction with a neck dissection followed by postoperative RT. Patients who are not surgical candidates are treated with EBRT and concomitant chemotherapy. Although it would be desirable to include brachytherapy as part of the treatment, the likelihood of adequately encompassing an advanced tumor with an interstitial implant is remote, and so these patients are treated with EBRT to 76.8 Gy in 64 twice-daily fractions over 6.5 weeks. The concurrent chemotherapy regimen that is used most often at our institution is once-weekly cisplatin, 30 mg/m^2.

The management of verrucous carcinomas is controversial because of the perceived risk that the tumor may become more aggressive if it recurs after RT. However, there is little evidence in the literature to support this theory.[126] Many tumors that recur after treatment (surgery, RT, or chemotherapy) are biologically more aggressive. Therefore, it is reasonable to treat these lesions with RT if surgery is not feasible.[127] The dose is essentially the same as that prescribed for other squamous cell carcinomas. Wang[128] reported a series of patients with verrucous carcinoma treated with RT; the results were comparable to those for patients treated for squamous cell carcinoma.

Results

Five-year DFS rates after RT range from 50% to 60%, depending on the stage of the primary lesion and the presence or absence of lymph node metastases.[62,128] Ash[62] reviewed the outcomes of 374 patients; 97% were initially treated with RT. The primary lesion was controlled in 52% of the patients; however only 25% of advanced lesions were controlled. Nair et al[129] evaluated the role of RT in the management of carcinomas of the buccal mucosa; RT was either administered with an interstitial implant consisting of 65 Gy over 6 days (45 patients), continuous course EBRT consisting of 52.5 Gy in

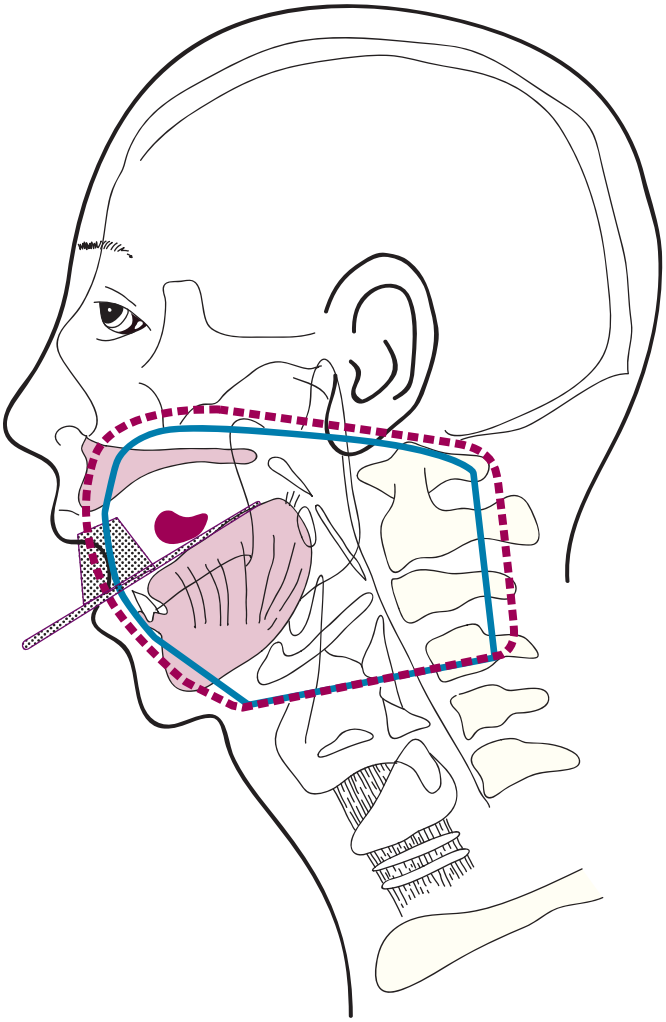

Figure 32-12 Buccal mucosa. Mixed ipsilateral en face 6-MV x-rays *(solid line)* and electrons *(dotted line)*. The electron field is 1 cm larger in all dimensions, as a result of beam constriction, except where it matches the anterior low neck field at the thyroid notch. *(Figure 1 from Mendenhall WM: Radiotherapy treatment technique. Cancer of the buccal mucosa. In Werning JW, editor: Oral cancer, New York, 2005, Thieme Medical Publishers Inc.).*

15 fractions over 19 days or 60 Gy in 25 fractions over 33 days (139 patients), or as planned split-course EBRT consisting of 35 Gy in 15 fractions over 19 days—3-week split—25 Gy in 10 fractions over 12 days (46 patients). The split-course technique tended to be used in elderly patients or for those with massive tumors. The results are shown in Table 32-15. Relapse at the primary site increased with T stage.

Urist et al[130] reviewed results of 105 patients with squamous cell carcinomas of the buccal mucosa treated by resection of the primary tumor and neck dissection (Table 32-16). In a multivariate analysis, tumor thickness greater than 6 mm was the only significant prognostic factor. Depth of invasion greater than 3 mm was also highly significant but only in the univariate analysis.

Diaz et al[125] reported on 119 patients with buccal mucosal carcinomas treated at the M. D. Anderson Cancer Center (MDACC). Eighty-four were treated with surgery alone (71%), whereas 22 received postoperative RT and 13 received preoperative RT. None were treated with RT alone. Thirty-eight patients (32%) experienced local recurrences. Five-year OS by T category were T1, 79%; T2, 65%; T3, 56%; and T4, 69%. Muscle invasion, Stensen's duct involvement, and extracapsular spread of involved nodes were significantly associated with decreased survival.[125]

Techniques of Irradiation

T1 and T2

The patient is immobilized in the supine position with an aquaplast face mask. EBRT is administered with an ipsilateral field arrangement that includes the primary lesion and the levels I and II lymph nodes. The anterior and superior borders of the field should be at least 2 cm from the borders of the primary tumor. The posterior border should be at the posterior aspect of the spinous processes if the nodes are to be irradiated; the inferior border is at the thyroid notch. The oral commissures and lips are shielded if possible to reduce the acute effects. Patients may be treated with either a "wedge pair" of 6-MV x-ray beams or an en face "mixed beam" of 6-MV x-rays and electrons (Figure 32-12). The electron energy used in the mixed beam technique varies depending on the depth of

the tumor. Because of the steep falloff of the electron beam at depth, it is preferable to risk overshooting rather than underdosing the deep extent of the tumor, and to use higher electron beam energies such as 15-MeV or 20-MeV beams. The EBRT dose fractionation schedule is 38.4 Gy at 1.6 Gy per fraction, twice daily. The ipsilateral low neck is treated with en face 6-MV x-ray field matched at the level of the thyroid notch.

If possible, a portion of the treatment should be given with intraoral cone irradiation or an interstitial implant to minimize the high dose volume and reduce the overall treatment time. Interstitial implantation is accomplished using ^{192}Ir via the plastic tube technique. The implant consists of a single plane of three to five horizontal tubes spaced 10 mm to 12 mm apart with crossing tubes at either end of the horizontal tubes. Ribbons containing ^{192}Ir seeds are afterloaded into the tubes to deliver approximately 30 Gy to 35 Gy at 10 Gy to 12 Gy per day specified at 5 mm from the plane of the sources after EBRT.

T3 and T4 Lesions

Well-lateralized tumors may be treated with the ipsilateral field arrangement as previously described. Patients with significant tumor extension toward the midline are treated with parallel-opposed fields weighted 3:2 toward the side of the lesion. Field reductions occur at 40.8 Gy to 45.6 Gy and at 60 Gy. The clinically negative low neck is treated with an anterior field with a 6-MV x-ray beam to 50 Gy in 25 fractions once daily. Thereafter, part or all of the low neck may be boosted depending on the presence and location of clinically positive neck nodes. IMRT may be considered, depending on the extent of the lesion, to optimize tumor coverage while limiting the dose to adjacent critical structures such as the cerebellum and temporal lobe.

For postoperative RT, the target volume includes the primary tumor bed and ipsilateral submandibular (level I) and subdigastric (level II) nodes. Patients with extensive positive ipsilateral nodes should be considered for RT to both sides of the neck. Patients with a tumor category of T2 or higher, tumor thickness more than 6 mm, or depth of invasion more than 3 mm have a greater than 30% risk of local recurrence, and should be treated with postoperative RT.[130]

Patients with advanced cancers unsuitable for aggressive therapy are treated with palliative RT. The fractionation scheme is either 20 Gy in 2 fractions with a 1-week interfraction interval, or 30 Gy in 10 fractions over 2 weeks.

Complications

The buccal mucosa tolerates high-dose RT with a low risk of late complications. Trismus may develop if the muscles of mastication receive high doses of RT.

GINGIVA

Anatomy

The gingiva is composed of fibrous tissue covered by mucous membrane that is firmly attached to the periosteum of the alveolar processes of the mandible and maxilla. The lower gingiva includes the mucosa covering the mandible from the gingival-buccal gutter to the origins of the mobile mucosa on the floor of the mouth. There are no minor salivary glands in the mucous membranes of the alveolar ridges.

The gingiva receives sensory innervation from the nerves supplying the teeth that are branches of cranial nerves V2 and V3 (buccal, infraorbital, greater palatine, and mental nerves).

Pathology and Patterns of Spread

Squamous cell carcinomas are most common, usually arise from the posterior portion of the mandibular gingiva, and are often associated with leukoplakia. Verrucous carcinomas may also occur, usually on the lower gingiva.

Squamous cell carcinomas of the mandibular gingiva may invade the underlying bone, retromolar trigone, adjacent buccal mucosa, and floor of the mouth. Byers et al[131] reported that 22% had associated leukoplakia, 36% had mandibular invasion, and 5% had perineural involvement. Bone invasion usually starts because there is no complete bony barrier in the edentulous portion of the mandible. The lingual and buccal plates are relatively resistant to tumor penetration. Tumor entry through the mental, mandibular, and other small foramina tend to occur in less than 10% of patients.[132]

Metastatic spread occurs first to the submandibular (level I) and upper internal jugular (level II) lymph nodes. Byers et al[131] reported 16% clinically positive nodes at diagnosis; contralateral lymph node involvement was found in only 3% of cases. Subclinical lymph node disease has been reported in 17% to 19% of cases.[131] The incidence of involved lymph nodes was 12% for T1 and T2 lesions, and 13% for T3 and T4 stage cancers.[65] The distribution of positive lymph nodes after elective neck dissection is shown in Figure 32-13.[65]

Clinical Manifestations and Staging

The patient with squamous cell carcinoma of the gingiva may first present to the dentist with ill-fitting dentures, pain, loose teeth, or a sore that will not heal. Intermittent bleeding and pain may occur when the lesion is traumatized. Invasion of the inferior dental nerve may produce paresthesia or anesthesia of the lower lip.

Because bone invasion compromises the results of RT, careful radiographic examination of the mandible with panoramic x-ray films, dental radiographs, and CT scan is essential. The AJCC staging system is shown in Table 32-2.[31]

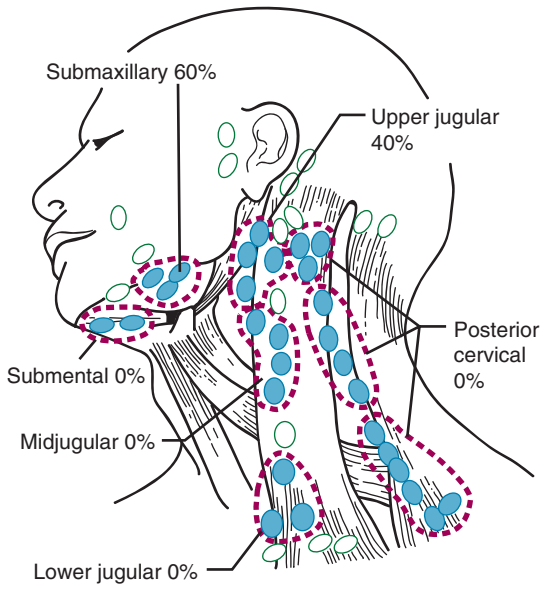

Figure 32-13 Carcinoma of the gingiva. The distribution of involved lymph nodes after elective modified neck dissection for patients with a clinically negative neck.
(From Byers RM, Wolff PF, Ballantyne AJ: Rationale for elective modified neck dissection. Head Neck Surg 10:163, 1988).

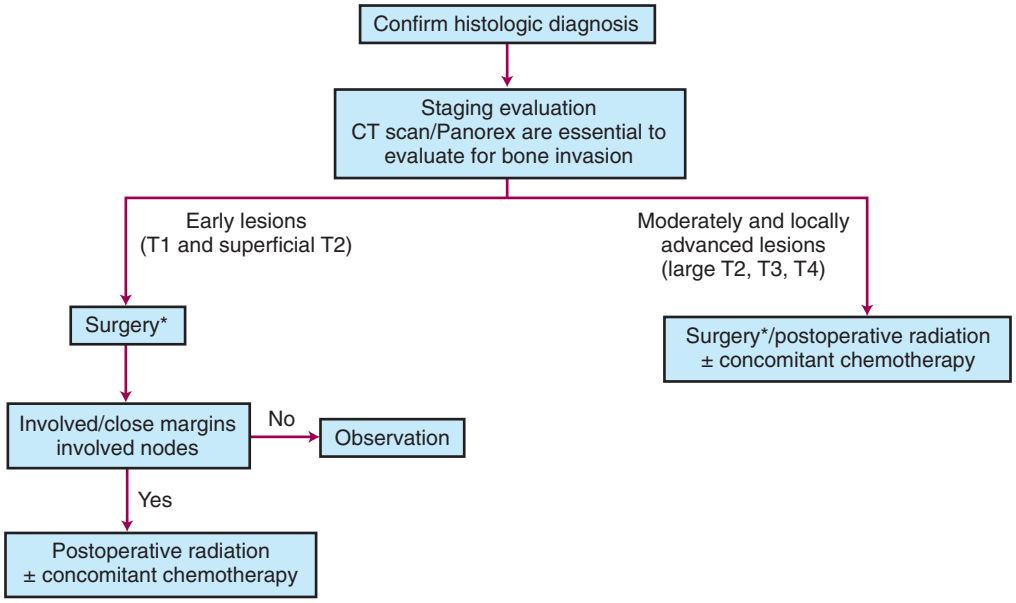

Figure 32-14 Treatment algorithm for de novo gingival cancer. *Treat neck (neck dissection).[65,131]

Treatment

Early Lesions (T1 and Superficial T2 Lesions)

The majority of these lesions are managed by surgery. Small lesions may be removed by transoral resection; however, rim resection is necessary in most cases. When direct bone invasion is present, removal of a segment of the mandible (segmental mandibulectomy) or maxilla is required. A treatment algorithm is shown in Figure 32-14.

Moderate to Locally Advanced Lesions (Large T2, T3, and T4 Lesions)

Large lesions may require a segmental mandibulectomy or partial maxillectomy.[133] Because of the likelihood of local invasion through or along the subperiosteal lymphatics, RT is often indicated after resection to eradicate microscopic disease at the margins, to sterilize subclinical disease in the cervical lymph nodes, and thus improve the likelihood of cure.[33] Postoperative RT is also indicated in the presence of perineural invasion and extensive nodal disease (large node(s) or multiple positive nodes or extranodal extension).[53] Concomitant chemotherapy during EBRT is also recommended in the postoperative setting, as outlined elsewhere in this chapter.

Results

Cady and Catlin[133] reviewed 606 patients with squamous cell carcinoma of the gingiva treated by surgery. The survival rate was 43% for patients with mandibular gingival lesions and 40% for those with maxillary alveolar ridge cancers. Soo et al[134] reviewed a 20-year experience with squamous carcinoma of the gums in 347 patients treated at the MSKCC. Sixty-four percent of patients presented with a clinically negative necks (N0). Ninety-seven percent of patients were treated surgically. The 5-year CSS was 54%. Advanced clinical stage (stages III and IV), prior dental extractions, bone invasion, and involvement of surgical margins were predictive of a lower survival rate on univariate analysis. Clinical stage was the only significant predictor of survival on multivariate analysis.

Byers et al[131] reported a 5-year OS of 43% for patients with squamous cell carcinoma of the mandibular gingiva. Fifty-one of these patients were treated with surgery that included resection of bone in 28 patients with early lesions. Only 1 of 28 patients developed a recurrence. Segmental mandibulectomy and neck dissection were used for 23 patients with advanced disease; there were no local failures. Postoperative RT was given for close margins, nerve invasion, or extensive nodal metastases (large nodes, multiple nodes, or extracapsular extension). For those treated with surgery and postoperative RT, control above the clavicles was achieved in 95% of patients.

Overholt et al[135] retrospectively reviewed results of 155 patients treated surgically for carcinoma of the mandibular gingiva. Decreased local control was observed for primary lesions larger than 3 cm ($p = 0.021$) and persistently positive surgical margins ($p = 0.027$). Survival was adversely affected by advanced T category ($p = 0.001$), positive initial and final surgical margins ($p = 0.004$), mandibular invasion ($p = 0.014$), and cervical metastases ($p < 0.001$). Local control and survival were not affected by extent of mandibular resection, tumor extension beyond the mandibular gingiva, recent dental extractions in the region of the primary tumor, perineural invasion, or histologic grade.

Patients treated with RT alone for T3 and T4 lesions have 5-year OS ranging from 30% to 40%.[123,131] Wang[128] reported a 78% control rate for patients with T1 lesions and 27% for those with T2 cancers after treatment with RT alone. Fayos[136] reported a 50% local control rate after RT alone for lesions with early bone invasion and a 25% local control rate after RT alone for those with extensive invasion.

Techniques of Irradiation

T1 and T2 Lesions

Patients who are not deemed to be surgical candidates are treated with RT. Small lesions may be treated by intraoral cone RT combined with EBRT. Interstitial implant has no place in the management of this disease because of the proximity of the bone and the high risk of osteoradionecrosis.

EBRT may be administered with either an ipsilateral en face combination of 4-MV or 6-MV x-rays and electrons, or with two 4-MV or 6-MV x-ray beams arranged in a wedge pair (Figure 32-15). The latter technique is preferred because it is possible to vary the depth of the target volume more precisely,

Figure 32-15 Patient with an early-stage carcinoma of the retromolar trigone. Radiotherapy is delivered with two 6-MV x-ray beams via a "wedge-pair" arrangement.
(Figure 1 from Mendenhall WM: Radiotherapy treatment technique. Cancer of the maxillary alveolar ridge and retromolar trigone. In Werning JW, editor: Oral cancer, New York, 2005, Thieme Publishing.)

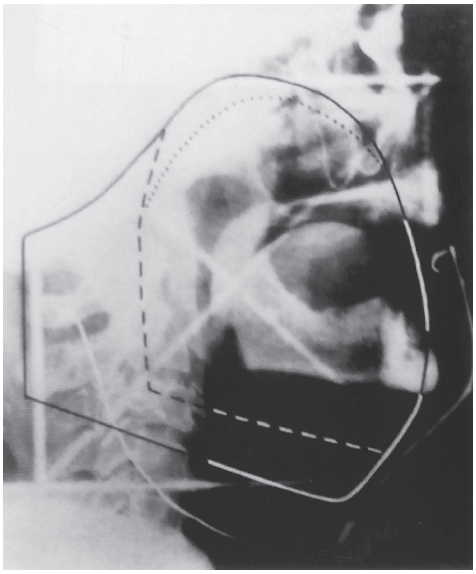

Figure 32-16 Typical portal for irradiation after hemimandibulectomy, partial maxillectomy, and radical neck dissection for pathologic T4N0 retromolar trigone lesion. **(A)** Field reductions made at 45 Gy *(dashed line)* and 60 Gy *(dotted line)*.
(Figure 2 from Amdur RJ1, Parsons JT, Mendenhall WM, et al: Postoperative irradiation for squamous cell carcinoma of the head and neck: an analysis of treatment results and complications. Int J Radiat Oncol Biol Phys 16(1):25-36, 1989.)

and underdosing the medial extent of the tumor is less likely. Lesions that exhibit significant extension onto the soft palate, or into the tongue (unusual for a T1 or T2 tumor) would be treated with parallel-opposed fields weighted 3:2 to the side of the tumor. Alternatively, IMRT may be employed to spare the contralateral parotid. The doses used are from 60 to 65 Gy over 6 to 6½ weeks for T1 tumors, and 70 Gy over 7 weeks or 74.4 Gy in 62 fractions twice daily for T2 tumors. The low neck (levels III and IV) is treated with an anterior 4-MV or 6-MV x-ray field matched at the thyroid notch and receives 50 Gy in 25 fractions.

T3 and T4 Lesions

Patients with T3 and T4 carcinomas have a relatively low chance of cure with RT alone and are optimally treated with surgery and postoperative RT. The postoperative dose varies with the margins. Patients with negative margins generally receive 60 Gy at 2 Gy per fraction. Altered fractionation is considered for patients with positive margins and for those with multiple risk factors or a prolonged interval between surgery and radiation therapy. At our institution, the preferred schedule is 74.4 Gy at 1.2 Gy per fraction administered twice daily in a continuous course over 6.5 weeks. As with other sites, concomitant cisplatin is also recommended for high-risk situations.

Patients are treated with parallel-opposed portals that include the primary tumor and upper neck nodes (levels I and II) (Figure 32-16). The fields are weighted 3:2 toward the side of the tumor. The anterior low neck (levels III and IV) is treated with an en face 6-MV x-ray field matched at the level of the thyroid notch. A petroleum jelly gauze bolus is placed on the incisions to ensure an adequate surface dose. Fields are reduced off of the spinal cord at approximately 45 Gy. An electron beam may be used to irradiate the posterior neck (level V) if additional RT to these sites is indicated after off-cord reduction.

Patients who are not suitable for surgery are treated with twice-daily EBRT to 76.8 Gy in 64 fractions over 6.5 weeks combined with concomitant chemotherapy. The field arrangements are similar to those previously described. We routinely exclude the spinal cord at 40 Gy if chemotherapy is used concomitantly. IMRT may be used to reduce the dose to the contralateral parotid unless bilateral positive nodes are present. Patients who are unsuitable for aggressive treatment receive moderate dose palliative RT; 30 Gy in 10 fractions over 2 weeks or 20 Gy in 2 fractions with a 1 week interfraction interval.

For postoperative cases, radiation volumes include the adjacent segment of the mandible or maxilla. The entire hemimandible or hemimaxilla from the distal neural foramen to the pterygopalatine ganglion must be treated when perineural invasion is present. The low neck must be irradiated if involved nodes are present or if the primary tumor is advanced. Postoperative EBRT doses range from 60 Gy to 75 Gy at 1.8 Gy to 2.0 Gy per day. If the resection margins are positive, 74.4 Gy at 1.2 Gy per fraction, twice daily with a minimum 6-hour interfraction interval is currently used at our institution. Cisplatin is administered concomitantly, based on the results of recently published randomized data from the RTOG and EORTC.[50,52]

Complications

Surgical complications include orocutaneous fistulae and bone exposure. The complications of RT include dental caries, soft-tissue necrosis, and osteoradionecrosis. The risk is greatest for more advanced lesions.

RETROMOLAR TRIGONE

Anatomy

The small triangular surface posterior to the third mandibular molar, overlying the ascending ramus is called the

retromolar trigone. Beneath the mucosa of the retromolar trigone is the pterygomandibular raphe, which is attached to the pterygoid hamulus on the posterior mylohyoid ridge of the mandible. It serves as the insertion of the buccinator and superior constrictor muscles. Behind the pterygomandibular raphe (between the medial pterygoid muscle and the ascending ramus of the mandible) is the pterygomandibular space, which contains the lingual and dental nerves. There is a small fat pad between the pterygoid muscle group and the mandibular foramen through which the mandibular nerve passes before it enters the alveolar canal. The subdigastric lymph (level II) nodes are the first echelon nodes for the retromolar trigone.

Pathology and Patterns of Spread

The vast majority of these tumors are squamous cell carcinomas. The primary tumor may spread to the adjacent buccal mucosa, anterior tonsillar pillar, mandibular gingiva, and mandible. Posterior spread to the pterygomandibular space and medial pterygoid muscle may occur. Invasion of the periosteum may occur early. Byers et al[137] reported a 25% incidence of bone invasion at diagnosis.

The incidence of clinically positive ipsilateral nodes on presentation is 39% and the risk of subclinical disease in the cervical lymph nodes is approximately 25%.[137] The distribution of positive nodes after an elective neck dissection is shown in Figure 32-17.[65]

Clinical Manifestations and Staging

Retromolar trigone cancers tend to produce pain that may be referred to the external auditory canal and preauricular area. Invasion of the pterygoid muscles can produce trismus and is better demonstrated by MRI than by CT.[66] CT scan of the head and neck (and MRI in selected cases) is useful for determining the deep extent of the primary tumor, bone invasion, and presence of positive neck nodes. The staging system is depicted in Table 32-2.

Treatment

Early Lesions (T1 and T2 Lesions)

Local control rates for T1 and T2 lesions are similar following surgery or RT.[137] If the tumor extends to the tonsillar pillar, soft palate, or buccal mucosa, and an extensive resection is required, RT is selected. If possible, intraoral cone irradiation should be used for a portion of the treatment. Small lesions without detectable bone invasion can be resected with removal of the periosteum or a rim resection of the mandible. A treatment algorithm is shown in Figure 32-18.

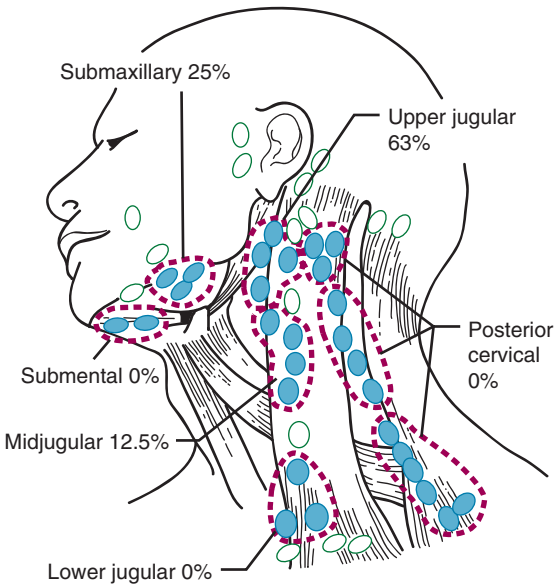

Figure 32-17 Carcinoma of the retromolar trigone. The distribution of involved lymph nodes after elective modified neck dissection for patients with a clinically negative neck.
(From Byers RM, Wolf PF, Ballantyne AJ: Rationale for elective modified neck dissection. Head Neck Surg 10:163, 1988.)

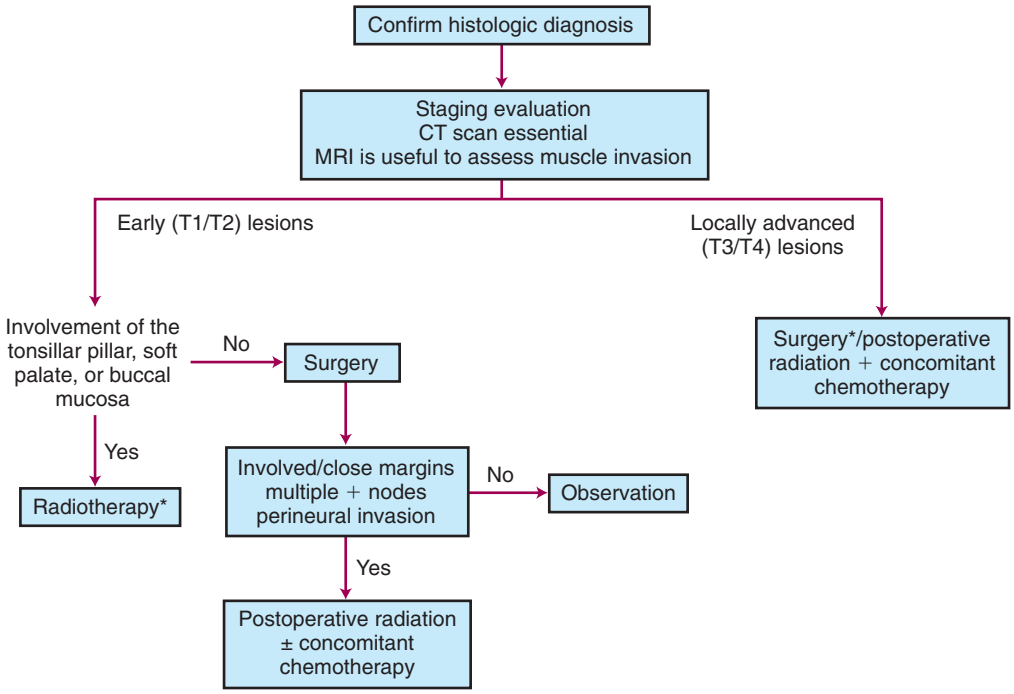

Figure 32-18 **Treatment algorithm for de novo retromolar trigone cancer.** *Treat neck (radiotherapy or neck dissection).

Locally Advanced Lesions (T3 and T4)

Superficial T3 lesions can be treated by RT. Locally advanced cancers (especially those with evidence of bony invasion) require a segmental mandibulectomy followed, in almost all cases by postoperative RT.

Results

Lo et al[138] reported on a series of patients treated with RT at the MDACC (Table 32-17). Patients with retromolar trigone cancers were grouped with those having anterior tonsillar pillar lesions. Local control varied from 70% to 76% after RT for those with T1, T2, and T3 cancers. Salvage surgery resulted in ultimate local control rates varying from 92% to 100%.

Mendenhall et al reported on 99 patients treated with RT alone or combined with surgery at the University of Florida.[139] The likelihood of cure was influenced by extent of disease and treatment; those treated with surgery and RT had a better chance of cure than those treated with RT alone (Table 32-18).

Kowalski et al[140] reported on 114 patients who underwent an extended "commando" operation between 1960 and 1991 for carcinoma of the retromolar trigone. Sixty-six patients received postoperative RT (median 50 Gy). Tumor categories were: T1, 5 patients; T2, 44 patients; T3, 24 patients; T4, 28 patients; and TX, 13 patients. Forty-one patients (36%) experienced a recurrence at one or more sites: local 31 (27%); dissected neck, 9(22%); contralateral neck, 3 (7%); and distant, 7 (17%). The 5-year overall survival rates by T stage were: T1, 80.0%; T2, 57.8%; T3, 46.5%; T4, 65.2%, and overall, 55.3%.

Byers et al[137] reported on 110 patients with squamous carcinoma of the retromolar trigone who were treated at the MDACC from 1965 to 1977 and followed for ≥5 years. Seventy patients had T1 and T2 tumors, and 77 patients had a clinically negative neck. Sixty patients received either surgery alone (n = 46) or combined with preoperative or postoperative RT (n = 14). Fifty patients were treated with RT alone. Failure at the primary site occurred in 7 of 60 patients (12%) treated surgically, and in 8 of 50 patients (16%) of patients treated with RT alone.

Techniques of Irradiation

Treatment techniques for retromolar trigone cancers are similar to those discussed in the preceding section on gingival cancers.

Complications

Thirty percent of the patients reported by Lo et al[138] developed some degree of bone exposure but only 9 patients (5.6%) required a segmental mandibulectomy. The probability of bone exposure was not found to be dose related. Huang et al[141] reported on 65 patients treated for retromolar trigone cancer and observed complications that included bone necrosis, soft-tissue necrosis, and severe trismus, occurring in 12% after surgery and postoperative RT, 11% after RT alone, and none after preoperative RT and surgery.

Kowalski et al[140] observed complications in 51.8% of 114 patients who underwent an extended commando operation between 1960 to 1991; 21 patients (18.4%) had a wound infection.

HARD PALATE

Squamous cell carcinoma of the hard palate is relatively rare. In a series of about 5000 patients with oral cavity cancers, only 25 patients (0.5%) had squamous cell carcinoma of the hard

palate.[142] In a similar study, carcinoma of the hard palate represented 3% of all oral cavity carcinomas.[143]

The male-to-female ratio is approximately 1:1. For both males and females, the peak incidence tends to occur in the seventh decade, with more than 98% of patients older than the age of 40.[144]

Anatomy

The palate forms the roof of the oral cavity and the floor of the nasal cavity. The anterior two thirds, or bony part of the palate, is called the hard palate and is formed by the palatine processes of the maxilla and the horizontal plates of the palatine bones. Anteriorly and laterally, the hard palate is bounded by the maxillary alveolar ridge and gingiva. Posteriorly, the hard palate is contiguous with the soft palate. The hard palate is covered by a mucous membrane overlying the periosteum. Deep to the mucosa are the secreting palatine glands. The incisive foramen is posterior to the maxillary central incisors; the nasopalatine nerves pass through this foramen.

The greater palatine foramina are medial to the third maxillary molars; the greater palatine vessels and nerves emerge from this foramen. The greater palatine nerve innervates the gingiva, mucous membrane, and glands of the hard palate. The nasopalatine nerve innervates the mucous membrane of the anterior part of the hard palate. Because of the rich blood supply from the greater palatine artery, the incidence of osteoradionecrosis and soft-tissue necrosis is lower than that reported for the mandible.[145]

Pathology and Patterns of Spread

Malignant tumors of the hard palate are most often adenoid cystic carcinomas and mucoepidermoid carcinomas arising from minor salivary glands. Squamous cell carcinoma is relatively uncommon. Kaposi's sarcoma and melanomas may also originate from the mucosa of the hard palate.[144]

Most squamous cell carcinomas originate on the gingiva and spread secondarily to the hard palate. Perineural invasion occurs via the greater palatine foramen. The risk of positive lymph nodes is 13% to 24% at diagnosis.[146,147] The incidence of subclinical disease in the cervical lymphatics is 22%.[62]

Clinical Manifestations, Patient Evaluation, and Staging

Patients with squamous cell carcinomas of the hard palate may first present to the dentist with ill-fitting dentures, pain, loose teeth, or a sore that will not heal. Intermittent bleeding and paresthesias may also occur.

Imaging of the hard palate is primarily with CT scanning and is occasionally supplemented with MRI. Imaging of the neck nodes must include the facial and retrozygomatic nodes.[66] Facial nodes are best assessed by bimanual examination, particularly in patients with dental fillings. If the lesion is an adenoid cystic carcinoma, it is essential to search for perineural spread. The AJCC staging system is shown in Table 32-2.[31]

Treatment

Surgery is the usual initial treatment for most lesions; postoperative RT is indicated for patients with more extensive cancers. The role of primary RT in the management of hard palate carcinomas is ill defined. If the lesion has a large surface area and is superficial, RT can be used as initial treatment. However, most patients are treated with surgery because the underlying bone is often involved and, in that scenario, RT is unlikely to be effective.[148] Postoperative RT is indicated for close or involved margins, perineural or vascular invasion, multiple involved nodes, extracapsular extension, or bone invasion.[53] Dose and fractionation recommendations are similar to those given for other sites. A treatment algorithm is shown in Figure 32-19.

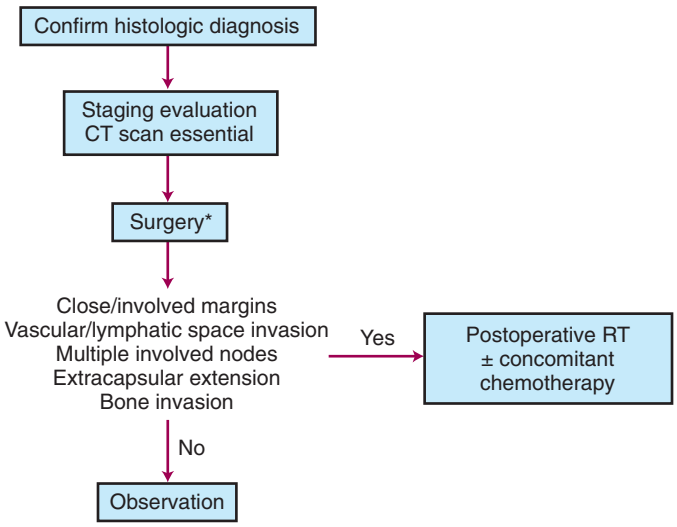

Figure 32-19 Treatment algorithm for de novo hard palate cancer.
*Treat neck (neck dissection).

Malignant salivary gland tumors of the hard palate are often treated by a combination of surgery and postoperative RT, particularly if they are high-grade tumors (adenocarcinoma, salivary duct carcinoma, high-grade mucoepidermoid, myoepithelial carcinoma, others?). Low-grade (acinic cell carcinoma, adenoid cystic carcinoma, low-grade mucoepidermoid) minor salivary gland carcinomas can be treated by surgery alone if negative margins can be achieved. Some malignant minor salivary gland tumors have been successfully controlled by high-dose RT alone.[149]

Results

Shibuya et al[150] reported the RT results for malignant lesions of the hard palate; the 5-year OS for those with squamous cell carcinomas was approximately 45%. For patients with minimal bone invasion and clinically negative neck, the 5-year OS was 75%. Data from the University of Virginia are presented in Table 32-19 for 41 patients treated with surgery, RT or both.[151]

Yorozu et al[152] reported on 31 patients treated with EBRT at the Christie Hospital between 1990 and 1997. Twenty-six received RT alone and five were treated postoperatively for positive surgical margins. The 5-year local and ultimate local control rates after salvage surgery were 53% and 69%, respectively. Survival rates were 48% for patients with squamous carcinomas and 63% for those with minor salivary gland carcinomas. T category was the only significant predictor of 5-year local control rates, which were 80% for T1 and T2 lesions and 24% for T3 and T4 lesions, respectively. The only significant predictor for survival was N category.

Tran et al[153] reported on 38 patients treated for salivary gland tumors of the palate at University of California at Los Angeles. Twenty-three of 38 tumors were on the hard palate; adenoid cystic carcinoma was the most common histologic type. Twenty-five patients received surgery alone; 13 were treated with surgery and postoperative RT. The local control rates were comparable for the two groups of patients (88% and 85%, respectively).

TABLE 32-19 Hard Palate Malignancies Treated by Surgery, Radiotherapy, or Both: 5- and 10-Year Survival Rates

	5-Year		10-Year	
Histology	**Absolute**	**Cause-Specific**	**Absolute**	**Cause-Specific**
Squamous cell carcinoma	10/26 (38%)	10/17 (59%)	8/25 (32%)	8/15 (53%)
Salivary gland tumors				
Adenocarcinoma	5/7 (71%)	5/7 (71%)	3/6 (50%)	3/5 (60%)
Adenoid cystic carcinoma	3/3	3/3	1/2	1/1
Malignant mixed tumor	5/5	5/5	1/4	1/1

Reprinted from Chung CK, Johns ME, Cantrell RW, et al: Radiotherapy in the management of primary malignancies of the hard palate. Laryngoscope 90:576–584, 1980.

Kovalic et al[154] reported on 13 patients with carcinoma of the hard palate treated at Washington University. Histologic types included adenoid cystic carcinoma, 9 patients; squamous cell carcinoma, 3 patients; and mucoepidermoid carcinoma, 1 patient. T-stages were T1, 1 patient; T2, 5 patients; T3, 3 patients; and T4, 4 patients. All had a clinically negative neck. Ten patients received excision and postoperative RT; 3 patients were treated with RT alone. The 10-year DFS and local control rates were 77% and 92%, respectively.

A group of 50 patients was treated surgically at the University of Cincinnati and included 25 patients with squamous cell carcinomas, 11 with adenoid cystic carcinomas, 6 with adenocarcinomas and 8 with miscellaneous histologies.[155] The 5-year OS by histology were squamous carcinoma, 76%; adenoid cystic carcinoma, 90%; and overall, 85%. The 10-year OS for adenoid cystic carcinomas fell to 75%, consistent with their tendency to develop late recurrences, including distant metastases.

Most relapses are found at the primary site. Evans and Shah reported a 53% incidence of isolated primary site failure.[144] The incidence of recurrence in the cervical nodes was 30%; failure involving both the primary site as well as the cervical lymph nodes was 10%. No patient treatment failed with results of distant metastases only. Seven percent of the patients experienced treatment failure in both distant and local regional sites.[144]

The risk of developing metachronous carcinomas is high. In the University of Virginia's experience, 28% of the patients developed a metachronous primary carcinoma during their lifetime and 13% developed a third, fourth, or fifth carcinoma. The oral cavity was the most common site for metachronous cancers.[146]

Techniques of Irradiation: Hard Palate and Maxillary Alveolar Ridge

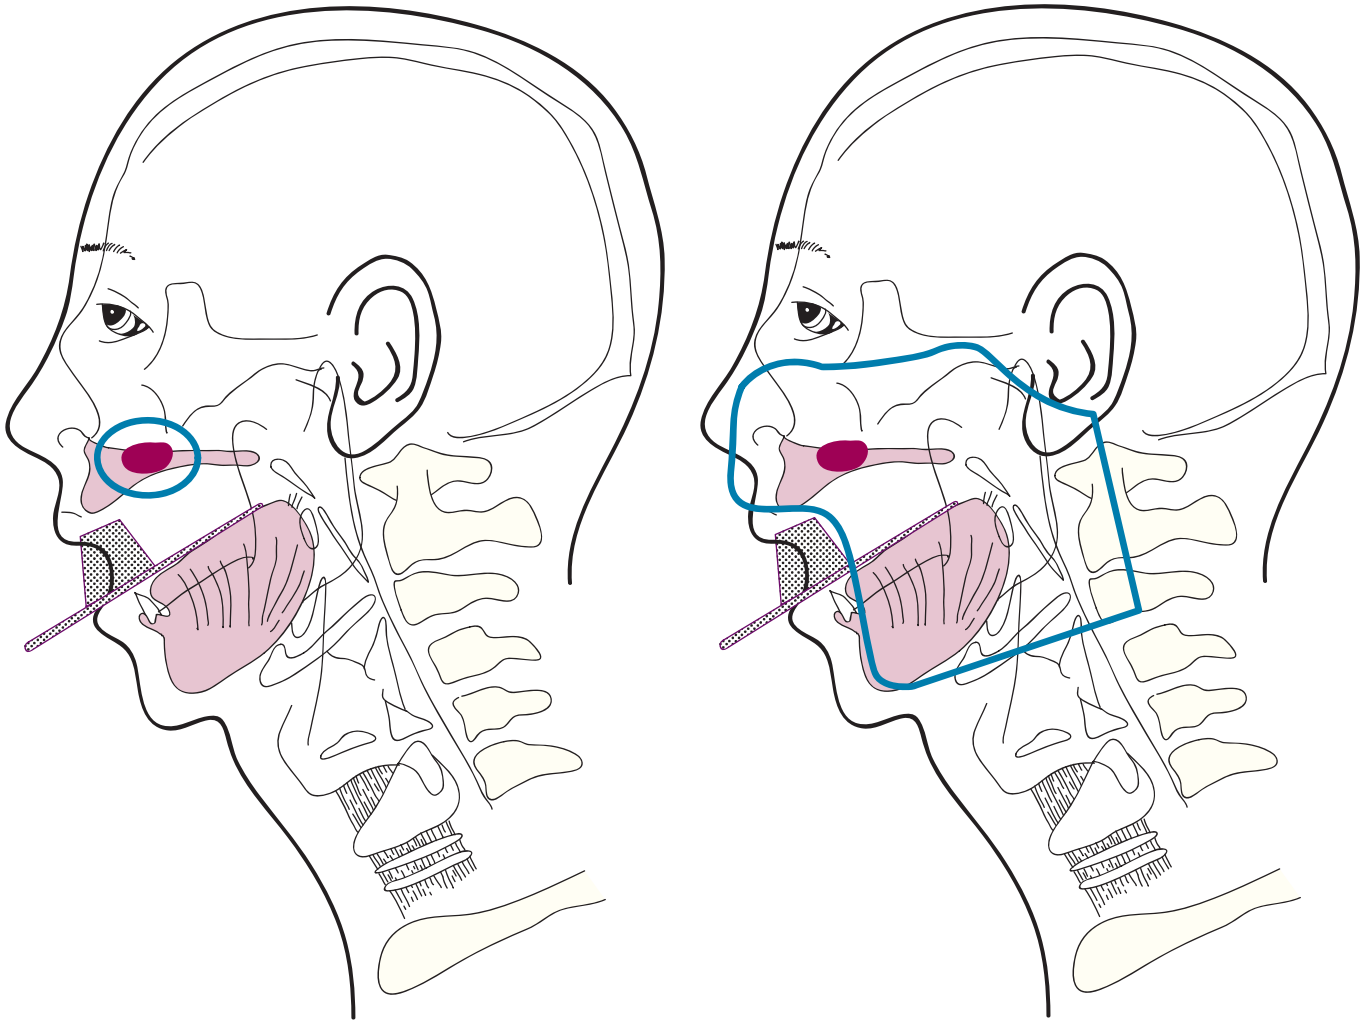
T1 and T2 Lesions

The preferred initial treatment for patients with T1 and T2 carcinomas of the hard palate is surgery. RT is used by default to treat the occasional patient who is not a surgical candidate. Most of these lesions are not well lateralized, consequently, RT is administered with parallel-opposed fields encompassing the primary tumor with a margin of 2 cm or less. A cork-and-tongue block is placed in the mouth to displace the tongue, mandible, and lower lip inferiorly and to reduce the amount of normal tissue included in the fields (Figure 32-20, *A*). These lesions are not amenable to brachytherapy and so patients are treated with EBRT alone. The likelihood of cure with RT alone, even for early-stage lesions, is relatively low so that an altered fractionation technique should be employed. We prefer hyperfractionated RT and use 74.4 Gy to 76.8 Gy at 1.2 Gy per fraction, twice daily, over 6 to 6.5 weeks. The volumes are extended to include the regional lymph nodes (levels I and II) for patients with aggressive, poorly differentiated cancers (see Figure 32-20, *B*). The disadvantage of irradiating the regional lymph nodes is that the acute toxicity of the treatment is significantly increased. Fields are reduced at 45.6 Gy in 38 fractions to limited portals that adequately encompass the primary cancer. The low neck (levels III and IV) is irradiated with an anterior field that abuts the primary fields at the level of the thyroid notch and receives 50 Gy in 25 fractions over 5 weeks.

T3 and T4 Lesions

Patients with T3 and T4 cancers are optimally treated with surgery and postoperative RT using fields encompassing the primary tumor and regional lymph nodes as previously described. Postoperative RT is initiated within 6 weeks of surgery. Patients with negative margins generally receive 60 Gy at 2 Gy per fraction. Reduction off of the spinal cord is performed at 44 Gy to 46 Gy and the posterior strips are treated with 8 MeV to 10 MeV elections if it is necessary to irradiate these areas to a higher dose. An altered fractionation technique should be considered for those who have positive margins, multiple risk factors, or a prolonged surgery-RT interval.[53] Systemic cisplatin chemotherapy is usually administered concomitantly with RT in the postoperative setting.[50,52]

Patients with T3 and T4 cancers who are not surgical candidates have a low chance of cure with RT. Patients are treated to 76.8 Gy at 1.2 Gy per fraction twice daily over 6.5 weeks combined with concomitant chemotherapy such as weekly cisplatin 30 mg/m^2. Patients who are not candidates for aggressive therapy are treated with moderate dose palliative RT over 1 to 2 weeks.



Complications

No severe complications occurred in the patients who received RT (60 Gy in 5 to 6 weeks) at the University of Virginia.[151] Most patients developed xerostomia and temporary loss of taste.[146]

Yorozu et al[152] reported results for 31 patients treated with EBRT at the Christie Hospital between 1990 and 1997. Twenty-six patients received RT alone and five were treated postoperatively for positive surgical margins; necrosis occurred in 1 patient.

CONCLUSIONS AND FUTURE POSSIBILITIES

Treatment algorithms by site within the oral cavity are covered in the separate site presentations and discussions within this chapter. In general, early lesions at any site in the oral cavity can be treated by single modality treatment with excellent results. As lesions become more extensive, the need for combined modality treatment increases (i.e., surgery plus RT with or without chemotherapy, RT plus concomitant chemotherapy, or all three modalities). Future trials should address issues of sequencing when combined modality treatment is indicated,

A B

Figure 32-20 **A,** Early-stage hard palate carcinomas. Parallel-opposed 6-MV x-ray fields include the tumor with a 2-cm margin. Cork-and-tongue block displace the tongue and mandible inferiorly to minimize the amount of normal tissue included in the fields. **B,** Advanced hard palate carcinoma. Portals include the primary tumor and upper neck nodes (levels I and II). The superior margin of the portals is extended to include V_2 to the skull base.

CHAPTER

33 Oropharyngeal Cancer

George M. Cannon, David J. Adelstein, Lindell R. Gentry, and Paul M. Harari

INCIDENCE

The estimated annual incidence of oropharyngeal cancer in the United States is slightly more than 10,000 patients. The incidence of oropharyngeal cancer has gradually increased over the past several decades, particularly in younger patients.

BIOLOGIC CHARACTERISTICS

Squamous cell carcinomas (SCCs) represent more than 95% of all tumors arising within the oropharynx. Approximately 70% of patients present with nodal involvement, and 10% to 15% of these have distant metastases. Human papillomavirus (HPV) has been associated with an increasing proportion of oropharyngeal carcinomas, particularly those arising from the tonsillar fossa and base of tongue in patients without significant tobacco or alcohol exposure. Patients with HPV-positive tumors have notably better clinical outcomes than those with HPV-negative tumors and are more responsive to conventional therapies.

STAGING EVALUATION

Staging entails a detailed history and physical evaluation, cross-sectional imaging with computed tomography (CT) or magnetic resonance imaging (MRI), chest imaging, routine blood cell counts, and serum chemistry studies. A chest CT scan should be obtained if the risk of pulmonary metastases is elevated; this occurs in patients with advanced nodal involvement, a locally advanced primary tumor (stages T3 and T4), low cervical lymph nodes, or recurrent disease. 18F-fluorodeoxyglucose positron emission tomography (FDG PET) has assumed increased importance in the initial staging, treatment planning, and postradiation nodal evaluation of these patients.

PRIMARY THERAPY

Traditionally, the preferred treatment for patients with small (stages T1 and T2) oropharyngeal SCCs has been radiation therapy. Historical data show equivalent outcomes between radiation and surgery for early-stage oropharyngeal cancers, but less functional compromise has conventionally been seen with radiation therapy. Newer transoral surgical techniques have diminished morbidity and improved recovery times associated with surgery, making this a viable alternative to radiation alone in early stage oropharyngeal cancers. For those undergoing radiation, long-term toxicities have been reduced by intensity-modulated radiation (IMRT) techniques that diminish the dose to the salivary glands and other critical structures or by unilateral radiation techniques when appropriate.

LOCALLY ADVANCED DISEASE

Multiple Phase III trials and a comprehensive meta-analysis demonstrate that concurrent chemotherapy enhances the radiation response in locoregionally advanced head and neck cancers, leading to improved locoregional control and survival. Given the functional compromise often induced by surgical resection, even with free-flap reconstruction, concurrent chemoradiation has emerged as a standard of care for the majority of locally advanced oropharyngeal cancers provided the patient can tolerate the rigors of combined modality treatment. Molecular targeting agents, specifically cetuximab, can improve overall survival (OS) rates if the patient is not a suitable candidate for cytotoxic chemotherapy.

Contraindications to an "organ-sparing" approach include bone invasion or the anticipation of severe functional deficits following treatment. Patients with these contraindications should be treated with surgery and postoperative radiation. The addition of concurrent chemotherapy to postoperative radiation has demonstrated benefit for patients with high-risk pathologic features including positive surgical margins and extracapsular nodal spread.

For patients with advanced nodal disease who undergo definitive radiation with or without chemotherapy but have an incomplete nodal response to treatment, a neck dissection is warranted.

The recent recognition of the excellent prognosis of patients with HPV-associated oropharynx cancer, coupled with the significant incidence of long-term toxicity and functional disability in some patients after definitive chemoradiation, has increased interest and clinical investigation of transoral surgical techniques. These surgical approaches have less morbidity that traditional open surgical procedures and may allow for a reduction in the need for, or the intensity of, postoperative radiation and chemotherapy.

The oropharynx consists of the base of the tongue, tonsillar region, soft palate, and lateral and posterior oropharyngeal walls (Figure 33-1). Determining the precise annual incidence for new cancers of the oropharynx is difficult because there is overlap with other head and neck sites within various reporting classifications. The cumulative incidence of cancers of the "oral cavity and pharynx," comprised of the tongue, mouth, pharynx, and oral cavity, was estimated at 42,440 in the United States in 2014, with 30,220 male and 12,220 female patients.[1] Malignant tumors within the oropharynx, defined as tumors arising from the base of tongue, tonsillar complex, soft palate, or lateral and posterior pharyngeal walls by the American Joint Committee on Cancer (AJCC) staging definition,[2] are generally thought to represent approximately 25% of the total. This places the estimated total at slightly more than 10,000 new oropharyngeal carcinomas per year in the United States, although some believe the rate is lower.[2]

The incidence of head and neck cancers has increased during the twentieth century, particularly in persons born after 1920. The higher cancer incidence over this time period is associated with the rise in alcohol and tobacco consumption in the United States and other westernized countries over the

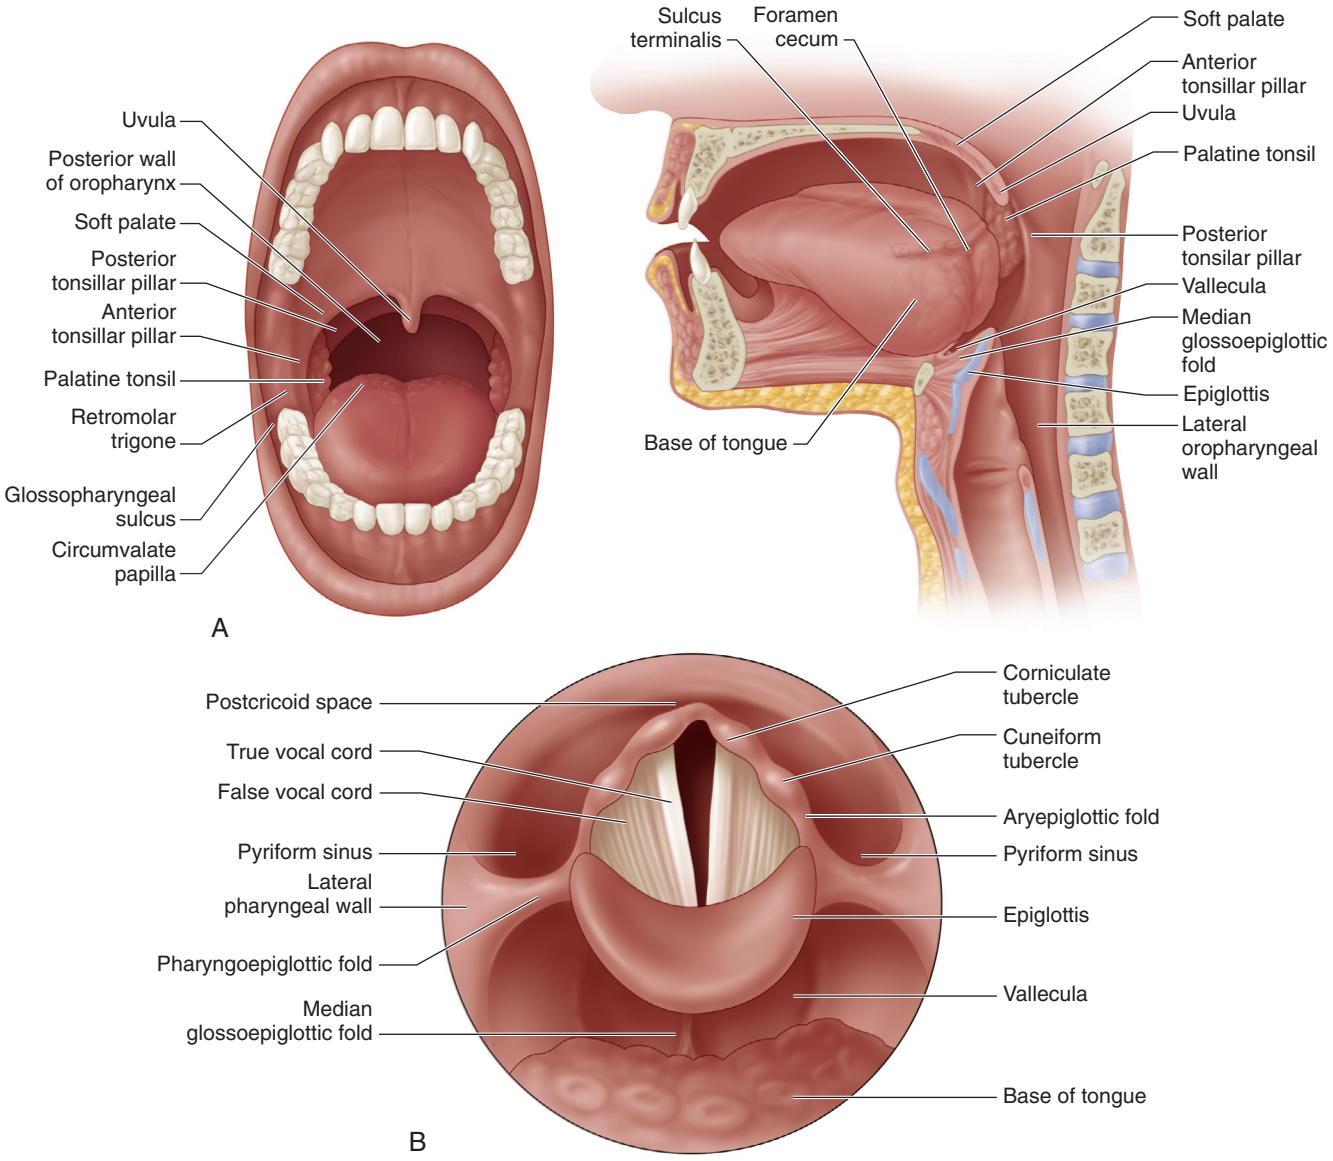

Figure 33-1 Normal anatomy of the oropharynx. **A,** Anterior view and lateral view of the oropharynx with left lateral structures removed. **B,** Oropharynx as viewed through a fiberoptic endoscope.

same era.[3,4] This trend has reversed over the past two decades in the United States, with a small decline in SCCs of the head and neck, likely secondary to a reduction in tobacco use. Despite this general reduction in head and neck cancers and the diminished incidence rate seen for the neighboring oral cavity, the incidence of oropharyngeal carcinomas has continued to increase since the early 1980s, predominantly in men younger than age 60 years.[5-7] The increase in oropharyngeal cancers is not thought to be attributable to the reduction in tonsillectomy frequency between the 1970s and the 1990s because this trend would not be expected to alter the incidence of base of tongue primary tumors.[8]

The worldwide estimated annual incidence of tumors defined as arising either from the oral cavity or the pharynx excluding the nasopharynx, including oropharyngeal site tumors, was 404,585 in 2002. Over two thirds of the patients were male, and the mortality rate on average was less than half of the incidence rate.[9] Such an analysis comes with the typical challenges in documenting such malignant diseases, particularly among the medically underserved internationally. Geographic variations in global rates reflect the prevalence of known risk factors, such as tobacco and alcohol use, within specific populations.

ETIOLOGY AND EPIDEMIOLOGY

Tobacco and Alcohol Use

SCC of the oropharynx most commonly affects patients older than 50 years, and men more than women. Despite this generalization, over the past 30 years oropharyngeal cancer rates have been on the rise in both men and women under the age of 45 years.[6] Both alcohol and tobacco use are long-known, well-defined risk factors for SCCs of the head and neck, including those arising within the oropharynx. Again, separating data regarding oral cavity tumors and oropharyngeal tumors within published series can be challenging given reporting methods, and results may overstate the role of tobacco and alcohol use in oropharyngeal malignant diseases. The two substances individually and together contribute to a

field cancerization effect within the upper aerodigestive tract. The effect of alcohol consumption and cigarette smoking on oropharyngeal cancer risk is reported to be dependent on both the intensity and duration of use and was traditionally responsible for approximately 80% of oropharyngeal cancers, with a higher proportion in men than in women in one series.[10]

A population-based study in Sweden compared 605 patients with head and neck cancer with 756 controls. A hazard ratio (HR) of 8.4 was seen with current smokers; this figure was increased by an earlier starting age, longer duration of smoking, greater lifetime total consumption, and increased intensity of daily tobacco use.[11] Increasing alcohol intake, particularly more than 50 g per day, was also associated with an increased relative risk of head and neck cancers. A compilation of case-control studies places the tobacco-associated odds ratio at 2.13 for tobacco users when compared with never users, with the ratio doubling in persons who smoke more than 30 cigarettes per day or those who have smoked for more than 30 pack-years.[12] Involuntary or secondhand tobacco exposure may also be a risk factor, particularly when the person has been exposed for more than 15 years either at home or at work.[13] Alcohol use increases the rate of oropharyngeal carcinomas in never smokers, prior smokers, and current smokers, and the risk decreases with cessation of alcohol use.[14] Although use of either alcohol or tobacco elevates the risk of oral cavity and oropharyngeal cancer, there is a synergistic effect from the use of both simultaneously. The risk is calculated to be 13-fold the expected risk of each used independently, creating an approximately 50-fold greater risk for oral cavity and oropharyngeal cancer compared with that of nonsmokers and nondrinkers.[14,15] Tobacco cessation decreased the risk of head and neck cancer by 40% in years 1 through 4, although the risk of head and neck cancers did not return to baseline until 20 years had elapsed after either tobacco or alcohol cessation.[16]

Human Papillomavirus Infection

Additional behavioral risk factors have been described besides classic tobacco and alcohol abuse, and they appear to correlate with an elevated risk of oral HPV infection. The role of HPV corresponds to the identified increase in head and neck cancer incidences seen in younger nonsmokers and nondrinkers. The increased incidence has been seen both in the United States and in European countries, despite the general trend of fewer head and neck cancers. This rise has been most marked among young patients in sites associated with HPV.[6] HPV is a sexually transmitted disease recently recognized as a risk factor for SCC of the head and neck, particularly in the oropharyngeal subsite, although the connection was initially suggested in 1983.[17] HPV has been implicated in approximately 25% of head and neck cancers based on polymerase chain reaction (PCR) detection of HPV DNA. This prevalence is site specific, with a significantly higher percentage of HPV-associated cancers in the oropharynx compared with the oral cavity or larynx.[18] A recent meta-analysis found the overall prevalence of HPV in oropharyngeal cancers to have increased over time. Before 2000, the rate of positivity was 40.5%, increasing to 64.3% from 2000 to 2004 and 72.2% between 2005 and 2009.[19] Evaluation of more distant time periods demonstrates an even lower rate of HPV involvement, with a 16.3% detection rate from 1984 to 1989, increasing to 71.7% from 2001 to 2004.[20] These trends constitute a population-based HPV-positive increase of 225% over this time period, whereas the HPV-negative incidence dropped by 50%.

The link between HPV and oropharyngeal cancers is several-fold and mimics the lines of evidence associating HPV and cervical cancer. First, HPV has been identified in tumor cells of head and neck SCCs.[17,21] HPV status is most commonly assessed by either immunohistochemistry for p16 or in situ hybridization for high-risk HPV subtypes. Both methods have demonstrated prognostic significance despite some studies suggesting a 15% to 20% false-positive and false-negative rates for p16 immunohistochemistry testing as a surrogate for HPV.[22,23] Identified prevalence rates have varied, depending on the tumor subsite, sensitivity of the HPV detection method, and geographic location, with associated ethnic variance.[24] HPV-16 is the most common HPV subtype associated with oropharyngeal SCCs, seen in 85% to 90% of HPV-associated cancers.[18,21] The remainder are associated with HPV subtypes 18, 31, 33, and 35, which also play a role in the development of cervical cancer. Second, HPV-positive SCCs of the head and neck have viral characteristics concordant with HPV-associated carcinogenesis, including a high viral load and viral oncoprotein expression.[24] The oncogenic function of these HPV-associated oncoproteins ultimately accounts for the different molecular alterations found in HPV-positive tumors compared with HPV-negative tumors.

Additional evidence for an HPV association includes significant links in case-control studies between HPV seropositivity and SCCs of the head and neck. A case-control study comparing 100 patients diagnosed with oropharyngeal cancer and 200 controls found oropharyngeal cancer to be closely associated with oral HPV-16 infection (odds ratio, 14.6), oral infection with any of the HPV types (odds ratio, 12.3), and seropositivity for the HPV-16 L1 capsid protein (odds ratio, 32.2), strongly associating oral HPV with oropharyngeal cancer.[25] Behavioral risk factors associated with oral HPV infection have also been correlated with an increased risk of oropharyngeal cancer. They include a high lifetime number of vaginal sex partners and oral sex partners.[25] This correlation between HPV DNA in tumor specimens and lifetime sex partners has also been identified by others,[26] as has age at first intercourse and genital warts.[27] Patients with HPV-associated head and neck cancers also have an increased risk of anogenital cancers, of which cervical and anal cancers have been strongly associated with HPV infection, and vice versa.[28] Again, this supports the influence of sexual behavior and HPV infection on oropharyngeal cancer risk.

Patients with HPV-associated oropharyngeal cancers tend to have distinct clinical and pathologic features compared with those with HPV-negative cancers (Table 33-1). Besides the history of high-risk sexual behavior described earlier, patients with HPV-associated oropharyngeal cancers are more likely to be light users or nonusers of alcohol and tobacco,[29,30] although this lack of connection has not been universally identified.[27]

TABLE 33-1 Distinctive Clinicopathologic Characteristics for HPV-Positive and HPV-Negative Head and Neck SCC

	HPV-Positive	HPV-Negative
Anatomic site	Tonsil, base of tongue	All sites
Histology	Basaloid	Keratinized
Age	Younger	Older
Social economic status	Trend higher	Trend lower
Risk factors	Sexual behavior	Alcohol and tobacco
Survival	Improved	Worse
Incidence	Increasing	Decreasing
EGFR expression	Commonly negative	Commonly positive

Adapted from Vidal L, Gillison ML: Human papillomavirus in HNSCC: Recognition of a distinct disease type. Hematol Oncol Clin North Am 22(6):1125–1142, vii, 2008.

Despite the apparent lack of association between HPV-associated oropharyngeal cancers and tobacco use, there is a correlation with marijuana use and its intensity and duration.[5] Individuals with HPV-positive SCC of the head and neck tend to be younger by approximately 5 years compared with patients who are HPV negative.[24] Pathologically, HPV-positive cancers are more likely to be poorly differentiated with basaloid features.[31]

A meta-analysis of the prognostic impact of HPV in head and neck SCCs demonstrated that patients who are HPV positive were likely to have improvements in rates of OS (HR, 0.85) and disease-free survival (DFS) (HR, 0.62). Similar improvements in OS and DFS were identified specifically within the oropharyngeal subsite.[32] Improved outcomes with HPV positivity were confirmed in an Eastern Cooperative Oncology Group (ECOG) Phase II multicenter trial in which higher response rates were seen after induction chemotherapy and after chemoradiation treatment. This led to a statistically improved OS and a lower risk of progression.[31] Analysis of the subset of patients with stage III or IV oropharyngeal cancer in Radiation Therapy Oncology Group (RTOG) study 0129 found HPV status to be the major determinant of OS, followed by duration of tobacco use and tumor stage.[33] Locoregional recurrences were reduced at 3 years (13.6% versus 35.1%) in HPV-positive tumors, and OS was 82.4% versus 57.1%. Although the bulk of the survival difference was attributable to HPV positivity, favorable prognostic features associated with the HPV-positive subgroup accounted for approximately 10% of the outcome difference.

Patients who are HPV positive also have a lower risk of second malignant tumors because such patients lack the field cancerization effect produced by alcohol and tobacco exposure.[29,30] Given the different clinical, pathologic, and molecular characteristics, as well as the improved prognosis and treatment response, it has been proposed that HPV-positive and HPV-negative SCCs of the oropharynx should be considered distinct disease entities with different goals and expectations from treatment.[34]

PREVENTION AND EARLY DETECTION

Classic prevention for SCC of the oropharynx, and head and neck cancers in general, has revolved around tobacco cessation and bringing alcohol use to more moderate levels. With the impact of HPV now better understood, ongoing HPV vaccination campaigns to lower the incidence of cervical cancer may simultaneously reduce HPV-related head and neck cancers. Two vaccines are currently available for HPV: one against HPV types 16 and 18, Cervarix (GlaxoSmithKline), and a quadrivalent vaccine against HPV types 16, 18, 6, and 11, Gardasil (Merck). Both vaccines have been advised for women between the ages of 13 and 26 years because they lead to a reduction in precancerous cervical lesions and cancer incidence related to HPV.[37] The vaccine is also now recommended for young men between the ages of 13 and 26 because of its ability to reduce the incidence of genital warts, and, in the population of men who have sex with men, the incidence of anal intraepithelial neoplasia.[38,39]

Routine examinations of the oral cavity and proximal oropharynx should be part of a standard medical history and physical and dental examination. Routine oral examinations in high-risk patients have the potential to reduce cancer-related deaths through the discovery of premalignant and early-stage malignant changes. Unfortunately, the same substance abuse conditions that predispose individuals to head and neck cancers correlate with underuse of health and dental services,[36] often leading to late detection and diagnosis of head and neck cancers. Radiation oncologists can play a role in the early detection of secondary oral cavity and oropharyngeal cancers attributable to field cancerization in patients who have been treated for primary head and neck cancers and are undergoing follow-up in the radiation oncology clinic.

Potentially malignant lesions include erythroplakia, leukoplakia, erythroleukoplakia, oral submucous fibrosis, and lichen planus.[40-44] *Leukoplakia* and *erythroplakia* are Greek terms translated as "white plaque" and "red plaque," respectively. Leukoplakia is an exclusionary diagnosis and is currently defined as "a white plaque of questionable risk having excluded (other) known diseases or disorders that carry no increased risk for cancer."[40] The worldwide prevalence of leukoplakia is estimated at approximately 2% of the general population,[41] with the highest incidence in men from the fifth through the seventh decades; histologic findings show hyperplasia of the squamous epithelium. Most leukoplakia lesions do not progress to SCC; the annual transformation rate is estimated at 1%.[42] This rate is strongly dependent on the presence and severity of dysplasia.[43] Dysplasia, carcinoma in situ, or carcinoma is frequently present within erythroplakia, which has only one sixth of the prevalence of leukoplakia. Of the premalignant lesions, transformation to malignancy is highest in erythroplakia, particularly when dysplastic changes are present, with an annual transformation rate of at least 2.9%.[44] Others have predicted that the vast majority of erythroplakias will ultimately undergo malignant transformation.[42]

Multiple chemopreventive regimens have been evaluated to prevent progression of dysplasia within the upper aerodigestive tract. At least one randomized study demonstrated a decreased rate of biopsy-proven dysplasia after the administration of isotretinoin.[45] However, the toxicity was significant, with almost half of patients requiring dose reduction. In addition, most responders relapsed within the first 3 months after treatment. Larger randomized trials found no reduction in the rate of second primary tumors with isotretinoin.[46-48]

Currently, no chemopreventive strategies have been validated or are widely in use for high-risk patients, including those with known dysplasia. Clinical trials continue to search for effective treatment approaches. Close follow-up with biopsy and surgical excision or laser therapy as indicated remains mandatory for patients with premalignant lesions.

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

Significant research is ongoing to determine the genetic and molecular impact of HPV on associated oropharyngeal SCCs. Molecular profiles of HPV-positive tumors are distinct from those of HPV-negative tumors. The oncogenic function of viral E6 and E7 from HPV appears to propel the molecular abnormalities present in HPV-positive tumors. Inactivation of TP53 and PRB is seen with both types but are the result of separate mechanisms. E6 inactivates TP53 function in HPV-positive tumors, whereas disruptive mutations of TP53 are more common in HPV-negative tumors. Besides TP53, disparate effects on 14-3-3σ, RASSF1A, cyclin D, PRB, and P16 have been identified between HPV-positive and HPV-negative tumors. Disruption of TP53 by alcohol- and tobacco-mediated damage seems to be a critical genetic alteration in HPV-negative tumors. A molecular impact of tobacco exposure has also been identified in cells with HPV present. Normal oral keratinocytes transfected with HPV and subsequently exposed to tobacco carcinogens are found to have enhanced E6 and E7, increased resistance to apoptosis, impaired DNA repair, and activated telomerase.[49]

Epidermal growth factor receptor (EGFR) expression in oropharyngeal cancers correlates inversely with HPV status.[50,51]

Other Risk Factors

Numerous other potential risk factors have been described for oropharyngeal cancer and head and neck cancers in general. A family history of head and neck cancers produces an odds ratio risk increase of 1.7, although this is only seen in subjects exposed to tobacco, suggesting that this factor may represent an environmental as much as a genetic influence.[35] Diets low in raw vegetables and citrus and noncitrus fruits have increased the oral cancer risk in a majority of studies.[8] These results seem to hold true even when studies have been controlled for alcohol and tobacco usage, although the effect on diet and nutritional deficiencies from heavy alcohol and tobacco abuse is substantial and such factors can be difficult to account for in case-control studies.

Nutritional deficiencies, as signified by a body mass index decline before diagnosis, have also been associated with oral cancer risk. This was again seen primarily among individuals with active or prior alcohol and tobacco use. Poor oral hygiene, as measured by surrogates such as tooth loss and infrequent dental visits, also correlates with an elevated rate of oral and oropharyngeal carcinomas.[36] In short, the family history, diet, nutritional status, and oral hygiene may all play a role in oropharyngeal carcinoma predisposition, but defining the impact of each of these in the setting of the more dominant risk factors of alcohol and tobacco use is challenging, particularly given the potential interplay between such factors.

Not surprisingly, given its association with HPV-negative tumors, EGFR expression predicts for a lower rate of response to induction chemotherapy and inferior OS and disease-specific survival rates. A similar effect was seen in an analysis of the conventional arm of RTOG 90-03, in which 155 patients with adequate pathologic specimens were evaluated for expression of EGFR by immunohistochemical testing.[52] EGFR expression did not correlate with T category, N category, or category grouping, but high EGFR-expressing tumors had higher local recurrence rates and worse DFS and OS. Distant metastases did not differ between the two groups.

PATHOLOGY AND PATHWAYS OF SPREAD

Pathologic Findings

Primary oropharyngeal tumors are almost exclusively SCC (≈95% of tumors). Alternative pathologic types include melanoma (eFigure 33-1), primary lymphoid malignant tumors (eFigure 33-2), minor salivary gland tumors, sarcomas, and other oddities. Given the preponderance of SCC in this site, this chapter will refer to the evaluation and treatment of SCC unless another type is specifically indicated.

A substantial literature has been generated evaluating the histologic subtypes of SCC of the head and neck, the appropriate nomenclature for these tumors, and their clinical impact. Specific subtypes include the spindle cell variant characterized by noncohesive spindle cells, which closely resembles sarcoma microscopically. The basaloid squamous variant is a distinct subtype traditionally correlated with aggressive behavior and poor patient outcomes.[53] However, the recent correlation of HPV-associated malignant disease with the basaloid subtype has shown that the basaloid group is a mixture of both HPV-16-positive and HPV-16-negative carcinomas. Because the HPV status imparts a substantially favorable influence on outcome, the implication is that the basaloid phenotype alone does not confer a worse clinical outcome.[54] Angiolymphatic invasion and perineural invasion are both associated with increased rates of cervical nodal metastases and a worse prognosis.[55]

The prototypical SCC of the head and neck, including the oropharynx, is moderately differentiated, with approximately 60% moderately differentiated, 20% well differentiated, and 20% poorly differentiated. Some studies have found tumor grade to be predictive of regional nodal metastasis and, subsequently, clinical outcome. The determination of tumor grade based on traditional cytologic and histologic features of differentiation is challenging to reproduce because of interobserver variability. As a result, the tumor grade seems to have limited prognostic value, particularly when compared with the clinical staging parameters.[55] Undifferentiated carcinomas with a lymphoid stroma arising from the tonsil have biologic behavioral characteristics and an increased radiosensitivity that are more similar to undifferentiated nonkeratinizing nasopharyngeal carcinomas rather than conventional types of SCC.[56] Again, this subtype seems to serve as a surrogate for HPV positivity.

Pathways of Spread

The oropharynx makes up the central portion of the upper aerodigestive tract, encompassing the tongue base, palatine (faucial) tonsils, inferior aspect of the soft palate, and posterior and lateral oropharyngeal walls[57] (Figures 33-1, 33-2, and 33-3). The anterior margins are the anterior tonsillar pillars, the hard-soft palate junction, and the circumvallate papillae of the tongue, placing the posterior third of the tongue within the oropharynx. Superiorly, the oropharynx is bounded by the inferior aspect of the soft palate, posteroinferiorly by the pharyngoepiglottic folds that lie approximately at the level of the hyoid bone, and inferiorly by the glossoepiglottic fold and vallecula. The lateral and posterior borders of the oropharynx are defined by the pharyngeal constrictor muscles and their overlying mucosa. Understanding the anatomy of the oropharynx is necessary when identifying the typical pathways of spread by oropharyngeal neoplasms.[58-60]

Soft Palate

The soft palate is a mobile flap of soft tissue with a central aponeurosis that serves as the attachment point for several palatine muscles. Five muscles form the bulk of the posterior and lateral portions of the soft palate. These muscles (levator veli palatini and tensor veli palatini muscles, muscle of the uvula, palatoglossus muscle, and palatopharyngeal muscle) insert on the palatine aponeurosis but have important attachments to the tongue base, posterolateral pharyngeal wall, and torus tubarius. The palatoglossus muscle and overlying mucosa form the anterior tonsillar pillar, which is the anteriormost part of the lateral oropharynx. The palatopharyngeal muscle, with its overlying mucosa, forms the posterior

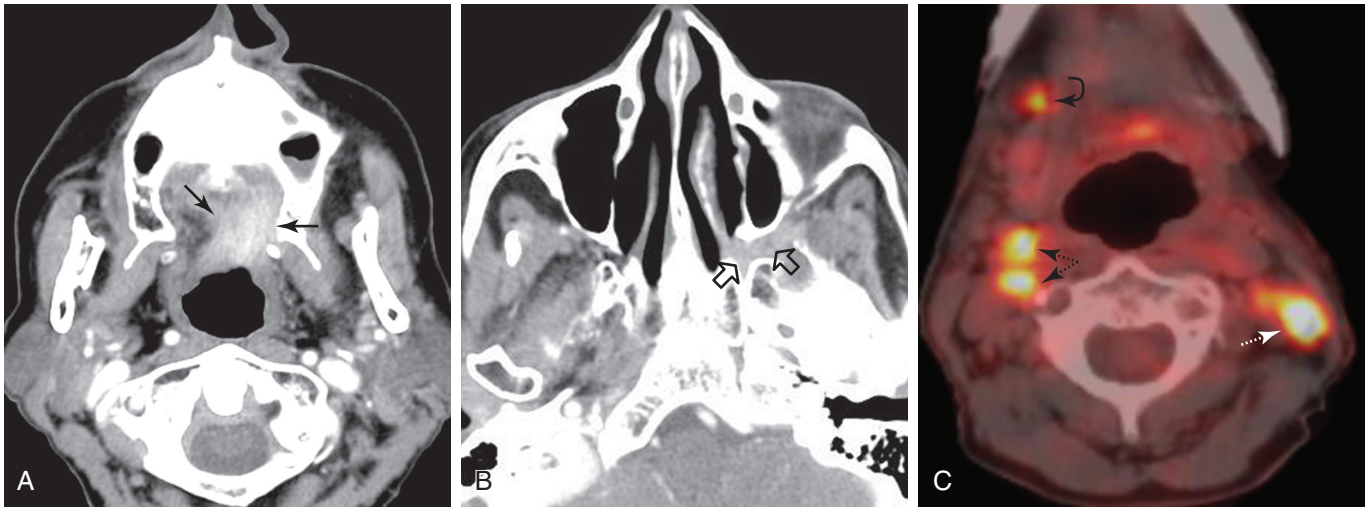

Figure 33-4 T4bN2c soft palate SCC: Axial **(A** and **B)** contrast-enhanced CT scans demonstrate a large enhancing mass of the soft palate *(black arrows)* with erosion of the hard palate. There is upward spread of mass along the lateral nasopharynx wall as well as upward perineural tumor spread via the greater palatine foramen into the pterygopalatine fossa *(open arrows).* The CT and PET/CT **(C)** images demonstrate N2c nodal metastasis involving levels Ia, Ib *(curved black arrow)*, IIa *(dashed black arrows)*, and IIb *(dashed white arrow).*

tonsillar pillar. The two pillars connect laterally and inferiorly with the lateral oropharyngeal wall.

The inferior aspect of the soft palate, which forms the upper portion of the oropharynx, is the site of the majority of soft palate tumors. The superior surface of the soft palate, part of the nasopharynx, is seldom a primary site of neoplasm. The soft palate also contains a substantial number of minor salivary glands. These glands are the site of origin for nonsquamous neoplasms of the soft palate.

A soft palate tumor can spread anteriorly to involve the hard palate. There is also potential for perineural spread along the greater and lesser palatine branches of the maxillary nerve superiorly into the pterygopalatine fossa[61] (Figure 33-4). Further perineural spread from the pterygopalatine fossa can result in extension along branches of the maxillary division of the trigeminal nerve into the orbit via the inferior orbital fissure, into the central skull base via the foramen rotundum, and into the facial nerve and temporal bone via the nerve of the pterygoid canal (vidian nerve). This perineural spread can result in palsies of both the trigeminal and facial nerves. Patients with advanced disease and perineural spread may present with trismus resulting from involvement of the pterygoid muscles or branches of the trigeminal nerve.

Tonsillar Region

The palatine (faucial) tonsils consist of lymphoid tissue constrained within a fibrous capsule that projects into the oropharynx between the triangle formed by the anterior and posterior tonsillar pillars. The tonsillar fossa is bounded laterally by the superior pharyngeal constrictor muscle. The anterior and posterior tonsillar pillars consist of the mucosa overlying the palatoglossus and palatopharyngeal muscles, respectively. SCC is the most frequent neoplasm of the palatine tonsils, followed distantly by non-Hodgkin's lymphoma. Tumors within the tonsillar region can spread superiorly to the soft palate along the vertically oriented palatoglossus and palatopharyngeal muscles, as well as inferiorly to the tongue base and posterolaterally to the oropharyngeal wall[62] (Figures 33-4 and 33-5).

The superior pharyngeal constrictor muscle, in addition to forming the posterior and lateral borders of the oropharynx, courses deep to the palatine tonsils as it extends anteriorly to

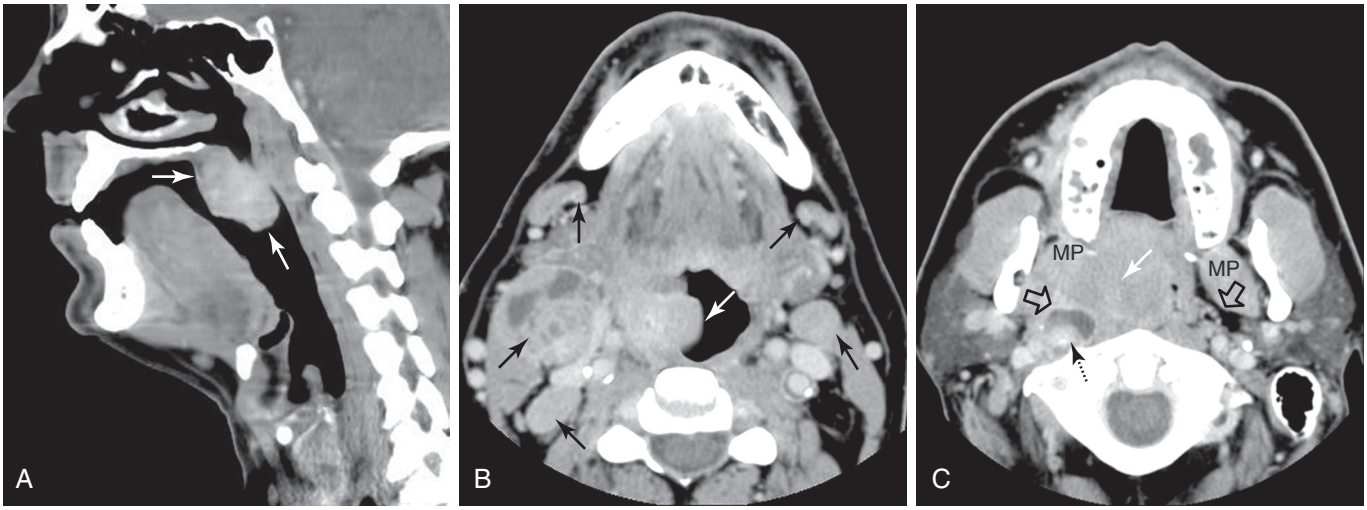

Figure 33-5 T4aN2c SCC of tonsil and soft palate: Sagittal **(A)**, and axial **(B** and **C)** contrast-enhanced CT scans demonstrate a large enhancing mass of the palatine tonsil and soft palate *(white arrows).* There is invasion of the medial pterygoid (MP) muscle indicating a T4a lesion. There are bilateral enlarged and abnormally enhancing level Ib and IIa lymph nodes *(black arrows)* as well as an abnormal right level IIb node consistent with N2c nodal spread. An abnormal heterogeneously enhancing right lateral retropharyngeal lymph node is identified *(dashed black arrow)* with extracapsular spread into the parapharyngeal space *(open arrows).*

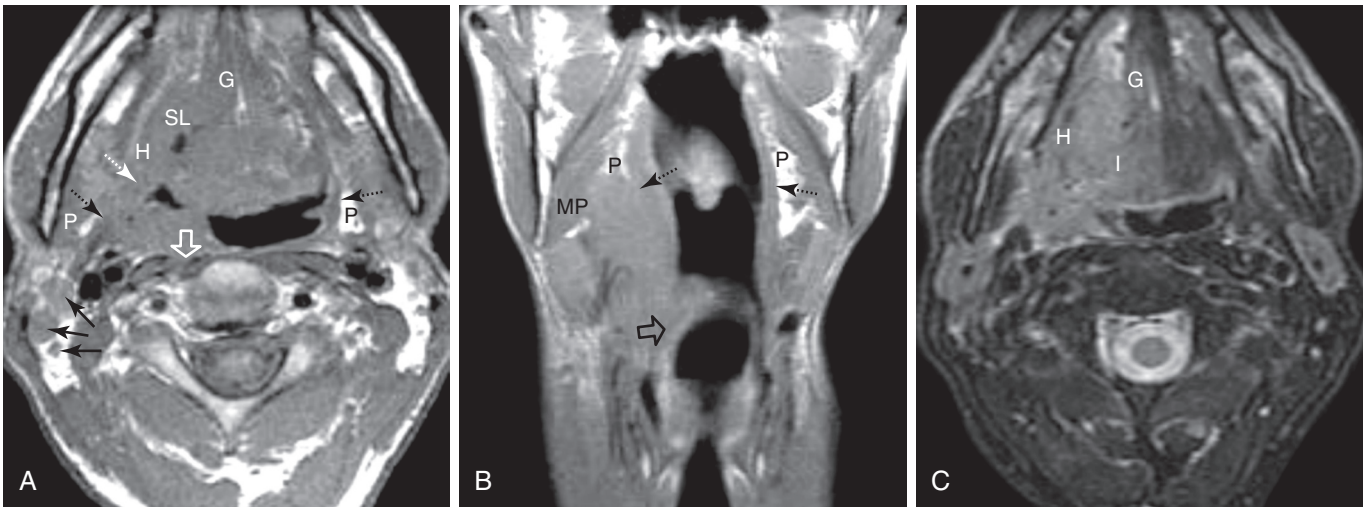

Figure 33-6 T4bN2b tonsillar SCC: Axial T1-weighted **(A)**, coronal T1-weighted **(B)**, and axial T2-weighted **(C)** noncontrast-enhanced MRI images demonstrate an extensive right tonsillar and posterior oropharyngeal wall neoplasm. The lesion extends across the glossotonsillar sulcus *(dashed white arrow)* into the oral tongue and sublingual space (SL). There is invasion of the intrinsic tongue musculature (I) as well as the hyoglossus (H) and genioglossus (G) muscles. The lesion infiltrates the superior pharyngeal constrictor muscle *(dashed black arrows)* to involve the parapharyngeal space (P) and MP muscle. The lesion invades the prevertebral space *(open white arrow).* There is inferior spread into the supraglottic larynx *(open black arrow).* Several enlarged right level IIb lymph nodes are seen *(black arrows).* These findings are consistent with a stage of T4bN2b.

insert on the pterygomandibular raphe.[57] This fibrous raphe is a shared insertion site with the buccinator muscle, with the raphe extending to the medial pterygoid plates superiorly and the lingual cortex of the mandible inferiorly just posterior to the mylohyoid line. Tonsillar neoplasms that invade the superior pharyngeal constrictor muscle and involve the pterygomandibular raphe, therefore, can spread anteriorly to the buccinator muscle and space, superiorly to the medial pterygoid plate and masticator space, and inferiorly to the lingual cortex of the mandible. Lateral extension of tumor allows its entry into the parapharyngeal space (Figure 33-6). Involvement of the parapharyngeal space by tonsillar neoplasms may result in spread to and along the styloglossus and stylopharyngeal muscles, which extend superiorly toward the skull base and attach to the styloid process. Lateral extension into the medial pterygoid muscle is often associated with involvement of the mandibular division (V3) of the trigeminal nerve. Involvement of V3 can allow perineural tumor spread inferiorly into the mandible along the inferior alveolar nerve and superiorly along the main trunk of V3 to the foramen ovale and cavernous sinus.[61]

Oropharyngeal Wall

The posterior and lateral walls of the oropharynx are formed by the superior pharyngeal constrictor muscle and overlying mucosa. The deep aspect of the superior constrictor muscle is separated from the prevertebral fascia by a thin layer of retropharyngeal fat. Tumors within the posterior aspect of the oropharynx can extend through this layer of fat and fascia and into the prevertebral space[63,64] (see Figure 33-6). Advanced

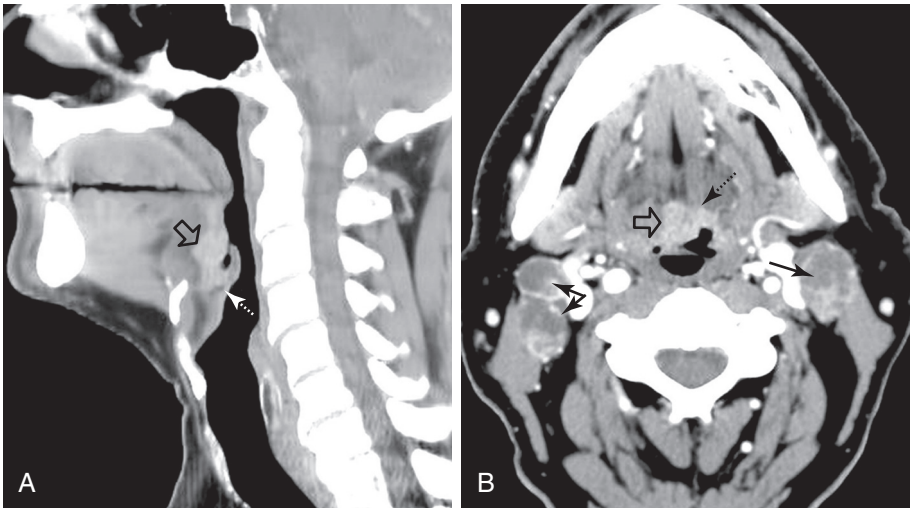

Figure 33-7 T2N2c base-of-tongue SCC: Sagittal **(A)** and axial **(B)** views. A 2.2-cm enhancing neoplasm of the tongue base *(open arrows)* indicating a T2 primary. The lesion extends into the vallecula *(dashed white arrow)* but does not invade the adjacent genioglossus muscle *(dashed black arrow).* There are abnormal heterogeneously enhancing bilateral level IIa and right level IIb lymph nodes *(black arrows)* consistent with N2c nodal spread.

tumors can ultimately involve the vertebral column, although such spread is typically inhibited by the multiple intervening fascial planes and the longus colli and longus capitis muscles. Tumors of the posterolateral oropharyngeal wall can extend into the nasopharynx and hypopharynx by way of either mucosal or submucosal spread (Figure 33-6).

Tongue Base

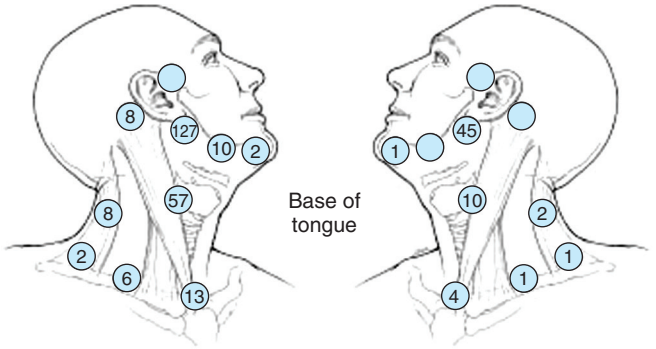
The tongue base is separated from the oral tongue anteriorly by the circumvallate papillae. It extends posteriorly and inferiorly to terminate near the level of the hyoid bone (see Figures 31-2 and 31-3). Laterally, it is separated from the palatine tonsils by the glossotonsillar sulcus. The lingual tonsils lie along the posterior surface of the tongue base. The lingual tonsils are variable in size and may be quite large in the first two decades of life and in patients with concurrent head and neck infections.

Neoplasms of the tongue base spread along several pathways as they increase in size. They may infiltrate along the intrinsic muscles of the tongue into the oral tongue and deep tongue musculature. It is especially important to identify involvement of the extrinsic muscles of the tongue (i.e., the hyoglossus, styloglossus, and genioglossus muscles) because this indicates a T4 lesion.[65] Tumor may track superolaterally along the mylohyoid muscle to invade the lingual surface of the mandible. Deep anterior extension may also involve the hypoglossal or lingual neurovascular bundles. Tumor can track posteriorly along these nerves between the superior and middle pharyngeal constrictor muscles into the parapharyngeal and masticator spaces.

Base-of-tongue cancer can also spread superficially along the mucosa. Posteroinferior extension can involve the vallecula, lingual surface of the epiglottis, and pharyngoepiglottic folds (Figure 33-7). There may be invasion of the preepiglottic space whenever the vallecula or glossoepiglottic folds are involved.

Nodal Involvement

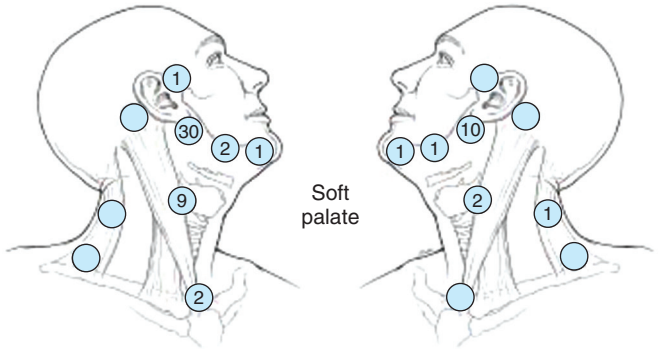
Nodal metastasis has been reported in 40% to 66% of patients presenting with soft palate carcinoma.[66,67] Level II nodal involvement is most frequent, with extension into levels III and IV nodes commonly seen. Level I, level V, and lateral retropharyngeal nodal involvement is uncommon.[68] Lymph node metastasis from SCC of the palatine tonsils is common (69% to 74%) at the time of presentation.[67,69] The incidence of nodal involvement at diagnosis in patients diagnosed with tongue-base carcinoma has been reported to be between 64% and 78%.[66,67] Bilateral nodal disease is commonplace with base-of-tongue cancer, especially in patients with tumors near or crossing the midline. The incidence of nodal involvement in patients with oropharyngeal wall squamous carcinomas has been reported to be between 57% and 60%[70] (eFigures 33-3 to 33-5). Radiographic involvement of the retropharyngeal nodes is present in 16% of all patients with oropharynx cancer, rising to 23% with pathologic nodal disease in other neck sites. With nodal involvement elsewhere in the neck, retropharyngeal nodal involvement varies by subsite and is identified in 13% of base-of-tongue tumors, 14% of tonsillar tumors, 38% of posterior pharyngeal wall tumors, and 56% of soft-palate tumors.[71] This has implications for both primary treatment modality as well as design of the radiation treatment volumes.



CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Symptoms at the time of diagnosis of an oropharyngeal cancer depend on the subsite but commonly include pain, either local or referred. Local pain is frequently described as a sore throat and may lead to dysphagia and weight loss secondary to the pain. Referred pain can occur through cranial nerves (CN) IX and X. CN IX (glossopharyngeal nerve) involvement can lead to referred pain via the tympanic nerve of Jacobson localized to the inner ear or temporomandibular joint. CN X (vagus nerve) causes referred pain through the auricular nerve of Arnold to the external auditory canal.

An asymptomatic mass within the upper neck is another frequent presenting symptom. More advanced symptoms can include odynophagia, dysphagia, dysarthria (including "hot potato" voice caused by CN XII involvement or narrowing of the pharyngeal air column), trismus (as a result of involvement of the pterygoids), and necrotic odor. Presentation with distant metastases is uncommon.



Patient Evaluation

A comprehensive history with an emphasis on head and neck–related symptoms should be taken for all patients, and a detailed physical examination of the head and neck region should be performed (Table 33-2). The examination should include a direct inspection of the oral cavity and proximal oropharynx; an indirect (mirror) examination of the distal oropharynx, hypopharynx, nasopharynx, and larynx; careful

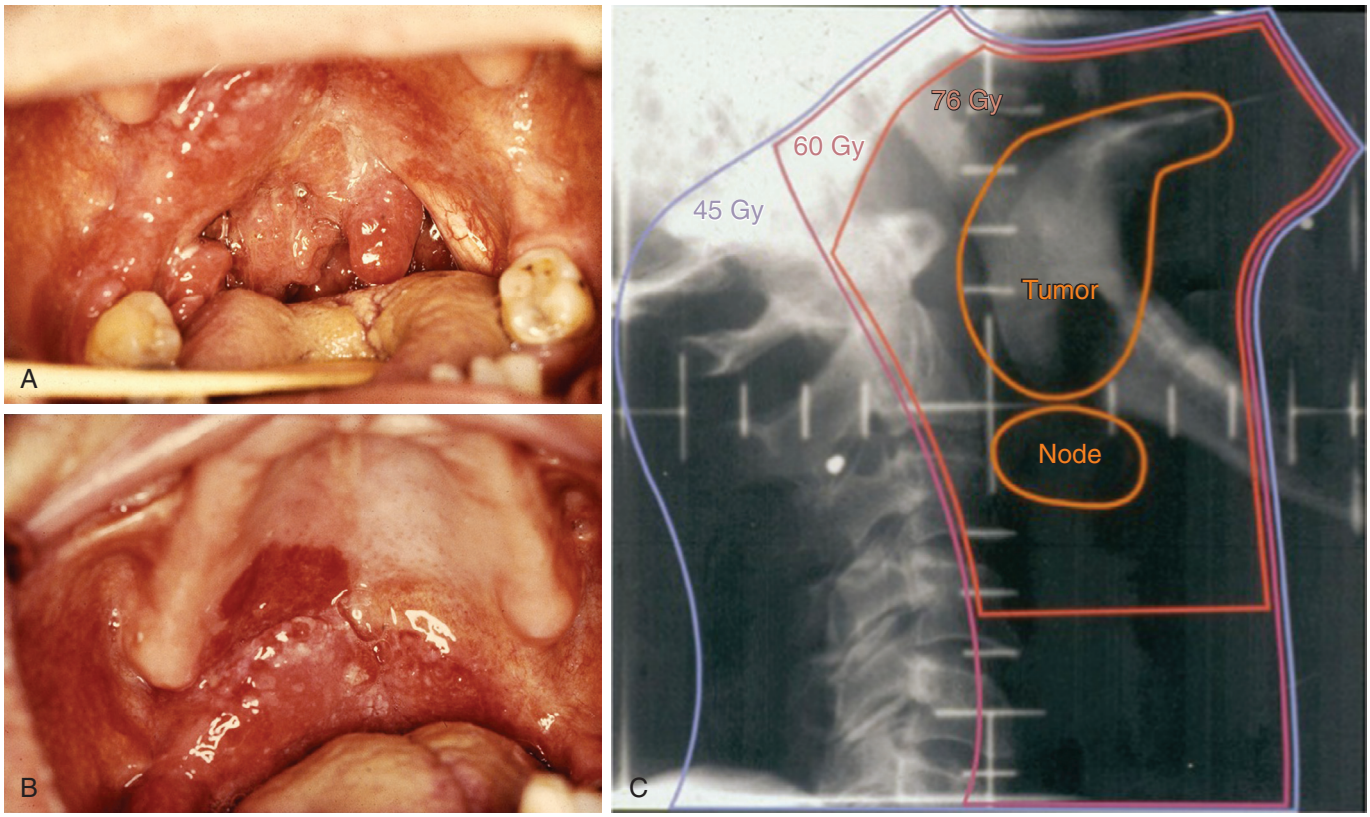
palpation of the oral cavity and proximal oropharynx; and inspection and palpation of the cervical lymph nodes (Figure 33-8). Relaxing the sternocleidomastoid muscle by tilting the head slightly to the ipsilateral side allows easier palpation of the jugulodigastric nodes. Flexible fiberoptic nasopharyngoscopy is used as indicated by examination findings and the quality of the indirect examination.

Physical examination includes assessment of both the size and local extent of the primary tumor and the presence, size, and location of the cervical lymphadenopathy. The size of the primary tumor and nodal disease should be measured as this is the basis of the AJCC staging system for oropharyngeal cancers. Consideration should be given to documentation of the extent of disease before treatment with still photography and videography in the electronic medical record.

Additional staging information can be gleaned during the physical examination. Trismus, documented by measuring the distance between the upper and lower incisors, or alveolar ridges in edentulous patients, is a consequence of tumor invasion into the pterygoid musculature. Deviation of the tongue on protrusion suggests involvement of the deep or extrinsic muscles of the tongue or invasion or compression of the hypoglossal nerve (CN XII) (eFigure 33-6). A detailed physical examination is especially important with oropharyngeal cancers because treatment-altering findings may manifest themselves on visual inspection but not on radiographic evaluation and can alter both radiation treatment coverage and staging. For example, subtle superficial mucosal extension of a tonsillar tumor onto the adjacent soft palate or retromolar trigone may only be apparent during direct inspection and must be documented. Such regions may be more apparent during radiation treatment at approximately 20 Gy to 30 Gy because "tumoritis" causes increased erythema of these regions compared with the surrounding normal tissue (eFigure 33-7). With base-of-tongue tumors in particular, digital palpation is essential to determine the size and extent of local spread because these tumors are frequently not seen by or are underestimated by visual examination, especially if they are endophytic. All borders of the tumor must be determined precisely because this has a crucial impact on target volume delineation and treatment field arrangement. Precision in defining tumor borders becomes even more paramount when IMRT is anticipated. Detailed examination of the remainder of the head and neck is also important because of field cancerization and the risk of synchronous primary tumors.

Aside from a complete history and physical examination, the workup should include biopsy confirmation of the mass. Biopsy should be performed by the least invasive means possible and can include fine-needle aspiration of involved cervical nodes or biopsy of the primary site. In general, excisional biopsy of the primary site or involved lymph nodes is not recommended because of concerns about prolonged healing times that may delay definitive radiation and surgery-associated hypoxic changes. Patients who present with malignant jugulodigastric nodes or, less commonly, midcervical nodes and no clear primary tumor are statistically most likely to have a primary tumor of the oropharynx, and a thorough examination of the oropharynx should be performed as part of the evaluation.[72] Ipsilateral tonsillectomy is a recommended component of the evaluation for patients with head and neck cancers presenting with upper cervical or midcervical nodal metastases without an apparent mucosal primary tumor.

Given the significant prognostic importance and the implications for clinical investigation, assessing oropharynx SCCs for HPV has become routine. Immunohistochemical staining for p16 is a readily available and well correlated surrogate for HPV, although interpretation requires some experience.[73] In situ hybridization testing for HPV is also widely used although it is technically more challenging.



Imaging Studies

Selection of Imaging Studies

Recommended radiographic studies include CT or MRI scanning of the neck with contrast enhancement, chest imaging, and dental studies as indicated.[74] CT is generally considered to be the examination of choice for the initial diagnostic evaluation of oropharyngeal neoplasms when compared with MRI and PET imaging.[75-77] The benefits of CT include lower cost, faster acquisition speed, less motion artifact, better detection of bone invasion, higher spatial resolution, greater reproducibility on sequential examinations, and wide availability. MRI is superior to CT in specific situations, including delineating orbital or skull-base involvement and defining intracranial perineural tumor spread. MRI also has slightly superior multiplanar imaging capabilities and is better able to identify subtle soft-tissue involvement by tumor, deep osseous invasion and marrow replacement, perineural spread of disease, and extent of anterior spread of base-of-tongue tumors. MRI is also useful for patients in whom dental

eFigure 33-6 Atrophy of the right hemitongue with rightward deviation on protrusion consistent with right CN 12 palsy.

eFigure 33-7 **A,** T3N1 right tonsillar SCC before treatment in which precise tumor borders are difficult to demarcate. **B,** T3N1 right tonsil at approximately 24 Gy of comprehensive radiation using large lateral fields showing tumoritis well across the midline and extending into the ipsilateral hard palate mucosa and retromolar trigone. **C,** Schematic drawing of treatment field design with shrinking-field technique for hyperfractionated treatment.

amalgam artifact renders the CT examination suboptimal. MRI and PET/CT are used in most institutions as ancillary diagnostic studies for oropharyngeal cancers when CT imaging inadequately addresses specific clinical questions. Imaging modalities are often complementary, however, and both CT and MRI are useful in some instances. PET/CT studies can provide additive information relative to the extent of the primary tumor, nodal involvement, and metastatic disease.

Imaging is indispensable for assessing regional lymphatic spread.[78] This is particularly true in patients in whom clinical assessment of nodal disease is difficult (because of a large or muscular neck), in whom there is occult involvement of normal-sized nodes, or in whom nodal chains are involved that cannot be palpated on physical examination (i.e., retropharyngeal nodes). Multiple criteria must be used to determine whether a specific lymph node is involved by tumor on CT or MRI studies. These criteria include the node's size, homogeneity, distinctness of outer margin, focal areas of enhancement, location, loss of fatty hilum, and spherical shape and the presence of a clustering of lymph nodes. These criteria are best used as a whole and not considered in isolation. When imaging tests have been directly compared in the same patient population, PET and PET/CT studies have typically been found to be slightly more accurate in lymph node staging, followed by CT scanning and then by MRI.[77,79] See the Expert Consult website for further information on lymph node staging.

The overall incidence of pulmonary metastases has traditionally been placed at 1% to 2% in newly diagnosed patients with cancers of the head and neck. The traditional practice has been to obtain a chest radiograph to evaluate for pulmonary disease, but chest CTs allow better definition of the thoracic cavity and have a higher sensitivity for detection of pulmonary parenchymal metastases or mediastinal or hilar nodal disease. A review of the literature found a pooled prevalence of 7.9% for abnormalities on chest CT scans in patients with head and neck SCC.[81] Abnormal findings were more prevalent in patients with N2 or N3 nodal involvement or stage III or IV disease and less prevalent for oral cavity primary tumors. Not surprisingly, patients with recurrent disease had higher rates of positive chest CT scans (25.3%). These risk factors correlated closely with the clinical factors statistically associated with the development of distant metastases (T stage, N stage, gender, nodal level, and locoregional control [LRC]).[82] Although there is significant institutional variation regarding chest imaging, a measured approach would include chest CT scans for patients with advanced nodal involvement (N2b, N2c, and N3), locally advanced primary disease (T3 and T4), low cervical nodes, and other risk factors, including recurrent disease. A CT scan of the chest can be performed at the same time as the neck CT scan, and modern multislice scanners can provide contrast-enhanced images with the same contrast bolus.

Imaging Technique

The Expert Consult website contains information on imaging technique.

Staging

Table 33-3 shows the AJCC seventh edition staging system for oropharyngeal carcinomas.[61] Endoscopic, radiographic, and physical examination findings are included and collated when determining the clinical stage. Pathologic staging may also be performed using the same criteria as clinical staging. Even

TABLE 33-3 TNM Definitions and Stage Groupings for Oropharyngeal Carcinomas

Primary Tumor (T)	**Regional Lymph Nodes (N)**
TX: Primary tumor cannot be assessed	NX: Regional lymph nodes cannot be assessed
T0: No evidence of primary tumor	N0: No regional lymph node metastasis
Tis: Carcinoma in situ	N1: Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
T1: Tumor 2 cm or less in greatest dimension	N2: Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension, or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension, or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
T2: Tumor more than 2 cm but not more than 4 cm in greatest dimension	N2a: Metastasis in a single ipsilateral lymph node more than 3 cm but not more than 6 cm in greatest dimension
T3: Tumor more than 4 cm in greatest dimension	N2b: Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
T4a: Tumor invades the larynx, deep/extrinsic muscle of tongue, medial pterygoid, hard palate, or mandible	N2c: Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
T4b: Tumor invades lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, or skull base or encases carotid artery	N3: Metastasis in a lymph node more than 6 cm in greatest dimension

Stage Grouping for Tumors of the Oropharynx			
Stage 0	Tis	N0	M0

Stage IVB	T4b Any T	Any N N3	M0 M0
Stage IVC	Any T	Any N	M1

There is varied opinion regarding size criteria and how to best measure lymph nodes in order to label them as radiographically involved. Measurements of 10 mm in the long axis and 8 mm in the short axis are often used as the upper limits of normal for nodes in most cervical levels. Upper level II nodes (jugulodigastric nodes) and level Ib nodes, however, may normally be slightly larger (12 mm to 15 mm). Lateral retropharyngeal nodes are considered abnormal if larger than 8 mm. Very young patients, those with severe dental disease, or those with concomitant head and neck infection may have reactive lymph nodes that are larger than the stated norm. Lymph node size should be considered as only one diagnostic criterion and must be modified in certain circumstances. One should specifically look for focal enhancement of a lymph node along its outer aspect where the afferent lymphatics enter the node. This is often the earliest evidence of lymphadenopathy and may even be seen in patients with normal-sized nodes. Assessment of lymphadenopathy on MRI scans can be more challenging than on CT scans.[75,77] In addition to the aforementioned criteria, one should look for areas of decreased signal intensity on T2-weighted images, which typically represent intranodal tumoral deposits. Meta-analysis suggests that the mean sensitivity of a neck CT scan for the detection of cervical lymph node metastasis is 81% (95% CI, 68% to 90%), of an MRI scan is 81% (95% CI, 65% to 91%), and of a PET scan is 79% (95% CI, 72% to 85%). The specificity of CT scanning has been found to be 76% (95% CI, 62% to 87%); of MRI scanning, 63% (95% CI, 43% to 80%); and of PET scanning, 86% (95% CI, 83% to 89%).[77,79] The quoted sensitivity and specificity for these studies depends greatly on the criteria that are used in declaring a lymph node positive. When imaging tests have been directly compared in the same patient population, PET and PET/CT studies have typically been found to be slightly more accurate in lymph node staging, followed by CT scanning and then by MRI.

PET/CT and PET can serve a complementary role in the imaging evaluation of oropharyngeal primary tumors. Besides the slightly improved accuracy for nodal disease, PET/CT is particularly useful in evaluating for a primary site in patients with cervical nodal disease but an unidentified primary site. An oropharyngeal origin remains the most likely source of an occult primary tumor in patients with level II or III lymph node involvement. PET/CT scanning can also identify synchronous second primary tumors in patients with oropharyngeal SCCs.[80] A PET/CT scan can also be used to screen for metastatic disease and excels at identifying atypical metastases outside of the standard metastatic search pattern, although metastatic spread at presentation is rare. The performance of PET/CT scanning can be improved with a dedicated head and neck protocol, which can also be incorporated into treatment planning. Although PET/CT in particular may have value in oropharyngeal cancer workup and staging, overuse of this expensive resource remains a persistent concern as more standard imaging modalities typically supply equivalent diagnostic information.

Limitations of imaging should also be acknowledged. CT and MRI have limited sensitivity for the detection of superficial mucosal disease, again emphasizing the necessity of a detailed head and neck examination. Also, dental amalgam artifact can limit visualization of the structures of interest, more so for CT than MRI. Motion artifact may degrade the image quality; this is particularly a problem with MRI, where images may be acquired over a several-minute time span. CT, MRI, and even physical examination are known to have limited sensitivity and specificity for the detection of small metastatic deposits within normal-sized lymph nodes. PET scans may be falsely negative in histologically low-grade lesions and in lesions that are less than 5 mm in size and falsely positive when inflammatory changes are present, particularly postoperatively or in the setting of poor dentition.

The development of multiple detector-row CT (MDCT) scanning in conjunction with helical acquisition techniques over the last decade has revolutionized the cross sectional imaging of patients with head and neck cancer. The ability to simultaneously obtain axial image information from 64 to 256 rows of detectors allows rapid scanning of patients with almost no motion artifact. The multiple rows of detectors can simultaneously produce 64 to 256 images, each with a slice thickness of 0.5 mm to 0.625 mm. This enables acquisition of a three-dimensional volume of image data that can be processed into images of varying slice thicknesses generated in sagittal, coronal, or oblique imaging planes. These two-dimensional reformations offer improved visualization of the three-dimensional extent of the primary neoplasm and involved cervical lymph nodes.

Because of the possibility that lower cervical and upper mediastinal nodes may be involved by tumor, it is important to start the CT acquisition just below the aortic arch at the level of the aortopulmonary window. The scans should extend superiorly to the level of the cavernous sinus and skull-base foramina to detect perineural tumor spread along cranial nerve branches, invasion of the masticator and parapharyngeal spaces, and skull-base invasion. Non–contrast-enhanced scans before contrast administration are rarely beneficial and do not need to be routinely obtained. Sufficient time must be allowed for the injected contrast material to enhance the primary tumor and lymph nodes before scanning begins. As a result, a scanner-specific time delay must be inserted between the start of the contrast injection and the initiation of the CT scan to obtain maximal enhancement, with the goal of providing differentiating tissue enhancement rather than vascular opacification. Tight compact bolus injection of the contrast medium (3 mL to 4 mL per second) offers superior enhancement of lesions. Bone and soft-tissue reconstruction algorithms should both be obtained for maximal diagnostic information.

MRI protocols should be constructed in a similar manner to cover the region from the skull base and cavernous sinuses to the aortic arch. It is particularly important to obtain both high-quality non–contrast-enhanced T1- and T2-weighted images because these are often more helpful than contrast-enhanced images at defining the extent of the primary neoplasm and assessing nodal disease. Post-contrast-enhanced T1-weighted images obtained with fat suppression are helpful for identifying perineural tumor spread, skull-base invasion, and deep spread to the masticator and parapharyngeal spaces, as well as for detecting intranodal tumor deposits. Because of the extensive pterygoid plexus of veins in the masticator space and normal enhancement of mucosal areas of the head and neck, contrast-enhanced scans are often challenging to interpret. These images must be carefully compared with non–contrast-enhanced images in the same plane.

when histologic evaluation of the disease is available, information obtained during clinical staging should be incorporated. Comparisons of surgical and radiation-based treatment outcomes should be based on clinical staging because up-staging and down-staging may occur with surgical intervention and both should be reported.

There are a few changes between the sixth and seventh editions of the AJCC oropharyngeal staging recommendations. Stage T4 lesions were previously divided between T4a (resectable) lesions and T4b (unresectable) lesions. Although the qualifications for stage T4a and T4b disease remain unchanged, the description has been altered in the seventh edition to account for advancement in surgical techniques with free-flap and other reconstructive options that allow previously "unresectable" primary lesions to be resected. Therefore, stage T4 is now divided into moderately advanced local disease (T4a) and very advanced local disease (T4b). Extracapsular spread has been added as a descriptor for nodal disease, although this does not currently alter nodal staging. The diagnosis of extracapsular spread is allowed clinically through identification of matted nodes adherent to the overlying skin or adjacent structures or through clinical evidence of extranodal invasion (e.g., cranial nerve palsies). Radiologic signs of extracapsular spread may include perinodal soft-tissue stranding seen before treatment and the presence of amorphous nodal margins. Nodal metastases to level VII are now considered regional disease in oropharyngeal and hypopharyngeal primaries. Level VII nodes are termed the *superior mediastinal group* and extend from the innominate artery to the suprasternal notch.

PRIMARY THERAPY

General Principles of Treatment

The primary goal of treatment is to maximize the chance for cancer cure while minimizing functional impairment and treatment-related morbidities. Selection of the treatment modality depends on the tumor stage, extent of nodal involvement, oropharyngeal subsite, and skill set of the healthcare team. As a whole, the effectiveness of radiation and the potential functional compromise from large surgical resections has historically made the oropharynx the realm of the radiation oncologist. The recent success of low-morbidity transoral surgical resection has challenged this assumption, however. Given the central role of radiotherapy in the treatment of oropharyngeal tumors, a substantial body of work has accumulated in an effort to optimize local control (LC) through altered treatment schedules such as accelerated fractionation, hyperfractionation, and accelerated hyperfractionation. The addition of concurrent chemotherapy over the past 15 years has also improved rates of LRC and OS, although at the expense of increased acute and late toxicities. IMRT provides LC rates similar to those of conventional irradiation while decreasing potential acute and late toxicities through dosimetric avoidance of critical structures.

To date, only a single randomized trial evaluating primary surgery versus radiation therapy has been conducted for primary oropharyngeal squamous cell carcinomas (RTOG 73-03).[83] Seventy patients were randomized to definitive radiotherapy, preoperative radiotherapy followed by surgery, or surgery followed by radiotherapy. No significant difference was identified in rates of either OS or LC, although the study was grossly underpowered.

The heterogeneity of tumors within the oropharynx given the multiple combinations of primary and nodal stages also makes broad treatment recommendations difficult. Furthermore, the recent epidemiologic shift in this disease, with the dramatic increase in good-prognosis HPV-initiated tumors, has brought into question the utility of historical comparisons.

Early-stage oropharyngeal carcinomas (T1 to T2, N0 to N1) can be treated with either radiation or surgery, with the addition of adjuvant radiation as indicated by surgical pathologic findings. Surgery and radiation therapy provide similar local and regional control rates.[84] Treatment selection is consequently based on the anticipated modality-specific functional and cosmetic outcome, the most appropriate treatment for lymph nodes at risk, and patient goals and preferences. Well-lateralized tumors, particularly of the tonsillar complex, can be treated with unilateral radiation and resultantly have a more favorable toxicity profile. Radiation has traditionally been used for early-stage oropharyngeal tumors based on excellent LC rates and acceptable morbidity and the higher rate of severe complications identified with surgery, particularly in older series. However, minimally invasive surgery with robotics or transoral laser microsurgery has demonstrated lower morbidity than older surgical techniques and is increasingly used in early stage disease.

Intermediate-stage carcinomas (large T2 lesions, nonextensive T3 lesions, with or without advanced nodal disease) are preferentially treated by primary radiation with or without chemotherapy because most patients undergoing surgical resection ultimately receive postoperative radiation therapy for the presence of multiple positive nodes, extranodal extension, or close resection margins. In this setting, definitive radiation spares the combined toxicity of both surgery and adjuvant radiation, particularly because resection of intermediate-stage carcinomas frequently leads to functional loss.

Locally advanced primary tumors (large, infiltrative T3 or T4 lesions) can be treated with radiation, preferably with concurrent chemotherapy, or with primary resection, nodal dissection, and postoperative irradiation with or without concurrent chemotherapy. The large tissue defects typically required for such a resection can be reconstructed with microvascular free flaps, which decrease the degree of functional loss. Because this functional loss exceeds that expected by radiation therapy, primary radiation plus concurrent chemotherapy is typically recommended. Surgical resection, however, is recommended for locally advanced cases with invasion of the mandible or other excisable osseous structures or if functional deficits such as gross aspiration or laryngeal impairment are present. Postoperative radiation follows surgical resection in these cases.

Surgery

Primary surgery followed by (chemo)radiation as indicated is a viable treatment approach. Surgical techniques continue to evolve and improve with less invasive procedures showing lower functional morbidity and equivalent oncologic outcomes. Traditional "open" surgical approaches include the lateral pharyngotomy, a transhyoid approach, or an anterior approach with a midline or lateral mandibulotomy with a combined lip-splitting incision. These procedures offer improved exposure of the tumor for oncologic resection at the expense of prolonged recovery and potential functional impairment.[85] Transoral approaches for tonsillar tumors have been used for years at some institutions because of the ready visibility and accessibility of the tonsillar fossa with standard surgical tools.[86] The more distal oropharynx, including the base of tongue, has less optimal transoral exposure, limiting transoral surgical excision with standard tools.[87] However, with the pioneering of a rod telescope for visualization and a carbon dioxide laser for excision, Steiner et al published results of 48 previously untreated patients with base-of-tongue tumors treated with this technique from 1986 to 1997.[88] These

transoral approaches have been labeled transoral laser microsurgery (TLM) and deviate from the previous standard for oncologic surgeries requiring en bloc resection of the tumor. As part of these procedures, the tumor is frequently removed piecemeal until the interface between tumor and normal tissue is identified, with an appropriate surgical margin taken at that point. TLM, particularly when used to resect base-of-tongue tumors, is challenging because the carbon dioxide laser is typically used in a line of sight fashion, requiring significant manipulation of the tumor. The carbon dioxide laser is also less robust than cautery in achieving hemostasis, leading to alternation between the two instruments intraoperatively. Finally, the microscope and laryngoscope can have limited exposure and illumination of the surgical site, frequently giving surgeons the impression that "they are operating with limited dexterity in a dark hole."[87]

Transoral robotic surgery (TORS) was first used in head and neck tumors in 2005, using a combination of the camera and two of the robotic arms.[89] Advantages of a TORS approach include improved field of view and illumination as well as more facile three-dimensional manipulation of the robotic arms. Mechanical limitations of the robotic device restrict its application for more distal tumors of the larynx and hypopharynx, but most oropharynx and supraglottic tumors are accessible via TORS.

Primary surgery offers the possibility for improved LC with a negative margin excision followed by radiation as needed, particularly in HPV-negative cancers. Primary surgery may also allow for lower radiation doses in the adjuvant setting and case-dependent omission of concurrent chemotherapy, diminishing potential treatment-related toxicities. This approach is currently being tested in clinical trials.[90]

The increasing use of transoral surgical approaches reflects accumulating institutional data showing good oncologic and functional outcomes (Table 33-4). The majority of data to date derives from single institution series. The Washington University experience[91] of 84 patients with stages III and IV oropharyngeal cancers treated with TLM followed by radiation as indicated described rates of disease-specific survival (DSS) and OS of 92% and 88%, respectively, at 5 years, with only one local failure and four regional failures; only 3.4% of patients remained gastrostomy-tube dependent at 3 years. Only 26% of the patients had stage T3 and T4 disease, however, and these patients had a statistically worse OS. In addition, 95% of the patients were HPV-16 positive, and this may have contributed to the high rates of LRC. Again, such potential benefits are weighed against the hazards of surgery, which included a 6% reoperation rate, an 11% temporary tracheotomy rate, and an 11% rate of velopharyngeal incompetence (although oral intake and speech were not interrupted).

Although the Mayo Clinic experience[96] details a similarly high LC rate with transoral excision, others have found higher rates of locoregional recurrence.[97] The Göttingen group, which pioneered TLM, has reported LRC of 76% and 79% in tonsillar and base-of-tongue resections, respectively.[94,95] These series contain a higher percentage of patients with locally advanced primary tumors, which in other series has significantly impacted locoregional control, with one series showing a 2.5 factor increase in death or recurrence when comparing T1 and T2 with T3 and T4 tumors.[92] Canis et al, however, found no internal differences in LRC or DFS when comparing the primary tumor stage.[94] Although the Göttingen series does not specify HPV positivity, the inclusion of patients extending back to 1986 infers a higher rate of HPV-negative patients, with an anticipated elevation of recurrence rates. The increasing rate of HPV-positivity and the likely impact of primary tumor stage on oncologic outcome underscores the challenge of comparing results from modern surgical series with selected surgically resectable tumors and older, randomized data evaluating radiation-based treatment.

Prior analysis of the patients treated at the University of Göttingen demonstrated a worse DSS and LRC in patients in which adjuvant split-course radiation was used when compared to conventional radiation.[98] The improved outcome with conventional radiation underscores the importance of adjuvant radiotherapy when indicated following transoral resection. Similarly, the largest series evaluating transoral resection found adjuvant radiation therapy, with or without chemotherapy, to favorably impact both OS and DFS (HR 0.33 to 0.48 and 0.38, respectively).[92] Primary tumor stage, HPV status, and margin status were also found impact OS on multivariate analysis.

Treatment Recommendations by Subsite

Tonsillar Region Carcinomas

A review of North American experiences[84] published between 1970 and 2000 compiled data comparing surgery with or without adjuvant radiation with definitive radiation with or without neck dissection. The 51 reported series represented approximately 6400 patients. Results for the tonsillar region showed strikingly similar oncologic outcomes between primary surgery and radiation therapy: LC (70% versus 68%), LRC (65% versus 69%), 5-year OS (47% versus 43%), and 5-year cause-specific survival (CSS) (57% versus 59%), none of which were statistically significant. However, rates of severe

complications (23% versus 6%) and fatal complications (3.2% versus 0.8%) were significantly higher in the surgical group. The less toxic side effect profile of definitive radiation therapy led the authors to recommend this approach for most patients with SCC of the tonsillar complex.

Oncologic and function outcomes from definitive radiation therapy have improved over time based on institutional series. eTable 33-1 summarizes historical institutional experiences with more than 100 patients treated with conventional radiation for SCC of the tonsillar region (with the exception of 17 patients in the Florida series receiving IMRT). The improved outcomes seen in recent reports are likely the result of improved imaging modalities leading to stage migration, improved planning techniques, the increased prevalence of HPV-positive tumors, and the concurrent use of chemotherapy when indicated (Table 33-5).

The largest study of radiation therapy for oropharyngeal cancer in the IMRT era reviewed 776 patients treated at M. D. Anderson Cancer Center (MDACC) with IMRT from 2000 onward.[104] Half of these patients had tonsillar tumors, 46% had base-of-tongue tumors, and small percentages had soft palate and pharyngeal wall primaries. LRC and OS were 90% and 84% at 5 years, respectively (Table 33-5). Sixteen percent of the patients had pretreatment tonsillectomies, largely for diagnostic purposes, and 9% had nodal excision biopsies. The implementation of IMRT has previously raised concern that LRC may be impaired as a result of marginal misses. This did not occur in this series as locoregional recurrences, when they occurred, were primarily in the high-dose volumes, with only 12 patients (2% of the cohort) experiencing recurrence outside of these volumes. Tumor stage, overall stage, current tobacco use, and low neck nodes all impacted OS. Memorial Sloan Kettering Cancer Center (MSKCC) and the University of Florida reported similar high rates of LC, LRC, and OS in the IMRT era (Table 33-5).[105,106] Of note, the rate of chronic gastrostomy tube dependence in these IMRT-based series was much lower (2.3% to 4%) than those reported for conventional radiation and concurrent chemotherapy and mirror those seen with transoral surgical resection.

Unilateral Radiation

Unilateral radiation, including coverage of the ipsilateral neck but not the contralateral neck, has been delivered in the past using conventional techniques in patients with well-lateralized tonsillar fossa tumors. Such an approach in the era before IMRT became available offered sparing of the contralateral parotid and submandibular glands and was designed to avoid permanent xerostomia. Jackson et al[100] reported a risk of contralateral node recurrence in 2.5% of patients treated with ipsilateral irradiation for a tonsillar primary tumor that was clinically N0 or N1 (Table 33-6). Of the 642 patients treated for carcinoma of the tonsillar region at Princess Margaret Hospital from 1970 to 1991, 228 patients were treated with ipsilateral irradiation.[107] Contralateral neck failures occurred in eight patients (3.5%), with only three patients having contralateral nodal failure alone (1.7% of patients). These three patients all had significant soft palate involvement (to within 1 cm of the midline in two cases and involving more than 1 cm of the soft palate in the other case) and ipsilateral neck disease. No contralateral neck failures were seen in patients who had clinical stage T1 disease, regardless of nodal disease extent, or N0 disease, regardless of tumor size or involvement of midline

structures. The margin of coverage placed on the primary site had a significant impact on LC rates, with a 30% LC rate for a margin of less than 1 cm and an 89% LC rate for a margin of more than 1 cm. O'Sullivan et al advocated ipsilateral irradiation after informed patient consent for all lateralized lesions with less than 1 cm of medial soft palate or tongue base extension.

Side effects appear to be reduced in patients treated to the ipsilateral neck only. The Aarhus University group found no impact on LRC or survival with ipsilateral radiation, but side effects were reduced for all endpoints (i.e., dysphagia, xerostomia, hoarseness, atrophy, fibrosis, and edema)[110] Moderate to severe toxicity was reduced by more than 50% for all endpoints except fibrosis. When compared to IMRT-based comprehensive MSKCC series 29% and 11% of IMRT patients had late greater than grade 2 xerostomia and dysphagia, respectively, compared to 7.5% and 5.4% with ipsilateral radiation.[105,109] In addition, in more modern experiences reporting ipsilateral radiation, no chronic gastrostomy tube reliance has been identified.

Our use of unilateral radiation at the University of Wisconsin has evolved over time, with increased frequency as studies confirming its safety have accumulated. We typically have confined ipsilateral radiation to patients with well-lateralized T1 to T2, N0 to N1 tonsillar cancers and ipsilateral radiation has not been employed when the primary tumor extends to involve midline structures such as the base of the tongue or more than minimal extension onto the soft palate. This is consistent with the American College of Radiology (ACR) consensus that deemed ipsilateral radiation appropriate in tonsillar tumors that have less than 1 cm invasion into the soft palate or base of tongue and a nodal stage of N0 or N1.[111] Others have argued that the contralateral neck only needs to be covered if the tumor extends beyond the midline of the soft palate (uvula) or beyond the lateral one third of the ipsilateral base of the tongue.[97,112] The dominant criticism of ipsilateral radiation is the potential risk of contralateral regional recurrence. In all large published series, however, the risk of contralateral nodal failure is significantly less than 5%, despite two studies including patients from before the CT era (see Table 33-6). This suggests that the current criteria for ipsilateral radiation may be overly conservative. Of note, in comparing late side effects of treatment, ipsilateral radiation seems to have more limited late toxicity than the transoral resections, although identifying the late toxicity of transoral resection can be confounded by adjuvant (chemo)radiation.

Surgery

The advances in surgical techniques and outcomes associated with transoral resections were discussed previously. Many patients present to the radiation oncology clinic having undergone tonsillectomy for either a tonsillar abnormality or as part of an evaluation for an unknown primary tumor in the setting of cervical nodal disease. Yildirim et al[113] evaluated 120 patients treated with radiotherapy at MDACC following gross removal of their disease by tonsillectomy. Most of these tonsillectomies were performed for diagnostic purposes, including 29% that had no preoperative tonsillar abnormality. The population included 36 patients with stage III disease and 64 patients with stage IV disease. Only 12 patients received systemic chemotherapy. Five-year LRC, recurrence-free survival (RFS), and OS were high at 97%, 92%, and 86%, respectively, with only a single patient experiencing disease recurrence at the primary site. Fifty-one percent of tumors had negative surgical margins, 35% had positive surgical margins, 10% had close margins (<5 mm), and 3% had an unknown margin status. The tonsillar bed received 66 Gy of radiation in 82% of patients. The authors concluded that the high LC rate present, particularly with T2 disease, may be a result of patient selection rather than the potential benefit of tonsillectomy because there was not invasion into adjacent mucosal sites such as the soft palate or base of the tongue in this patient group. Margin status and nodal disease dictated that adjuvant radiation be delivered, making the benefit from surgery with its associated toxicities, including potential velopharyngeal insufficiency, unclear. Surgery may be a reasonable approach for small, stage T1 or T2 primary tumors without nodal disease in which adjuvant radiation would not be required postoperatively, but this is a small subset of patients with early disease.[114]

Base-of-Tongue Cancers

SCCs of the base of the tongue tend to be more locally, regionally, and systemically aggressive with worse outcomes when compared with tonsillar primary cancers. Parsons et al[84] also reviewed the radiation oncology and surgical literature from 1970 to 2000 and compared reported outcomes between surgery with and without radiation and definitive radiation with or without a lymph node dissection for base-of-tongue primaries. For surgical-based versus radiation-based treatments, similar outcomes were identified for rates of LC (79% versus 76%), 5-year OS (49% versus 52%), and 5-year CSS (62% versus 63%). LRC rates were slightly better with radiation as the primary modality (60% versus 69%). Again, the rate of severe complications was higher if primary surgery was performed (32% versus 3.8%), as was the rate of fatal complications (3.5% versus 0.4%). The authors concluded that radiation therapy with or without lymph node dissection was preferable for the majority of SCCs of the base of the tongue based on the discrepant toxicity profiles.

Reported historical LC rates of large series published in the last 20 years are listed in eTable 33-2. The largest series from the University of Florida describes a LC rate of 93% for T1 to T2 tumors.[115] Multivariate analysis demonstrated that the T category, histologic differentiation, adjuvant chemotherapy (if T4 disease), and race all affected LC rates. More poorly differentiated cancers had better LC when compared with the more differentiated neoplasms, potentially acting as a surrogate for HPV-positivity. LRC rates were affected by the same factors and were also statistically associated with postradiotherapy neck dissections and overall stage. Seventy-five percent of patients in this series were treated with hyperfractionated regimens (twice-daily hyperfractionation or concomitant boost), although this was not correlated with LC or LRC. Compared with tonsillar fossa tumors, base-of-tongue tumors had lower rates of LC, particularly when clinically T3. Sixteen percent of patients (52 patients) developed one or more severe complications from treatment, including the need for a permanent gastrostomy tube (21 patients) and mandibular osteoradionecrosis (8 patients). Eleven patients had surgery-related complications following either a postradiation neck dissection or salvage surgery.[115]

Brachytherapy

High local and regional control rates have been achieved using a combination of external beam radiation therapy (EBRT) and a brachytherapy boost. Harrison et al[116] treated 68 patients with this approach, with a high overall LC of 89%. EBRT was delivered to the primary site and upper neck (54 Gy) and low neck (50 Gy), followed by a boost of 20 Gy to 30 Gy of iridium-192 (^{192}Ir) brachytherapy approximately 3 weeks later. Contraindications for a brachytherapy implant included disease extending below the hyoid bone, into the preepiglottic space, mandibular invasion, or posterior pharyngeal wall extension, with 15% to 20% of cases being unsuitable for brachytherapy. Similar high rates of LC have been identified at other institutions,[117,118] although the University of Florida discontinued

interstitial implant because of inferior results compared with conventional EBRT.[115]

Soft Palate Carcinomas

Carcinomas originating from the soft palate are a small minority of oropharyngeal cancers, occurring less frequently than cancer arising from the base of the tongue or tonsillar regions, and they typically account less than 10% of the total cases. A higher prevalence is seen in studies evaluating early-stage (stages I and II) carcinomas of the oropharynx because soft palate carcinomas are less likely to be locally advanced or regionally metastatic and resultantly represent a higher percentage of the early-stage tumors.[119] Because of the lower frequency of soft palate carcinomas, accumulation of large numbers of patients for studies is challenging. Generally, in patients who have not been previously radiated, definitive radiation is preferred to surgery. Surgical defects can lead to velopharyngeal incompetence, affecting both speech and swallowing. The drainage pattern from the soft palate can also include the retropharyngeal nodes, which are unaddressed in a standard neck dissection.

Chera et al[120] reviewed the University of Florida experience of 145 patients treated curatively with definitive radiation for soft palate carcinomas between 1963 and 2004. Hyperfractionation was used in 42% of patients, an orthovoltage intraoral cone in 27%, and an interstitial implant in 6%. Thirteen percent had synchronous SCCs elsewhere in the upper aerodigestive tract. At 5 years, LC rates were T1 90%, T2 91%, T3 67%, and T4 57%. The OS at 5 years was 44%, with many patients dying of comorbid disease and second primary tumors (CSS at 5 years was 73%). An overall treatment time of more than 47 days and a higher overall stage both adversely affected LRC rates, whereas nodal category affected OS. In an inter-era comparison, patients treated after 1985 had improved control rates (87% versus 73%). Similar high rates of LC were identified in older single-institution studies. Keus et al[121] reported on 146 patients treated at Institut Curie for soft palate carcinoma, 71% with EBRT alone and 29% with an intraoral applicator. Patients receiving radiation through the intraoral applicator had fewer normal tissue complications, although most patients receiving this had smaller primary tumors (stage T1 or T2). LC rates at 3 years for T1 and T2 tumors were 92% and 70%, respectively. Neck disease recurred in 19 patients, of whom 9 had no component of local recurrence; reexamination of the treatment portals suggested a marginal miss in 7 patients. No dose response was ascertained in locally advanced tumors receiving between 60 Gy and 75 Gy, leading the authors to recommend limiting the EBRT dose to 70 Gy to minimize complications.

Several French groups have described high LRC rates with a combination of interstitial brachytherapy and EBRT. Mazeron et al[122] described 5-year LC and nodal control of 91% and 95%, respectively, in patients treated with EBRT followed by a ^{192}Ir implant for T1 and T2 soft palate carcinomas. The 5-year necrosis rate in this group was just under 20%. When compared with rates for patients treated with EBRT alone, both LC and OS were improved.

Lateral and Posterior Pharyngeal Wall Tumors

SCC of the pharyngeal wall is a relatively uncommon primary location and has the lowest incidence of the oropharyngeal subsites. The oropharynx and hypopharynx are demarcated by an artificial plane placed at the superior surface of the hyoid bone. However, the fact that the lateral and posterior pharyngeal walls are in continuity can create challenges when one is attempting to assign a head and neck site to a tumor that may continuously involve a large segment of the pharyngeal wall.

Both surgery and radiation therapy have been employed to treat pharyngeal wall cancers, and comparison of the two modalities is problematic because of the low incidence and inherent staging variability of these lesions as well as the limited amount of literature addressing them. Hull et al[123] reported on 148 patients with SCCs of the pharyngeal wall treated with definitive radiation between 1964 and 2000; 93 lesions (63%) arose from the hypopharynx and 55 (37%) arose from the oropharynx. LC rates at 5 years were T1 93%, T2 82%, T3 59%, and T4 50%. With surgical salvage, the LC rate increased to 87% for T2 tumors. Earlier-stage disease (stages I and II), an oropharyngeal primary site, and twice-daily fractionation were all associated with improved LRC. Treatment complications resulted in the deaths of 5% of the patients, and 16% of patients experienced severe complications, the most frequent of which was the need for a permanent gastrostomy tube.

Julieron et al[124] reviewed 77 patients treated surgically for posterior pharyngeal wall tumors, of which 22 required a total laryngectomy. For previously untreated patients, local failure occurred in 11% of individuals treated with surgery and adjuvant radiation and in 18% with tumors larger than 4 cm. The total failure rate, including local, regional, and distant relapses and second primary tumors, was 50% in the primary surgery group. Nineteen percent continued to rely on a gastrostomy tube at 1 year. Local failure was seen in 52% of patients who had received prior radiation therapy, and 5-year OS was inferior to that of the nonrecurrent disease group; the authors concluded that conservative surgery should not be performed in the setting of postradiation failure.

LOCOREGIONALLY ADVANCED DISEASE AND PALLIATION

Chemotherapy/Concurrent Chemoradiation

The benefit of adding chemotherapy to the treatment of locoregionally advanced SCC of the head and neck has been established by the Meta-Analysis of Chemotherapy on Head and Neck Cancer (MACH-NC), a meta-analysis based on individual patient data, first published in 2000 and most recently updated in 2009.[125,126] The updated meta-analysis included 87 randomized trials that enrolled 16,485 patients comparing locoregional treatment versus the same locoregional treatment plus chemotherapy. An absolute survival benefit of 4.5% was observed at 5 years, but this benefit depended on how the chemotherapy was scheduled (induction, adjuvant, or concurrent) (Table 33-7).

Induction or Adjuvant Chemotherapy

Induction chemotherapy, the delivery of chemotherapy before definitive surgery or radiation therapy, is an approach based on the recognition that systemic chemotherapy is most active in previously untreated patients. Combination chemotherapy regimens with drugs such as fluorouracil and cisplatin can produce response rates of 80% to 90%, which are clinically complete in up to 40% of these patients.[127] Although the responses are temporary, the use of chemotherapy as the initial treatment modality is an attractive model and has the potential to maximize the benefit of the chemotherapy while both reducing the magnitude and improving the outcomes of the locoregional therapy.

Multiple Phase III trials of induction chemotherapy schedules have been conducted, but the results have been generally disappointing. In the updated MACH-NC meta-analysis, individual patient data from 31 induction trials (5311 patients) were analyzed, and no significant survival benefit was identified.[126] It is of note, however, that among the trials that used

induction regimens containing a platinum and fluorouracil, the hazard ratio was more favorable at 0.90 (95% CI, 0.82 to 0.99). Although induction chemotherapy significantly reduced distant metastases, it had only a minimal impact on LRC, the more frequent cause of treatment failure. Similarly, in 12 trials (2567 patients) which explored the use of adjuvant, single-modality chemotherapy after definitive locoregional management, no survival benefit was identified in this meta-analysis.

Concurrent Chemoradiation

The results were distinctly different for those trials using concomitant chemotherapy and radiation. This approach is based on the recognition that chemotherapy, in addition to its independent antineoplastic activity, has the potential to radiosensitize and thereby improves the outcomes achieved after radiation alone. Such radiosensitization, however, also increases the acute toxicity from treatment. In the MACH-NC meta-analysis of the 50 concomitant trials (9615 patients), the absolute benefit from chemotherapy was 6.5% at 5 years. The concomitant schedules markedly improved the LRC (HR, 0.74; 95% CI, 0.70 to 0.79; $p < 0.001$) with a significant but less impressive improvement in distant control (HR, 0.88; 95% CI, 0.77 to 1.00; $p = 0.04$).[126] This report solidified the role of concomitant chemoradiation as a treatment standard in the definitive management of locoregionally advanced head and neck squamous cell cancer.

The MACH-NC investigators also noted that the proportion of deaths not resulting from head and neck cancers increased progressively with age from 15% in patients younger than 50 years to 39% in those aged 71 years and over. There was a concomitant diminishing benefit of chemotherapy on survival such that patients aged 71 years or older essentially derived no improvement at 5 years. Others have suggested, however, that appropriately selected elderly patients have outcomes after treatment that are equivalent to their younger counterparts.[128]

Monotherapy with single-agent cisplatin and concomitant EBRT is the most frequently tested regimen and has become a standard of care.[129] Other acceptable alternatives include multiagent combinations of cisplatin or carboplatin with 5-fluorouracil (5-FU). Monotherapy with a drug other than cisplatin has led to inferior results and is not recommended in routine practice. The effect of the total dose of cisplatin administered may be relevant to clinical outcome but has not been addressed systematically.[130] Rates of acute toxicities, including mucositis, skin toxicity, and hematologic adverse events, are clearly increased by the addition of concurrent chemotherapy. Late toxicities, however, are less well described, although a trend toward an increase in severe late toxicity after chemoradiation was identified in the Phase III GORTEC 94-01 oropharynx cancer trial.[131]

Table 33-8 summarizes some of the recently published cooperative group randomized Phase III trials of concurrent chemoradiation. These studies have addressed the possibility of improving outcomes either by using accelerated radiation fractionation or by adding additional noncytotoxic systemic agents, such as cetuximab, a monoclonal antibody EGFR inhibitor, or tirapazamine, a hypoxic cell sensitizer. In general, these efforts have proven unsuccessful. Several important observations have nonetheless emerged from these trials. First, like most trials in head and neck cancers, eligibility was not restricted to patients with oropharynx tumors. Nonetheless it is apparent that the study populations were dominated by patients with stage IV oropharynx cancer who were largely p16 or HPV positive, and that in these large prospective trials the highly favorable prognostic import of HPV positivity was confirmed. This has led to the general consensus that, at the least, HPV status must be included as a stratification factor in all future clinical trials that include oropharyngeal cancer.

Ideally, separate clinical trials based on tumor HPV status should be designed.[34] In the HPV-negative cancers, continued efforts directed at improving outcomes remain the priority. In the good prognosis HPV-positive oropharyngeal cancer population, however, the focus should be on reducing acute and long-term toxicity, without loss of efficacy. The RTOG 1016 trial, which compares radiation with cisplatin to radiation with cetuximab, and the ECOG 1308 trial, a Phase II study exploring a reduced dose of radiation in patients with HPV-positive oropharynx cancer achieving a complete response to induction chemotherapy, are two examples of such trials in this population. Both studies await full analysis.

Additional observations from these recent randomized trials include the recognition that the highly accelerated fractionation schedule from the GORTEC trial[135] produced a significantly greater mucosal reaction. In the absence of a clear outcome improvement, such a schedule cannot be recommended. The TROG 02.02 trial confirmed the conventional wisdom that poor radiation therapy quality produces inferior outcomes, and it noted that the probability of receiving poor-quality radiation was highly correlated with lower enrollment on the trial, presumably reflecting lower overall patient volume and experience.[132] The TROG trial also identified a strong trend toward an improvement in LRC in the patients who were p16-negative treated with the hypoxic sensitizer; raising the possibility that such agents might be useful in that subset of patients.[133]

Although concurrent chemoradiation remains the standard of care for patients with locally advanced, nonmetastatic SCC of the head and neck, the short-term benefit of induction chemotherapy, and in particular its impact on the risk of distant metastases, has been of continued interest. Phase II testing of more intensive three-drug induction regimens adding a taxane (paclitaxel or docetaxel) to the well-tested cisplatin and fluorouracil backbone have suggested an improvement in overall response rate. To date, there have been four separate Phase III trials that have supported this observation (Table 33-9).[136-139] A meta-analysis has confirmed the findings.[140]

This has led several groups to explore more intensive sequential treatment schedules of induction chemotherapy followed by concurrent chemoradiation in an effort to optimize both distant and LRC effects. Four separate Phase III randomized trials have been completed attempting to define whether the addition of induction chemotherapy to concurrent chemoradiation will improve outcomes achieved with chemoradiation alone. Three of these studies have been reported and have all been negative.[141-143] No survival benefit was identified and the sequential regimens proved more toxic. Further use of this approach therefore remains investigational.

Biologic Therapy

In 2006, Bonner et al reported results from a landmark study that compared radiation therapy alone (once-daily dose of 70 Gy in 35 fractions; twice-daily dose of 72 Gy to 76.8 Gy in 60 to 64 fractions; or concomitant boost of 72 Gy in 42 fractions) with radiation plus the anti-EGFR monoclonal antibody cetuximab.[144] This study demonstrated that the use of a biologic agent in combination with EBRT could improve survival rates for locoregionally advanced SCC of the head and neck, and led to the approval of cetuximab by the U.S. Food and Drug Administration (FDA) in 2006 for this indication. The median duration of LRC, the primary endpoint, was 24.4 months in the combined-therapy arm and 14.9 months in the radiation alone arm (HR for locoregional progression or death, 0.68; 95% CI, 0.52 to 0.89; $p = 0.005$). Five-year OS was 45.6% versus 36.4%, with median survival durations of 49 versus 29.3 months (HR, 0.73; $p = 0.018$), respectively, favoring the combined-therapy arm.[145] With the exception of acneiform rash and infusion reactions, the incidence of grade III or greater toxic effects, including mucositis, did not differ significantly between the two groups. Rates of grade III or IV late toxicities were also similar.

In subgroup analyses, it would appear that patients who received radiation with the concomitant boost regimen derived the greatest benefit from the addition of cetuximab. When analyzed by disease site, patients with primary tumors in the oropharynx benefited most compared to those with primary tumors in the larynx (HR, 0.87) and in the hypopharynx (HR, 0.94), suggesting that there might be a relationship between HPV-related SCC and responsiveness to the anti-EGFR antibody, a postulate that requires verification by randomized data.

TABLE 33-9 Response Rates in Four Randomized Trials of a Taxane, Cisplatin, Fluorouracil (TPF) Versus Cisplatin, Fluorouracil (PF)-Induction Chemotherapy

Posner[138]	2007	docetaxel	64	72	0.07
Pointreau[139]	2009	docetaxel	59	80	0.002

Management of the Neck

Adjuvant Radiation or Chemoradiation

Two large, multicenter, randomized Phase III trials, EORTC 22931 and RTOG 9501, have evaluated the role of adjuvant high-dose cisplatin chemotherapy administered concomitantly on days 1, 22, and 43 with EBRT (60 Gy to 66 Gy in 30 to 33 fractions) in the postoperative setting for patients with locally advanced SCC of the head and neck.[146,147] Initial reports from both trials demonstrated statistically significant improvements in the rates of LRC and DFS or progression-free survival (PFS). The EORTC 22931 trial also demonstrated a significant OS benefit for postoperative chemoradiation, although the RTOG 9501 study only trended in that direction. The eligibility criteria of the two trials differed somewhat, and the overall patient population appeared to have somewhat worse baseline characteristics in the EORTC 22931 trial. A meta-analysis of these two trials has been published, identifying microscopically involved resection margins and extracapsular spread of tumor from neck nodes as the two most important prognostic factors for poor outcome.[148] Patients with these risk factors appear to gain the most benefit from concurrent chemoradiation. It is of note that in an analysis of the 10-year follow-up from the RTOG 9501 cohort, benefit was identified only in those patients with these two high-risk features.[149] Based on the results of these two studies, patients with one or both of these high-risk factors who are medically fit should be treated with postoperative chemoradiation using cisplatin, whereas radiation therapy alone should remain as the standard of care for those without these high-risk factors.

There have been subsequent efforts to improve on these results. The RTOG 0234 trial was a randomized Phase II trial of surgery followed by chemoradiation using cetuximab with either cisplatin or docetaxel in patients with resected stage III or IV SCC of the head and neck who had high-risk pathologic features, including microscopically positive resection margins, two or more metastatic neck nodes, or extranodal capsular spread. The trial accrued 238 patients and, with a median

follow-up of 4.4 years, the cetuximab-docetaxel arm compared favorably with the cetuximab-cisplatin arm, and appeared to produce an improvement in DFS when retrospectively compared to the cisplatin chemoradiation arm from RTOG 9501.[150] As a result, the RTOG has launched a follow-up Phase II-III trial (RTOG 1216) in high-risk postoperative patients comparing radiation with either single-agent cisplatin, single-agent docetaxel, or the cetuximab-docetaxel combination from RTOG 0234.

The RTOG has also activated a randomized Phase III trial (RTOG 0920) comparing radiation alone with radiation plus cetuximab in patients with locally advanced SCC of the oral cavity, oropharynx, or larynx whose tumors exhibited one or more "intermediate-risk" features. These intermediate-risk features include perineural invasion; lymphovascular invasion; a single lymph node greater than 3 cm or two or more lymph nodes (all <6 cm) and no extracapsular extension; close surgical resection margins (<5 mm); a T3 or T4a primary tumor; or a T2 oral cavity cancer with more than 5 mm depth of invasion.

Postradiation Neck Dissection

Current issues in the management of the neck in oropharyngeal SCCs revolve around the dose and volume of radiation delivered to nodal regions and the role of posttreatment neck dissections. Before the IMRT era, a common approach was to deliver 50 Gy to the draining regional lymphatics followed by a boost to the nodal disease using photon or electron beam therapy to 60 Gy in patients presenting with palpable cervical lymph node metastases. Radiation was subsequently followed by a postradiation planned neck dissection. Reported neck control rates with this approach at the MSKCC were 96% overall and 100% in patients who went on to have neck dissection.[151] Pathologic complete response was observed in 70% of patients. In the patients with residual disease, more than half had a complete clinical response and 83% had multiple residual pathologically positive nodes. The downside of this approach was overtreatment of the neck in the patients with a pathologic complete response who could have avoided neck dissection and the associated potential for complications and heightened late effects. The late side effects of neck dissection are not negligible; a meta-analysis of multiple RTOG studies showed that neck dissection after chemoradiation was one of the risk factors for severe late toxicity.[152]

Despite concern for side effects associated with neck dissection, some caution is warranted in choosing to forego a planned neck dissection in patients with N2-N3 nodal disease. Early, planned neck dissections have several distinct advantages. Most important are the potential improvements in oncologic outcomes such as DSS and regional control.[153] Most studies have found residual nodal disease in at least 20% of patients, with the caveat that pathologic presence following treatment does not establish cancer viability. Neck dissections performed during the 6 to 12 weeks immediately following the completion of radiation also take advantage of a window of time between the acute and late effects of radiation treatment. Although technically demanding in the postradiation setting, complications requiring additional surgery are typically around 5%, although they may be increased by high doses and concurrent chemotherapy.[154,155] Subcutaneous fibrosis is limited before the 12-week mark, allowing selective neck dissections to occur. In oropharyngeal cancer, a selective neck dissection involving levels II to IV is usually sufficient, although decision making regarding the neck dissection should be driven by pretreatment clinical and radiographic findings. In a primarily oropharyngeal cohort, residual nodal disease outside of levels II to IV was seen in less than 5% of patients following radiation.[156] Although salvage surgery can be performed in the undissected neck with recurrent disease, it carries a greater risk of complications, often requires a more extensive resection, and may lead to inferior regional control rates.

Most institutions have moved away from planned neck dissections despite these concerns. This treatment plan has relied on increasing the rate of pathologic complete responses and successfully detecting patients with residual disease following radiation. It has become common to deliver a full dose (70 Gy) to clinically and radiographically involved lymph nodes with IMRT technique. Radiographically involved lymph nodes are defined as being positive on PET scanning or having a maximal size of more than 1 cm. Critical structure toxicities are respected when planning full-dose nodal radiation. For example, involved lymph nodes within level IV and the supraclavicular fossa are frequently taken to 60 Gy with a planned neck dissection rather than risk an increased rate of brachial plexopathy by proceeding to 70 Gy.

Evaluation for residual disease occurs 8 to 12 weeks following completion of radiation with a PET/CT scan, diagnostic neck CT scan, and clinical neck examination. No isolated nodal failures were identified in a prospective trial in which neck dissection was foregone in patients with N2 and N3 disease and clinical and radiographic complete responses.[157] A radiographic complete response required that any previous lymphadenopathy measure less than 1 cm in maximum dimension and have no radiographically suspicious features. Of note, only 59% of patients with N2 and N3 disease had a clinical and radiologic complete response, and this dropped to 40% when considering N3 patients alone. Liauw et al[153] reported the University of Florida experience, which similarly found a negative predictive value of 94% for a radiographic complete response and no regional relapses in 34 patients with a radiographic complete response who did not undergo a postradiation neck dissection.

Locoregional Recurrent Disease

Locoregional recurrence after definitive treatment in the absence of distant metastases represents a challenging clinical scenario. Although the prognosis is limited, these patients are theoretically curable. Curative treatment options include salvage surgery, frequently made more challenging by prior radiation treatment, or reirradiation. Patients treated previously with surgery alone may have the option of surgery followed by adjuvant radiation or definitive radiation with or without chemotherapy. Factors to be considered in aggressive retreatment include time elapsed from initial definitive treatment; site, stage, and resectability of the tumor; patient performance status; and comorbidities.

Salvage Surgery

In patients with locally recurrent, resectable oropharyngeal tumors, salvage surgery provides the best opportunity for long-term locoregional control and potential cure. This is weighed against the morbidity of surgical resections, which may include permanent loss of swallowing function, poor cosmesis, and significant medical cost. In addition, such surgical procedures in patients who have had prior radiation carry higher complication rates than primary surgery alone. The introduction of free-flap reconstructions for large tissue defects has improved salvage surgery options and outcomes. This ability to transfer nonirradiated tissue with normal vasculature into the treatment field can decrease postsurgical complications.

A meta-analysis of 1080 patients treated with salvage surgery from 28 institutions showed a 5-year OS of 39%, with this better than expected outcome buoyed by the large number

of recurrent early-stage laryngeal cancers.[158] Pharyngeal primaries in this meta-analysis had a 2-year DFS of 25% and a 5-year OS of 26%. The operative mortality rate was 5.2%, with a complication rate of 39% and a major complication rate of 27%. Surgical complication rates appear to be significantly increased following primary chemoradiation compared with radiation alone.[159] A prospective trial that accompanied the meta-analysis found that OS declines progressively with a more advanced recurrent stage (24.3 months for stage I disease versus 9.3 months for stage IV disease) and the prior use of chemotherapy (26.9 months versus 8.8 months with prior chemotherapy).[158] The author concluded that patients with stages I and II recurrent cancer had a 70% chance of being disease-free at 2 years and a 60% to 85% probability of a successful outcome relative to quality of life and a low surgical complication rate. On the other hand, patients with recurrent cancer that initially had stage IV lesions had a less than 25% chance of being disease free at 2 years, with disease recurring in half of these patients within 5 months. Significant complications were present in 30% of stage IV salvage surgeries, and 30% of patients had a good quality-of-life outcome.

Bachar et al[160] reviewed the largest single-institution oropharynx salvage experience, in which 239 out of 640 patients treated definitively at the Princess Margaret Hospital with radiation for tonsillar carcinomas had subsequent recurrence. Of the 239, 175 (73.5%) were surgical salvage candidates. The median time to death was 1.3 years, and 5-year CSS and OS were 40% and 23%, respectively. The majority of patients died with disease. Both the T and N categories were predictors of time to death. Although the prognosis for recurrent disease was poor overall, the survivorship of 23% of patients at 5 years defines a finite group of patients cured by salvage surgery and argues in favor of a salvage surgical procedure when feasible.

Reirradiation

In attempting to determine which patients might benefit from repeating full-dose radiation to the head and neck, some have warned that "experience has shown that indiscriminate use of high-dose reirradiation often makes a bad matter worse."[161] Reirradiation has been pursued at some centers in the situation of a patient with good performance status, locoregional recurrence, and no other potentially curative treatment options. Appropriate patient selection is important, and patients should be fully informed of the increased complication rate incurred by cumulative radiation doses frequently topping 100 Gy. The use of systemic chemotherapy concurrently with reirradiation is an attractive option given its clear benefit in the previously untreated setting. This must be counterbalanced, however, by the further increase in toxicity expected with this approach.[162]

Investigations at several academic centers have demonstrated that between 10% and 20% of selected patients who are reirradiated can be long-term survivors. The University of Chicago reported on 115 patients who underwent reirradiation with a median lifetime dose of 131 Gy, including 30 patients with oropharyngeal carcinoma.[163] Radiation was delivered with concurrent chemotherapy as part of seven consecutive Phase I and II protocols in which radiation was given for five fractions every other week. Median OS and DFS were limited at 11 and 7 months, respectively. A subset of patients had long-term benefits from the repeat treatment, however, as 3-year OS, PFS, and LRC were 22%, 33%, and 51%, respectively. Improved outcomes were seen with higher doses of radiation (>58 Gy), multiagent chemotherapy, and surgery before repeat radiation. Conversely, only 11% of patients treated with repeat radiation alone were alive at 3 years. Side effects were substantial, with 19 patients (16.5%) dying of treatment-related complications and another 13 (11%) requiring surgery for osteoradionecrosis of the mandible.

The inability to undergo surgery as a negative prognostic indicator was reinforced by the RTOG 9610 clinical trial, which delivered 60 Gy at 1.5 Gy twice daily with concurrent chemotherapy. Patients were ineligible for surgical resection, and 2-year and 5-year OS were 15.2% and 3.8%, respectively.[164] A follow-up study (RTOG 9911) with concurrent cisplatin and paclitaxel found 2-year OS of 25.9%, which exceeded the results generally seen with chemotherapy alone, although 8% of patients still died of treatment-related complications.[165] Further study of this approach is ongoing, using other radiation schedules, and alternative cytotoxics or targeted therapies.[162]

The side effects of reirradiation may be partially tempered by employing highly conformal treatment techniques. An MDACC 5-year experience of 74 patients reirradiated with IMRT reported a 20% rate of major toxic events, defined as hospitalization or corrective surgery, and one patient death.[166] The median lifetime radiation dose was 116.1 Gy, and 41% of the lesions were oropharyngeal in origin. Two-year OS and LRC were encouraging at 58% and 64%, respectively. Salvage surgical resection had been previously performed in 27% of patients, and 81% of patients were treated for gross disease with margins only. Locoregional failure rates decreased with IMRT in the MSKCC experience, which described 2-year OS of 37% and a severe late complication rate of 11.4%.[167] Brachytherapy[168] and intraoperative radiation (IORT)[169] can also be used in the setting of focal reirradiation with reasonable LC. IORT as a treatment option is discussed further in the Head and Neck Overview.

Janot et al[170] reported on a randomized trial evaluating reirradiation with concurrent chemotherapy in patients who had recurrent disease or a second primary tumor in a previously irradiated region, no major sequelae from the prior treatment, a good performance status, no distant metastases, and salvage surgery with macroscopic complete resection. The radiation dose was 60 Gy over 11 weeks (five fractions, followed by the next week off) with concurrent 5-FU and hydroxyurea. Chemoreirradiation improved the DFS (HR, 1.68) but did not affect OS. Grade 3 or 4 late toxicities at 2 years were 39% in the radiation therapy arm and 10% in the observation arm ($p = 0.06$).

Locoregional radiation failures preferably undergo salvage surgery if feasible. Reirradiation following salvage surgery is not routinely added unless there is radiographic or clinical suspicion of residual gross disease or pathologic margins are diffusely positive. Reirradiation, with or without concurrent chemotherapy, is performed in a highly selected group of patients who are surgically unresectable, without marked sequelae from prior treatment, have a high performance status, are strongly motivated, and understand the high potential of significant treatment-related morbidity, and the modest likelihood of long-term survival. Generally, these patients also have limited-volume, well-circumscribed recurrent disease, and a prolonged time from initial definitive treatment. All attempts are made to limit the volume of full-dose retreatment, typically by the use of IMRT and daily image-guided radiation therapy (IGRT).

Recurrent or Metastatic Disease

Cytotoxic Chemotherapy

Large randomized clinical trials conducted over the last two decades evaluating cytotoxic chemotherapy in patients with recurrent or metastatic SCC of the head and neck have demonstrated little progress; the median survival time remains only 6 to 8 months. Single-agent chemotherapy with drugs

such as methotrexate, cisplatin, or fluorouracil typically yields lower objective response rates (8% to 17%) compared to cisplatin-based chemotherapy combinations (12% to 32%), but the latter have not demonstrated survival benefits in this patient population.[171-174] These chemotherapy combinations, however, can cause significant toxicity, and their effect on the quality of life in recurrent or metastatic disease has not been well studied. Intensification of chemotherapeutic regimens, such as the use of high-dose paclitaxel in combination with cisplatin and growth factor support in the ECOG study E1393, has led to excessive toxicity and failed to improve survival outcomes.[175] Such observations have motivated oncologists to continue to seek novel treatments to improve disease control and palliation for these patients.

Molecularly Targeted Agents

The biologic relevance of EGFR in SCC of the head and neck is validated not only through clinicopathologic correlations[176] but also by the results of the Bonner trial, which demonstrated improvements in both LRC and OS when cetuximab was added to definitive EBRT in locally advanced disease.[144,145] Multiple Phase II and III clinical trials of anti-EGFR molecularly targeted therapies in recurrent or metastatic SCC of the head and neck have been reported.[177-185] Overall, the large molecule monoclonal antibodies appear to produce higher objective response rates than the small molecule oral tyrosine kinase inhibitors although direct comparisons have not been performed. A Phase III comparison of single-agent chemotherapy with methotrexate and the oral tyrosine kinase inhibitor gefitinib failed to demonstrate a difference in outcome.[181]

In 2005, Burtness et al published the results of E5397, an ECOG trial comparing single-agent cisplatin with the combination of cisplatin and cetuximab in patients with recurrent or metastatic disease. The response rate was significantly better with the use of the cetuximab.[186] In 2008, Vermorken et al published the results of the EXTREME trial, which compared the combination of fluorouracil and a platinum with or without cetuximab in the same patient population. An improvement in overall response rate, and for the first time in recurrent/metastatic head and neck cancer, an improvement in PFS and OS was identified from the addition of cetuximab. However, an increased incidence of grade 3 or 4 sepsis, skin reactions, anorexia, and hypomagnesemia were also encountered in the cetuximab arm.[187] A similar trial (SPECTRUM) using the fully humanized anti-EGFR monoclonal antibody panitumumab instead of cetuximab, also demonstrated an improvement in PFS, although no statistically significant OS benefit was found.[188] Interestingly, median OS improved in patients who were p16-negative with no impact on OS in patients who were p16-positive.

There is continued intense interest in the use of targeted therapy in patients with recurrent/metastatic disease. The monoclonal anti-EGFR antibody zalutumumab has been tested in the second line setting,[189] as have other oral tyrosine kinase inhibitors such as afatinib.[190] Other molecular targets besides EGFR, including vascular endothelial growth factor receptor(VEGFR), PI3-kinase-Akt-mTOR, insulin-like growth factors, and cancer stem cell pathways, among others, are also being interrogated in the attempt to continue to identify promising therapies in head and neck SCC.

RADIATION TECHNIQUES AND TOLERANCE

Fractionation

Because radiation has served as a cornerstone of the treatment of head and neck cancers, a substantial amount of scientific and clinical effort has been devoted to optimizing radiation fractionation, treatment time, and total dose. Altered fractionation approaches were conceived to exploit the differential radiation response between normal tissues and tumors and resultantly improve the therapeutic ratio through either dose escalation or truncation of the overall treatment time. Radiobiologic modeling based on retrospective data from 676 patients with tonsillar carcinomas treated at nine centers found an increase of local tumor control probability by nearly 2% for each 1-Gy increase in total dose for a constant treatment duration.[191] Accelerated repopulation was estimated to begin approximately 30 days following treatment initiation, with a compensatory dose of 0.73 Gy per day required for treatments lasting beyond 30 days. Alternatively, the LC probability was decreased by at least 1% for each day that treatment was extended. This exquisite sensitivity of oropharyngeal tumor control to both total dose and treatment duration has highlighted the importance of optimizing treatment schedules.

Changes in radiation schedules generally fall under three general classifications, with some regimens containing elements of more than one group.[192] Hyperfractionation increases the total dose by using multiple small fractions daily over a conventional treatment time course. Accelerated fractionation without total dose reduction delivers a standard dose over 5 to 6 weeks rather than 7 weeks (i.e., concomitant boost or more treatments per week). Accelerated fractionation with total dose reduction involves a smaller total dose given over 3 to 4 weeks. Investigation of altered fractionation schedules was particularly prominent in the era immediately preceding the adoption of concurrent chemotherapy in locally advanced disease.

Hyperfractionation

A conventional course of radiotherapy, composed of a total dose of 70 Gy in 35 fractions of 2 Gy per day, 5 days per week for 7 weeks, is delivered to the primary tumor site and nodal disease, with lower doses to clinical regions without known disease. RTOG 9003 compared conventional radiation with hyperfractionation (81.6 Gy in 68 fractions, 1.2 Gy twice daily), accelerated fractionation with a concomitant boost (72 Gy in 42 fractions over 6 weeks; 54 Gy in 30 fractions of 1.8 Gy to initial fields plus 18 Gy in 1.5-Gy fractions to a cone-down boost field as a second daily dose during the final 12 treatments), and accelerated split-course fractionation (67.2 Gy in 42 fractions, 1.6 Gy twice daily with a 2-week break after 38.4 Gy), all delivered 5 days per week (Table 33-10).[193] All twice-daily treatments required 6 hours between fractions, and the concomitant boost field contained gross clinical disease. Improved LC rates were seen with both the hyperfractionation and accelerated fractionation with concomitant boost in this large, randomized study of 1113 patients, of whom 60% had oropharyngeal primary tumors. These schedules also trended toward improved DFS, although DFS and OS were not significantly different.

Significantly greater acute side effects were present with all three altered fractionation groups. Only the accelerated fractionation cohort had statistically worse late side effects when tabulated for events 90 days or more following treatment; however, late side effects at 6 to 24 months were equivalent between all four groups because some of the events initially scored as late effects at 90 days were acute toxicities that had persisted. The importance of total dose and treatment duration in the outcome of radiotherapy was emphasized by this trial, and altered fractionation was adopted as an acceptable standard for further RTOG trials. Split-course fractionation did not show a LC improvement despite increased acute side effects.

TABLE 33-10 RTOG 9003 Altered Fractionation 2-Year Outcomes

RTOG 9003	LRC (%)	2-yr DFS (%)	2-yr OS (%)	≥Gr 3 Acute (%)	≥Gr 3 Late (%)
Standard fractionation	46.0	31.7	46.1	35.0	26.8
Hyperfractionation	54.4*	37.6 ($p = 0.067$)	54.5	54.5*	28.0
Accelerated split course	47.5	33.2	46.2	50.4*	27.6
Accelerated concomitant boost	54.5*	39.3 ($p = 0.054$)	50.9	58.8*	37.2*

*p < *0.05.*

Acceleration without Dose Reduction

Outcomes from the concomitant boost technique, which delivers doses slightly higher than those of conventional treatment (72 Gy versus 70 Gy) over a shortened time period of 6 weeks, are described previously. The Danish Head and Neck Cancer Study Group (DAHANCA) randomized 1485 patients between 1992 and 1999 treated with radiation alone to five or six fractions per week delivered to the same cumulative dose at 2 Gy per fraction.[194] Most patients had laryngeal cancer, but 29% had primary tumors of the pharynx. The median overall treatment time was reduced from 46 days to 39 days with the six-fraction-per-week group. The sixth fraction was given either on a weekend day or as a second fraction on a weekday, with a minimum of 6 hours elapsed between treatments. The shortened treatment time led to an improved 5-year LRC rate (70% versus 60%), which was significant for LC but not neck node control. DSS was also improved (73% versus 66%), but OS was not. Again, acute side effects were increased with accelerated treatment, but there was no difference in adherence to the treatment regimen and the increase in acute adverse events did not translate into worsened late side effects. The improvements in LC without associated late effects led the authors to adopt the six-fractions-per-week approach as their standard of care.

In the current era of conformal therapy, a simultaneous integrated boost assigns different dose levels to various target volumes within a single treatment. Radiobiologic advantages of this approach include potential hypofractionation to the gross tumor volume (GTV) and acceleration of the overall treatment time. The logistic benefit of a simultaneous integrated boost technique is the ability to deliver IMRT with a single treatment plan rather than sequential IMRT plans delivered to "shrinking-field" equivalent volumes. This approach has gained widespread adoption and is currently mandated for the RTOG trial evaluating postoperative radiation therapy (0920) with doses per fraction ranging from 1.8 Gy to 2.2 Gy. For example, the highest-risk clinical target volume (CTV) could receive a total of 66 Gy at 2.2 Gy per fraction, the high-risk CTV 60 Gy at 2 Gy per fraction, and the lower-risk CTV 56 Gy at 1.85 Gy per fraction. RTOG 0522 used a simultaneous integrated boost technique without a hypofractionated component, with doses ranging from 1.6 Gy to 2 Gy and a requirement that the treatment be completed in 6 weeks (six fractions per week). The optimal simultaneous integrated boost method remains unknown. Hypofractionating high-risk regions (2.2 Gy per day) may increase the risk of both acute and late side effects within the treated volumes, while capping the high-dose region at 2 Gy per day may deliver inadequate daily doses to lower-risk regions on a daily basis (1.5 Gy per fraction) or unnecessarily elevate cumulative doses to low-risk areas if higher fraction sizes are chosen (59.5 Gy in 35 fractions of 1.7 Gy per fraction to the supraclavicular region). The widespread adoption of the simultaneous integrated boost technique has been driven primarily by the potential radiobiologic benefits and logistic ease of use, despite the lack of randomized data comparing simultaneous integrated boost schemes to more studied radiation fractionation schemes.[195]

Acceleration with Dose Reduction

Continuous, hyperfractionated, accelerated radiotherapy (CHART) has been evaluated in the treatment of multiple cancers, including SCCs of the head and neck. Dische et al[196] reported on the largest CHART study, which randomized 552 patients to 54 Gy in 36 fractions delivered three times a day over 12 days and 366 patients to 66 Gy delivered in 33 fractions over 6.5 weeks. An interval of 6 hours was required between each of the three daily treatments. Primary tumors of the oropharynx were present in 26% of patients. CHART did not improve rates of LRC, DFS, or OS. Confluent mucositis was higher with CHART, occurring in 73% compared with 43% of those treated conventionally, and it peaked earlier. Skin desquamation was less with CHART, and the late side effects of telangiectasias, mucosal ulceration, and laryngeal edema were also diminished. A Trans-Tasman randomized study[197] had similar outcomes, with trends toward improved oncologic outcomes and a significant reduction in late effects, although late effects related to the mucosal membranes were similar between the treatment arms. Although the prospect of decreased late toxicity with similar oncologic outcomes and a markedly reduced treatment duration is appealing, the CHART regimen has not been widely pursued because of the logistic challenges of thrice-daily radiation administration over 12 consecutive days, the familiarity of clinicians with other altered fractionation schemes, and the inability to incorporate chemotherapy into the regimen given the already elevated acute side effects.

Fractionation Summary

A meta-analysis of altered fractionation regimens included 6515 patients from 15 trials, with most patients having laryngeal or oropharyngeal cancers and stage III or IV disease. The meta-analysis found a 3.4% 5-year OS benefit to altered fractionation radiotherapy, with a benefit of 8% and 2% for hyperfractionated and accelerated radiotherapy, respectively.[192] The LRC rate improved by 6.4% at 5 years with altered fractionation; greater benefit was seen with local compared with nodal control. The benefit of altered fractionation was most pronounced in younger patients, with a statistically lower impact with advancing age.

In conclusion, altered fractionation may be used to either decrease the probability of late complications or to improve the curative potential of a regimen. Altered fractionation appears to improve the rates of LRC, DFS, and, based on the meta-analysis, OS, at the expense of increased acute side effects. Because oropharyngeal primary lesions, like most head and neck cancers, are sensitive to both overall treatment time and total dose, altered fractionation should be used primarily in the definitive rather than the postoperative setting (Table 33-11). Concurrent chemotherapy has been added to

TABLE 33-11 Radiation Schedules

Regimen	Description	Advantages	Disadvantages
Standard fractionation	70 Gy in 35 Fx of 2 Gy	—	—
Hyperfractionation	81.6 Gy in 68 Fx, 1.2 Gy b.i.d.*	Largest improvement in meta-analysis data	Logistically challenging
Accelerated fractionation with concomitant boost	72 Gy in 42 Fx, 6 wks: initial field: 54 Gy/30Fx, 1.8 Gy/6 wks; boost field: 18 Gy, 1.5 Gy per day over the final 12 treatments	Fewer total fractions than hyperfractionation	May increase late side effects
DHANCA (6 fractions/week)	62-68 Gy at 2 Gy per Fx, 6 Fx/week	Logistically attractive, no increase in fraction total	
Simultaneous integrated boost	Differential dosing to different target volumes (1.6-2.2 Gy)	Single IMRT plan, hypofractionation to GTV, treatment acceleration	Lack of supportive randomized data

DAHANCA, *Danish Head and Neck Cancer Study Group;* Fx, *fractions;* Gy, *Gray;* GTV, *gross tumor volume;* HFX, *hyperfractionation;* IMRT, *intensity-modulated radiation therapy;* wks, *weeks.*

both hyperfractionated and accelerated regimens in randomized trials and is discussed elsewhere in the chapter.

Radiation Treatment Planning

Radiation treatment planning for oropharyngeal cancer requires knowledge and commitment on the part of the radiation oncologist. Anatomic knowledge, head and neck physical examination skills, and imaging expertise are required to appropriately define regions of tumor involvement, and familiarity with pathophysiology and patterns of spread is necessary for appropriate selection of elective coverage areas. Given the complexity of head and neck planning, CT-based planning is standard.

Appropriate setup during patient simulation is vital because this forms the basis for subsequent radiotherapy planning. The supine position with the chin extended is used most commonly in the curative setting. A thermoplastic mask is created to provide daily reproducibility. Thermoplastic mask options include a mask covering the head and neck only or a mask that extends from the head and neck to include the shoulders. We most commonly recommend the head and shoulder mask because this improves daily reproducibility within the lower neck and shoulder region.[198] Shoulder straps can be used when warranted to lower the shoulders and improve beam accessibility to the lower neck. An intraoral stent can be considered in base-of-tongue cancers to diminish the dose to the palate and vice versa with soft palate tumors. A tongue depressor can be coupled to the mask to help to limit movement of the mandible and minimize flexion and extension during treatment.

CT images are obtained at 2.5-mm slices to balance image resolution and signal-to-noise issues. We typically administer bolus intravenous contrast medium when medically appropriate to better define gross disease and nodal structures. The treatment planning software can also be used to fuse prior diagnostic CT, PET-CT, or MRI studies. Fusion, however, can be challenging secondary to variations in patient positioning, particularly the changes brought about in cervical spine curvature and mandibular position by neck extension. In some centers, the PET-CT and MRI can be performed with patients in treatment planning position. Alternatively, software programs have become available that allow deformable registration, which helps to reduce the variability associated with differences in patient position for various imaging studies.

Precise localization of the tumor is essential, particularly when planning IMRT fields. Information from the physical examination, including fiberoptic pharyngoscopy, and imaging studies should be taken into account when defining target volumes. Even if three-dimensional conformal radiation therapy is to be employed, we still advocate precise contouring of the primary site as well as the radiographically and clinically involved lymph nodes. These regions are defined as the GTV, although the GTV may be subdivided into primary and nodal GTVs to assist in radiation planning. The CTV should extend at least 1 cm from the GTV in all dimensions, unless bounded by restrictive anatomic boundaries (such as skin, bone, air cavities, or central nervous system structures), and also covers the nodal volumes at risk for microscopic disease. Definition of the GTV should be generous, particularly with endophytic, infiltrative tumors in which the size can be frequently underestimated. SCCs of the base of the tongue are notoriously difficult to size accurately for deep extension on physical examination and with conventional imaging. Planning target volume (PTV) margins are dictated by institutional policy based on quality assurance measurement and the presence of image or optical guidance and are typically about 5 mm.

The primary and nodal CTVs receive 70 Gy in most instances, although 66 Gy can be delivered for stage T1 and small T2 primaries. We commonly use 2.12-Gy daily fractions to the GTV, thereby achieving 70 Gy in 33 fractions over 6.5 weeks. Many centers use 2 Gy per fraction to the GTV over 35 fractions. Nodal basins surrounding involved nodes receive 60 Gy to 66 Gy. Intermediate-risk nodal basins, typically an uninvolved level II to III basin contralateral to involved lymph nodes at the same level or a level IV basin ipsilateral to involved levels II or III nodes, are prescribed 54 Gy to 56 Gy. The low-risk neck can be treated via a separate anterior field and commonly receives 50 Gy in 2 Gy fractions prescribed most commonly to a 3-cm depth.

Clinical issues such as dental extractions or obtaining biopsy and imaging results as well as the complexity of radiation planning in oropharyngeal cancers can lead to delays in treatment initiation. Jensen et al[199] found a measurable increase in tumor volume in 62% of patients with SCCs of the head and neck at a mean interval of 28 days. Tumor volume increase correlated to length of the time delay and histologic differentiation. In 20% of patients, new lymph node metastases were seen, and 16% of patients had upstaging of their TNM classification. Head and neck radiation planning and treatment initiation are time-consuming processes but should proceed as expeditiously as possible (ideally, within 2 weeks) once definitive radiation is recommended to avoid not only the progression of disease but also potentially discrepant treatment fields and tumor volumes secondary to interval growth.

Conventional Radiation

Conventional radiation techniques remain a perfectly acceptable approach for patients who are not suitable candidates for IMRT. Reasons may include advanced N2c or N3 disease in which effective parotid gland sparing is contraindicated or patients with an inability to tolerate prolonged immobilization for IMRT. Nevertheless, IMRT may still afford some advantages beyond salivary gland sparing, such as improved GTV coverage at the skull base, sparing of critical optic and auditory structures, and avoidance of match-line inhomogeneities associated with photon-photon and photon-electron matches.

Conventional radiation is most commonly delivered using a "shrinking-field" technique for the primary tumor bed and upper neck, matched to an anterior-posterior (AP) supraclavicular field for the lower neck (Figure 33-9). Broad opposed lateral fields covering the primary tumor bed and upper neck extending to the thyroid notch are initially treated to 42 Gy to 44 Gy in 2-Gy fractions. Four-MV to 6-MV photons are used to avoid underdosing of superficial nodal disease. The isocenter is typically placed at approximately the C1 to C2 level just anterior to the intervertebral space. An off-cord boost is then created by shifting the posterior field border anteriorly to split the vertebral bodies vertically, and the cumulative dose is then taken to 50 Gy to 54 Gy. Electron fields (commonly, 6 MeV to 9 MeV; occasionally, 12 MeV for bulky nodal disease) are matched on the skin to abut the posterior aspect of the off-cord photon field and thereby treat the posterior neck to 50 Gy to 54 Gy, with higher doses if positive posterior nodes are present. Involved nodes at the match line warrant 2 mm to 3 mm of photon-electron field overlap to limit underdosing at depth. The posterior electron field border can be extended by

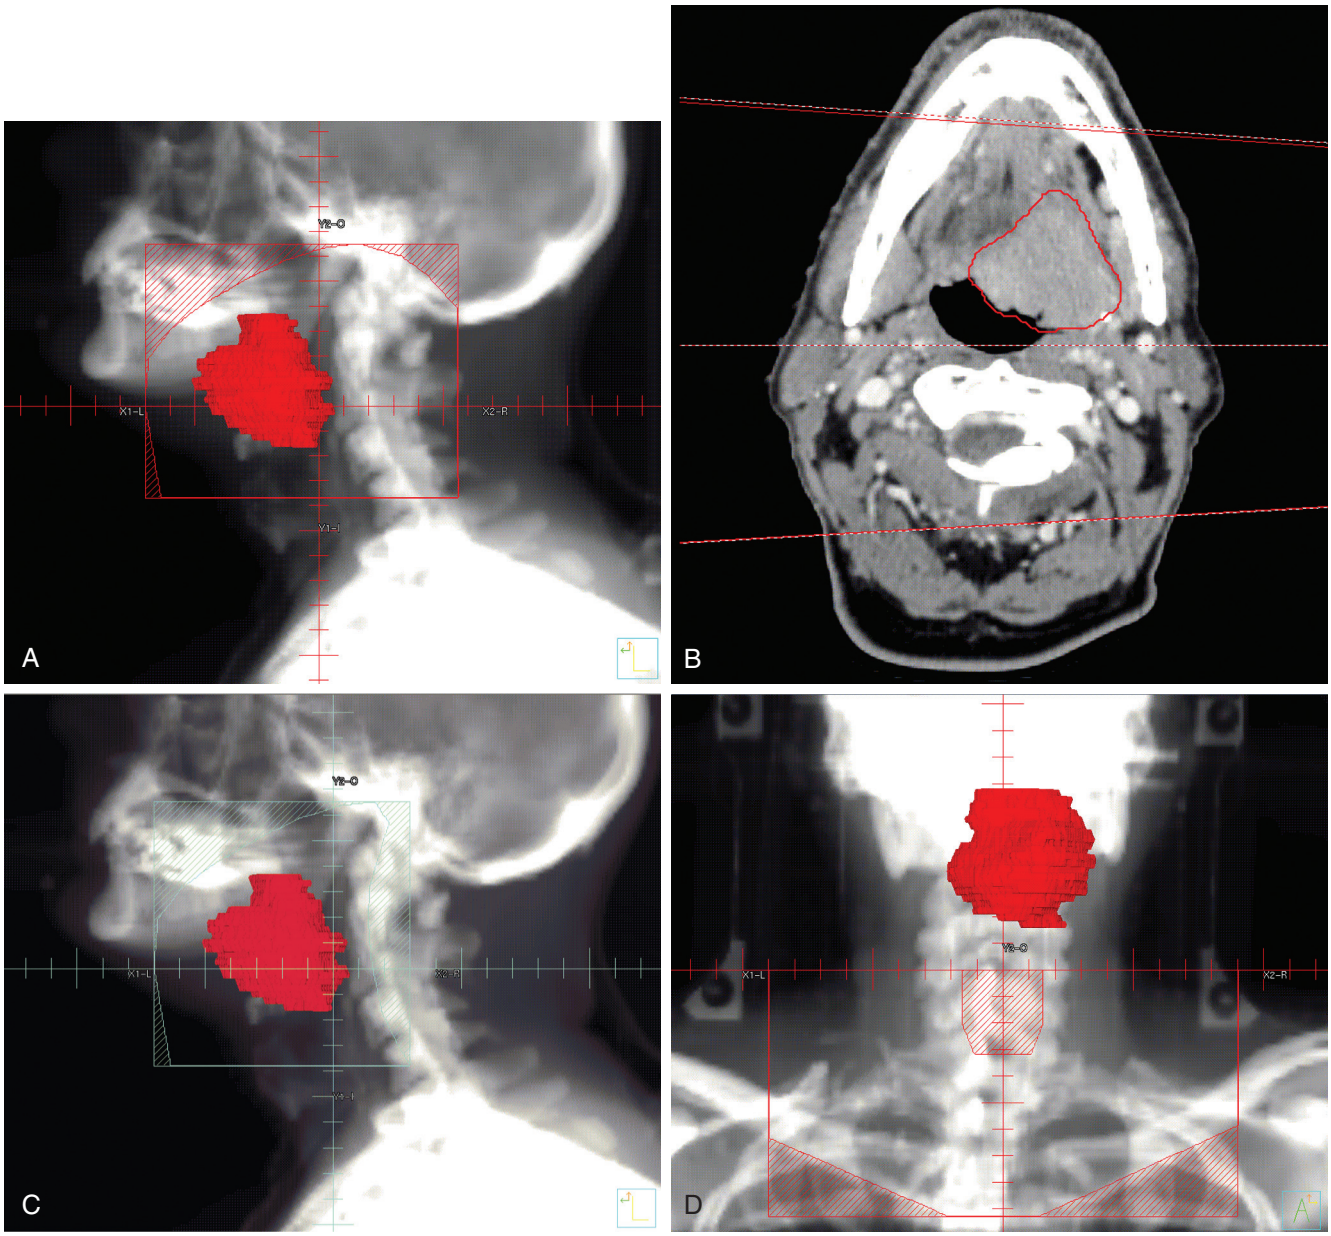

Figure 33-9 Two-dimensional conventional fields for an infiltrative stage IVA (T4aN2bM0) SCC of the left base of the tongue with deep tongue invasion. **A,** Initial lateral field with base of tongue gross tumor volume (GTV) represented by red colorwash. **B,** Axial CT image demonstrating lateral field coverage relative to the GTV with an anterior margin on the GTV. **C,** Off-cord lateral field providing a cord block while respecting the posterior extension of the primary tumor. **D,** Anterior-posterior supraclavicular field with a laryngeal/cord block.

5 mm to help compensate for electron dose constriction at depth. The final field reduction boost carries the tumor GTV plus a margin to 66 Gy to 70 Gy. If higher doses are required within the low neck and supraclavicular region, an AP (or AP:PA) hemineck supraclavicular field that blocks the spinal cord can be used for an additional 4 Gy to 16 Gy. Alternatively, an electron boost can supplement the dose to the supraclavicular regions.

Borders of the lateral photon fields are specific to the subsite and individual patient. More important than any generic field recommendations is the accurate identification of the involved primary site and inclusion of the defined GTV and regions of risk with adequate margins. In general, at least a 1-cm expansion is recommended on the GTV to create the CTV, with the PTV margin determined by institutional policy based on hardware-specific intrafraction and interfraction reproducibility. The beam penumbra must always be considered with conventional fields. General recommendations, to be tailored by individual findings, are as follows:

- *Superior border:* This should cover the retropharyngeal and jugulodigastric lymph nodes and approach the jugular fossa in patients with advanced nodal disease. The ipsilateral medial pterygoid insertion for early-stage tumors and the pterygoid plates for more advanced-stage tumors are worthy of coverage for tonsillar carcinomas.
- *Anterior border:* This is defined by the most anterior extent of the primary site with margin. This may be extended more anteriorly if level IB lymph node coverage is warranted. Tonsillar carcinoma fields have traditionally covered the ipsilateral retromolar trigone. Anterior coverage of base of tongue tumors should be generous (commonly, 2 cm) to respect the infiltrative nature of the primary tumor.
- *Posterior border:* This border is approximately 2 cm behind the mastoid process and just posterior to the cervical vertebral spinous processes, with additional posterior extension if warranted by level V nodal metastases. Adequate dosimetric margins must be ensured with posterior pharyngeal wall tumors, and the photon off-cord boost is typically placed at the posterior third of the vertebral body. The posterior margin may be moved 1 cm to 2 cm anteriorly for early-stage, node-negative tonsillar and soft palate tumors.
- *Inferior border:* This is placed just cranial to the arytenoids to limit posttreatment supraglottic edema. However, this border may be lowered to account for extension of the primary tumor into the larynx or hypopharynx. Location of the inferior border may also be affected by shoulder positioning.

The AP supraclavicular field extends from the inferior lateral photon border to the bottom of the sternoclavicular joints and covers the middle and lower neck nodes. Laterally, the supraclavicular field extends to the mid-clavicle and typically measures 18 cm to 20 cm in width, again tailored to known nodal disease. The isocenter is typically placed at the thyroid notch. A laryngeal block is created if no contraindications are present. This both decreases the toxicity to the central larynx and provides a "cheater block" to prevent three-field junctional overdosing to the spinal cord. The laryngeal block typically measures 3 cm to 4 cm in the craniocaudal dimension and 2 cm to 3 cm in the greatest width, with tapering inferiorly to avoid blocking of medial level IV and level VI nodes. The supraclavicular field can be half-beam blocked to prevent divergence into the lateral photon fields. Lateral fields can similarly be half-beam blocked to match the supraclavicular field, although this leads to increased divergence along the cranial aspect of the lateral field. We have preferentially allowed trace hot matching along the lateral and supraclavicular field junction rather than half-beam blocking the lateral field. The dose to the supraclavicular field is commonly 50 Gy with 6-MV photons to a depth of 3 cm or calculated to the optimal isodose line based on CT planning. Level VII within the superior mediastinum is typically not included within the supraclavicular field except when low nodal involvement is identified within the supraclavicular region for which level VII is the next potential echelon of nodal involvement or for advanced hypopharyngeal tumors, particularly those with inferior extension to the esophageal inlet.

Large jugulodigastric nodal disease is frequently located at the junction of the off-cord and electron fields. Rather than a 2-mm overlap "hot match," the coverage of the nodal disease may be improved by using oblique off-cord and boost fields, angled to prevent transection of nodal disease. Beam angles of 20 degrees to 30 degrees may be warranted to achieve this coverage. Alternatively, these may be patients in which IMRT is beneficial.

Unilateral Radiation for Tonsillar Cancer

Conventional radiation to the ipsilateral neck for early-stage tonsillar cancers typically consists of a two-field, wedge-pair beam arrangement covering the primary tumor and ipsilateral level II lymph nodes. The levels III and IV lymph nodes ipsilaterally are covered by an anterior supraclavicular field directed to the hemineck. Close attention should be paid to ensuring that adequate margins of primary tumors are treated because margins of less than 1 cm are strongly associated with local recurrence.[107] A risk of underdosing extension to the more medial structures (soft palate and base of the tongue) exists because the dose distribution significantly narrows along the medial portion of the volume, which can be partially compensated for by a narrower hinge angle. The use of five to six oblique beams can further reduce the dose to the contralateral parotid gland by a few Gray and better conform the prescribed dose to the PTV. In addition, disease involvement of the posterior tonsillar pillar can be challenging because coverage may be limited by the need to prevent the posterior oblique beam from traveling through the spinal cord and brainstem. Many institutions have adopted IMRT techniques for ipsilateral radiation with strict contralateral constraints (Figure 33-10).

Intensity-Modulated Radiation Therapy

IMRT can increase the dose gradient between target volumes and surrounding normal tissue. This improved conformality offers the potential of decreased acute and late side effects or, through dose escalation made available from the improved conformality, higher tumor control rates. The hazard of IMRT, however, is the potential for marginal misses and local failures from overly restrictive radiation deposition in regions that received comprehensive radiation with conventional techniques.[200] Multiinstitutional IMRT studies have found significantly more locoregional failures in patients who had a major underdose deviation of the target volume.[201] Benefit from IMRT requires appropriate patient selection, accurate delineation of organs at risk and treatment volumes, meticulous quality control in radiation planning and delivery, and limiting of interfraction and intrafraction variability.[202]

Patient Selection

IMRT has traditionally been championed to diminish the risk of long-term xerostomia by "sparing" the contralateral parotid gland. Locally advanced oropharyngeal cancers treated at MSKCC with IMRT had a diminished incidence of grade 2 or greater xerostomia at 2 years when compared with

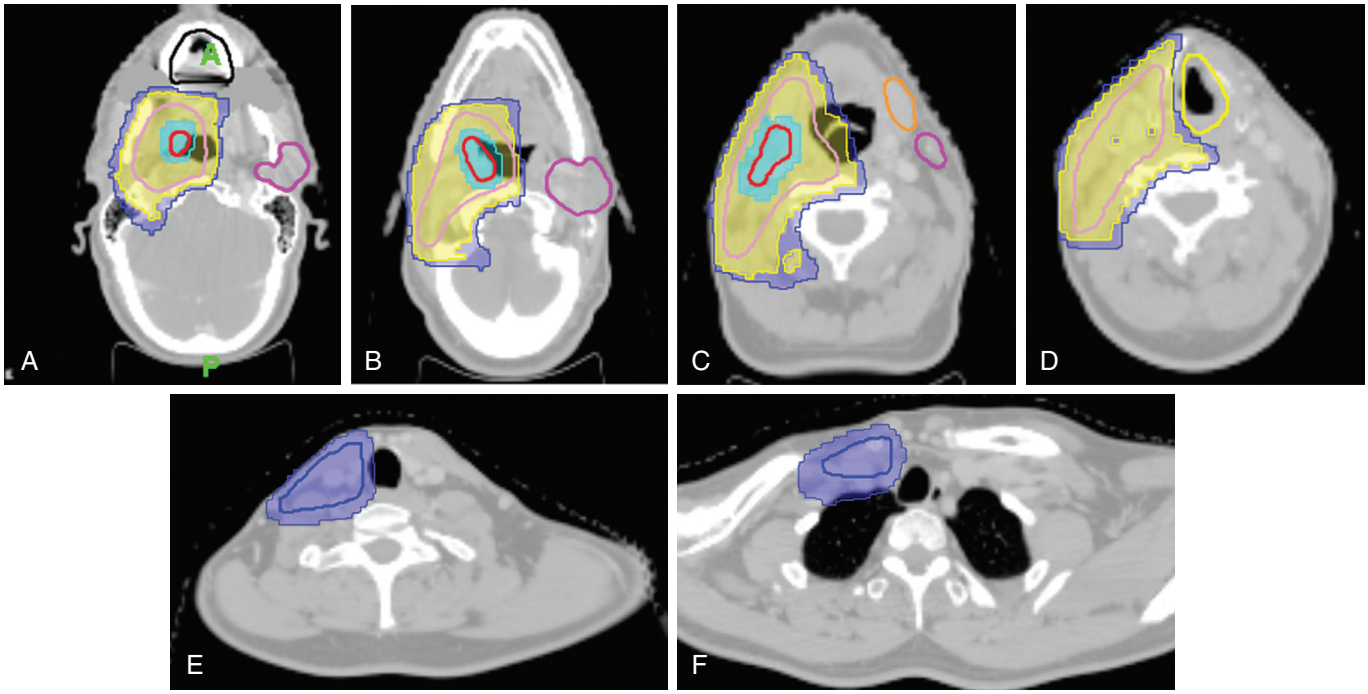

Figure 33-10 A 55-year-old man with a stage IVA (T1N2bM0) SCC of the right tonsil treated with radiation alone. The right tonsil (gross tumor volume [GTV]) was prescribed 70 Gy in 33 daily fractions of 2.12 Gy using tomotherapy IMRT with differential dosing to the upper neck (CTV1, 60 Gy) and lower neck (CTV2, 54 Gy). **A** to **F,** Axial CT images demonstrating contours and isodose distribution. Avoidance structures include an oral cavity block *(black)*, the left parotid gland *(pink)*, the left submandibular gland *(orange)*, and the larynx *(yellow).* Treatment volumes are GTV *(red)*, CTV1 *(peach)*, and CTV 2 *(blue)*; planning target volumes (PTVs) are not shown. Isodose lines in colorwash: 70 Gy *(teal)*, 60 Gy *(yellow)*, and 54 Gy *(blue).* Ipsilateral treatment was elected secondary to the small primary tumor and limited ipsilateral nodal disease.

conventional treatment techniques (12% versus 67%).[203] Xerostomia prevention has proven to be complex, with increasing recognition that the submandibular glands and oral cavity contribute to subjective and objective xerostomia.[204] The MSKCC study also found that gastrostomy dependence at 2 years was reduced with IMRT (4% versus 21%). Minimizing the late sequela of dysphagia has been a beneficial byproduct of IMRT and has evolved as an explicit goal within the IMRT treatment planning process. IMRT with concurrent chemotherapy that includes sparing of noninvolved swallowing structures has been shown to maintain high LRC rates and simultaneously reduce long-term dysphagia when compared to historical controls.[205]

Patients with bulky primary tumors and extensive bilateral nodal metastases may not derive significant benefit from IMRT approaches, at least in terms of salivary gland sparing. Some of these patients may be best served by the use of comprehensive conventional radiation techniques that broadly encompass regions at risk. Parotid gland sparing should be approached with caution in patients with ipsilateral cervical metastases, such as patients with N2c neck staging. Parotid sparing is particularly challenging for patients who are N+ with ipsilateral level II cervical metastases and may place patients with nodal disease at risk for superior cervical or periparotid recurrences.[200] Although conventional radiation is appropriate in patients with a heavy burden of disease particularly in the bilateral neck regions, IMRT is frequently used in these patients both as a practical matter of treatment planning and delivery flow within a clinic as well as the potential minimizing of long-term dysphagia.

Caution is also warranted when clinical factors exist that may impair accurate estimation of regions at risk. A neck dissection more than 1 year before treatment may contribute to the development of collateral lymphatic drainage patterns that circumvent conventional lymphatic flow. Neoadjuvant chemotherapy may also substantially reduce the disease burden and lead to an underestimation of regions at risk if pretreatment imaging is not used for radiation treatment planning.[201]

IMRT Planning

We generally begin head and neck radiation treatment planning by placing conventional fields on the digitally reconstructed radiographs (DRRs) to provide an "outer bound" contouring roadmap. The role of GTV, CTV, and PTV has been discussed previously. Contoured volumes and projected doses are described in Table 33-12. To provide adequate contralateral parotid gland sparing, the jugular chain in the N0 neck is contoured only up to the level of the posterior belly of the digastric muscle as it crosses the internal jugular vein. This is done because the first-echelon node within the jugulodigastric region lies below the junction of the posterior belly of the digastric muscle and the jugular vein, as described by Gregoire et al[206] in the consensus guidelines for the node-negative neck. This region is at low risk for recurrence provided the neck is clinically and radiographically negative.[207] The retropharyngeal lymph nodes can also be omitted given the low likelihood of involvement in the contralateral N0 neck.[208]

In general, the jugular digastric chains (levels II, III, and IV) are contoured to include the sternocleidomastoid muscle and the superficial paraspinal musculature if ipsilateral lymphadenopathy is present and particularly if there is clinical concern for extracapsular tumor extension.[209] At our institution, the ipsilateral CTV1 is typically extended to the ipsilateral base of the skull as well as levels IB and V when level II or III nodes are involved. When level IV is involved, contoured regions include the superior mediastinum, level V, and level VI. If no clinical ipsilateral lymphadenopathy is present, we extend the CTV only to the medial aspect of the sternocleidomastoid

muscle and typically do not cover level Va by terminating the contours approximately 1 cm to 2 cm posterior to the carotid and jugular vessels. CTV contours of the uninvolved hemineck typically cover the equivalent of the GTV and nodal extension from the involved side. Determining the appropriate CTVs continues to require physician expertise for each individual patient and may evolve as further clinical data are accumulated. For example, Sanguineti et al[210] found less than a 5% risk of level IB and V involvement when CT imaging was negative, even with ipsilaterally proven neck disease, and questioned the routine inclusion of these levels as part of the target volume.

Two traditional treatment options for IMRT planning are to incorporate the oropharynx and upper neck with an IMRT plan and match this to a conventional AP supraclavicular field or to treat the oropharynx and entire neck with an IMRT plan. A conventional AP supraclavicular field is reasonable if the region is without clinically involved lymph nodes because it offers simpler planning, good sparing of the larynx, reduced monitor units, and a shorter treatment time.[201] The potential for overdosing or underdosing at the junction of the IMRT and conventional fields, however, is present. IMRT to the low neck in higher-risk patients obviates this risk and also offers opportunities for dose sparing to the brachial plexus and upper esophagus.

The IMRT plan for the head and neck is most commonly a single plan with differential dosing (Figure 33-11). Sequential large- to small-volume IMRT plans can alternatively be created. The advantage of sequential IMRT plans is the ability to maintain standard fraction doses (1.8 Gy to 2 Gy) to all PTV volumes rather than employing hypofractionated doses to the higher dose volumes and frequently doses less than 1.8 Gy to the low risk volumes. The downside of sequential IMRT planning is the loss of conformality when two or more separate

TABLE 33-12 IMRT Treatment Volumes (University of Wisconsin)

Contour	Definition	Dose
GTV	Gross primary tumor and involved nodes	66 Gy-70 Gy
CTV1 (high-risk CTV)	GTV + 1 cm margin, nodal basins with involved lymph nodes, areas at high risk for subclinical spread	60 Gy-66 Gy
CTV2 (intermediate-risk CTV)	Nodal basins adjacent or contralateral to involved nodal regions	54 Gy-56 Gy
CTV3 (low risk)	Supraclavicular region with no ipsilateral high neck lymphadenopathy	50 Gy-54 Gy
CTVint (optional)	GTV + 1 cm margin for poorly defined or infiltrative tumors	63 Gy-66 Gy

CTV, *Clinical target volume;* GTV, *gross tumor volume;* int, *intermediate.*

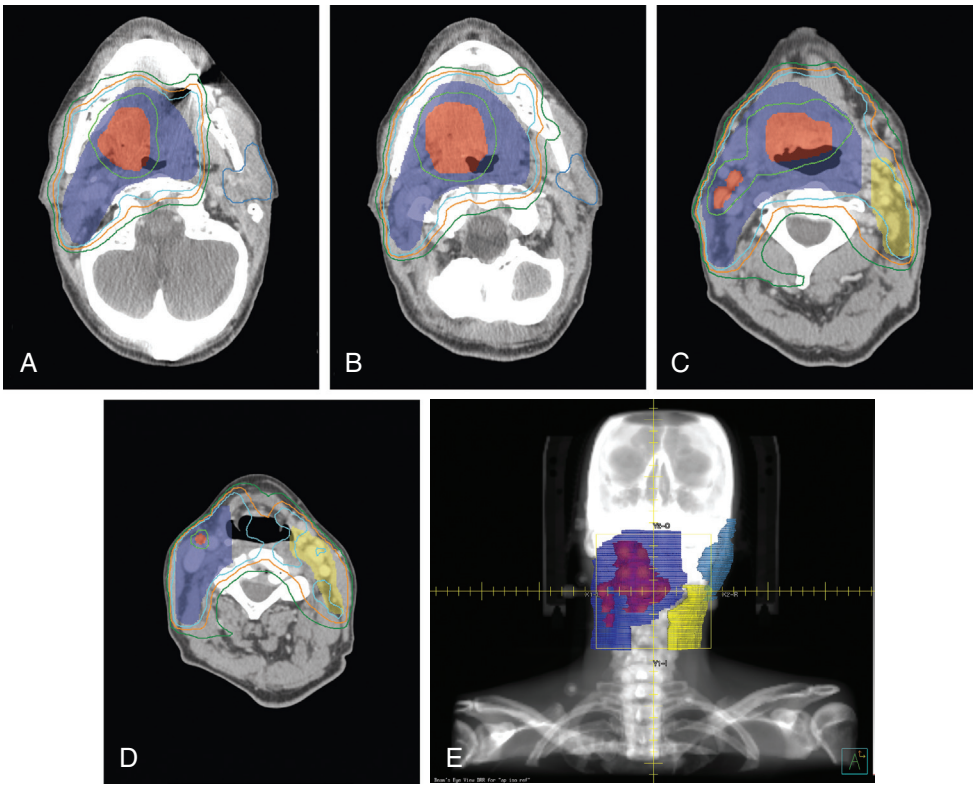

Figure 33-11 A 61-year-old woman who presented with otalgia and jaw pain. Physical examination confirmed a firm, right tongue base tumor with deep intrinsic tongue invasion and extension to the glossotonsillar fold (T4aN2bM0). The patient was treated with concurrent chemotherapy (cisplatin 30 mg/m^2 and avastin as part of a clinical trial) with the primary and nodal gross disease receiving 70 Gy using IMRT. Contours: red colorwash (GTV, 70 Gy), blue colorwash (CTV1, 60 Gy), yellow colorwash (CTV2, 56 Gy), blue (left parotid gland). Parts **A** to **D** are sequential axial isodose images with the following isodose lines: green (70 Gy), teal (60 Gy), orange (56 Gy), and dark green (50 Gy). **E,** A reconstructed AP radiographic study shows the contoured structures projected craniocaudally. Note the cessation of CTV2 at the level of the C1 transverse process (caudal to the majority of the contralateral parotid gland).

TABLE 33-13 IMRT Planning Avoidance Structures

High Priority	Complication
Spinal cord	Transverse myelitis
Brainstem	Neurologic deficits
Optic nerves and chiasm	Blindness
Intermediate Priority	
Parotid gland (contralateral)	Xerostomia (stimulated)
Additional Structures	
Oral cavity	Acute mucositis
Larynx	Voice changes, edema
Mandible	Osteoradionecrosis
Proposed Additional Structures	
Submandibular gland	Xerostomia (unstimulated)
Pharyngeal constrictors	Dysphagia
Cochlea	Sensorineural hearing loss
Brachial plexus	Brachial plexopathy
Esophagus	Dysphagia

IMRT plans are evaluated as a composite. Details of the simultaneous integrated boost are covered in the fractionation section.

IMRT Constraints

A critical component of high-quality IMRT head and neck plans is accurate contouring of critical organs and appropriate weighting during IMRT planning to optimize tumor coverage while minimizing the dose to these regions (Table 33-13). The primary goals of IMRT planning should be to provide adequate coverage of the contoured target volumes, particularly the GTV, and dose restriction to critical organs for which radiation damage may lead to death or severe morbidity (i.e., brainstem and spinal cord). Secondary, but important, goals include dose restriction to the salivary glands, optic and auditory structures, larynx (if appropriate), mandible, oral cavity, and other normal tissues, depending on the tumor extent and anatomy of the individual patient.

A substantial focus of IMRT in the treatment of head and neck cancers is to diminish the severity of xerostomia, initially by parotid sparing. Although historical data suggested a salivary gland tolerance dose of approximately 40 Gy,[211] it appears that the parotid gland tolerance may in fact be much lower. Eisbruch et al[212] reported in a seminal publication that a mean parotid dose of 26 Gy was associated with a threshold for impairment of stimulated salivary flow. In this report, most glands that received more than 26 Gy produced little saliva, with no significant recovery over time. Partial volume thresholds were also reported as well by these investigators. Since the publication of this report, numerous other reports have characterized the dose-response relationship.[213-216] Although a standard threshold of a mean dose of 26 Gy is commonly used, the parotid dose effect is clearly a continuum, with additional impact from concurrent treatments and intrinsic patient factors. Ultimately, the lower the integral dose to the parotid gland the more likely stimulated salivation will be retained. The submandibular gland produces unstimulated saliva, and the loss of submandibular salivary function may account for the xerostomia reported by many patients despite adequate parotid sparing. Submandibular salivary production appears to be partially maintained by a mean dose of less than 39 Gy.[217] Dose to the oral cavity also plays an independent role in the development of xerostomia.[218] Swallowing is a complex physiologic action, requiring timing and coordination of more than 30 pairs of muscles and six cranial nerves.[219] The reduction of dysphagia and aspiration via IMRT requires the identification of the appropriate structures and establishing dose correlates. The persistent dysphagia seen after head and neck radiation has been correlated with the dose delivered to the pharyngeal constrictors, with several dose thresholds reported.[220,221] The University of Michigan group reported aspiration in patients who received more than 60 Gy to the pharyngeal constrictors, and worsened liquid and solid swallowing was correlated with higher pharyngeal constrictor mean doses.[220] Dose to the glottic and supraglottic larynx and cervical esophagus also impacts long-term dysphagia.[205,222] Although various studies document separate structures as the most critical component in dysphagia prevention, improved dysphagia outcomes will likely be reliant on comprehensive avoidance of the pharyngeal constrictors, larynx, and cervical esophagus. As the dose effect on different structures and subsequent functional side effects are better defined, it is anticipated that IMRT planning can further incorporate these data as dose constraints. However, for each additional dose restriction applied to organs at risk, there is pressure brought to bear on the integrity of the overall IMRT plan in terms of target coverage and spread of dose to additional new regions. Physician overview of the comprehensive treatment plan selected for each patient with head and neck cancers is critical to ensure adequate tumor target coverage and personalize the therapy approach.

Reproducibility

Reproducible and accurate treatment delivery is required for the high-quality successful implementation of head and neck IMRT. The PTV is generally designed from a 3-mm to 5-mm expansion of the CTV. With a conventional thermoplastic mask, baseplate fixation, three-point laser alignment, and weekly port films, the mean daily setup error for patients with head and neck cancers can easily be several millimeters.[223] Not surprisingly, partial geographic tumor miss and overdosing of adjacent normal tissues can occur with daily setup variation, potentially contributing to reduced LC and worsened normal tissue complications. Daily setup variation with conventional approaches may also lead to higher than anticipated parotid doses.[224] Accurate oropharyngeal IMRT delivery therefore requires rigorous immobilization and setup verification with each fraction because imaging every other day may still lead to daily deviation rates of more than 5 mm.[225] Setup verification may occur through either pretreatment image guidance or optical tracking. Kilovoltage orthogonal filming or cross-sectional imaging with either cone-beam CT or megavoltage CT is adequate for daily imaging. For IMRT cases at the University of Wisconsin, delivery quality assurance is performed for each patient plan before the first treatment using a two-dimensional ion chamber array. As recommended in the TG-148 report, the agreement between the planned and delivered point dose measurement must be within ±3% for treatment to be initiated. Profound weight loss or rapid regression of bulky nodal disease can impair radiation accuracy by loosening the designing immobilization and altering the dose distribution. In such patients, adaptive radiation replanning is valuable.

Brachytherapy

Brachytherapy has a long history in the treatment of tonsillar fossa, soft palate, and base-of-tongue primary cancers. Most commonly, brachytherapy is used as a boost after 45 Gy to 50 Gy of EBRT, although it has also been used as monotherapy for small exophytic, node-negative tumors or in the recurrent

setting. Although IMRT can produce excellent conformality, the dose gradients and normal tissue sparing offered by brachytherapy are unmatched. The use of brachytherapy in head and neck cancers, however, has become less prevalent with the introduction of advanced planning and conformal treatment techniques, especially with the advent of IMRT. Challenges in the administration of interstitial brachytherapy include the necessity of an additional invasive procedure and the subspecialty expertise required; oropharyngeal brachytherapy can be performed in only a few select centers with physician expertise. The GEC-ESTRO guidelines nicely summarize appropriate brachytherapy patient selection, treatment strategies, target definition, implant technique, and different dose rates available.[226]

Treatment-Related Side Effects

Acute Toxicities

Toxicities secondary to head and neck radiation are commonly divided into acute and late categories. Potential acute side effects from radiation therapy to the oropharynx include mucositis, dermatitis, dysphagia, sore throat, odynophagia, thickened secretions, candidiasis, in-field alopecia, xerostomia, and taste disturbance with associated weight loss, dehydration, compromised nutrition, and pain sometimes necessitating placement of a feeding tube. Transient acute parotiditis (sialadenitis) can also develop within the first 24 to 48 hours of radiation in patients as a result of acinar cell apoptosis and typically resolves by 48 to 72 hours following treatment initiation. The frequency of acute side effects is dependent on field size and shape, total dose, fractionation, and the inclusion of cytotoxic chemotherapy.

The addition of concurrent chemotherapy to EBRT can substantially increase the risk of acute toxicity, with one postoperative study evaluating radiation with or without concurrent cisplatin demonstrating a doubling of acute grade 3 side effects from 34% to 77%.[146] This increase in toxicity has not been universally identified in randomized trials evaluating chemotherapy, which has been at least partially attributed to the challenges of recording, analyzing, and reporting toxicity data.[227]

Mucositis is characterized by ulceration and pseudomembranous formations along the mucosal surface and represents a complex interaction of mucosal injury, inflammatory response, and healing (eFigure 33-8). Mucositis is seen among virtually all patients receiving high-dose radiation for head and neck cancers. Self-reported mucositis was identified in 99% of 126 patients with oral cavity or oropharyngeal tumors, with 85% scoring it as severe to extreme.[228] The quality of life worsened concordantly with the severity of the mucositis. At least one study points toward cumulative point doses of less than 32 Gy leading to mucositis of limited severity (grade ≤1) and shorter duration (≤1 week),[229] but such low doses are typically not feasible, in part because of the multiple mucosal regions within the high-dose radiation volumes. The development of mucositis is the most problematic of the acute oropharyngeal radiation side effects, leading to dysphagia, sore throat, odynophagia, dehydration, weight loss, and narcotic use, and it often requires treatment breaks, hospitalization, and enteral nutrition. Concurrent chemotherapy with oropharyngeal radiation hastens the onset, increases the severity, and lengthens the duration of mucositis. Because of the anticipated severity of mucositis and associated dysphagia from combined chemotherapy and radiation, the majority of patients undergoing concurrent regimens at our institution have a gastrostomy tube placed before treatment to enable adequate nutrition. Prophylactic nutritional support leads to significantly less weight loss by the end of treatment and less grades 3 and 4 mucositis, although at least one study raised concerns about diminished LC with aggressive nutritional support.[230] Others have also reported diminished swallowing function with the use of a gastrostomy tube. Patients, however, are encouraged to continue oral intake and swallow at least liquids during the radiation course to help preserve swallowing function and potentially avert long-term dysphagia.

The altered dose distribution of IMRT may contribute to different acute toxicities than were seen with conventional techniques because some nontarget structures receive increased radiation exposure. A mean brainstem dose of more than 36 Gy, an occipital scalp dose of more than 30 Gy, and an anterior mandible dose of more than 34 Gy have been associated with increased nausea and vomiting, scalp alopecia, and anterior oral cavity mucositis, respectively.[231] Inclusion of these structures within the IMRT planning algorithm can help diminish such toxicities.

Late Toxicities

Late complications after oropharyngeal cancer radiation treatment include xerostomia, dental caries, osteoradionecrosis, prolonged dysphagia with gastrostomy tube reliance, trismus, hypothyroidism, cervical fibrosis, neck lymphedema, altered taste, hearing loss, and radiation-induced malignant disease. Radiation side effects are worsened by comorbidities such as diabetes mellitus and hypertension, tobacco use, as well as other less common autoimmune entities that produce microvascular changes before radiation initiation.

Xerostomia

Damage from radiation to the acinar cells and stromal matrix of the salivary glands induces a rapid loss of salivary production, also known as *hyposalivation*. Subjectively, the patient notes the sensation of oral dryness, or xerostomia. The diminishment of either stimulated or unstimulated salivary flow rates has significant implications for both patient quality of life and oral health. The presence of xerostomia can create difficulty in forming a food bolus and lead to associated dietary adaptations, with an impact on nutritional status and diet quality. Saliva also plays an integral role in maintaining dental integrity. Hyposalivation allows the oral pH to decrease because saliva typically contains bicarbonate and returns the pH to a neutral range following meals. Dental enamel is prone to demineralization within an acid environment. Saliva also bathes the enamel with calcium and phosphate, and loss of these substrates leads to an impedance of remineralization. Lastly, hyposalivation changes the oral flora, leading to an increase in acid-producing bacteria and resultantly increasing dental caries. Hyposalivation interferes with the delivery of food particles to the taste buds, resulting in altered taste.

This predisposition to dental caries can partially be counteracted by meticulous dental care, including frequent dental visits and custom-made fluoride carrier trays to be used on a daily basis. The bacterial component may be helped by chlorhexidine or Biotene rinses with reduction of the cariogenic flora. Interventions to ameliorate symptoms for patients with severe xerostomia can include secretagogues such as cevimeline and pilocarpine. The results with pilocarpine have been mixed, with one study showing an improvement in oral dryness and speaking ability,[232] another study demonstrating no difference in xerostomia or quality of life,[233] and a third, RTOG 97-09, showing objective preservation of salivary function but no impact on quality of life or subjective xerostomia.[234] Cevimeline was found to subjectively improve xerostomia in only one of two study groups, with an objective increase in unstimulated salivary flow.[235] Although some patients may find symptomatic relief from these secretagogues, there is no evidence that they counteract the adverse sequelae of

eFigure 33-8 Confluent mucositis at approximately 70 Gy for a T4 base-of-tongue tumor treated with conventional lateral fields. The confluent grade-3 mucositis extends from the oropharynx to the posterior oral cavity.

hyposalivation. Many patients compensate for the diminished salivary production by frequently rinsing with water or using other salivary substitutes.

The use of radioprotective agents in the prevention of xerostomia has also been evaluated, and amifostine is currently approved by the Food and Drug Administration for prevention of moderate to severe xerostomia in patients who have undergone complete resection of the cancer and are receiving postoperative adjuvant radiation. Amifostine was found to reduce acute xerostomia of grade 2 or higher from 78% to 51% ($p < 0.0001$) and chronic xerostomia of grade 2 or higher from 57% to 24% ($p = 0.002$) and to improve median salivary production in patients receiving head and neck cancer radiation where 75% or more of the parotid glands received 40 Gy or more of radiation.[236] Almost half of these patients had primary tumors arising in the oropharynx. Side effects included nausea, vomiting, hypotension, and allergic reactions and led to the discontinuation of amifostine in 21% of patients. Amifostine did not appear to have a tumor-protective effect because rates of LRC, DFS, and OS were similar between the treatment arms. A follow-up Phase III study did not find improvements in acute xerostomia, acute mucositis, or chronic xerostomia with the administration of amifostine.[237] These contradictory Phase III studies, concerns about side effects including nausea and significant hypotension during administration, the logistical challenges of daily delivery, the high cost associated with amifostine, and the introduction of IMRT have prevented more widespread adoption of amifostine in routine clinical use.

Transfer of a submandibular gland to the submental space (away from conventional radiation beams) has also been investigated as a means of reducing chronic xerostomia. Although the parotid glands are responsible for the bulk of saliva produced when stimulated by eating, the submandibular gland contributes 65% of the total volume of unstimulated saliva.[238] This basal, unstimulated saliva seems to correspond more to the subjective perception of xerostomia, making it a target for xerostomia prevention. In a randomized study after an initial Phase II evaluation,[239] the submandibular gland transfer was found to improve baseline salivary flow, stimulated salivary flow, and subjective evaluations of both saliva amount and consistency when compared with pilocarpine alone. Candidacy for this procedure was restrictive because patients with carcinomas of the nasopharynx, oral cavity, and salivary gland, N3 disease, recurrent disease, preepiglottic space involvement, or level I lymph node involvement were excluded. Submandibular gland transfer was performed on the contralateral neck or, for midline primary tumors, the clinically node-negative neck. If final pathologic studies found any lymph node involvement on the transferred side, no attempt was made to shield the transferred submandibular gland because of concerns about undertreating regions at risk. Although a significant improvement was seen over conventional radiation and pilocarpine, the median baseline and stimulated salivary flows were still found to drop by over half even with the submandibular gland transfer. This result was not unexpected as only one of the submandibular glands was salvaged. Submandibular gland transfer remains a viable option for the prevention of chronic xerostomia in appropriately selected patients, although the technical expertise and experience are not widespread.

Osteoradionecrosis

Osteoradionecrosis occurs in less than 5% to 10% of patients treated with definitive high-dose radiation and is primarily seen with cancers of the oral cavity and, to a lesser extent, the oropharynx.[240,241] Osteoradionecrosis rates have decreased over time with improved radiation techniques.[242] By definition, osteoradionecrosis occurs in previously radiated, often exposed bone that has failed to heal over a 3-month time period. As a process, osteoradionecrosis is characterized by hypocellularity, hypovascularity, and hypoxia, generating a failed ability to repair following injury. Symptoms can include pain, trismus, and anesthesia along the inferior alveolar nerve distribution. Findings may include exposed bone and spicule formation. Osteoradionecrosis is seen primarily involving the mandible, likely as a result of the combination of a more tenuous vascular supply when compared with the maxilla and more adjacent structures requiring full-dose radiotherapy. Lower rates of osteoradionecrosis are observed in patients that are edentulous. Given this finding and the clinical association of osteoradionecrosis with severe dental caries following radiation, removal of poorly conditioned teeth within the high-dose radiation field followed by a 10- to 14-day healing period before radiation initiation has been a standard practice in an attempt to limit osteoradionecrosis rates. Chang et al published the University of Florida experience, which did not identify an improvement in grade 2 or greater osteoradionecrosis rates with prophylactic extractions (edentulous, <1%; teeth in-field with preradiotherapy extractions, 15%; and teeth in-field without preradiotherapy extractions, 9%), bringing into question the utility of this approach.[241] Nevertheless, the authors of the paper still recommended prophylactic extractions of teeth in poor repair. Currently, we recommend a complete dental evaluation, including Panorex, before initiation of EBRT by a dental professional familiar with radiation treatments and toxicities. Teeth that are in poor repair and nonrestorable within the high-dose EBRT field are extracted; we typically do not recommend prophylactic extraction for teeth in good condition.[243]

The risk of osteoradionecrosis is dependent on the primary site, T category, proximity of bone to tumor, radiation dose, and dentition.[244] Simple steps toward preventing osteoradionecrosis include meticulous dental care following radiation and avoidance of poorly fitting dentures that can cause mucosal erosion, leading to bone exposure and increased osteoradionecrosis rates. See the Expert Consult website for further information on osteoradionecrosis.[237-239]

Dysphagia

Preservation of organ function is a driving force in the selection of the radiation regimen in the treatment of oropharyngeal cancer. Altered fractionation and concurrent chemotherapy have led to improved rates of LC and OS in head and neck cancers over the past two decades. However, this oncologic success has been accompanied by increased rates of chronic dysphagia, particularly before the advent of IMRT. Patients who exhibit chronic laryngopharyngeal dysfunction are a strong reminder of the potential toxicity cost that can be associated with definitive radiation techniques and are contrary to the goal of cancer cure with functional preservation.

Swallowing is a complex process with a series of coordinated actions involving more than 30 pairs of muscles and six cranial nerves. Many patients have an impaired swallowing mechanism before treatment. In one study, only 33% of patients had normal swallowing before treatment; aspiration and cervical esophageal impairment was seen more commonly with laryngeal or hypopharyngeal primary tumors.[248] Although pretreatment deficits may exist, radiation negatively affects swallowing initially through tissue edema, xerostomia, mucositis, pain, and viscous secretions during the acute phase. Late dysphagia results when tissues become fibrotic, leading to rigidity and loss of function, with potential contribution from late-effect lymphedema and neuropathy.[249] Strictures following treatment may also be contributory.[250] Chronic gastrostomy tube dependence, a surrogate for persistent dysphagia, is seen in approximately 20% of patients after concurrent

Osteoradionecrosis severity can range from asymptomatic bone exposures that are stable or improve with conservative management to more severe necrosis that requires more aggressive interventions. Small, asymptomatic bone spurs can be treated conservatively with surgical excision or polishing of bone spicules. For more severe osteoradionecrosis, hyperbaric oxygen and surgical excision, consisting of débridement and potential segmental mandibulectomy and reconstruction, may be required. Hyperbaric oxygen is typically recommended to counteract the hypoxia and hypovascularity that contribute to osteoradionecrosis. In patients requiring dental work following radiation therapy, hyperbaric oxygen delivered over 30 sessions (20 before and 10 following dental extraction) was found to decrease the rate of osteoradionecrosis when compared with penicillin alone.[245] Conversely, a randomized study examining hyperbaric oxygen for treatment of moderate osteoradionecrosis was stopped early because of a lack of improvement, and a trend toward detriment, within the hyperbaric arm.[246] Patients with more severe osteoradionecrosis, as demonstrated by bone resorption along the inferior mandible and mandibular fracture, were specifically excluded from this study, so it remains uncertain whether such patients may benefit from hyperbaric oxygen. However, the morbidity of persistent, unremitted osteoradionecrosis leads most clinicians to involve hyperbaric oxygen therapy in their treatment plan despite the lack of randomized data supporting its benefit. Delanian et al reported using a combination of pentoxifylline, vitamin E, clodronate, prednisone, and ciprofloxacin in patients with exteriorized, refractory mandibular osteoradionecrosis.[247] Remarkably, all 54 patients experienced a complete recovery at a median of 9 months, and this data warrants confirmation and repetition to solidify the promising results.

chemoradiation for head and neck cancers when delivered with conventional techniques. These rates are particularly elevated in patients who received concurrent chemoradiation and altered fractionation,[251,252] with Staar et al[253] reporting a rate of 51% at 2 years. Other factors in long-term dysphagia include primary site and increasing age.[222] The persistence of a gastrostomy tube strongly correlates with a poor quality of life following treatment.[254] Given the intimate relation of laryngeal action and swallowing, it is not surprising that aspiration is a frequent consequence of dysphagia. Before the implementation of IMRT designed to spare the important swallowing structures, Eisbruch et al found that 65% of their patients had aspiration shortly after the completion of radiation.[255] Nearly one-third of the patients with aspiration in post-therapy studies developed pneumonia.

Attempts to limit chronic dysphagia and aspiration have revolved around target avoidance during the planning process and prompt intervention both during and following treatment. Eisbruch et al[256] identified radiographic changes within the pharyngeal constrictors, supraglottic larynx, and glottic larynx after intensive chemotherapy and radiotherapy for head and neck cancers that correlated with functional detriment by videofluoroscopy. These structures were identified as "dysphagia/aspiration-related structures" (DARS), and, as discussed in the treatment planning section, partial dosimetric avoidance of these structures can be incorporated into IMRT planning. Limiting radiation to the uninvolved larynx can also be accomplished through a traditional anterior supraclavicular beam with a laryngeal block in place. Such limitations simultaneously decrease the dose to the adjacent cervical esophagus and cricopharyngeal inlet, potentially diminishing the risk of posttreatment dysphagia. As discussed previously, rates of long-term dysphagia and aspiration have been significantly reduced with IMRT when compared to three-dimensional conformal radiation therapy.[104,105] IMRT techniques to reduce dysphagia identify long-term patient-reported, objective, and observer-rated swallowing outcomes to be only slightly worse than pretherapy measures while maintaining excellent oncologic outcomes.[205]

Expert swallowing evaluation and therapy as appropriate before, during, and after treatment is valuable for patients undergoing head and neck cancers therapy. Modifications can include changes in diet to ensure safe and appropriate oral intake, exercises and routines that may improve swallowing function, and swallowing techniques to limit aspiration events. A modified barium swallow or fiberoptic endoscopic evaluation of swallowing is recommended for all patients with oropharyngeal cancer at risk for dysphagia or aspiration to assist in guiding interventions. Circumventing dysphagia through rehabilitation has had modest overall success. At least one retrospective study suggested that pretreatment swallowing exercises led to improvements in swallowing after therapy.[257] The same group found improvements in tongue base position and epiglottic inversion if swallowing exercises were used 2 weeks before and during concurrent chemoradiotherapy but no difference in gastrostomy tube rates 12 months after treatment.[258]

The role of feeding tubes to counteract dysphagia secondary to acute mucositis remains controversial. Dehydration from poor oral intake can lead to hospitalizations and treatment breaks. Malnourishment and weight loss may also prolong recovery from treatment-related side effects and have been shown to be prognostic for head and neck tumor outcomes.[219] Options for tube feedings include both nasogastric (NG) feeding tubes and percutaneous endoscopic gastrostomy (PEG) feeding tubes. Controversy exists as to which feeding tube should be used and whether it should be placed prophylactically or as needed during treatment.[259] NG tubes decrease cosmesis, mobility, and quality of life when compared with PEG tubes during treatment.[227,260] A randomized study comparing prophylactic PEG tubes versus a reactive initiation of enteral feeds demonstrated fewer malnourished patients and improved quality of life at 6 months at the expense of longer use of enteral nutrition.[261] A previous retrospective study comparing NG tubes with PEG tubes demonstrated worse outcomes with PEG tube placement independent of other tumor or clinical factors: worsened dysphagia at 3 and 6 months, increased median tube duration (28 weeks versus 8 weeks), and more patients undergoing pharyngoesophageal dilatation (23% versus 4%).[262] A prospective study found less weight loss immediately after treatment with PEG tubes but a higher rate of insertion site infection, longer median duration of use (146 days versus 57 days), and more grade 3 dysphagia at 6 months (25% versus 8%), leading the authors to conclude that PEG tube use should be selective rather than routine in patients requiring nutritional support.[263] These data point toward PEG tubes being more effective and convenient, leading to increased patient reliance with a greater period of diminished oral intake and atrophy of the muscles of deglutition. If prophylactic PEG placement is pursued, we recommend aggressive intervention from support staff, including speech pathologists, to maintain oral intake during and immediately after radiation treatment to preserve the swallowing mechanism. Alternatively, a reactive approach is viable, with placement of a feeding tube triggered by clinical concerns such as weight loss (e.g., >10%) or inadequate caloric intake (e.g., 50% to 60% of daily allotment). Such an approach allows avoidance of feeding tube placement in 25% to 50% of patients undergoing chemoradiation.[259]

Quality of Life

Despite clear toxicity from definitive radiation, particularly with the addition of concurrent chemotherapy, much of the toxicity in the treatment of locally advanced oropharyngeal cancer is dictated by tumor extent and location. Traditional surgical toxicity for oropharyngeal carcinomas is also marked with regard to functional and cosmetic outcome. Harrison et al found consistently better performance scores and quality of life for patients treated with a combination of EBRT and brachytherapy for base-of-tongue primaries when compared with primary surgical therapy.[264] Patients were more likely to eat out, have a normal diet, and have understandable speech. The differences were particularly marked when considering patients with more advanced disease. The same group found that despite long-term symptoms, including xerostomia, dysphagia, decreased energy, pain, and taste alteration in more than 30% of the patients, most individuals after base-of tongue radiation were still able to work full-time, had unchanged income, and had good to excellent overall functional status.[265] With the advent of transoral surgical techniques, quality of life is a major consideration in employing these surgical approaches and attempting to limit adjuvant treatments. Incorporation of quality of life as well as oncologic outcomes will ultimately guide the optimal selection of modalities in treating oropharyngeal carcinomas.

TREATMENT ALGORITHM, CHALLENGES, AND FUTURE POSSIBILITIES

A general treatment algorithm for SCC of the oropharynx is shown in Figures 33-12 and 33-13. Ipsilateral radiation is appropriate for small, well-lateralized tonsillar cancers with limited ipsilateral lymphadenopathy. Concurrent chemoradiation is generally pursued for T3 and T4 primary tumors or extensive lymphadenopathy.

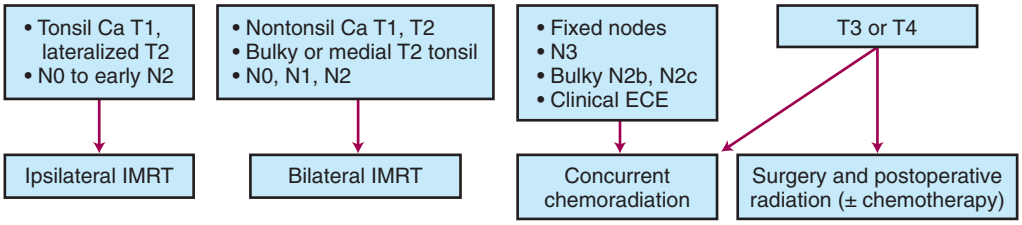

Figure 33-12 Treatment algorithm for primary tumor and regional nodes in oropharyngeal carcinoma. Indications for concurrent chemoradiation include local or regionally advanced disease (T3 or T4 primary; N3, fixed, bulky lymph nodes, or clinical extracapsular extension [ECE]).

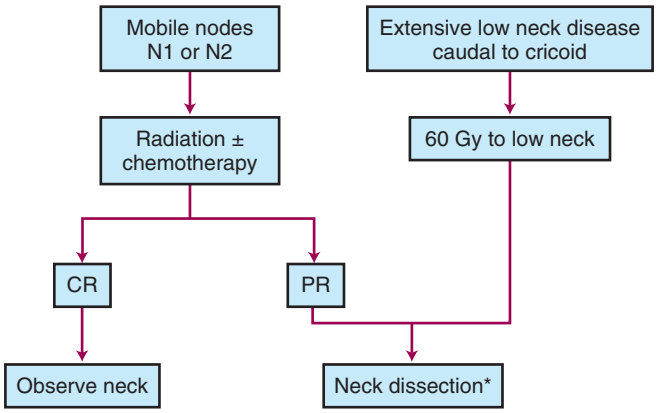

Figure 33-13 Treatment algorithm for addressing regional nodal disease identified before treatment. *CR*, Complete response (typically by CT and PET/CT imaging and clinical examination); *PR*, partial response. *Selective neck dissection is frequently appropriate treatment.

Potential deescalation of treatment intensity in HPV-positive oropharyngeal cancer is an ongoing focus of discussion and clinical research within the head and neck oncology community. Identification of HPV as a causative agent has highlighted a subgroup with improved LRC and OS rates. This discovery has come in an era of increased recognition of the significant acute and late toxicities associated with concurrent chemoradiation, albeit toxicities that have diminished with the broad implementation of IMRT. As these tumors appear more responsive to radiation, it may be possible to treat them with radiation alone and forego the additional toxicity of concurrent chemotherapy. Similarly, it may be possible to reduce the total radiation dose. However, to date, there are no data to confirm that the radiation or chemotherapy dose can be safely reduced. Ongoing clinical trials continue to examine potential avenues for deescalation in a controlled setting. Although these HPV-associated tumors may present with advanced stages, this is partially an artifact of the staging system as many have small (T1 or T2) primary tumors with advanced nodal disease that places them within the stage IV category. The relatively small primaries, however, may make them amenable to radiation alone, with neck dissection reserved for incomplete cervical nodal response. There is also renewed interest in the surgical community to consider transoral resections of small oropharyngeal tumors to maximize tumor control and maintain high-quality functional outcome.

Proton beam and heavy ion radiation may further minimize the dose to the surrounding normal tissues, improving the quality of life by reducing toxicity. At least one dosimetric study has demonstrated an improved ability to spare organs at risk when comparing intensity-modulated proton therapy with IMRT.[266] Clinical investigation is warranted, however, because the dose-depth characteristics of particle beam therapy make it susceptible to small changes in the treatment volume, which can frequently be seen in oropharyngeal cancers because of factors such as tumor shrinkage and patient weight loss.[267,268]

Conclusions

The evaluation and treatment of patients with cancer of the oropharynx are evolving. The implementation of IMRT in large series has reduced the spectrum and severity of normal tissue toxicities. The relatively recent advances in molecular targeting agents (e.g., cetuximab) are enabling new treatment options for patients with both locoregional and metastatic/recurrent disease. Advances in surgical technology (e.g., improved microvascular free-flap reconstruction and transoral surgery) are similarly affording new opportunities to tailor therapy and diminish toxicities. The emergence of HPV as a critical prognostic biomarker is changing the landscape of future clinical trials in oropharyngeal cancer. With each new tool there emerge new questions and opportunities to further refine treatment and thereby improve the ultimate outcome for patients with this challenging malignant disease.

CHAPTER

34 Nasopharyngeal Carcinoma

Nancy Lee, Nadeem Riaz, Roger Ove, Marsha Laufer Reyngold, Robert L. Foote, and James A. Bonner

INCIDENCE

In the United States, nasopharyngeal carcinoma (NPC) is uncommon, occurring at a rate of 0.2 to 0.5 cases per 100,000 people. In contrast, in southern China and Hong Kong, the incidence is 25 to 50 per 100,000 people and among the Inuit in Alaska and Greenland, 15 to 20 per 100,000 people.

BIOLOGY

A potential link between Epstein-Barr virus (EBV) and NPC was first described more than 30 years ago; advances in molecular biology have furthered our understanding of this association. The rate of positive EBV serology is higher with nonkeratinizing or poorly differentiated versus well-differentiated lesions, and EBV DNA is detected less frequently in patients with keratinizing squamous cell carcinomas.

STAGING EVALUATION

Evaluation for NPC includes detailed palpation of neck nodes, flexible nasopharyngoscopy with biopsy, computed tomography (CT), magnetic resonance imaging (MRI) of the head and neck, a complete blood count, a chemistry panel, and a chest radiograph. Positron emission tomography (PET) should be considered.

PRIMARY THERAPY

When treated with radiotherapy as a single modality, patients with NPC have a similar 10-year survival rate in the United States, Denmark, and Hong Kong (34%, 37%, and 43%, respectively).

Advancing technology promises to allow better optimization of radiotherapy, improving target coverage and minimizing morbidity.

The Intergroup study 0099 showed an advantage to the addition of concurrent plus adjuvant chemotherapy to radiotherapy for stages III and IV disease, with a survival advantage at 3 years (78% versus 48%; $p = 0.005$).[1] The advantage of concurrent chemotherapy for advanced disease is now well established, although the benefit of adjuvant chemotherapy remains unclear.

LOCALLY RECURRENT OR PERSISTENT DISEASE

For persistent or recurrent nodal disease, surgical resection is the preferred treatment if technically possible, but recurrent disease at the site of the primary lesion is difficult to approach surgically.

Radiation remains the mainstay of salvage therapy, and in the era of modern techniques can achieve local control without excessive risk of toxicity. Reirradiation for recurrent disease appears to be most effective in patients with a prolonged disease-free interval and small tumor volume treated to a high reirradiation dose (≥60 Gy).

Advances in clinical and basic science research have led to a better understanding of the carcinogenesis of NPC and to better treatment of this condition; however, such advances have also raised many new questions about this disease. This chapter provides an overview of the current understanding of etiologic factors, such as EBV, and the present diagnostic and therapeutic interventions for NPC. Therapeutic controversies are highlighted, and the data relevant to controversial issues are reviewed to guide treating physicians in applying clinical data to individual patients.

ETIOLOGY AND EPIDEMIOLOGY

NPC more commonly occurs in men than women, with up to a two- to threefold difference in incidence. It is an uncommon tumor in the United States, where the incidence is approximately 0.2 to 0.5 cases per 100,000 people.[2] In comparison, the incidence is considerably greater in southern China and Hong Kong (25 to 50 cases per 100,000 people) and among the Inuit residing in Alaska and Greenland (15 to 20 cases per 100,000 people). The incidence of NPC is also higher in other parts of Southeast Asia (Taiwan, Vietnam, and Thailand), the Philippines, and Malaysia and in some Mediterranean and North African populations (8 to 12 per 100,000 people). These areas of increased incidence of NPC are considered endemic areas, and the incidence outside endemic areas is much lower and more often associated with tobacco use. Although incidence of NPC has declined in some endemic areas over the past 20 years (Hong Kong, Taiwan), it has remained stable in other endemic regions.[3-5]

Several geographic-specific etiologic factors have been implicated in the incidence variations throughout the world. The high consumption of salted fish in southern China and Hong Kong has been implicated as a possible etiologic factor for NPC in these areas.[6,7] It has been suggested that various macromolecular lignins associated with these foods in southern China (and perhaps other areas such as Alaska) may activate EBV,[8] which has also been identified as a probable etiologic factor in NPC.[9,10] Studies by Bouvier et al[8] involved the fractionation of harissa, a homemade spice mixture used in Tunisia on various foods, including salted fish. Harissa was separated into various macromolecular fractions by column chromatography. The lignin-containing complexes extracted from harissa induced the EBV promoter in Raji cells.[8] The possibility that these environmental factors are important in the etiology of NPCs is further supported by the finding that incidence rates decrease for successive generations of people who originally emigrated from southern China to California.[11]

Other potential environmental etiologic factors that have been associated with NPC include alcohol consumption and exposure to dust, fumes, formaldehyde, and cigarette smoke.[12,13] Cigarette smoke and alcohol have long been associated with many other head and neck carcinomas, but their association with NPC has been controversial. Some studies have suggested that alcohol consumption and cigarette usage were not associated with NPC.[12-14] Nam et al[13] conducted a case-control study using a National Mortality Follow-Back Survey based on death certificates and found that cigarette smoking and alcohol consumption are independent statistically significant risk factors for NPC. The increased risk of NPC with heavy smoking (adjusted for alcohol consumption) was threefold, and an excess risk of 80% was demonstrated for heavy alcohol consumption (adjusted for cigarette usage).

In addition to environmental factors, genetic factors have also recently been discovered that may explain some of the risk of developing NPC. Multiple investigators have found genetic variation in human leukocyte antigen (HLA) region to be associated with the increased incidence of NPC in southern China.[15] Simons et al[16] originally described an association in Chinese patients with NPC and the HLA-A2 antigen with a deficit of the second antigen at the second locus (B locus). Two large genomewide association studies have subsequently confirmed the role of HLA locus in mediating risk of development of NPC.[17,18] It remains unclear whether specific HLA alleles may influence development of NPC directly, possibly by affecting the immune reaction to EBV, or whether, and perhaps more likely, the genetic susceptibility to NPC is encoded by a locus in close linkage disequilibrium. Several other single-nucleotide polymorphisms have also been implicated with risk for NPC, including genes involved in DNA repair and metabolism of various toxins. However, these latter studies have generally been smaller studies and have not yet been replicated.[19]

PREVENTION AND EARLY DETECTION

The nasopharynx cannot be visualized externally, and tumors of this area often present after they have eroded into vital structure and thus produced symptoms. The association of EBV and NPC has led some investigators to hypothesize that serologic screening (EBV titer) may be useful in certain high-risk populations to identify groups of patients who might benefit from frequent nasopharyngeal examinations.[20] In a study from China of 338,868 patients who underwent serologic screening for EBV titer, 9367 persons had immunoglobulin (Ig) A antibodies to EBV. Of these 9367 patients, 306 were positive for IgA to EBV early antigen. NPC was detected in 113 of the 9367 patients (1.2%) and in 63 of the 306 (20.5%) who were positive for IgA to EBV early antigen. Most of the tumors (>85%) were early-stage lesions. Serologic EBV IgA screening is currently being used in endemic areas.

In addition to EBV serologic screening as a means of early detection and possible prevention of advanced-stage disease, several environmental and genetic predisposing factors are being explored as possible markers that could identify groups of patients at high risk for NPC.[21] Real-time polymerase chain reaction (PCR) techniques show promise as screening tools for NPC.[22] EBV DNA detection, in particular detection of EBV nuclear antigen, eliminates many false-positive results and improves the sensitivity and specificity of EBV IgA serologic screening.[23] A retrospective analysis of blood samples from patients with disease relapse from previous clinical trials indicates that EBV nuclear antigen screening by PCR would have led to earlier detection of distant failure but, because of the quality of current imaging, would not have significantly affected detection of local recurrences.[24] Real-time PCR screening for EBV latent membrane protein 1 (LMP1) in nasopharyngeal swabs has also been shown to be a promising screening tool for high-risk populations, with a sensitivity of 87% and specificity of 98%.[25] These techniques are likely to replace serum IgA screening in endemic areas and have a promising role in screening for relapse in patients who are EBV-positive.[26] The further study of other environmental and genetic markers may lead to the identification of patient populations that could benefit from screening or chemoprevention.[21]

Chemoprevention has been tested extensively in patients with a prior diagnosis of head or neck malignant tumors because second primary tumors in the respiratory and digestive tracts are common in that population.[27-30] Hong et al[27,28] conducted a prevention trial for patients with head and neck carcinomas after curative surgery or radiotherapy, or both. Patients were randomly assigned to receive 1 year of 13-*cis*-retinoic acid (isotretinoin) as a chemoprevention agent (see Khuri et al[21] for a discussion of the biologic factors) or placebo. The treated group had significantly fewer second primary tumors (4%) than the placebo group (24%) ($p = 0.005$); however, there was no difference in rates of survival or incidence of relapse between the two groups. In addition, the chemopreventive effect appeared to abate after 3 years; the incidence of second primary tumors was similar in the two groups after 3 years. Acute toxicity was significant.[27]

The results of the trial by Hong et al[27] were not confirmed by a controlled trial of 316 patients by Bolla et al,[29] in which patients were randomly assigned to 2 years of etretinate (a retinoic acid similar to isotretinoin) at a maintenance dosage of 25 mg/day. Subsequently, a large intergroup effort was mounted, and 1302 patients with previously treated head and neck malignant tumors were randomly assigned to receive 3 years of isotretinoin or placebo.[30] Because of unacceptable toxicity seen with higher doses of isotretinoin (100 to 200 mg/m^2 [≈150 to 400 mg total]) in prior studies, the dosage was decreased to 30 mg/day in this trial. No difference was seen in the occurrence of second primary tumors (4.6% in both arms), which was the primary endpoint of the study.[31] A decrease in local recurrence was seen, however, and 13-*cis*-retinoic acid remains a topic of investigation.

The issue of whether retinoids or other chemopreventive agents should be used in the setting of premalignant lesions of the oral cavity has been considered, and many trials have suggested that retinoids can induce considerable responses in oral leukoplakia.[32,33] Toxicity has been a limiting issue in these trials, however. It will be important to determine whether these chemoprevention strategies, developed for leukoplakia, can be extrapolated to prevention of NPC in subgroups of patients at high risk for such malignant tumors.

Blockade of cyclooxygenase-2 (COX-2) has also shown some promise as a chemopreventive strategy, and COX-2 inhibitors were recently the topic of investigation for various malignant tumors, including head and neck cancers.[34] A Phase II study at Fox Chase Cancer Center evaluated a 3-month course of celecoxib in patients with biopsy-proven dysplastic or hyperplastic leukoplakia, with results pending (NCT00101335). In another pilot randomized study of celecoxib in oral premalignant lesions conducted by the M. D. Anderson Cancer Center (MDACC), doses of 100 mg and 200 mg twice daily were shown to be ineffective in controlling these lesions.[35] Most recent COX-2 inhibitor cancer prevention trials have been closed, except in very high-risk settings such as familial polyposis, because of the increased rate of cardiovascular events seen in a few of the celecoxib and rofecoxib prevention trials. Non-COX derivatives of nonsteroidal anti-inflammatory drugs have recently shown some promise as cancer prevention agents and may prove to have superior toxicity profile.[36]

PATHOLOGY

Malignant tumors of the nasopharyngeal area are generally carcinomas (90%), with lymphomas making up approximately 5% of lesions.[37] Histologic classification of carcinomas continues to evolve as we find out more about the biologic characteristics of these tumors. The most current pathologic classification of NPCs by the World Health Organization (WHO) includes three major categories: keratinizing squamous cell carcinoma (formerly, WHO type I), nonkeratinizing squamous cell carcinoma (including differentiated, or former WHO type II lesions, and undifferentiated, or former WHO type III lesions), as well as recently described basaloid squamous cell carcinoma.[38]

On histologic testing, keratinizing squamous cell carcinomas appear to be well differentiated with intercellular bridges. These lesions make up approximately 20% of carcinomas.[38,39] Differentiated nonkeratinizing carcinomas, representing 30% to 40% of NPCs, lack well-defined squamous cell characteristics but continue to show a "pavement stone pattern" characteristic of squamous cell histology.[38] Undifferentiated nonkeratinizing carcinomas, comprising 40% to 50% of carcinomas, also formerly known as lymphoepitheliomas, are characterized by a lymphoplasmacytic infiltrate.[38] On cytologic testing, the cells appear uniform, with round to oval nuclei and prominent nucleoli. The frequency of the different histologic types varies with geographic area. In the United States, the majority of NPCs have keratinizing squamous cell histologic findings, whereas in Asia, the undifferentiated histologic type is by far the most common (Table 34-1).

ANATOMY AND PATHWAYS OF SPREAD

The nasopharynx is a musculofascial tube that connects the nasal cavity and oropharynx. The anatomic borders of the nasopharynx are (1) the anterior border, consisting of the posterior nasal apertures and nasal septum; (2) the posterior border, the pharyngeal mucosa; (3) the superior border, the pharyngeal mucosa and body of the sphenoid; and (4) the inferior border, the oropharynx. The lateral wall of the nasopharynx contains the pharyngeal opening of the auditory tube. The medial cartilaginous extension of the auditory tube forms a protrusion from the lateral wall of the nasopharynx at the superior and posterior aspects of the opening of the auditory tube. This protrusion, with its overlying mucosa, creates the torus tubarius. Just posterior to the torus tubarius lies the pharyngeal fossa, or the fossa of Rosenmüller, which is formed by the junction of the lateral and posterior walls of the nasopharynx (Figure 34-1, *A* to *D*).

The superior wall of the nasopharynx warrants review. Extension of tumors superiorly often leads to invasion of structures, the symptoms of which are typical of the initial clinical presentation of patients. The sphenoid bone lies superior to the mucosa and pharyngobasilar fascia of the nasopharynx. Several cranial nerves exit the base of skull in this area. Critical foramina housed in the sphenoid include the superior orbital fissure (cranial nerves III, IV, V [ophthalmic division], and VI), the foramen rotundum (cranial nerve V [maxillary division]), the foramen ovale (cranial nerve V [mandibular division]), and the foramen spinosum (recurrent branch of cranial nerve V [mandibular division]). The foramen lacerum

is formed by the junction of the sphenoid and temporal bones. The internal carotid artery passes over the superior opening of the foramen lacerum but does not traverse through the foramen. The nerve of the pterygoid canal and the meningeal branch of the ascending pharyngeal artery course through the foramen lacerum. Deep to the mucosa of the superior aspect of the lateral wall of the nasopharynx lies the superior pharyngeal constrictor muscle. Beyond this muscle lie cranial nerves IX, X, and XI, which exit the base of the skull from the jugular foramen in the temporal bone, and cranial nerve XII, which exits the base of the skull through the hypoglossal canal of the temporal bone.

The sensory innervation is shown in Figure 34-1, *D*. The maxillary division of the trigeminal nerve supplies the upper nasopharynx, the posterior part of the nasal cavity, and most of the palate and upper gums of the oral cavity. The general sensory branches of the lingual and pharyngeal branches of the glossopharyngeal nerve supply the sensory innervation of the lower part of the nasopharynx, the posterior third of the tongue, and part of the soft palate and oropharynx.

Understanding the anatomic relationships of the nasopharynx and adjacent structures is important to correctly diagnose patients with NPC. The importance of superior extension into the sphenoid bone of the base of the skull is exemplified by the fact that cranial nerves can be involved at presentation. The frequency of involvement of cranial nerves has been described in two large series.[40,43] Cranial nerves V and VI are the most commonly involved. These nerves traverse the sphenoid bone and can be involved when tumors erode superiorly through bone. Tumors of the nasopharynx can also gain access to the cranial nerves of the base of the skull by eroding superiorly through the foramen lacerum, which is bordered superiorly by the internal carotid artery (Figure 34-1, *B*).

Lateral extension of NPCs can lead to erosion of the medial opening of the auditory tube and the medial pterygoid plate and can involve cranial nerves IX, X, XI, and XII (Figure 34-1, *B* and *C*). Lateral extension can lead to involvement of the carotid artery and internal jugular vein.

Lymph node involvement is common; 65% to 80% of patients present with clinically involved cervical neck nodes. The level VA and level II lymph nodes are commonly involved. The frequency of involvement of these areas in two large series[40,43] is presented in the "Clinical Manifestations" section. Recent studies have shown that, for clinically N0 or N1 disease, microscopic involvement of the inferior neck and posterior neck (levels IV and VB) is less frequent.[44,45]

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

The potential etiologic link between EBV and NPC was first described more than 30 years ago[9]; however, recent advances in molecular biology have shed further light on this association. Earlier work focused on the serologic response to EBV and showed elevated levels of IgA and IgG antibodies to the viral capsid antigen and a replication protein called early antigen in patients with NPC. Other studies have demonstrated the presence of EBV DNA and encoded proteins directly in the NPC tissue samples.[42] Latent infection of cells with EBV, initially studied in B lymphocytes, is associated with regulated expression of several viral genes, including latent membrane proteins (LMPs) 1, 2A, and 2B, six EBV nuclear antigens (EBNAs) 1, 2, 3A to C, and LP, and two small noncoding nuclear RNAs (EBERs).[46] Some of the molecular mechanisms by which expression of these genes can lead to transformation have been elucidated. For example, LMP1 induces expression of epidermal growth factor receptor (EGFR) and may therefore influence cellular growth. A restricted pattern of these EBV antigens is present in nasopharyngeal cancer cells, which may in part explain why immunotherapy directed against these antigens has been more successful in other EBV-associated diseases.[47] Allogeneic cytotoxic T cells to various EBV antigens have been developed and show some promise for treating locally recurrent nasopharyngeal carcinoma.[48]

Several studies have suggested that serologic responses to EBV may be more specific for the nonkeratinizing carcinoma (former WHO types II and III).[49] This, however, was not confirmed by another group.[50] Using the Southern blot technique to detect the viral DNA, Raab-Traub et al[51] showed the presence of EBV in all former histologic variants of NPC, but the EBV copy number was lowest in keratinizing squamous cell carcinomas. The presence of EBV in keratinizing squamous cell carcinoma has been consistently detected by other groups.[52-55] The differences in the rate of EBV detection by different investigators may stem from variability in the sensitivity of different assays. Alternatively, it may reflect differences in the sampled populations. The detection rate of EBV infection in keratinizing squamous cell NPC is highest in endemic areas.

Several groups have examined measuring circulating EBV DNA as a biomarker of tumor burden and response to treatment. The rationale for measuring circulating EBV DNA is that tumor cells are hypothesized to spill EBV DNA into the circulation, and as such pretreatment EBV DNA levels would serve as a measure of burden of disease and postradiotherapy EBV DNA levels might serve as an indicator of residual local or systemic disease. Lo et al demonstrated that using real-time quantitative PCR, cell-free EBV DNA was detectable in 96% of patients with NPC.[22] Investigators from Hong Kong then showed that EBV DNA levels 1 week postradiotherapy correlated with poor outcome,[56] with a 2 year overall survival (OS) of 56.3% for those with detectable EBV DNA compared to 96.7% for those with undetectable EBV DNA. Multiple other groups have also confirmed the prognostic value of posttreatment circulating EBV DNA.[57,58] At present, several Phase III studies are under way investigating whether the presence of circulating EBV DNA after definitive chemoradiotherapy can predict for the need of adjuvant chemotherapy.

Beyond examining the role of EBV in NPC, others are examining genomic alterations in NPC via genomic profiling. Initial investigations have focused either on copy number changes in nasopharyngeal tumors or alterations in gene expression. Deletions of the short arm of chromosome 3 (3p25, 3p14)[38] and of chromosome 9 (9p21-22)[59] are the most common cytogenetic changes. Candidate genes in these and other locations of interest are being identified. The first integrated genomic analysis, with whole exome sequencing and copy number profiling in over 50 tumors, and expression analysis in a limited set was published. (ref). These authors identified 9 significantly mutated genes (FDR $q < 0.2$), including TP53, PIK3CA, BAP1, MLL2, TSHZ3, ERBB2, ERBB3, KRAS, and NRAS. An integrated analysis identified multiple alterations in chromatin modifying genes, ERBB-PI3K signaling, and the autophagy machinery.[59a] These findings may lead to a greater understanding of the genetic basis of NPCs and eventually identify new therapies for treatment.

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

As mentioned, NPC is rare in the United States and, therefore, is not often suspected as a possible cause of a patient's early symptoms. In addition, the list of possible early symptoms of

NPCs includes many symptoms that could have more common causes. In a series of 378 patients from the MDACC,[40] the presenting symptoms included a neck mass in 41%; hearing loss, ear drainage, or otalgia in 27%; nasal bleeding or obstruction in 21%; cranial nerve deficits in 8%; and other nonspecific symptoms in 8%. Investigators from Washington University noted that the typical presentation involved multiple symptoms.[43] In this series of 143 patients, presenting symptoms included otitis in 43%, throat pain in 39%, nasal obstruction in 37%, a neck mass in 35%, nasal bleeding in 29%, cranial nerve involvement in 24%, and trismus or other symptoms in 5%.

Similar to these data, most series have shown that neck masses, obstructive ear symptoms, and cranial nerve deficits are common presenting symptoms for NPC. In the Washington University series,[43] 66% of patients were found to have ipsilateral neck masses and 28% had contralateral neck masses on examination, although only 35% of patients had reported a neck mass as the reason for seeking medical advice. Of the patients with clinically involved neck disease, 60% had enlarged ipsilateral level II lymph nodes and 32% had enlarged ipsilateral level V lymph nodes. The most frequently involved cranial nerves in the series were cranial nerve VI in 15% of patients, V in 7.7%, and VIII, X, and XII in 5.6% of patients each.

In the series from the MDACC,[40] the level VA lymph nodes were most commonly enlarged (54% of patients), followed by the level II nodes (49% of patients). The level III and lower level VA/upper level VB groups were involved in 24% and 22% of patients, respectively. The level IV lymph nodes, level VB lymph nodes, and supraclavicular lymph nodes were involved in 10%, 13%, and 10% of patients, respectively. Similar to the series from Washington University, cranial nerve VI was the most frequently involved nerve (6% of cases).

Patient Evaluation

The initial evaluation of patients with NPC should include a history and physical examination, with special attention to the level of nodal involvement (if any) (Figure 34-2).

Patients should undergo flexible fiberoptic nasopharyngoscopy to determine the involvement of mucosal surfaces. A diagram or digital photograph of these findings should also be made. Biopsy of the primary lesion should be attempted first. If this procedure gives indeterminate results, a needle biopsy of a potentially involved lymph node should be taken.

CT and MRI of the head and neck are useful in the evaluation of both erosion of tumor into the bony structures of the base of the skull and retropharyngeal and cervical lymphadenopathy. Although the same information is often provided by CT and MRI, some investigations have suggested that MRI may be more useful in delineating soft-tissue invasion outside the nasopharynx and the extent of retropharyngeal lymph node involvement,[60] whereas CT may be most useful in delineating skull base erosion.[61-63] Given the level of anatomic information required for the current T staging system, MRI is a critical imaging study in the evaluation of nasopharyngeal tumors.

PET can be useful for staging[64,65] as well as for posttherapy management where other imaging is unclear. PET/CT, which provides additional functional information, is more commonly used now and may be helpful for radiotherapy planning. Further PET/CT helps evaluate for distant metastatic disease before beginning definitive locoregional treatment.

The completion of the diagnostic evaluation involves acquiring routine complete blood counts, a chemistry panel, and a chest radiograph (see Figure 34-2). Further evaluation of possible metastases should be done on the basis of the clinical presentation of the patient.

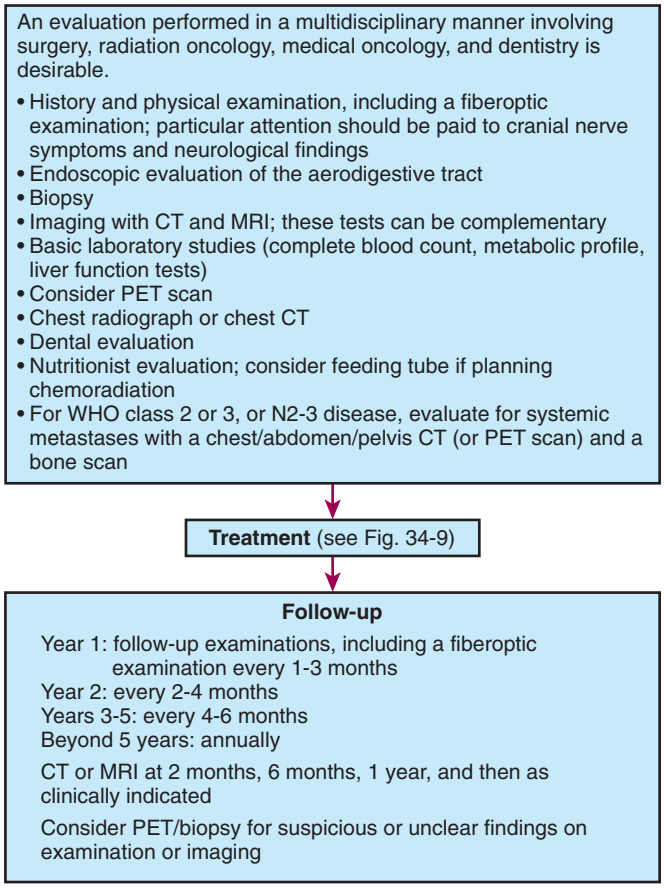

Figure 34-2 Diagnostic algorithm for nasopharyngeal carcinoma.

Staging

After a pathologic assessment has been made, the workup or evaluation leads to a clinical stage (Table 34-2). Clinical staging has been a matter of controversy, and the prognostic significance of the various TNM staging criteria remains under investigation. Several staging systems have been in use throughout the world. The most commonly used systems in North America and Europe are those of the American Joint Committee on Cancer (AJCC)[66] and the International Union Against Cancer (Union Internationale Contre le Cancer [UICC]),[67] which have become essentially analogous. In Asia, where NPC is endemic, the Ho[68] classification system was initially developed in Hong Kong. In addition, in 1992, Chinese physicians adopted an independent system similar to the Ho system.[69] All four systems, shown in Table 34-2, have limitations and continue to evolve, with researchers often drawing on each others' experience. Updated versions of the Chinese system and the AJCC system were released in 2008[70,71] and 2010,[72] respectively. The AJCC/UICC remains the most commonly used system in the English literature.

A well-recognized advantage of the Ho classification system lies in its approach to lymph node metastasis, namely, use of lymph node location in N-stage assignment and a more even distribution of nodal disease in stage grouping[68,74] (see Table 34-2). Nodal involvement appears in stage II, and supraclavicular nodal metastasis, which is known to carry a worse prognosis, is represented in a separate stage IV category (Table 34-2). The 1992 AJCC system used lymph node size and laterality in N-stage assignment, both of which carry some prognostic significance. However, only some patients with N1

TABLE 34-2 Comparison of Staging Systems

Classification	AJCC, 7th ed.[72]	2002/1997 AJCC[66,73]	Ho[68]	2008 Chinese[62]
T1	Confined to nasopharynx, or extends to oropharynx or nasal cavity	Confined to nasopharynx	Confined to nasopharynx	Confined to nasopharynx
T2	With parapharyngeal extension	Soft tissue invasion *A:* Without parapharyngeal extension *B:* With parapharyngeal extension	Nasal fossa, oropharynx, muscle, or nerves below base of skull	Nasal cavity, oropharynx, parapharyngeal extension
T3	Bony or paranasal sinus extension	Bony or paranasal sinus extension	*A:* Bone involvement below base of skull *B:* Involves base of skull *C:* Cranial nerves *D:* Orbits, laryngopharynx, or infratemporal fossa*	Skull base or medial pterygoid extension
T4	Intracranial extension, or cranial nerve or infratemporal fossa,* hypopharynx, or orbital involvement	Intracranial extension, or cranial nerve or infratemporal fossa,* hypopharynx, or orbital involvement	—	Cranial nerves, paranasal sinuses, masticator space* (excluding medial pterygoid muscles), intracranial (cavernous sinus, dural meninges) extension
N1	Unilateral, ≤6 cm or unilateral or bilateral retropharyngeal ≤6 cm	Unilateral, ≤6 cm	Upper neck above thyroid notch	*A:* Retropharyngeal *B:* Unilateral level Ib, II, III, and Va or ≤3 cm
N2	Bilateral, ≤6 cm	Bilateral, ≤6 cm	Below thyroid notch above line joining end of clavicle and superior margin of trapezius muscle	Bilateral level Ib, II, III, and Va or >3 cm or with extranodal spread
N3	*A:* >6-cm node *B:* Supraclavicular involvement	*A:* >6-cm node *B:* Supraclavicular involvement	Supraclavicular fossa† or skin involvement	Level IV or Vb involvement

Stage V	—	—	M1	—

**Masticator space is defined as infratemporal fossa.*
†Supraclavicular fossa as described by Ho is a triangular space defined by three points: (1) the superior margin of the sternal end of the clavicle, (2) the superior margin of the lateral end of the clavicle, and (3) the point where the neck meets the shoulder. This includes the caudal portion of level IV and Vb lymph nodes.

disease were included in stage III, and most patients with nodal involvement were grouped into stage IV, together with patients with metastatic disease. Modifications to the AJCC classification implemented in1997[75] and maintained in 2002[73] and 2010[72] have incorporated lymph node location into N-category assignment, designating involvement of the supraclavicular fossa, as originally defined by the Ho system, as N3 disease, and have placed all N3M0 lesions in a separate stage IVA grouping. In addition, stage groupings were changed to provide a more even stage distribution. These changes improved risk stratification of the 1997 AJCC classification in comparison to both the prior version of the AJCC system and the 1978 Ho system.[76,77]

Important changes to the most recent AJCC system targeted T-category assignment. Invasion into the soft tissues of the nasopharynx was used in the 1997 and 2002 AJCC classification to segregate T1 and T2 lesions, but studies have shown that this carries no prognostic significance.[78-80] The parapharyngeal space involvement used to segregate T2a and T2b lesions does,[81-83] however, and therefore the new 2010 AJCC system segregates lesions with parapharyngeal involvement into the T2 subgroup, whereas all tumors either confined to the nasopharynx or extending into surrounding subsites but without parapharyngeal involvement are now in the T1 subgroup. Furthermore, cranial nerve involvement carries a significantly worse prognosis than base-of-skull involvement,[43,79,84-86] but both were aspects of the T4 subgroup in the 1997 and 2002 AJCC systems and of the T3 subgroup in the Ho system. In the 2003 and 2010 versions, akin to the 2008 Chinese classification system, base-of-skull involvement

has been downstaged to T3. Furthermore, data are emerging that extensive cranial nerve involvement, orbit involvement, and intracranial extension are associated with worse outcomes within the T4 subgroup.[77,86] Therefore, some of the proposed modifications to the AJCC system include a separation of the T4 subgroup into two categories. T4a would include tumors with involvement of the masticator space (infratemporal fossae), asymptomatic radiographic cranial nerve involvement, and involvement of the hypopharynx. T4b would include tumors with intracranial extension, orbital involvement, and symptomatic cranial nerve palsies. However, more data need to be collected to validate this proposed modification.

With respect to N-category classification, the seventh edition of the AJCC staging manual for the first time includes disease that has spread to the retropharyngeal lymph nodes in staging, placing it in the N1 category. On MRI evaluation, these nodes are involved in 83% of patients with NPC compared with 74% involvement of the level II to IV nodes and are considered to be the first echelon of nodal spread.[87] Therefore, their inclusion into the staging system is expected to improve the prognostic accuracy.[88,89]

The evolution of technology and, specifically, CT and MRI, has allowed for more precise evaluation of tumor invasion into surrounding structures and lymph node involvement and will undoubtedly lead to improvement in staging accuracy and risk stratification.

PRIMARY THERAPY

Traditionally, the nasopharyngeal area has not been easy to examine without fiberoptic technology and has been difficult to approach surgically. Surgical exposure of the area and resection of tumors with adequate tumor margins have long been challenging.[90] For these reasons, primary surgical intervention fell out of favor in the 1950s; primary treatment has generally consisted of radiotherapy for early stage disease and chemoradiotherapy for locally advanced disease.

Single-Modality Therapy

Although histologic presentations of nasopharyngeal tumors vary throughout the world, with more undifferentiated tumors found in southern China and Hong Kong, the 10-year survival rates for patients treated with radiation therapy alone in the United States (MDACC),[40] Denmark,[41] and Hong Kong[91] are similar, at 34%, 37%, and 43%, respectively (see Table 34-1). The rate from the Hong Kong study may be somewhat inflated because many patients had early-stage disease (node-negative disease in 39%), and few patients with the keratinizing histology (0.3%) were present in the series.[91] However, elevation of EBV titers has been correlated with a poor prognosis,[46] and higher titers would be expected in Hong Kong, an endemic area. The North American and European populations have a greater percentage of patients with keratinizing (WHO type I) histologic findings than with nonkeratinizing histologic findings (WHO types II and III), however, and the prognosis for the former has been poorer than for the latter.[78] Therefore, comparison of groups from various parts of the world is difficult, and our understanding of the role of EBV and histologic classifications is incomplete. Still, some general statements can be made.

The MDACC series elucidated the long-term outcome in a large population of patients treated with radiotherapy alone.[40] Using the 1992 AJCC staging system (see Table 34-2), researchers found that advanced T category, squamous histologic typing, and cranial nerve deficits were predictive of poor prognosis for local control in univariate and multivariate analyses. Five-year local control rates for T1, T2, T3, and T4 categories were 93%, 79%, 68%, and 53%, respectively. Similar results were observed in other, smaller series.[43,92-95]

The MDACC results illustrate the good tumor control that can be achieved with radiotherapy alone for early-stage lesions but demonstrate the need to explore multimodality options for more advanced lesions. Significant improvements were achieved with a combined chemoradiation approach and the evolution of radiotherapy techniques. Altered fractionation schemes were initially explored, but the improved therapeutic ratio associated with the use of intensity-modulated radiotherapy (IMRT) has made this technique the radiotherapy of choice.

Combined-Modality Therapy

In general, the dramatic improvement in outcomes with combined-modality treatment has limited the use of single-modality radiotherapy to patients with T1 disease. Results from randomized trials of combined-modality therapy will be discussed.

Irradiation Plus Chemotherapy

The randomized trial of Sanchiz et al[96] served as an introduction for using chemotherapy in NPC. However, only a small number of patients with NPC were included.

Brizel et al[97] reported a small randomized trial comparing twice-daily irradiation (1.25 Gy to 75 Gy) to twice-daily irradiation (1.25 Gy to 70 Gy) with concurrent cisplatin and 5-fluorouracil (5-FU) treatment. This trial included 121 patients with locally advanced (T3 and T4) squamous cell carcinomas of all head and neck sites (including some NPCs). With a median follow-up of 41 months, the locoregional control rate at 3 years was 70% for the combined-modality arm versus 44% for the irradiation alone arm ($p = 0.01$). The OS at 3 years was 55% for the combined-modality arm versus 34% for the irradiation alone arm ($p = 0.07$). Mucositis appeared to be more prevalent in the combined-modality arm; 45% of patients required feeding tubes compared with 28% in the irradiation alone arm. However, the severe late complications of soft-tissue necrosis or osteoradionecrosis were uncommon, with similar numbers in both arms (three patients in the irradiation group and five in the combined-modality group).

Several groups have conducted Phase III trials specific to nasopharyngeal primary tumors (instead of a wide array of head and neck cancers). The trial design compared chemotherapy plus irradiation versus irradiation alone (Table 34-3).[1,69,98-105]

Intergroup study 0099 showed a dramatic improvement in survival rates with combined-modality treatment.[1] The trial was closed at a planned interim analysis (October 1995) after review of the preliminary results by the Data Safety and Monitoring Committee for the Southwest Oncology Group. The results are shown in Table 34-3. Patients treated with standard irradiation received 70 Gy to gross disease in daily fractions of 1.8 Gy to 2 Gy. Patients enrolled in the combined-modality arm received 100 mg/m^2 of cisplatin on days 1, 22, and 43 of irradiation, and cisplatin (80 mg/m^2) and 5-FU (1000 mg/m^2) on days 1 to 4 every 3 weeks for three courses after irradiation. A marked statistically significant improvement in both disease-free survival (DFS) and OS in the combined-modality arm was documented at both initial analysis and in the final update of the trial published in 2001.[1] The 5-year OS for patients with the keratinizing squamous cell carcinoma histologic type (WHO type I) was 37%; the differentiated nonkeratinizing histologic type (WHO type II), 55%; and the undifferentiated nonkeratinizing histologic type (WHO type III), 60%. This landmark trial defined a new standard of care for NPC,

resulting in the exclusion of nasopharyngeal cases from subsequent locally advanced head and neck cancers trials.

Although the first reported results from a chemoradiation trial conducted in an endemic area were disappointing,[100] the final update[102] as well as four additional independent trials conducted in Taiwan,[98] Hong Kong,[101,106] and Singapore[104] all confirmed an advantage to cisplatin-based chemoradiation (see Table 34-3). A randomized trial from Hong Kong of concurrent weekly cisplatin chemotherapy (40 mg/m^2), without adjuvant or neoadjuvant therapy, versus irradiation demonstrated a significant improvement in progression-free survival (PFS) at a median follow-up of 2.71 years[100] and in OS at a median follow-up of 5.5 years (hazard ratio [HR], 0.51; p = 0.013)[102] for a subset of patients with T3 to T4 disease. A trial conducted by Lin et al[98] in Taiwan randomized 284 patients to irradiation alone versus irradiation with two cycles of concurrent cisplatin (20 mg/m^2/day) and 5-FU (400 mg/m^2/day) by continuous infusion given over a course of 4 days. In this trial, combined-modality treatment was associated with a significant survival advantage. The differences in the degree of benefit derived from the combined-modality treatment in these two studies may stem from the different staging systems used to define entry criteria (AJCC system in the Lin study versus Ho system in the Chan et al study[100]), different histologic makeup of the tumors (73.2% differentiated nonkeratinizing carcinoma in the Lin study versus 93.7% undifferentiated carcinoma in the Chan study), or different chemotherapy or radiotherapy schedules. The role for concurrent chemotherapy in the management of NPC has been further supported by two other trials comparing concurrent and adjuvant chemotherapy with irradiation alone[101,104] (see Table 34-3).

A meta-analysis of seven endemic Phase III trials of concurrent chemoradiation versus radiotherapy alone, including 1608 patients, demonstrated an OS advantage of the concurrent regimen, with a relative risk of 0.74 at 5 years.[107] This survival advantage is less than that seen in trials from nonendemic regions.

Although the multiple aforementioned trials clearly established the role of concurrent chemoradiotherapy for stage III and IV disease, the role in stage II disease was ambiguous. The study by Chen et al randomized 230 patients with 1992 Chinese Stage II (vast majority AJCC stage II) disease to either radiotherapy alone or concurrent chemoradiotherapy with weekly cisplatin.[108] At a median follow-up of 5 years, the 5-year OS was 94.5% versus 85.8%, (p = 0.007) and PFS was 87.9% versus 77.8% (p = 0.017), both favoring the combined-modality arm. This trial more firmly establishes that patients with stage II disease should also receive combined-modality treatment.

Through the collective experience with cisplatin-based chemotherapy in these as well as other cancer trials, it became apparent that a weekly cisplatin regimen such as that used in the Chan study is better tolerated than the intergroup regimen. Ninety-five percent of the patients assigned to the concurrent chemoradiation arm with weekly cisplatin were compliant with the regimen, whereas only 65% of the patients in the high dose (every 3 weeks) combined treatment arm received all three cycles.

Many additional trials have been performed exploring combination chemotherapy and radiotherapy for NPC.[69,99,103,109] So far, no benefit was shown to neoadjuvant or adjuvant chemotherapy in these trials compared to radiotherapy alone. Likewise, a recent meta-analysis using combined individual data from eight randomized trials enrolling 1753 patients showed no OS benefit with either neoadjuvant or adjuvant chemotherapy, over radiotherapy alone, although a meaningful treatment effect was seen for concurrent chemoradiation.[110] However, the question remains whether addition of induction or adjuvant chemotherapy to concurrent chemoradiation may provide an additional advantage, by reducing the risk of distant metastasis.

A recent Phase III (n = 508) study compared concurrent chemoradiation plus adjuvant chemotherapy versus concurrent chemoradiation alone in patients with locally advanced NPC.[111] All patients received concurrent weekly cisplatin

(40 mg/m^2). Patients were randomized to receive adjuvant chemotherapy after definitive treatment with three cycles of 5-FU and cisplatin (251 patients) while 257 patients were randomized to observation. The 2 year failure-free survival was 86% in the adjuvant group and 84% in the observation group ($p = 0.13$). The authors concluded that there was no benefit to adjuvant chemotherapy. Limitations of this study include the short follow up (median of 37.8 months), the fact that the study was not designed as a noninferiority trial, and the borderline p-value. At present, National Comprehensive Cancer Network (NCCN) guidelines continue to recommend the use of adjuvant chemotherapy; however, its omission is available as a category 2B treatment recommendation. Multiple trials are under way to determine if circulating EBV DNA can be used to better determine which patients are at high risk for distant metastasis and may benefit the most from additional chemotherapy (see "Molecular Biology" section for more details).

Other ongoing trials that are examining induction and adjuvant chemotherapy regimens include a trial by the Nasopharyngeal Cancer Study Group of Hong Kong that is designed to compare induction versus adjuvant chemotherapy with cisplatin and 5-FU in combination with concurrent chemoradiation (NCT00379262). A multicenter Phase III trial opened by the Taiwan National Health Research Institutes is designed to compare a cisplatin-based multiagent induction regimen (mitomycin, epirubicin, cisplatin, 5-FU, and leucovorin) followed by concurrent chemoradiation with chemoradiation alone (NCT00201396). Both of these studies remain open and are near completion at the time of this publication. The potential benefit of sequential chemotherapy must be weighed against the increased morbidity and mortality from additional adjuvant or sequential chemotherapy.[112,113]

In addition to evaluating the best sequencing for chemotherapy and irradiation, investigators are also examining the role for other chemotherapeutic agents in the treatment of NPC. A recent study explored the efficacy of weekly carboplatin in the setting of concurrent chemoradiation for patients with locally advanced disease.[114] At a median time of 26 months, OS and DFS were similar in the cisplatin and carboplatin groups, with less toxicity noted in the latter group. Therefore, treatment with carboplatin is reasonable when use of cisplatin is precluded by patient comorbidities.

Several landmark randomized controlled Phase III studies have demonstrated that the addition of taxanes to induction cisplatin and 5FU in the neoadjuvant setting have the potential to improve outcomes in other head and neck carcinomas.[115,116] Phase II studies of patients with locally advanced NPC have already shown favorable results with paclitaxel, both in the neoadjuvant setting followed by concurrent therapy with platins or as a part of a concurrent regimen.[117-119] However, the DeCIDE and PARADIGM Phase III trials comparing taxane-based induction chemotherapy followed by concurrent chemoradiation, with concurrent chemoradiation alone, have so far failed to demonstrate an advantage to induction chemotherapy (at 2 years).[120,121] However, the relatively low incidence of distant metastases seen in the DeCIDE trial could translate to a survival advantage with longer follow-up. To further address this question, a Phase III trial was opened in 2009 by the international Groupe Oncologie Radiotherapie Tete et Cou (GORTEC), randomizing patients with NPC to receive induction chemotherapy with docetaxel, cisplatin, and 5-FU followed by concurrent chemoradiation with cisplatin or cisplatin-based concurrent chemoradiation alone (NCT00828386). This trial continues to accrue.

Molecular therapies are also under investigation. Although one trial showed a benefit to the use of cetuximab in other head and neck cancers,[122] it remains to be seen whether these data will be confirmed for squamous cell carcinomas of the head and neck in general[123] or for NPC in particular. The RTOG has conducted a 46 patient Phase II trial incorporating the vascular endothelial growth factor (VEGF) inhibitor bevacizumab into the standard chemoradiation regimen, with promising results in terms of distant disease control (90.8% freedom from distant metastases at 2 years).[124] Although there were grade 4 toxicities in nine patients, the treatment protocol was considered feasible.

Altered versus Standard Fractionation with or without Chemotherapy

In the last several decades, alongside trials exploring the role for chemotherapy in the treatment of NPC, other studies aimed to evaluate altered fractionation regimens. Hyperfractionation, accelerated fractionation, and a combination thereof were explored, either alone or in combination with concurrent chemotherapy. As in the trials focusing on chemotherapy, these were based on promising data from other head and neck sites.

A large randomized trial by Sanchiz et al[96] addressing the role of twice-daily versus once-daily irradiation for head and neck cancers included tumors of the nasopharynx. In this study, 892 patients (852 evaluable patients) with advanced head and neck cancers (T3-4N0-3M0 by UICC staging), including 92 patients with NPC, were randomly assigned to once-daily irradiation (group A), twice-daily irradiation (group B), and once-daily irradiation with 5-FU (group C). No differences were seen in median duration of response or OS between groups B and C; however, when either group B or C was compared individually with group A, there were significant improvements in both measures.

An accelerated fractionation regimen using six 2-Gy fractions per week to a total dose of 66 Gy to 68 Gy was compared with a conventional fractionation regimen to the same total dose in a large randomized Danish study of 1476 patients with head and neck cancers (435 patients with pharyngeal tumors, including nasopharyngeal tumors).[125] In this trial, accelerated fractionation resulted in significantly improved locoregional control and disease-specific survival (DSS) but not OS.

The same fractionation scheme, either with or without concurrent chemotherapy, was evaluated in a trial from the Hong Kong Nasopharyngeal Study Group of 189 patients with advanced NPC.[105] Patients were randomly assigned to one of four arms: (1) conventional fractionation alone, (2) accelerated fractionation alone, (3) conventional fractionation with concurrent cisplatin and 5-FU, and (4) accelerated fractionation with concurrent cisplatin and 5-FU. At 2.9 years of follow-up, accelerated fractionation with concurrent chemotherapy (arm 4) achieved the most substantial tumor control, with PFS of 97% versus 70% (arm 1), 63% (arm 2), and 74% (arm 3), without an improvement in OS. A significant increase in acute and late toxicity in the combined chemotherapy–accelerated fractionation arm was also noted.

Based on these and other experiences with altered fractionation schemes in NPC, as well as other head and neck cancers, it became apparent that both the total dose and overall treatment time were important determinants of outcome.[126] With the advent of IMRT, dose escalation (delivery of adequate doses to the gross and subclinical disease) has become possible without concomitant changes in the toxicity profile, significantly improving the therapeutic ratio of concurrent chemoradiation and rendering the above fractionation schemes obsolete.

Intensity-Modulated Radiotherapy with or without Chemotherapy

The proximity of numerous critical structures within the nasopharynx often makes it challenging to provide an adequate

dose to an irregularly shaped tumor while still keeping the dose to surrounding tissues within acceptable limits. Therefore the capacity of IMRT to provide highly conformal and precise coverage with sharp dose gradients has been widely embraced in the head and neck cancer community. In addition, the ability to assign different doses to a desired spatial distribution when using IMRT has allowed for simultaneous delivery of different fractionation schemes to different portions of the target. Multiple institutions both in the United States and the endemic regions have reported improved clinical outcomes since adoption of IMRT techniques for treatment of NPC (Table 34-4).

University of California–San Francisco (UCSF) researchers were the first to report their experience with IMRT in 67 patients with NPC, including 45 patients with stages III to IV disease, treated between 1995 and 2000.[127] Patients were prescribed 59.4 Gy in 1.8-Gy fractions to the planning target volume (PTV) encompassing microscopic and gross disease and typically received 65 Gy to 69.96 Gy to the gross disease and involved lymph nodes in 2.12-Gy to 2.25-Gy fractions. Twenty-six patients also had an intracavitary brachytherapy boost to a total dose of 5 Gy to 7 Gy at the discretion of the treating physician. Patients with advanced disease received concurrent and adjuvant chemotherapy. The reported 4-year estimates of local PFS, locoregional PFS, and OS were 97%, 98%, and 88%, respectively.[127] Long-term xerostomia was minimal at 2 years, with 66% of the patients having no xerostomia and no grade 2 or higher late xerostomia.

Locoregional control rates above 90% have since been noted in other single-institution prospective[128,130,133] and retrospective[132] series, as well as in a recently published multiinstitutional Radiation Therapy Oncology Group (RTOG) 0225 study.[131] Similar to the UCSF regimen, the RTOG 0225 trial used a simultaneous integration of the boost, with 2.12 Gy per fraction delivered to the gross disease with a minimal 5-mm margin (PTV_{70}), while 1.8 Gy was delivered to the subclinical PTV ($PTV_{59.4}$). Therefore, in 33 fractions, the PTV_{70} received a total dose of 69.96 Gy and the $PTV_{59.4}$ received 59.4 Gy. A total dose of 50.4 Gy in 28 fractions was delivered to the supraclavicular nodes using a non-IMRT technique. After a median follow-up of 2.6 years, the estimated 2-year local PFS, locoregional PFS, and OS rates were 92.6%, 89.3%, and 80.2%, respectively. Importantly, while providing similar or better locoregional tumor control in comparison with conventional irradiation techniques, IMRT has resulted in significantly lower rates of late complications. Only nine patients (13.5%) had grade 2 xerostomia at 1 year from the start of IMRT, two patients had grade 3 xerostomia, and none had grade 4 xerostomia. The improved toxicity profile of IMRT compared with conformal radiotherapy in the treatment of NPC has been since confirmed in two prospective randomized trials.[129,134]

LOCALLY RECURRENT OR PERSISTENT DISEASE

In contrast to other head and neck cancers, recurrent NPC can be successfully salvaged in a substantial number of patients. Therefore, aggressive management is usually advocated, and a number of different approaches, including surgery, brachytherapy, and external beam irradiation (EBRT), can be successfully used. Chemotherapy is generally used in combination with local treatment for all patients with advanced disease.

Surgical Management

Surgical resection is the preferred treatment for persistent or recurrent lymph node involvement in the neck. However, surgical management of recurrent NPC at the primary site is hampered by the same factors that make surgery at this site difficult as a primary treatment, such as difficulties in obtaining adequate exposure and surgical margins.[90,135-137] Salvage nasopharyngectomy has been achieved by several different approaches, the most common of which are the transpalatal, transmandibular, and transmaxillary approaches. Minimally invasive techniques, such as a transnasal approach and an endoscopic approach, have also been employed successfully in a select group of patients. The choice of surgical approach is dictated by the tumor size and its location. Generally, surgical treatment of recurrent NPC remains controversial, but it may offer a reasonable disease-free period in certain well-selected cases. Several recent surgical series reported locoregional control and OS of 40% to 72% and 30% to 54%, respectively.[138-141]

Reirradiation

Reirradiation remains the cornerstone of treatment for recurrent NPC within the nasopharynx. Early experiences with reirradiation were often associated with a high risk of late effects, including trismus, stricture, dysphagia requiring gastrostomy, hearing loss, unilateral blindness, cranial neuropathy, temporal lobe necrosis, and endocrinopathies. However, the evolution of radiotherapy techniques that allow for more precise

dose delivery, and imaging techniques that allow for earlier detection and more precise tumor delineation during treatment planning, have significantly improved the therapeutic ratio.

In general, earlier stage at recurrence and longer time to recurrence are associated with better outcomes for reirradiation.[142-144] Higher doses (≥60 Gy) are more effective than lower doses[144] and can be accomplished with EBRT alone or in combination with radiosurgery, or a brachytherapy boost (intracavitary or interstitial treatment).[142,144-147] Lee et al examined 654 patients with recurrent NPC reirradiated between 1976 and 1996 with conventional techniques and some without modern imaging.[142] Of these patients, 82% received external beam alone (median 45.6 Gy), and the other 18% had either brachytherapy or combined treatment. They found a 5-year actuarial local salvage rate of 23%. Investigators from Hong Kong examined 200 patients with local recurrence treated in the modern era (CT/MRI) and found a 3-year OS of 74%, suggesting a significant number of patients could be salvaged.[148] Of these 200 patients, 159 were salvaged with reirradiation, 108/159 with EBRT alone (dose > 60 Gy).

IMRT is particularly well suited for reirradiation, and results with this method are promising. At the Memorial Sloan-Kettering Cancer Center (MSKCC), 29 patients with recurrent NPC were treated with reirradiation between 1996 and 2008, in the era of modern techniques.[149] Sixteen patients received EBRT alone to an average dose of 59.4 Gy and 13 received EBRT to 45 Gy followed by intracavitary brachytherapy to 20 Gy (EBRT-brachy). Twenty-four patients, 14 in the EBRT alone group and 10 in the EBRT-brachy group, underwent IMRT. Choice of radiotherapy technique was at the discretion of the treating physician but was often dictated by the size and location of the recurrence. Thus, the EBRT-brachy group was primarily composed of patients with rT1 or T2 disease (85%), whereas the EBRT group included patients with more advanced disease (31%, rT1 or T2; 69%, rT3 or T4); 93% of the patients received chemotherapy. Five-year local control and OS were 52% and 60%, respectively. Although no significant differences were seen in local control or survival rates between the EBRT-brachy and EBRT groups, the EBRT-brachy approach was associated with fewer late complications (8% rate of grade 3 or greater late effects compared with 73% rate in patients receiving EBRT alone).

Hua et al examined 151 patients with NPC reirradiated with IMRT between 2001 and 2006.[150] They identified a 5-year OS for recurrent stages I, II, III, and IV of 71.4%, 62.9%, 35.5%, and 30.2%. The median reirradiation dose was 70.4 Gy (range 62.1 Gy to 77.6 Gy). Serious late toxicities included 12.6% with a cranial nerve palsy, 13.2% with hearing deficits, and 19.9% with radionecrosis detected by imaging. Qui et al reirradiated 70 patients with IMRT (median dose 70 Gy) between 2003 and 2009.[151] They found 2-year locoregional recurrence-free survival, DFS, and OS of 65.8%, 65.8%, and 67.4%. Significant late toxicity occurred in 35.7% of patients including cranial nerve palsies, posterior nasal space ulceration, and deafness.

Stereotactic radiosurgery (SRS), or stereotactic body radiotherapy (SBRT), treatment of recurrent head and neck lesions is another promising approach because the technique allows for rapid fall-off of the radiation dose outside of the tumor volume and nearby critical structures that surround this anatomic area. SRS has been used to treat recurrent nasopharyngeal lesions after prior irradiation, either alone or in combination with EBRT.[152-154] When used as the only local treatment modality, it is generally reserved for smaller lesions, and doses of 11 Gy to 35 Gy are used.[152,154-156] Fractionated SBRT in the reirradiation setting can provide satisfactory control with an improved late toxicity profile.[157]

Concurrent Chemoradiation

Concurrent chemoradiation is being used increasingly for treatment of recurrent head and neck cancer after primary radiotherapy.[158-161] In general, the late morbidity of these regimens is less severe than would be expected, given that reirradiation doses are comparable to the original radiotherapy doses.[160,161] These reirradiation trials have usually included few nasopharyngeal cases. Historically, reirradiation without chemotherapy, possibly including brachytherapy, has given better results for nasopharyngeal cases than for other head and neck sites.[158] However, given the superiority of chemoradiation over irradiation alone in the treatment of primary NPC, it is reasonable to extrapolate these results to recurrent disease. In fact, most of the recent salvage irradiation series have included concurrent cisplatin-based chemoradiation for advanced-stage recurrent disease (Table 34-5).

IRRADIATION TECHNIQUES AND TOLERANCE

The standard of care for patients treated with definitive radiotherapy per the NCCN guidelines is IMRT, but a brief

description of conventional treatment techniques is provided for historical purposes.

Conventional Irradiation

Treatment Fields

Traditional two-dimensional radiation fields are arranged to cover the possible pathways of spread that account for the previously noted clinical manifestations (Figure 34-3, *A* to *D*). Intergroup study 0099[1] (see Table 34-3) provides a structure for general irradiation guidelines with opposed lateral fields. The borders of this field arrangement are described herein but can be modified on the basis of individual tumor characteristics as discussed in the subsequent section:

1. *Superiorly:* The field margin should be at least 2 cm beyond tumor that is visible on the head CT scan and should include the base of the skull and sphenoid sinus.
2. *Posteriorly:* The field should allow 2 cm of margin beyond the mastoid process. The posterior margin may extend further to allow at least a 1.5-cm margin on enlarged nodes.
3. *Anteriorly:* The field should include the posterior third of the maxillary sinus, posterior ethmoid air cells, and nasal cavity. This anterior border can be modified to accommodate adequate margins (2 cm) for tumors with anterior extension while excluding as much of the oral cavity as possible.
4. *Inferiorly:* The lower field margin is at the thyroid notch (superior to the arytenoids) to allow sparing of the larynx by a central block on the anterior lower neck field, which is matched to these lateral fields.

The lower neck is generally treated with an anterior field with a tapered central larynx block that extends inferiorly to the cricoid. This lower neck field is matched to the lower edge of the lateral fields and, therefore, the larynx block also prevents the spinal cord from receiving an excessive dose. The lower neck field should extend inferiorly to the level of the lower border of the clavicle at the sternoclavicular joint. It is convenient at the level of the match between the upper lateral fields and the lower anteroposterior (AP) v field, to avoid divergence. We often prefer treating the primary site with and high neck with IMRT, and if the low neck is uninvolved with disease, treating it with an AP field.

Field Modifications and Boost Techniques

In addition to the opposed lateral field arrangement described, several other techniques have been used to optimize target dose delivery. For example, patients may initially be treated with opposed lateral fields to the primary site and upper neck, and then continue with a boost reduced off the brainstem and spinal cord to the primary site with either oblique fields, a single central field, or a three-field technique. The use of oblique and smaller opposed lateral fields is generally accepted and has been shown to have acceptable tolerance[40] (see Figure 34-3). Interestingly, the use of three-dimensional conformal techniques to optimize the final or boost portion of treatment has not been shown to lead to a decrease in complications.[165,166]

Brachytherapy

Brachytherapy can be used to deliver a boost to T1 to T2 lesions after EBRT or alone in the setting of reirradiation. Intracavitary and interstitial[167-169] techniques have been used. Multiple applicators have been developed for intracavitary insertions. The Rotterdam Nasopharynx Applicator, developed in The Netherlands, is most commonly used today in conjunction with a remote-controlled high-dose-rate afterloading device[170] (Figure 34-4, *A* and *B*). The device, made out of pliable silicone and shaped to conform to the nasopharynx, is guided into position through the oral cavity. After it is immobilized and dummy sources are inserted, orthogonal radiographs are obtained to define the anatomy for treatment planning (see Figure 34-4, *C* and *D*). Dose is prescribed to a fixed anatomic point. In cases in which brachytherapy is used as a boost for EBRT, 5 Gy to 6 Gy in two fractions 5 to 6 hours apart is generally given. Given the excellent results with IMRT in treatment of NPC, however, many institutions employ brachytherapy almost exclusively for reirradiation.[144,147,171-177]

Permanent interstitial implantation of either iodine-125 (^{125}I) seeds or gold-198 (^{198}Au) grains should be considered for localized lesions and can be accomplished through several approaches, depending on the location of disease.[167,168,178] For lesions in the low- to midposterior wall, transoral or transnasal approaches have been used, whereas a transpalatal approach is favored for lesions in the high posterior wall.[167,168] Alternatively, a split-palate approach can be used.[178]

Intensity-Modulated Radiation Therapy

In the 1970s and 1980s it was becoming clear that advancing technology would make it possible to optimize radiotherapy by deriving the set of optimal incident stationary and moving beams to form a desired dose distribution.[179,180] These techniques deliver a set of beamlets of varying weights, with the

weights chosen to optimally conform the resulting distribution of dose to a target.[181,182] More generally, the optimization can be performed to optimize the biologic or physical objective functions, based on minimizing complications and maximizing tumor control probabilities.[183] The technique of optimizing beam delivery with inverse planning has become known as intensity-modulated radiation therapy (IMRT) for historical reasons, although typically the beam intensity is not modulated.

Target movement places a potential limitation on the applicability of IMRT. Movement during beam delivery could lead to the unintentional overlap of beamlets or possibly to untreated portions of the target volume. For this reason, IMRT is currently used in situations in which motion is minimal or can be controlled for with gating techniques. The head and neck is an area where target motion can be controlled reasonably well with immobilization devices, and for this reason much of the early work on IMRT centered on head and neck cancer. IMRT is particularly applicable to the nasopharynx, in that several critical structures are in close proximity to the target and the incidence of morbidity with conventional radiotherapy techniques is high. Helical tomotherapy, an image-guided IMRT system that was developed from the ideas of CT inventor Andrew Cormack, has shown particular promise with NPC.[184] In the future, intensity modulated proton therapy (IMPT) is likely to surpass x-ray–based technologies as a result of the geometrical advantages of charged particles.[185]

Several institutions have shown a potential dosimetric improvement for IMRT over conventional techniques and three-dimensional conformal techniques in the setting of NPC.[166,186-189] As discussed previously, several single-institution series as well as a Phase II RTOG trial have shown the efficacy of IMRT in the treatment of NPC.[131]

Simulation and Treatment Planning

CT simulation is necessary for IMRT treatment planning. The patient's head, neck, and shoulders are immobilized with a thermoplastic mask with a standard head rest. The head should be hyperextended to allow for maximal separation between the primary nasopharyngeal tumor and lymphatics.[127] At present, MSKCC is exploring the use of an open face mask, to improve tolerability of treatment for patients. A limited CT scan or orthogonal radiographs are obtained to allow for isocenter localization, after which planning CT images are acquired, with contiguous slices of 3 mm or less in the region of the tumor and of 5 mm elsewhere. Some treatment planning systems require equal spacing of slices throughout the entire scan. Alternatively, the CT images can be obtained first and then a treatment isocenter placed within the treatment volume.

IMRT treatment planning requires precise spatial information on the full extent of gross disease and thorough knowledge of the potential sanctuaries of microscopic disease along the lymphatic routes of tumor spread because the therapeutic

TABLE 34-6 IMRT Target Delineation for NPC

PRIMARY TUMOR AND UPPER NECK	
CTV_{70} or gross disease Dose: 2.12 Gy/Fr to 69.96 Gy	GTV Primary tumor All (+) lymph nodes + 5-mm to 10-mm margin (1 mm is acceptable near the brainstem or spinal cord, optic nerve, and chiasm)
$CTV_{59.4}$ or subclinical disease Dose: 1.8 Gy/Fr to 59.4 Gy Can consider 54 Gy in N0 disease	GTV and entire nasopharynx Clivus Base of skull Pterygoid fossae Parapharyngeal space Sphenoid sinus Posterior ⅓ to ½ of nasal cavity Posterior ⅓ of maxillary sinuses Posterior ethmoid sinuses Bilateral cervical lymph nodes: Level Ib-IV for N+ disease Omit level Ib for N0 disease Retropharyngeal lymph nodes

Based on MSKCC guidelines. Expansion is 3 mm to 5 mm for planning tumor volume, except near brainstem or spinal cord, where 1 mm is acceptable.
CTV, *Clinical target volume;* Fr, *fraction(s);* GTV, *gross tumor volume;* Gy, *Gray.*

dose will only be delivered to the designated areas. Therefore, MRI, CT, or PET imaging is instrumental in supplementing the information from clinical examination when delineating the tumor volume. It is recommended that fusion of diagnostic MRI or PET scans to the planning CT is performed to accurately define the gross tumor volume (GTV) and surrounding critical structures. Several clinical target volumes (CTVs) are delineated, $CTV_{gross\ disease}$ and $CTV_{subclinical\ disease}$, which will receive different doses per fraction and total doses (Table 34-6). This practice is known as simultaneous integrated boost or dose painting. In addition, in the absence of low neck lymphadenopathy, a third dose schedule may be administered to the low neck, either with separate AP fields matched to the IMRT plan (split-field technique) or with extension of the IMRT plan (extended whole-field technique). If the extended whole-field technique is used, then a third $CTV_{low\text{-}risk\ subclinical\ disease}$ may be outlined. However, in the presence of any pathologic low neck lymph node, the uninvolved low neck lymph nodes are incorporated into the $CTV_{subclinical\ disease}$.

The primary tumor in the nasopharynx and any cervical or retropharyngeal lymph nodes larger than 1 cm or with evidence of necrosis on imaging are considered $GTV_{gross\ disease}$. $CTV_{gross\ disease}$ is composed of $GTV_{gross\ disease}$ with a 5-mm to 10-mm margin to account for possible microscopic disease (see Table 34-6). A notable exception is near the brainstem or spinal cord, where normal tissue tolerances necessitate that the margin be reduced, sometimes to as little as 1 mm. The $CTV_{subclinical\ disease}$ includes all areas at risk for microscopic spread, including the entire nasopharynx, clivus, base of skull, pterygoid fossae, parapharyngeal space, sphenoid sinus, posterior one third to one half of the nasal cavity, posterior ethmoid sinuses, posterior one third of the maxillary sinuses, and the following lymph node regions: bilateral upper deep jugular (junctional, parapharyngeal), level Ib, level II, level III, level Va, and retropharyngeal nodes. In a patient with no clinically or radiographically detectable cervical lymph node involvement, no coverage of the submandibular region (level Ib) is required. The delineation of cervical lymph node stations on the planning CT scans is based on the published image-based consensus guidelines.[190-193] The PTV is generally a 3-mm to 5-mm expansion of all the CTVs to account for potential setup errors and patient motion. Once again, limiting the margin to 1 mm around the CTV is allowed near the brainstem and spinal cord.

When the split-field technique is used to cover the low-neck lymph node regions (levels IV and Vb), the match is typically placed just above the arytenoids, so that a tapered midline block in the anterior field can be used to shield the larynx.

Dose-limiting critical normal structures that should be outlined on the planning CT include the brainstem, spinal cord, optic nerves and chiasm, parotid glands, pituitary, middle and inner ears, oral cavity, submandibular glands, thyroid gland, brachial plexus, retinas, lenses, cochlea, and larynx.

Treatment Planning and Delivery

Several commercial treatment planning systems are available.[194-197] Inverse planning is generally used to generate a treatment plan. However, in the absence of sufficient experience with inverse planning, forward planning can be used with comparable clinical outcomes.[198] At the MSKCC, IMRT is delivered with the dynamic multileaf collimator system using a sliding-window approach and megavoltage 6-MV or greater x-rays are used. Megavoltage beams with energy above 6 MV should not be used for cervical lymph node irradiation.

Figure 34-5, *B* to *D*, provides an example of an IMRT plan for a patient with NPC treated in the RTOG 0225 trial. Seven coplanar nonopposed fields were used with a 0.5-cm multileaf collimator using the sliding-window technique, optimized with a gradient inverse planning engine. For comparison, a conventional plan for the same patient is also illustrated (see Figure 34-5, *A* to *C*). The conventional ports used for the comparison are shown in Figure 34-6. Considerable sparing of normal tissues, in particular the parotid glands, is achieved with IMRT, and there is better coverage of the base of the skull than can be achieved with lateral fields. Figure 34-7 shows the dose-volume histograms for this case, again comparing conventional technique with IMRT.

Figure 34-8 illustrates the dosimetric coverage that can be obtained with modern IMRT techniques in a sample reirradiation case. This is a situation in which the critical need to spare normal structures makes IMRT essential. Volumetric modulated arc therapy (VMAT)-based radiotherapy techniques may further improve conformality of treatment while simultaneously reducing treatment time, and thus perhaps limiting patient movement during treatment.

Radiotherapy Dose

Based on the early experience with IMRT (see Table 34-4) and the consensus opinion used in and subsequently validated by the RTOG 0225, the prescribed dose to the $PTV_{gross\ disease}$ is 69.96 Gy in 2.12-Gy fractions, the dose to the $PTV_{subclinical\ disease}$ is 59.4 Gy in 1.8-Gy fractions, and the dose to the $PTV_{low\text{-}risk\ subclinical\ disease}$ (if the extended whole-field technique is used) is 54.12 Gy in 1.64-Gy fractions. If the split-field technique is used, the AP fields receive 50.4 Gy in 1.8-Gy fractions or 50 Gy in 25 fractions to a depth of 3 cm in an average sized patient.

See Box 34-1 for normal tissue dose constraints currently used at the MSKCC. The aim of the treatment plan design and optimization process is to deliver the prescribed dose to the target while limiting the dose to normal structures. Strict adherence to the dose constraints for the brainstem, optic structures, and spinal cord is recommended. Limiting the dose to other critical normal structures listed previously is encouraged but should not compromise target coverage. In cases where all treatment planning goals cannot be met, clinical judgment must be used to determine the best compromise. In

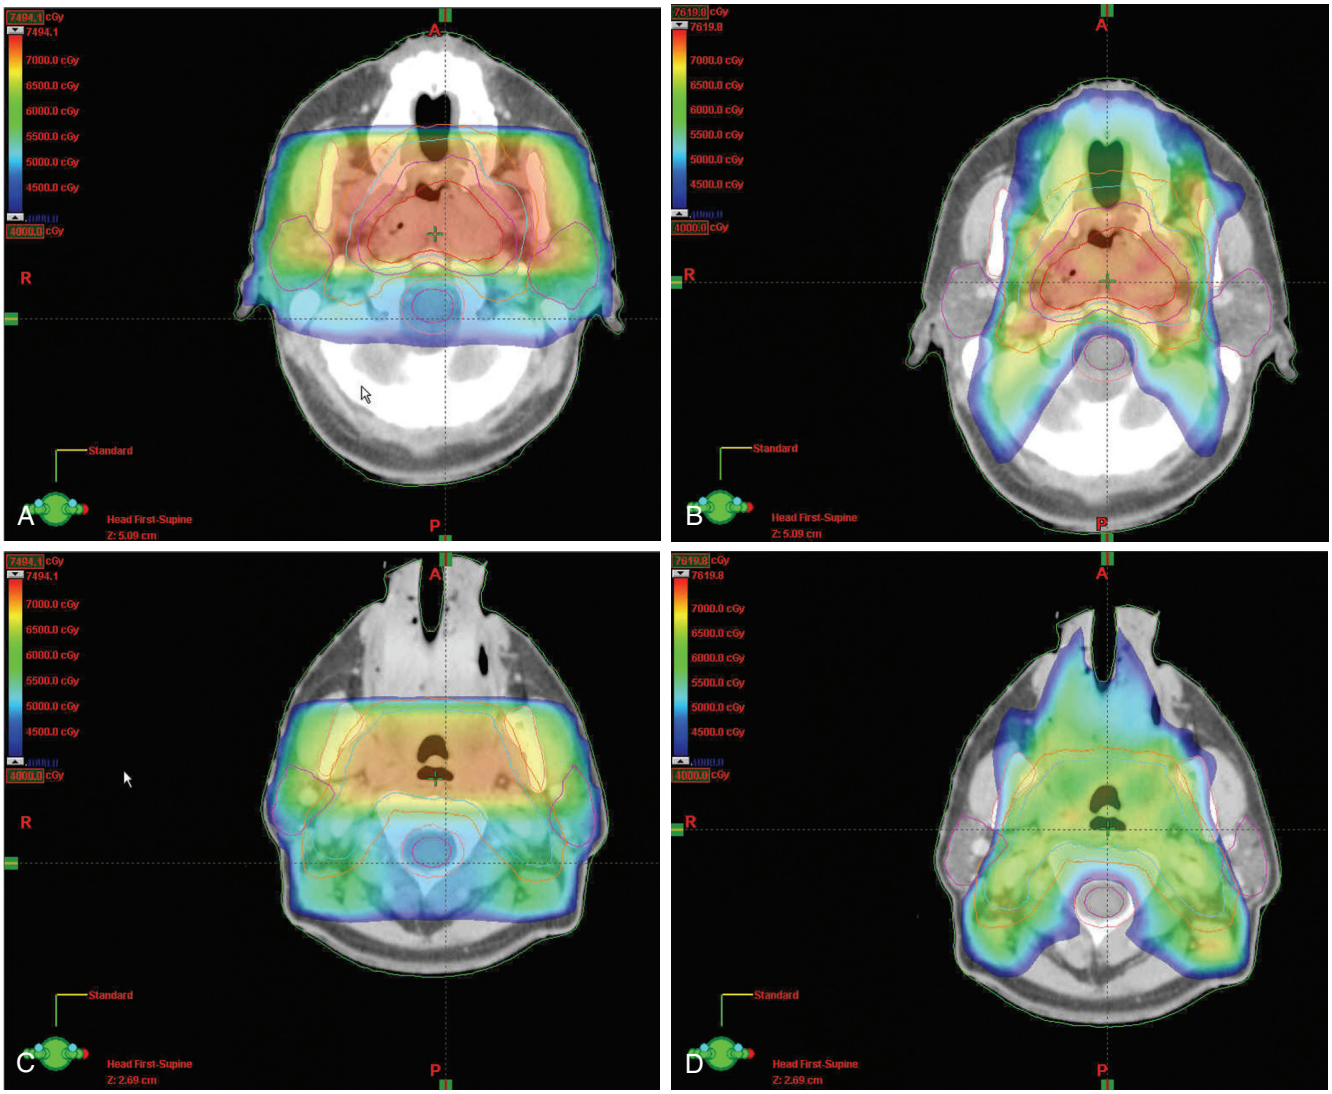

Figure 34-5 Dose colorwash comparison of coverage on a representative patient with stage T2bN0M0 NPC treated in the RTOG 0225 intensity-modulated radiotherapy (IMRT) trial. (For comparison, Figure 34-6 illustrates the conventional lateral ports used.) Computed tomography cuts are shown at the level of the pterygoid plates for conventional technique **(A)** and IMRT **(B)**. The level of the uvula is also shown for conventional radiotherapy **(C)** and IMRT **(D)**. The conventional plan is a composite of comprehensive head and neck fields with a boost to the primary lesion. Sparing of the parotid glands is the primary benefit of IMRT in this case. For the IMRT plan, seven coplanar nonopposed fields were used with a 0.5-cm multileaf collimator using the sliding-window technique, optimized with a gradient inverse planning algorithm.

addition to the listed constraints, no more than 5% of the nontarget tissue can receive more than 70 Gy. The dose constraints for noncritical normal structures listed are only suggestions and should be given the lowest priority in the treatment planning process.

Normal Tissue Tolerance and Complications

Because of the anatomic location and requirement for large treatment fields and high doses, conventional treatment of NPC was associated with complication rates of 31% to 66%[40,93,199] (see Table 34-1). Severe late complications included xerostomia, neck fibrosis, trismus, thyroid and hypothalamic-pituitary dysfunction, soft-tissue and bone necrosis, hearing loss, cranial nerve dysfunction, and transverse radiation myelitis.

The incidence and types of complications of irradiation for NPC at the MDACC between 1954 and 1992 are listed in Table 34-7. The actuarial frequency of grades-3 to -5 complications was 16%, 19%, and 29% at 5, 10, and 20 years, respectively.[32] However, the actuarial frequency of grades- 3 to -5 complications at 10 years decreased steadily over three consecutive time periods included in the study: 1954 to 1971, 14%; 1972 to 1982, 10%; and 1983 to 1992, 5%, respectively. Of nine severe spinal cord injuries, eight occurred in the early time period (1954 to 1971). On univariate analysis, the frequency of moderate-to-severe complications was dependent on treatment technique. The actuarial incidence of moderate-to-severe complications at 10 years was 58% for the single central field technique compared with 12% and 25% for the oblique fields and opposed lateral fields techniques, respectively ($p < 0.001$). It should be noted that patients treated with oblique and opposed lateral fields were treated in more recent periods, and the decreased frequency of complications may also be related to the use of custom blocking and CT treatment planning.

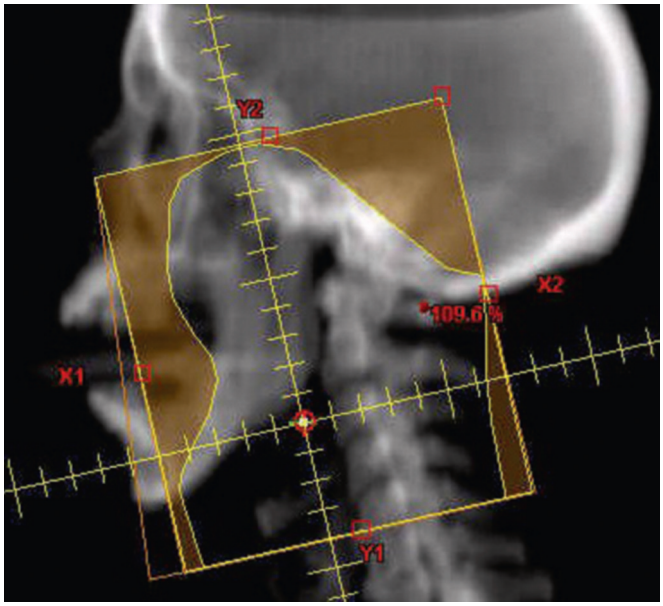

Figure 34-6 Digitally reconstructed radiograph of the conventional ports used in the comparison of intensity-modulated radiotherapy (IMRT) with conventional therapy illustrated (see Figures 34-5 and 34-7). The posterior neck was blocked and treated with electrons at 40 Gy, and the boost treated the primary tumor with margins using 15-MV photons.

RTOG, *Radiation Therapy Oncology Group.*

The use of conformal techniques for the final boost portion of radiotherapy could potentially decrease the risk of complications, but this has not been shown to be the case. Conformal techniques are associated with a 25% incidence of grades-3 to -4 morbidity, including hearing loss, trismus, dysphagia, chronic sinusitis, and cranial neuropathy.[165] This result has led to an interest in delivering the full course of therapy with IMRT.[127,165,166,200]

Xerostomia is the most common toxicity associated with conventional therapy and may lead to dental caries. Strict dental hygiene and prophylactic fluoride treatment should be instituted to guard against dental decay. The use of IMRT allows for improved preservation and faster recovery of parotid gland function.[127,129,130,134]

BOX 34-1 Normal Organ/Tissue Dose Constraints, MSKCC

Critical organ/tissue; dose constraint at MSKCC	
Brainstem	D_{max} = 54 Gy or 60 Gy to 1% of the volume
Optic nerves	D_{max} = 54 Gy or 60 Gy to 1% of the volume
Optic chiasm	D_{max} = 54 Gy or 60 Gy to 1% of the volume
Spinal cord	D_{max} = 45 Gy or 50 Gy to 1% of the volume
Temporal lobes	D_{max} = 60 Gy or 65 Gy to 1% of the volume
Mandible and TM joint	D_{max} = 70 Gy or 75 Gy to 1 cc of the volume
Noncritical	
Parotid glands	D_{mean} = 26 Gy (in at least one gland)
Submandibular glands	As low as possible
Oral cavity	D_{mean} = 40 Gy
Larynx	D_{mean} = 40 to 45 Gy or D_{max} = 70 Gy or = 105% of prescription
Cochlea	D_{max} = 50 Gy
Retinas (globes)	D_{max} = 45 Gy
Lenses	D_{max} = 5 Gy
Brachial plexus	D_{max} = 65 Gy and D05 D_{max} = 70 Gy

MSKCC, *Memorial Sloan Kettering Cancer Center.*

Functional hearing loss was reported in up to 8% of patients treated with conventional technique, and at least 30% of those evaluated with audiograms showed a high-frequency sensorineural hearing loss.[199,201,202] This radiation sequel may also be negatively affected by concurrent treatment with ototoxic chemotherapy. Dose-dependent cochlear damage is the likely mechanism of radiation-induced ototoxicity and can be minimized by keeping the mean dose to the cochlea below 48 Gy to 50 Gy.[201,202] Lowering the dose to the external auditory canal also reduces the incidence and severity of acute external otitis. Excluding the mastoid air cells reduces the incidence and severity of chronic serous otitis media. Unfortunately, given the location of the primary tumor in the nasopharynx, chronic eustachian tube dysfunction is unavoidable.

When treating lesions with base-of-skull involvement, it is important to consider the potential for optic neuropathy. A University of Florida review of 106 patients receiving treatment encompassing the optic nerves reported that patients who received more than 60 Gy and daily fractions of more than 1.9 Gy had a 47% incidence of optic nerve injury, compared with 11% for patients treated with daily fractions of less than 1.9 Gy.[203]

Clinically significant endocrine dysfunction has been described in 5% to 10% of patients.[40,199] Given the availability of pharmacologic treatment, one should have a low threshold for evaluating long-term survivors for the presence of hypothalamic-pituitary or thyroid endocrinopathies. Routine evaluation of survivors with serum sodium, cortisol, thyroid-stimulating hormone (TSH), follicle-stimulating hormone, luteinizing hormone, and testosterone levels may be considered.

TREATMENT ALGORITHM, CONCLUSIONS, AND FUTURE POSSIBILITIES

A preferred treatment algorithm for patients with NPC is illustrated in Figure 34-9. With early-stage disease, irradiation

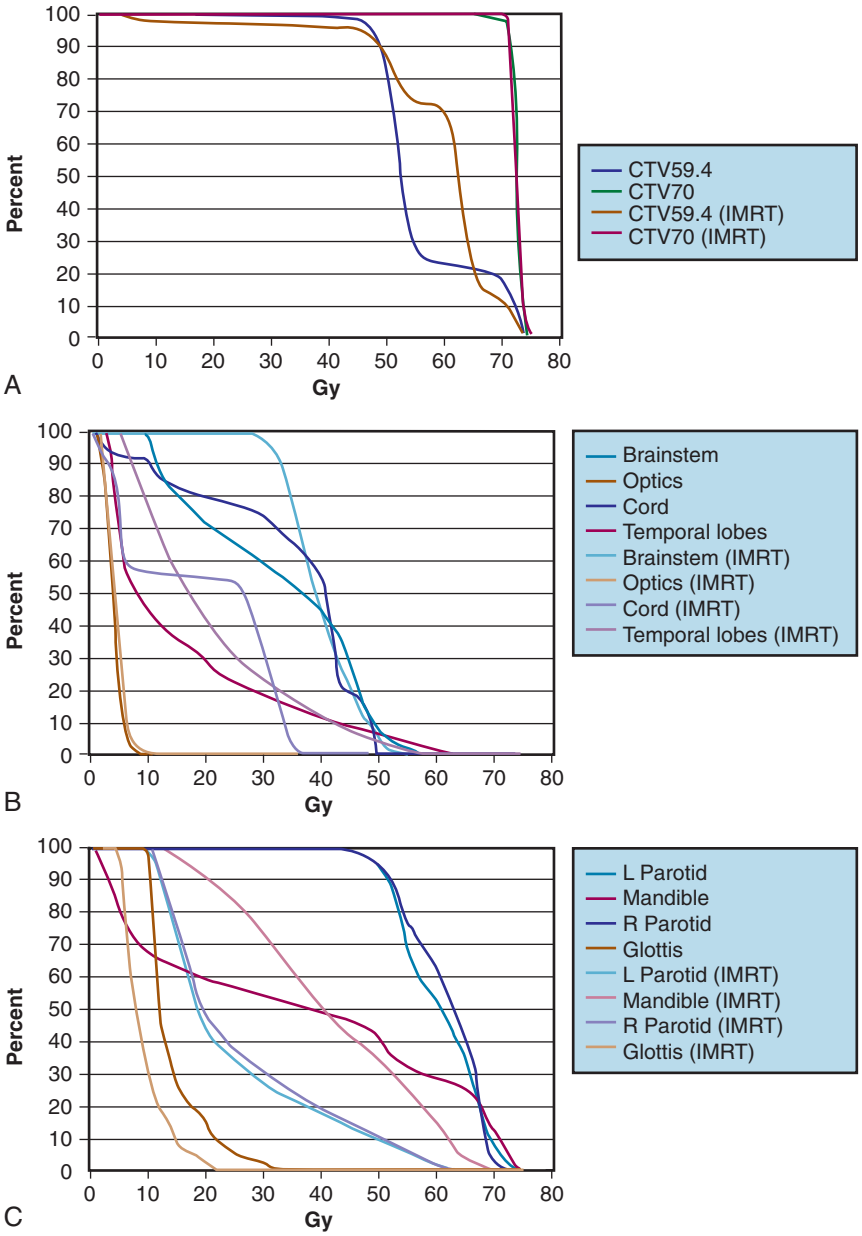

Figure 34-7 Dose-volume histograms (DVHs) for the patient in Figures 34-5 and 34-6, comparing intensity-modulated radiotherapy (IMRT) with conventional technique. Substantial gains can be made with IMRT in terms of target coverage and normal tissue sparing. **A,** Target coverage. Differences in the $CTV_{59.4}$ (clinical target volume to be covered by 59.4 Gy) target coverage reflect the relatively high dose given to subclinical risk areas per RTOG 0225, with much of this target volume being intentionally prescribed a dose of 50.4 Gy in the conventional plan. Also, a conventional anterior low-neck field was used in the IMRT plan, with a midline block over the spinal cord and larynx in that region, which blocked a portion of the $CTV_{59.4}$, a portion that was not included in the optimization but was included in the DVH. The DVHs for central nervous system (CNS) structures **(B)** and other normal structures **(C)** are also shown. Greater relative sparing of CNS structures by IMRT would be seen for higher-stage patients.

alone with once-daily fractionation generally yields excellent local control results. For locally advanced disease (nonmetastatic stage ≥T2 or ≥N1 in the current AJCC staging system), concomitant chemotherapy and radiotherapy results are encouraging, and entry of patients into further trials testing combined-modality treatment is indicated. Advancements in radiotherapy optimization and integration of functional imaging with radiotherapy planning both show promise for improvements in tumor control and decreased morbidity of treatment.

Because the rate of distant metastasis remains high in NPC, we continue to recommend adjuvant chemotherapy for most patients. Identifying which patients may benefit from adjuvant chemotherapy with the use of posttreatment circulating EBV DNA remains an area of active investigation. In the future, this may allow better selection of patients who require adjuvant chemotherapy and those that can be spared additional treatment. In addition the optimal combination of chemotherapeutics to serve as adjuvant therapy also remains to be determined.

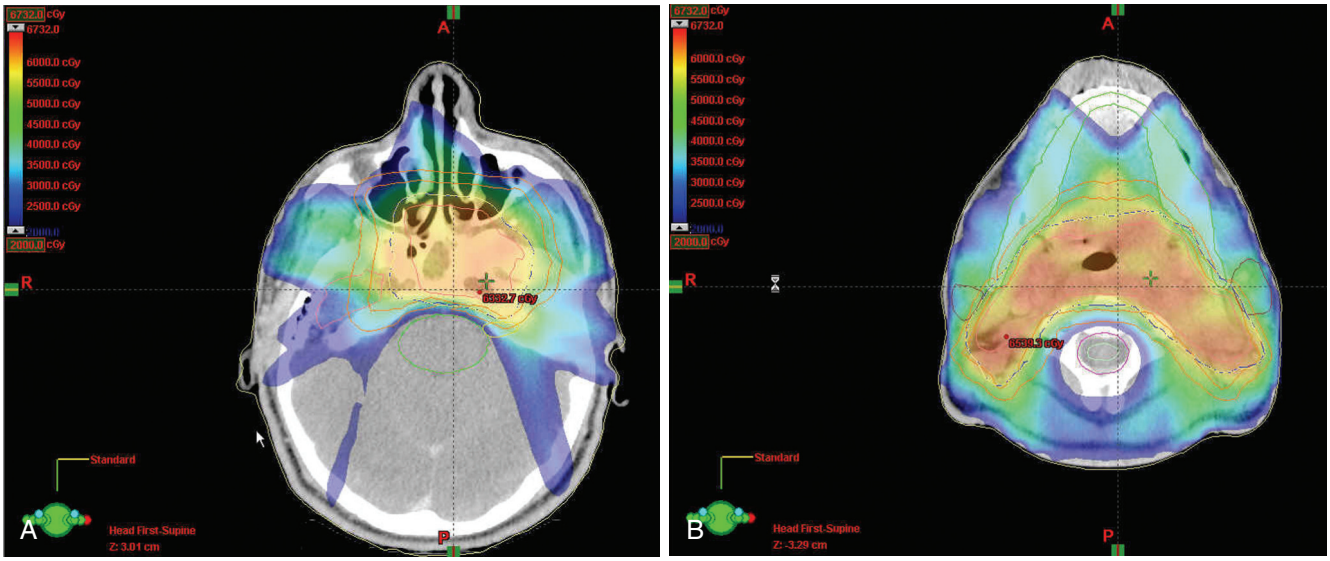

Figure 34-8 Dose colorwash illustrating radiotherapy coverage near the base of the skull for a case of recurrent NPC, in which intensity-modulated radiotherapy (IMRT) was used to minimize reirradiation risk to normal structures. Colorwash ranges between 20 Gy and maximum dose. **A,** The tolerance of the brainstem and temporal lobes places constraints on the dosimetry of the base of the skull. **B,** The mandible and spinal cord tolerance constraints the neck coverage. The IMRT technique used was similar to that in another case (see Figures 34-5 and 34-6) but with nine coplanar nonopposed fields.

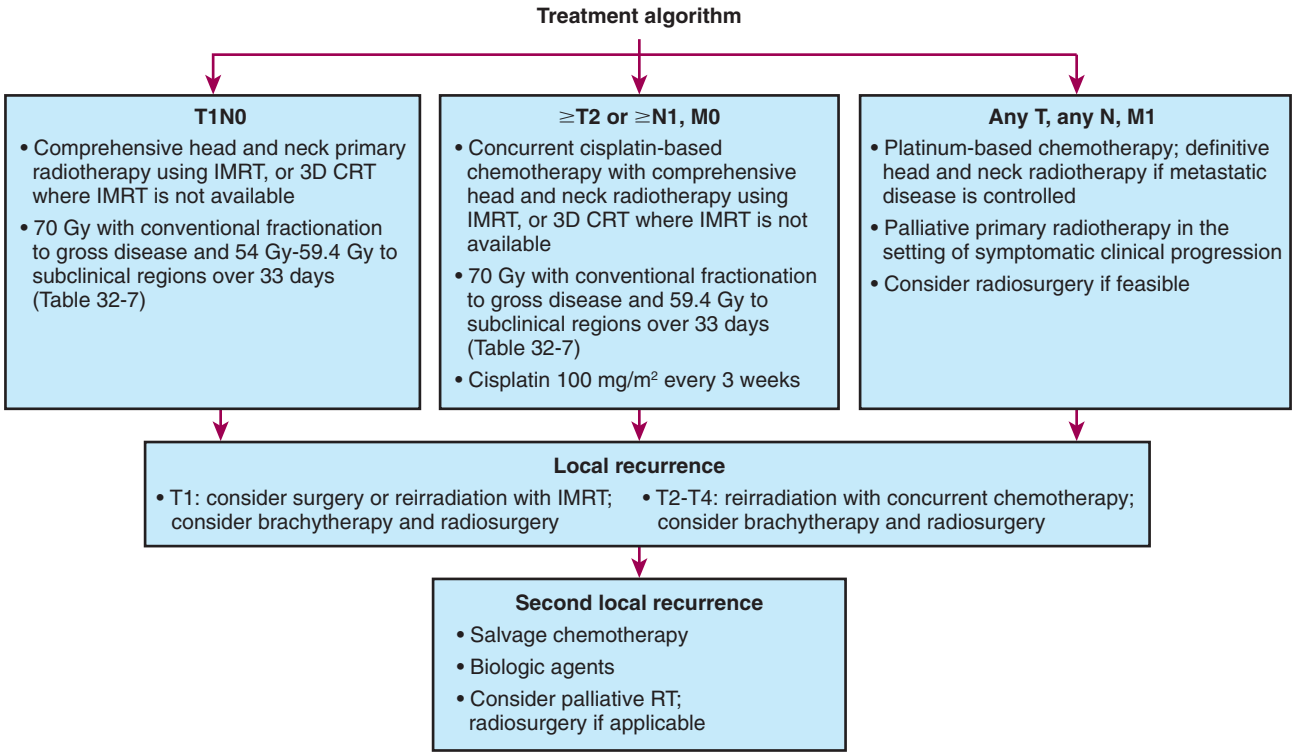

Figure 34-9 Treatment algorithm for NPC based on the AJCC, 7th edition staging system. Some patients with disease classified as stage II would have had stage III or IV disease when many of the chemoradiation trials were performed and are therefore included as having locally advanced disease. Intensity-modulated radiotherapy (IMRT) is generally recommended if available. In the case of local failure, reirradiation is a consideration if the time to recurrence exceeds 6 months. In elderly patients or in patients with multiple medical problems or poor performance status, concurrent chemotherapy should be used with caution. Such patients are not well represented in clinical trials, and meta-analysis of chemoradiation trials suggests less clinical benefit from chemotherapy. *5-FU,* 5-Fluorouracil; *MRI,* magnetic resonance imaging; *PET,* positron emission tomography; *WHO,* World Health Organization.

CHAPTER

35 Larynx and Hypopharynx Cancer

Adam S. Garden, Beth M. Beadle, and William H. Morrison

INCIDENCE

Larynx and hypopharynx cancers account for about one third of all head and neck neoplasms, affecting about 15,000 Americans per year.

BIOLOGIC CHARACTERISTICS

Prognosis for all tumors is primarily dependent on extent of disease, although it is also influenced by the anatomic site of origin.

Glottic tumors have the lowest incidence of metastases because they more commonly present with earlier-stage lesions and the true cords do not have a rich lymphatic supply compared with supraglottic and hypopharyngeal neoplasms. Hypopharyngeal cancers have a relatively high metastatic rate among head and neck cancers.

STAGING EVALUATION

Staging includes history, complete head and neck examination including indirect and direct laryngoscopy, contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI) of the head and neck region, blood chemistry, and chest radiography.

PRIMARY THERAPY

Early-stage disease can be treated with a single modality, either surgery or radiation therapy (RT). Reported cure rates range from 65% to 95% and depend primarily on the bulk of disease.

ADJUVANT THERAPY

High cure rates have not justified adjuvant therapies for early-stage disease.

Chemoprevention remains an area of active research for this group at high risk for second primary tumors.

LOCALLY ADVANCED DISEASE

The concept of larynx preservation has been validated as an option for patients with T3 disease.

Concurrent chemoradiation has been demonstrated to improve the larynx preservation rate compared with irradiation alone or treatment with neoadjuvant chemotherapy; the latter does not compromise survival compared with laryngectomy. Approximate 5-year survival rates for these patients are 50% to 55%.

For elderly patients in whom the toxicity of chemotherapy is a concern, irradiation alone is a valid alternative for patients desiring larynx preservation. Altered fractionation may be employed in these cases to improve locoregional control.

Surgery remains the mainstay for advanced, but resectable disease (category T4a), with adjuvant postoperative RT used for patients at high risk for local regional failure.

Concurrent chemoradiation is advocated for patients with inadequate margins or extranodal or soft-tissue disease extension. Local control rates for this group range from 60% to 90%, but 5-year survival rates are between 20% and 40%.

PALLIATION

Palliative therapies are dependent on prior therapies received and disease location and extent. RT, chemotherapy, and surgery are all used but are individualized.

Management of cancers of the larynx is a special challenge for head and neck oncologists. Laryngeal cancer, even in locally advanced stages, has a relatively high cure rate if managed appropriately. Because of this factor, it has become the paradigm for the concept of organ preservation in oncologic patient management. Curing the patient is not the only consideration in the management of this disease. Voice preservation and avoidance of tracheal stoma are important priorities.

In previous decades, surgery, RT, or a combination of the two therapies were used and individualized to best meet these endpoints. Both modalities have improved in eradicating the disease and preserving function over the years. Newer, more technically sophisticated voice-conserving surgical procedures have been developed. Similarly, radiation oncologists have grown in their understanding of the influences of dose, treatment duration, and target volumes to improve the results in managing these diseases. Important improvements in defining disease extent, by both physical examination with fiberoptic laryngoscopy and radiologic images obtained with CT MRI, have allowed for better selection of the appropriate therapy for an individual patient. Systemic therapies have been incorporated into the management of these diseases, thus increasing the options in trying to cure patients with this disease while maintaining function.

Carcinomas of the hypopharynx are often considered together with carcinomas of the larynx, because the anatomy of the hypopharynx is essentially created by the location of the voice box in the throat. Hypopharyngeal tumors frequently involve the larynx and vice versa. In these situations, it is one's best guess whether the epicenter of a large tumor is laryngeal or hypopharyngeal. It is therefore not unexpected that the concept of voice preservation also applies to the management of cancers of the hypopharynx. The pharynx is also involved in deglutition, and issues of preservation of swallowing are also important in the management of these tumors.

Although affecting the area immediately adjacent to the larynx and thus having similar management concerns to laryngeal carcinoma, hypopharyngeal cancers typically have different natural histories compared with cancers arising in the larynx. At diagnosis, hypopharyngeal tumors have much

higher rates of spread beyond the primary tumor; thus, even with successful local treatment, survival rates tend to be worse than other cancers of the head and neck.

Primary tumors of the hypopharynx also tend to present in locally advanced stages. However, local therapies have improved in recent years. Surgical grafting techniques have been developed to replace the resected pharyngeal tissues and allow the patient a better swallowing mechanism. Without these techniques, larger hypopharyngeal lesions would be unresectable. Improved control with altered RT schedules may allow preservation of the larynx and pharynx for intermediate-stage lesions. Adding systemic agents may also allow for organ preservation and help with the problem of distant disease prevalent in cancers of this site.

EPIDEMIOLOGY AND ETIOLOGY

Laryngeal cancer occurs in roughly 12,000 Americans per year, accounting for approximately one fourth to one third of all head and neck cancer cases. However, mortality resulting from cancers of the larynx is relatively low, accounting for approximately 4200 deaths per year in the United States.

The median age of patients presenting with larynx cancer is 65 years. Less than 4% of patients are younger than 45 years old. Laryngeal cancer remains predominantly a disease affecting men. The most recent data from the Surveillance, Epidemiology, and End Results (SEER) program (2003-2007)[1] estimated an overall incidence of 3.4 cases per 100,000 people per year, a slight decrease of 0.4 cases per 100,000 compared with the previous 5 years of data.[2] Comparisons reveal case incidences of 6.1 versus 1.3 in males and females, respectively. There is a higher incidence among blacks than among whites for both men and women.

Tobacco use is strongly associated with the development of cancer of the larynx, with the highest risk among active heavy smokers and an intermediate risk among ex-smokers.[3,4] More than 95% of patients with laryngeal cancer have a history of tobacco use.[5] Cigar and pipe smoking have also been associated with cancer of the larynx,[4] but studies on this issue have been more controversial.[3,6,7] In the years between 1965 and 2004, rates of cigarette smoking by adults in the United States were halved (42% to 21%); from 2005 to 2010, there was a less dramatic decrease in the rates of smoking (20.9% to 19.3%).[8] Given the correlation between smoking and the development of larynx cancer, these reductions would be expected to translate into a lower incidence of larynx cancer. Indeed, there have been statistically significant reductions in the age-adjusted incidence rates for glottic and supraglottic cancers, as measured from 1973 to 2003.[9]

Alcohol use is also associated with laryngeal cancer but is believed to act synergistically with tobacco rather than independently. It is unusual to see laryngeal cancer in nonsmoking patients with alcohol abuse histories.[7] A history of heavy alcohol use is more strongly associated with supraglottic and hypopharyngeal cancers.[4,10] Likewise, occupational exposures to asbestos,[4,11,12] mustard gas, nickel, soot, and tars have been linked to laryngeal cancer, but generally a tobacco use history is also present.[13] Several authors have evaluated the influence of diet on the development of larynx cancer and have found, while controlling for tobacco and alcohol use, a higher incidence among patients with vitamin- and nutrient-deficient diets.[6,14,15]

Attention has been directed at the influence of gastroesophageal reflux disease (GERD) on laryngeal diseases, including carcinomas. Three separate studies[16-18] have described cohorts of nonsmoking patients with GERD and larynx cancer. Bacciu et al[19] compared 36 consecutive patients with no history of tobacco and alcohol consumption who developed laryngeal carcinoma to a group of 125 lifetime nonsmokers who were cancer free. They found a much higher prevalence of GERD among the patients with laryngeal cancer. It is believed that chronic irritation on the larynx from acid may predispose these patients to cancer. It is thought that if this cancer is seen in nonsmokers, the influence of GERD on the development of laryngeal cancer in smokers and alcohol users (who are at higher risk for GERD) may be significant.

Human papillomavirus (HPV) has been causally linked to multiple cancers, including head and neck cancers,[20,21] particularly cancers of the tonsil. HPV has also been demonstrated to be associated with laryngeal cancers, although studies are, in general, retrospective, and the reported prevalence rates vary widely. The evidence for HPV having a role in laryngeal cancer is less obvious than in other malignancies, and its interaction with other carcinogens such as tobacco is unclear. As in cervical cancer in women and tonsillar cancer, HPV-16 is the most common type noted.

Hypopharyngeal cancers are less common than laryngeal tumors. The estimated incidence in the United States is 2500 cases per year. Etiologic risk factors are similar to those for laryngeal tumors,[14] with a predominance among men and older individuals. This type of cancer is closely linked to tobacco and alcohol use, and the ties to heavy alcohol use seem stronger than those for laryngeal cancer.

PREVENTION AND EARLY DETECTION

Prevention

The primary preventive methods taken to eliminate malignancies of the upper aerodigestive tract have come from public awareness that tobacco and alcohol are the major causative agents of these cancers. National public health measures have been directed at diminishing the prevalence of smoking and drinking. A by-product of these policies may be a decline in the incidence of laryngeal and hypopharyngeal carcinomas. The most recent SEER data have identified a decrease in the incidence of larynx cancer over the past two decades (1988-2007).[1] The annual percentage decrease over this time period is 2.6%.

Although government policies have been directed at diminishing carcinogenic etiologic agents for the general population, investigators have tried to identify high-risk groups in whom more direct measures can be taken. The major group identified consists of patients who have been cured of a cancer of the upper aerodigestive tract,[22-25] particularly patients who have smoking or alcohol use histories.[26] The incidence of second primary cancers of the upper aerodigestive tract ranges from 10% to 30%. The locations of these second cancers are evenly divided between the lungs, esophagus, and head and neck mucosal sites, including the larynx and hypopharynx.[26]

The high incidence of new cancers in this patient population has led investigators to develop programs designed to diminish the occurrence of second primary tumors. Hong et al[27] studied 13-*cis*-retinoic acid as a possible agent to prevent new cancers in patients with a history of head and neck malignancy. A randomized trial showed a 14% versus 31% incidence of second primary tumors in patients who received a relatively high dose of 13-*cis*-retinoic acid versus placebo.[28] In 2002, the Radiation Therapy Oncology Group (RTOG) completed accrual to a trial testing chemoprevention with 13-*cis*-retinoic acid in a multiinstitutional setting.[29] Nearly 1400 patients with stage I or II cancer were accrued. The dose of 13-*cis*-retinoic acid was lower than that used by Hong et al to ensure more compliance and less side effects. Unfortunately, the RTOG trial was negative and did not show any benefit to low-dose isotretinoin in the prevention of second primary cancers. The RTOG study did show that the continuation of smoking had adverse

effects on outcome and those who smoked were more likely to develop second cancers.

Papadimitralopoulou et al[30,31] investigated α-tocopherol, interferon-alfa, and isotretinoin in patients with laryngeal dysplasia and reported a 50% complete response rate at 12 months. The current thinking is that these agents may delay or prevent subclinical cancer from manifesting as clinical disease but are less likely to prevent cellular transformation. This three-drug combination was subsequently tested in a randomized trial adding a maintenance phase for non-progressors.[32] The drugs had only modest activity, and more than one third of patients developed cancer. The authors did find that cyclin D1 genotype and protein expression were risk markers for laryngeal cancer and suggested future trials target upstream regulators of *CD1* transcription.

New compounds for chemoprevention are currently being investigated. These include green tea extracts, curcumin analogs, soybeans, celecoxib, erlotinib, and rapamycin. These agents are being tested in coordination with efforts to identify molecular prognostic markers. Once these markers are identified, ideally they will be incorporated into randomized clinical trials by using these markers for risk stratification purposes.

Early Detection

Similar to the issues surrounding prevention, early detection of laryngeal and hypopharyngeal cancers centers on targeting the population at highest risk for developing these carcinomas. Cancers of the larynx and hypopharynx affect roughly 15,000 Americans a year and therefore is not considered a large enough health problem to warrant screening of the general population. Some investigators have studied the role of screening a more focused population, such as tobacco users who work at high-risk occupations, and question the value of screening even a more limited population.[33] However, Prout et al[34] argue that a primary care practitioner can, as part of a general evaluation, inquire about hoarseness in a patient from an at-risk population. If a positive response is obtained, the patient can be referred to an otolaryngologist for appropriate evaluations. The laryngeal carcinoma detection rate in this situation ranges between 3% and 4%.[34,35]

PATHOLOGY AND PATHWAYS OF SPREAD

Pathology

The majority of laryngeal and hypopharyngeal cancers are squamous cell carcinomas. Laryngeal carcinomas are usually well differentiated. Because patients with laryngeal tumors often present with early-stage disease, it is common to see a spectrum of pathologic tissue changes, ranging from premalignant atypia or dysplasia to carcinoma in situ and superficially invasive carcinomas, within the larynx.

Carcinoma in situ is a pathologic entity representing carcinomatous changes confined to the thickened epithelium without breaching the lamina propria. The clinical appearance of carcinoma in situ is a white or grayish white thickening of the mucosa. Penetration through the lamina propria makes the diagnosis of invasive carcinoma. Invasive tumor may be missed if biopsy samples are too small or too superficial for proper histologic evaluation.

Less frequently, the larynx and hypopharynx can give rise to variants of squamous cell carcinoma. The most common of these cancers is verrucous carcinoma, accounting for approximately 4% of all larynx cancers.[36] These are classically slow-growing tumors with a gross warty appearance. A less common variant with numerous nomenclatures is squamous cell carcinoma with spindle cell features. As its name implies, along with typical squamous cells, carcinoma cells are spindle cells. The significance of these spindle cells is the subject of debate, because theories range from these cells being a benign reactionary process with little clinical significance to highly malignant elements with adverse outcome.[37] Molecular evidence suggests the sarcomatoid carcinoma evolves from the conventional epithelium-type component and the sarcomatoid component has a malignant nature.[38] Grossly, they can often present as large polypoid lesions that sometimes act as ball valves in the larynx. Basaloid squamous cell carcinoma and lymphoepithelioma of non-nasopharyngeal origin are rare tumors seen in numerous head and neck mucosal sites, including the larynx and hypopharynx.

The remaining 5% of larynx cancers are composed of neoplasms more commonly found in other locations. Salivary gland cancers, neuroendocrine tumors[39] (including small cell carcinomas), sarcomas, and lymphomas have all been reported in the literature.[40]

Pathways of Spread

Primary Site and Regional Lymphatics

Larynx

The larynx is divided into three regions: the supraglottis, glottis, and subglottis. The supraglottic larynx lies above the level where the mucosa of the upper surface of the true vocal cords turns upward to form the lateral wall of the ventricle. It consists of the false vocal cords, arytenoids, aryepiglottic folds, and infrahyoid and suprahyoid epiglottis. The glottic region by definition includes the true vocal cords and extends 0.5 cm inferiorly, and the subglottic region extends from there to the superior aspect of the trachea (Figure 35-1).

Primary glottic cancers are about three times more common than supraglottic carcinomas, whereas subglottic carcinomas are extremely rare (about 2% of larynx cancers). At diagnosis, nearly two thirds of patients with laryngeal cancer have their disease confined to the laryngeal structures and less than 10% present with distant metastases. The patterns of spread, presentations, and management of cancers arising from these three subsites are different.

Glottis. Most glottic lesions arise on the free margin and upper surface of the anterior two thirds of the true cord. These

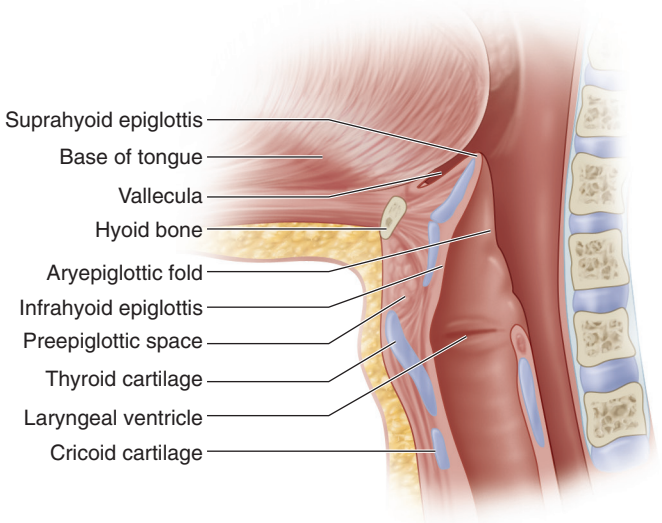

Figure 35-1 Anatomy of the larynx and its subdivisions.

tumors tend to grow slowly and remain confined to the mucosa of the true cords. Eventually they will spread superiorly or inferiorly onto the mucosa of the supraglottic or subglottic structures. Some tumors may grow outward, in an exophytic fashion, leading to voice changes and subsequently respiratory obstruction. Invasion into the intrinsic musculature and joints of the larynx decreases vocal cord mobility and ultimately causes vocal cord fixation. Noteworthy is that tumor bulk alone can cause impaired mobility. Less commonly, infiltration of the recurrent laryngeal nerve may also cause impairment of mobility.

Infiltrative tumors will breach into the paraglottic and preepiglottic spaces. These spaces lie between the external frame of the larynx (thyroid-cricoid cartilages and hyoid bone) and the internal components of the larynx (epiglottis, muscles, and ligaments) and are filled with fat and hence offer little resistance to infiltration. From these spaces, infiltrative tumors may break through ligaments above or below the thyroid cartilage into the neck or may invade the cartilage directly.

The mucosa of the true vocal cords has a sparse lymphatic supply. Thus, glottic carcinomas have a low propensity for lymphatic spread. The incidence of lymphadenopathy at diagnosis is approximately 5% for T1 and T2 lesions and approximately 20% for T3 and T4 tumors.[41] The frequency of occult nodal involvement is also low. Byers et al[42] found microscopic nodal involvement in 9 of 57 patients who underwent elective nodal dissection for T3 or T4 vocal cord lesions; most frequently involved nodes were the upper jugular (level II), midjugular (level III), and paratracheal groups (level VI).

Supraglottis. There are some variations of growth patterns within subsites of the supraglottic larynx. Suprahyoid epiglottic tumors sometimes grow in an exophytic pattern off the tip of the epiglottis, causing no symptoms until they become quite large. At other times they spread inferiorly, infiltrating and eroding the epiglottis. These lesions can eventually autoamputate the tip of the epiglottis. Complete regression of these tumors after RT may leave only a small epiglottic stump. Such an anatomic aberration increases the risk for aspiration.

Infrahyoid epiglottic lesions tend to spread anteriorly or circumferentially. They can invade directly through the base of the epiglottis into the preepiglottic space, spread onto the lingual epiglottis, and subsequently invade the vallecula, pharyngoepiglottic folds, and tongue base. At other times, they spread onto the aryepiglottic folds, usually spreading from their midline position in both directions to involve both folds, producing a horseshoe-like appearance. They then spread either inferiorly onto the false vocal cords or over the aryepiglottic folds into the piriform sinuses.

Lesions originating on the aryepiglottic folds can spread in all directions, that is, anteromedially onto the epiglottis, posteriorly to the arytenoids, inferiorly to the false cords, or laterally into the piriform sinus. Similar to lesions of the false vocal cords, they have variable growth patterns but often are infiltrative with easy access to the paraglottic space. They can frequently involve the cricoarytenoid joints or the musculature of the larynx, impairing mobility.

The primary difference between supraglottic cancers and true glottic cancers is the likelihood of developing cervical nodal metastases. At diagnosis, 55% of patients with supraglottic cancers have clinically involved lymph nodes. Lymphatic vessels in the supraglottic larynx collect in channels that pass through the piriform sinuses to drain to nodes along the jugular chain, particularly the upper (level II) and midjugular (level III) lymph nodes. Lee et al[43] reported on the data of a subgroup of patients with intermediate-stage disease who underwent supraglottic laryngectomy with neck dissections. One third of patients had palpable nodes on presentation, and nearly an additional third of patients had pathologic nodal involvement.

Subglottis. Subglottic tumors spread inferiorly to the trachea, extend through the cricothyroid membrane into the neck, or directly invade the cricoid cartilage. Superiorly, they almost always involve the undersurface of the true glottis; from a staging perspective, it is sometimes difficult to differentiate between a tumor truly originating from the subglottis and a glottic tumor with significant subglottic extension.

Primary subglottic tumors drain to the paratracheal nodes (levels VI and VII). The jugular nodes (levels II, III, and IV) are a secondary echelon and are rarely involved in the absence of metastases to the paratracheal nodes. Because of the rarity of subglottic tumors, the true incidence of involvement of nodes is difficult to determine, with estimates varying from <5% to 25%.[44]

Hypopharynx

The hypopharynx is the inferior portion of the three divisions of the pharynx (Figure 35-2). It extends from the hyoid bone superiorly to the cricoid inferiorly. Valleculae, pharyngoepiglottic fold, and lateral projections of aryepiglottic folds are considered the superior border separating the hypopharynx from oropharynx. Inferiorly, the hypopharynx ends at the cervical esophageal inlet. The hypopharynx is subdivided into three components: the pharyngeal walls, the piriform sinus, and the postcricoid pharynx. The hypopharyngeal walls are a continuation of the lateral and posterior oropharyngeal walls. The pair of piriform sinuses is created by the invagination of the larynx into the hypopharynx. They are conical (more truly pear shaped, hence the derivation of its name). Each sinus (or recess) consists of three walls. The medial wall is essentially the lateral aspect of the larynx; superiorly, it becomes the aryepiglottic fold. The lateral wall is a continuation of the lateral wall of the oropharynx. Anteriorly, the medial and lateral walls converge to form the narrow anterior wall. Superior is

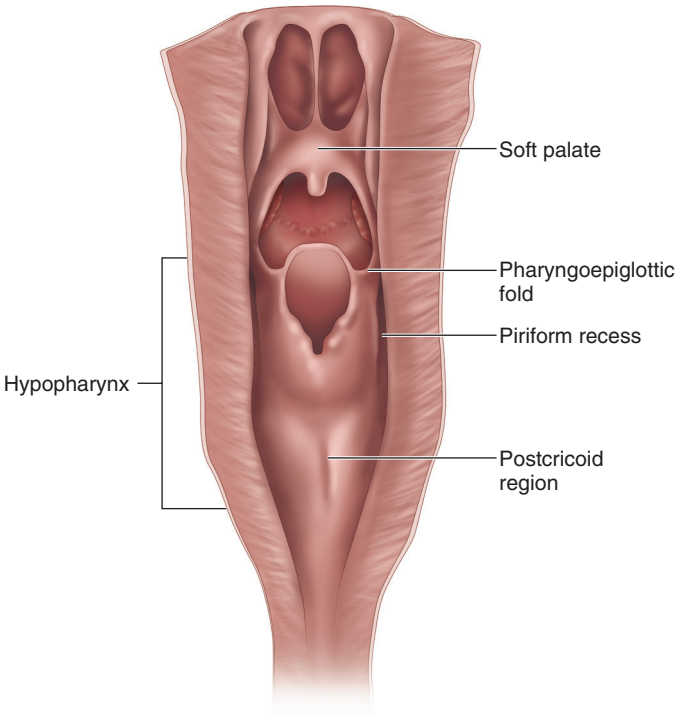

Figure 35-2 Anatomic relationship of the hypopharynx to the pharyngeal axis.

the base or vestibule formed by the rim of the three walls. Inferiorly, the three walls merge to form the apex.

The postcricoid pharynx begins superiorly at the level of the arytenoids and ends inferiorly at the esophagus, covering the posterior aspect of the cricoid cartilage. The posterior larynx makes its anterior border, and posteriorly it again is a continuation of the posterior pharyngeal wall.

Hypopharyngeal cancers also commonly present with nodal metastases. Lindberg[45] reported a 75% incidence of nodal metastases in patients presenting to the M. D. Anderson Cancer Center (MDACC) with hypopharyngeal tumors. Levels II and III nodes were most frequently involved, and bilateral lymphadenopathy was seen in 15% of patients. These tumors also have access to deep jugular and retropharyngeal lymph nodes.

Piriform Sinus Tumors. Piriform sinus tumors account for 70% of cancers originating in the hypopharynx. Tumors originating from the medial wall of the piriform sinus behave similarly to supraglottic tumors arising from the aryepiglottic folds, and it is often difficult to know the true origin of some of these lesions. Posteriorly, there is little to impede tumor extension into the postcricoid space or crossing from the ipsilateral arytenoid to the contralateral arytenoid. Lateral wall tumors also have few barriers to growth. They can extend medially along the mucosa to involve the posterior hypopharyngeal wall or anteromedially to involve the other two walls of the piriform sinus. Inferiorly, they have quick access to the apex and usually extend deep to the sinus submucosally to involve other adjacent structures, including the thyroid and cricoid cartilages, or directly into the thyroid gland. It is not uncommon to see advanced tumors from this location that have direct soft-tissue extension into the neck. These tumors can also extend into the cervical esophagus, primarily through submucosal routes, making a true definition of disease extent extremely difficult. They can also behave similarly to more classic esophageal tumors with extensive spread along lymphatic spaces and with skip lesions.

Hypopharyngeal Wall Tumors. Tumors originating from the hypopharyngeal walls are less common. Because early presentations are infrequent, it is unusual to see a lesion confined to and clearly originating from the lateral or posterior hypopharyngeal wall. Hypopharyngeal wall tumors frequently spread along the walls to involve either the posterior or lateral oropharyngeal walls and can also spread inferiorly and invade the cervical esophagus. Posterior wall tumors can also invade the prevertebral tissues or invade even more deeply to the bones of the cervical spine.

Postcricoid Tumors. Postcricoid tumors are the least common hypopharyngeal tumors. They almost always present in advanced stages. They can extend laterally into one or both piriform sinuses, directly invade laryngeal structures and can also spread inferiorly and invade the cervical esophagus.

Distant Metastases

The incidence of distant metastases from cancers of the head and neck and specifically laryngeal and hypopharyngeal cancers is low and is generally thought to be less than 10%. An often-referenced study by Crile in 1906[46] reported an incidence of 1% distant metastases in 4500 patients with epidermoid cancers of the head and neck. In subsets of patients with head and neck squamous cell cancers, patients with glottic tumors usually have the lowest rates of distant metastases whereas patients with hypopharyngeal carcinomas often have the highest rates.

Merino et al[47] analyzed the incidence of distant disease in more than 5000 patients with head and neck squamous cell carcinomas treated from 1948 through 1967. Among patients with control of disease above the clavicle, the incidence of distant failure was 1%, 13%, and 23% for patients with carcinomas of the true vocal cords, supraglottic larynx, and hypopharynx, respectively. Similarly, Marks et al[47a] found that 23% of patients with piriform sinus cancers developed distant metastases, with a higher rate among patients who underwent total laryngectomies as part of their therapy. The incidence of metastases is associated with stage of disease because the clinical incidence of metastases is approximately 20% in patients with stage IV disease.

The sites of presentation of distant metastases are similar for cancers of the larynx and hypopharynx.[43] The lungs are the most common site and are the first site of presentation in nearly 60% of patients. Bones are the next most common site because 20% of patients with distant disease develop osseous metastases. Liver metastases are common in autopsy studies, but clinical liver metastases develop in only 10% of patients with hematogenous spread of disease from the larynx and hypopharynx.[48] Spread to mediastinal lymph nodes, the brain, or other organs is uncommon.

MOLECULAR BIOLOGY

The critical events of carcinogenesis and tumor progression occurring at a molecular level have been heavily studied over several decades. Paradoxically, as our knowledge of molecular tumor biology increases, the complexity of tumorigenesis at this level also appears to increase. This is in part as a result of the realization that laryngeal and hypopharyngeal tumors, while developing in a "single" site, represent a heterogeneous group of neoplasms. Investigators have found genotypic markers, either chromosomal rearrangements or the presence of an oncogene, tumor suppressor gene, or other markers but have only found them in some varying percentage of laryngeal and hypopharyngeal tumors.

A general view is that tumorigenesis of head and neck malignancies occur because of a combination of factors. Carcinogen exposure (primarily tobacco) results in genetic damage. However, not all smokers develop cancer. The genetic damage in individuals varies based on the degree of exposure to the offending agent as well as the individual's inherent sensitivity to genetic damage. The latter can be tested indirectly in individuals using an assay quantifying chromosomal breakage induced by in vitro exposure to bleomycin. Patients with upper aerodigestive tract malignancies were compared with healthy controls. Mutagen-sensitive individuals had a higher likelihood of having a cancer, and mutagen-sensitive smokers were at the highest risk.[49]

A field of mucosa is placed at risk for developing carcinoma by the exposure and sensitivity described previously, but it requires a number of events to develop a frank cancer. The concept of field cancerization was first described in 1953 by Slaughter et al.[50] These researchers found widespread microscopic abnormalities in "normal" mucosa adjacent to tumor obtained from resected specimens. These abnormalities ranged from hyperplasia to areas of carcinoma both invasive and in situ away from the known resected cancer. Califano et al[51] proposed a genetic progression model in which the local clinical phenomenon of field cancerization involves the expansion and migration of clonally related preneoplastic cells.

The molecular events leading to the development of carcinomas are believed to occur by a multistep process and have been described for other cancers.[52] This theory is applicable to head and neck cancers and appears consistent with the pathologic findings of field cancerization. Genotypic alterations in histologically normal epithelium adjacent to invasive carcinomas have been described. Voravud et al[53] found increased chromosomal polysomies in normal mucosa of smokers with invasive carcinomas but not in mucosa of healthy nonsmoking

volunteers. The most frequent findings in premalignant tissue are deletions of one of the two alleles at chromosomes 3p and 9p21.[54] These regions harbor tumor suppressor genes and thus may be involved with malignant transformation. It has also been observed that telomerase is activated in head and neck squamous carcinoma and dysplasia and may be an early event in the tumorigenic process.[54]

TP53 is a tumor suppressor gene. A mutation in *TP53* is regarded as the most common related genetic change in human cancers.[55] The normal TP53 protein has a short half-life, so its detection is thought to represent *TP53* mutation. Shin et al[56] found *TP53* expression in normal tissue and premalignant lesions adjacent to head and neck tumors but not in normal tissues from normal control patients. Numerous investigators have found overexpression of TP53 protein in laryngeal carcinomas, typically in approximately half the tumors studied.[56,57] Alterations in *TP53* are thought to be an important step early in the carcinogenic process but not a necessary step for all laryngeal and hypopharyngeal tumors. The finding of this protein in laryngeal specimens is also unclear; although there are diverging study results, most investigators have not found a prognostic value to the finding of TP53 protein in larynx tumor specimens.[57-60]

Other cellular changes in laryngeal carcinogenesis involve epidermal growth factor receptor (EGFR), CCND1 (formerly cyclin D1), and CDKN2A. Weichselbaum et al[61] described elevations in EGFR expression in head and neck tumor cell lines. In an analysis of premalignant and malignant head and neck tumor specimens, EGFR levels correlated with increasing severity of dysplasia.[62] Furthermore, Shin et al[63] found elevated EGFR levels in premalignant tissues but dramatic up-regulation in invasive carcinoma specimens. EGFR was amplified in DNA from 29% of sampled hypopharyngeal cancers, and it is overexpressed in at least 80% of head and neck cancers. This overexpression has been demonstrated to be an independent prognosticator in head and neck cancer.[62]

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Clinical Manifestations

Hoarseness is the main presenting symptom in patients with glottic carcinoma. Patients with neglected advanced disease can also present with airway obstruction, pain, or dysphagia. Recurrent laryngeal nerve involvement may cause local pain or referred otalgia.

Patients with supraglottic cancers have differing symptomatology depending on the location of the primary lesion. Patients with false vocal cord lesions can present with hoarseness, whereas patients with epiglottic tumors can have voice changes often referred to as a supraglottic or "hot potato" voice. Patients can also present with throat pain, referred otalgia, and sometimes dysphagia. On rare occasions, patients may present with an asymptomatic neck metastasis. Similar to glottic cancers, advanced tumors can cause airway obstruction and have direct extension into the neck.

Patients with hypopharyngeal cancer usually present with throat pain with or without referred otalgia. Other symptoms include varying degree of dysphagia, ranging from the sensation of food "hanging up" in the throat to inability to swallow solids. Weight loss develops frequently in these patients, who often have malnutrition and poor performance status. Hoarseness occurs with larynx invasion that impairs vocal cord mobility. Because of the high incidence of nodal involvement, patients with hypopharyngeal cancer can occasionally present with asymptomatic neck masses.

TABLE 35-1 Evaluation of Patients with Suspected Laryngeal or Hypopharyngeal Cancer

Medical history
Physical examination
Directed examination of oral tissues and neck
Fiberoptic laryngopharyngoscopy
Chest radiography
Thin-slice CT or MRI of the larynx
Direct laryngoscopy and biopsy of the primary tumor
*Optional examinations**
CT of chest
PET
Barium swallow
Esophagogastroduodenoscopy (EGD)

**In patients with more advanced disease, these tests may augment the workup for metastatic disease; PET and barium studies may help better define the inferior extent of advanced hypopharyngeal cancers.*

Patient Evaluation

Laryngeal Cancer

Clinical evaluation of laryngeal cancer includes indirect laryngoscopy with a mirror that is frequently supplemented by fiberoptic endoscopy (Table 35-1). Similar to other tumors in the head and neck, the examiner assesses the tumor size, morphology, infiltration (defect, distortion) of adjacent structures, and vocal cord mobility. It is important to palpate the base of the tongue to determine direct invasion from the supraglottic larynx and to look for indirect signs of preepiglottic space invasion such as fullness of the vallecula or ulceration of the infrahyoid epiglottis. A direct laryngoscopy is often the final step in evaluation. It is needed to further outline the disease extent and, in particular, to obtain biopsy specimens for tissue diagnosis.

Examination of the neck is important to detect lymphadenopathy or direct tumor extension manifesting as tenderness of the thyroid cartilage or the presence of a subcutaneous mass. Firm fullness over the thyroid notch is suggestive for preepiglottic space involvement.

Radiologic studies are indicated when there is the suggestion of deep infiltration. CT (Figure 35-3) or MRI is useful for the assessment of the preepiglottic space, tongue base, paraglottic region, and subglottis (which is sometimes difficult to evaluate from above with the mirror or fiberoptic scope). These images may help differentiate direct primary tumor extension to the soft tissue of the neck from nodal involvement. Anterior commissure lesions may have subtle thyroid cartilage invasion only detectable by CT.

Hypopharyngeal Cancer

Evaluation of hypopharyngeal tumors is similar to that of larynx cancers. Because these lesions are typically at an advanced stage, it is not uncommon to palpate disease in the neck by direct extension. The thyroid click may be lost owing to anterior displacement of the larynx by a posteriorly located (particularly postcricoid) lesion. Phonation may provide better visualization of the piriform sinus on indirect mirror and fiberoptic examination. If unsuccessful, a Valsalva maneuver may open the sinus. Deep infiltrative lesions in the apex may be hard to see but are suspected by either pooling of secretions or arytenoid edema. Assessment of laryngeal mobility is important in medial wall lesions because they can invade directly into the laryngeal framework. In addition to CT (Figure 35-4), combined ^{20}F-fluorodeoxyglucose–labeled positron emission tomography and CT (FDG-PET/CT) may be helpful in defining tumor extent, particularly the inferior

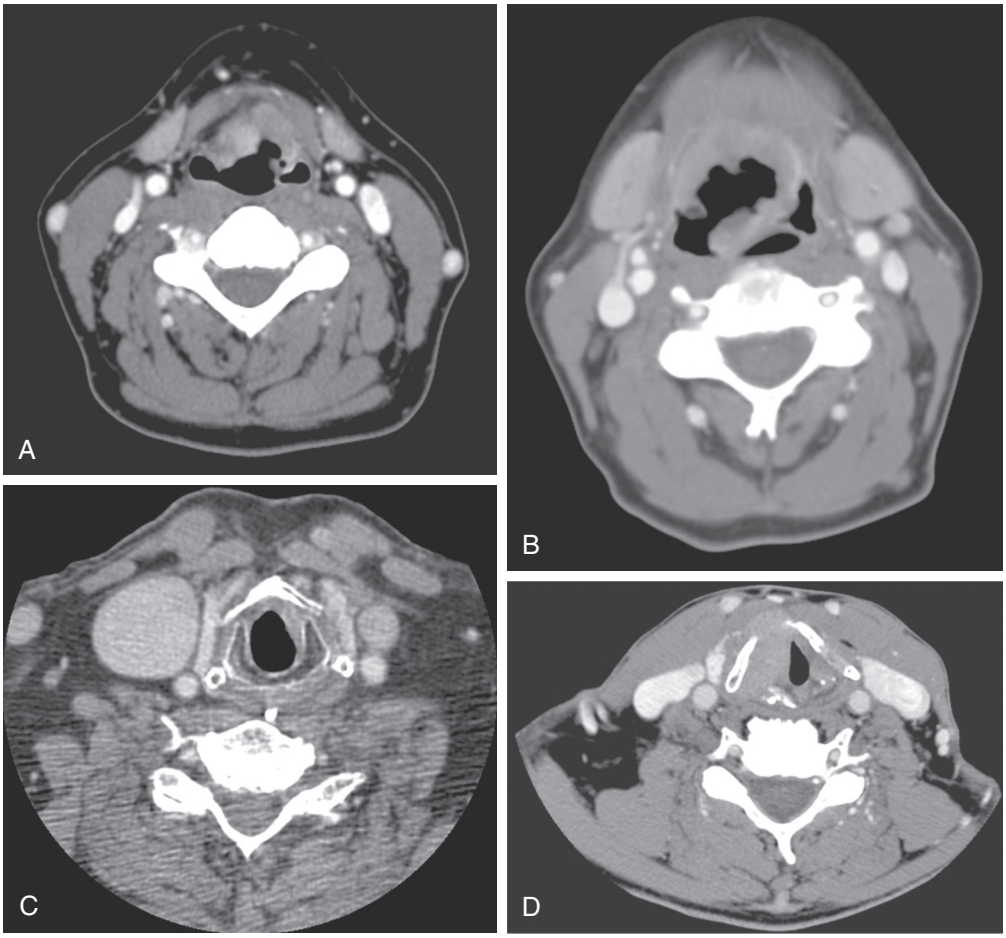

Figure 35-3 CT of laryngeal cancers. **A,** Cancer of the supraglottis invades the preepiglottic space *(left).* **B,** Cancer of the epiglottis with direct extension into the base of the tongue. **C,** Cancer of the true vocal cord with subglottic extension *(left).* **D,** T4 laryngeal cancer, with destruction of the cartilage and invasion of the anterior strap muscles.

border where subtle changes in the inferior hypopharynx and superior cervical esophagus may be hard to identify solely on anatomic images. A laryngoscopy and biopsy is often required to confirm the diagnosis. At that time, esophagoscopy is prudent to assess disease extent inferiorly.

Staging

Larynx

Tumors are staged using the American Joint Committee for Cancer (AJCC) TNM system[29] (Table 35-2). The system is currently in its seventh iteration, most recently revised in 2010. The system classifies/categorizes larynx cancer primary tumors (T) by sites of extension and cord mobility but not size. For glottic tumors, stage T1 is disease limited to the vocal cord(s). The AJCC staging system further divides T1 glottic tumors into T1a for tumors confined to one true vocal cord and T1b for tumors involving both vocal cords. In general, this subdivision is more useful for communication and may influence the treatment decision (i.e., limited surgery versus RT) but does not have a strong impact on prognosis. T2 glottic tumors have either supraglottic or subglottic extension or impaired mobility (but not fixation). Although not defined by the AJCC, T2 glottic lesions can be subdivided into T2a for normal mobility and T2b for impaired mobility. This subdivision is not uniformly used, however, because there is no general agreement that treatment outcomes differ among the substages.

Two significant revisions were made to the sixth edition of the staging system.[64] Historically, the definition of T3 glottic disease has been fixation of the vocal cord. The sixth edition expanded on this definition and included paraglottic space invasion or minor thyroid cartilage invasion. Previous editions had defined T4 disease as invasion *through* the thyroid cartilage, but a common misinterpretation was to include any thyroid cartilage invasion into the T4 category. The new definition was made to clarify this point. The significance of this distinction is in the era of larynx preservation (see discussion in this chapter); many still think that the presentation of invasion through the cartilage into the extralaryngeal tissues precludes a nonsurgical approach, but patients presenting with minimal invasion into the inner cortex may have disease suitable for larynx preservation.

The second modification is the subdivision of T4 disease. For head and neck cancers in general, the sixth edition had subdivided stage T4 into resectable (T4a) and unresectable (T4b) categories. Thus, glottic cancer T4a disease has been defined as tumor that invades through the thyroid cartilage or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus), and T4b is tumor invading prevertebral space, encasing carotid artery, or invading mediastinal structures. Subsequently, the only change made in the seventh edition was descriptive. Category T4a now describes moderately advanced local disease, and T4b describes advanced local disease.

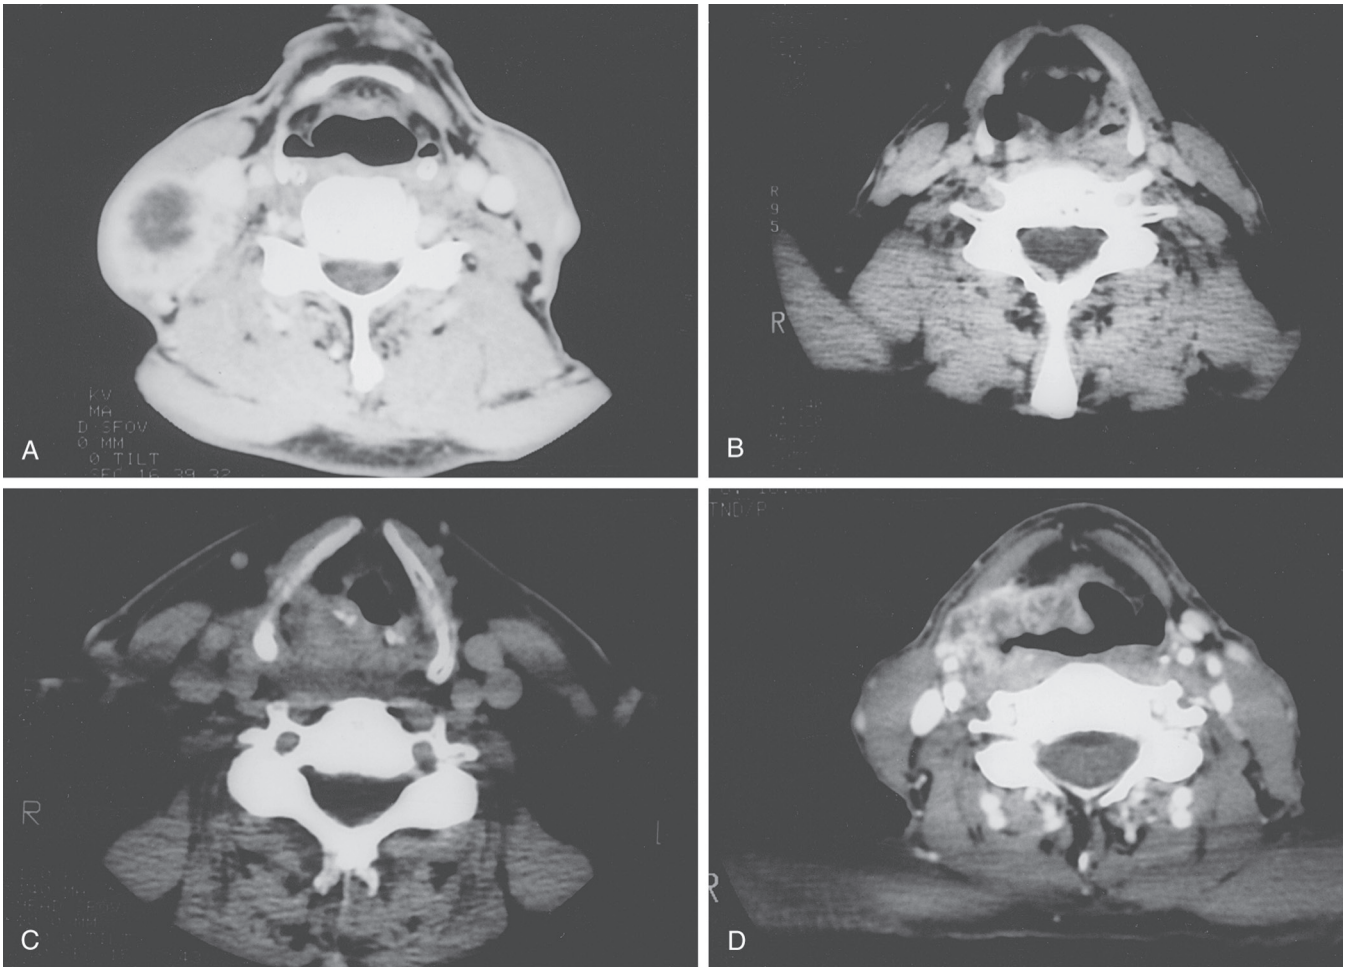

Figure 35-4 CT of hypopharyngeal cancers. **A,** A small (<1-cm) lesion arises off the posterior hypopharyngeal wall (T1) with large (N3) neck metastases. The primary tumor was managed with irradiation only, and the neck was treated with combined irradiation and surgery. **B,** An exophytic lesion was confined to the walls of the left piriform sinus (T2) and was treated with hyperfractionated RT. **C,** An infiltrative lesion off the medial wall of the piriform sinus invaded and fixed the hemilarynx (T3). This patient was treated within the framework of a study of induction chemotherapy and irradiation. **D,** An advanced lesion of the piriform sinus extended directly into the soft tissues of the neck. This lesion required a resection with a free jejunal autograft repair followed by postoperative RT.

The staging of supraglottic cancers requires the division of the supraglottis into five subsites: the suprahyoid epiglottis, infrahyoid epiglottis, aryepiglottic folds, arytenoids, and ventricular bands (false cords). T1 disease is disease confined to one subsite (with normal vocal cord mobility). T2 disease invades more than one adjacent subsite or region outside the supraglottis (mucosa of base of tongue, vallecula, or medial wall of the piriform sinus). T3 disease is similar to glottic carcinoma, although it also includes preepiglottic space invasion or postcricoid involvement. Last, in the newest edition, the definition of T4 supraglottic cancer is the same as that for glottic cancer with subdivisions into moderately advanced and advanced (T4a and T4b) categories.

Hypopharynx

T category for hypopharyngeal tumors is also based on sites of involvement and larynx motion (an indirect measurement of disease extension). The fifth edition of this staging classification had a significant modification to also include the size of the tumor in staging.[65] This change addressed a major deficiency in prior systems because the older systems tended to understage hypopharynx tumors relative to other head and neck mucosal cancers. The hypopharyngeal T category still does not reflect morphology, which remains an important criterion for selection of local therapies because exophytic tumors in this site are usually selected more frequently than infiltrative lesions for organ-preserving therapies. The sixth edition made one additional modification. As described for laryngeal cancers, resectable T4a and unresectable T4b categories were defined. T4a hypopharyngeal disease can invade thyroid or cricoid cartilages, hyoid bone, thyroid gland, esophagus, or central compartment, whereas T4b disease invades prevertebral fascia, encases carotid artery, or involves mediastinal structures. The newest edition now defines T4a and T4b as moderately advanced and very advanced.

Regional Classification and Categorization

The nodal (N) category is uniform for all head and neck cancers, including laryngeal and hypopharyngeal tumors. No changes were made in the seventh edition. The details of T and N categories for laryngeal (glottic and supraglottic) and hypopharyngeal cancers are summarized in Table 35-2.

TABLE 35-2 American Joint Committee on Cancer Staging of Laryngeal and Hypopharyngeal Cancers

GLOTTIS	
Tis	Carcinoma in situ
T1	Tumor limited to the vocal cord(s) with normal mobility
T2	Tumor extends to supraglottis or subglottis or with impaired cord mobility
T3	Tumor limited to the larynx with vocal cord fixation or invades paraglottic space or minor thyroid cartilage erosion
T4a	Tumor invades through the thyroid cartilage or invades tissues beyond the larynx
T4b	Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures
SUPRAGLOTTIS	
Tis	Carcinoma in situ
T1	Tumor limited to one subsite of the supraglottis with normal vocal cord mobility
T2	Tumor invades mucosa of more than one subsite of the supraglottis or glottis or adjacent site outside the glottis, without fixation of the larynx
T3	Tumor limited to the larynx with vocal cord fixation and/or invades any of the following: the preepiglottic space, the postcricoid area, or minor thyroid cartilage erosion
T4a	Tumor invades through the thyroid cartilage or invades tissues beyond the larynx
T4b	Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures
HYPOPHARYNX	
T1	Tumor limited to one subsite of hypopharynx and 2 cm or less in greatest dimension
T2	Tumor invades more than one subsite of hypopharynx or an adjacent site or measures between 2 cm and 4 cm in greatest dimension, without fixation of hemilarynx
T3	Tumor measures greater than 4 cm or with fixation of hemilarynx
T4a	Tumor invades thyroid/cricoid cartilage, hyoid bone, thyroid gland, esophagus, or central compartment soft tissue
T4b	Tumor invades prevertebral fascia, encases carotid artery, or involves mediastinal structures
NODAL INVOLVEMENT (N)	
Nx	Nodes cannot be assessed
N0	No clinically positive node
N1	Single clinically positive ipsilateral node 3 cm or less in diameter
N2	Single clinically positive ipsilateral node more than 3 cm, but not more than 6 cm in diameter or multiple clinically positive ipsilateral or bilateral or contralateral nodes, none more than 6 cm in diameter
N2a	Single clinically positive ipsilateral node more than 3 cm, but not more than 6 cm in diameter
N2b	Multiple clinically positive ipsilateral nodes, none more than 6 cm in diameter
N2c	Bilateral or contralateral lymph node, none more than 6 cm in greatest dimension
N3	Metastases in a lymph node more than 6 cm in greatest dimension
STAGE GROUPINGS	
Stage I	T1N0M0
Stage II	T2N0M0
Stage III	T3N0M0 T1-3N1
Stage IVA	T4aN0-1M0 T1-4aN2M0
Stage IVB	T4bN0-3M0 T1-4bN3M0
Stage IVC	T1-4N0-3M1

PRIMARY THERAPY

Early Carcinomas

T1 and T2 Glottic Tumors

The management of early glottic carcinomas is controversial and is often determined by the preferences and expertise of the attending physicians. Oncologists advocate either irradiation or voice-preserving partial laryngectomy. Large published series have for all practical purposes demonstrated equivalent control rates with surgery (excision, cordectomy, or hemilaryngectomy) and RT. There has not been a true comparative study between these two modalities, and it is highly unlikely that a prospective trial will be performed. Therefore, it is imperative that the patient visit with both a surgeon and radiation oncologist before making a treatment decision so that their preferences, desires, and goals can be considered in the treatment making decision.

There are several difficulties in comparing the results of various treatment options. Nearly all series are retrospective single-institutional studies. It is thus difficult to ascertain if small differences in control rates between series are real.

**4.2% treated with initial total laryngectomy. Data given for T2a and T2b separately.*

Mendenhall et al[66] address this issue by defining the surgical procedure that would have been recommended in their patients who were irradiated. They found that the surgical treatment option would have required total laryngectomy, rather than partial voice-conserving procedures, in 10% of patients with T1 disease and 55% of those with T2 disease. However, the supracricoid laryngectomy, a procedure that removes an entire circumferential portion of the larynx and subsequently reconstitutes the larynx, has largely been developed during the past decade.[67] Many patients described by Mendenhall et al in 1993 deemed suitable only for total laryngectomy may now be managed with this voice-preserving surgery. Olsen[68] states that it is unusual for disease that does not fix the arytenoids to require total laryngectomy. Although this is possibly true from a technical standpoint, many patients who have larynx cancer are older, have long histories of tobacco exposure, and medically may not be suitable for partial laryngeal surgery other than excisions of small T1 lesions on the midcord.

In general, T1 tumors can be treated effectively with transoral laser excision,[69] laryngofissure,[70] partial laryngectomy,[71,72] or irradiation. Table 35-3 summarizes the results of RT. Local control rates of RT range from 85% to 95%, and ultimate control rates after salvage surgery for recurrences are greater than 95%. Surgical salvage for the uncommon local relapse often requires a total laryngectomy, but an occasional patient can have a lesion amenable to a voice-conserving partial laryngectomy.[73-77]

An important factor in selecting therapy for individual patients is the anticipated voice quality after therapy. Unfortunately, studies comparing voice quality between laser excision and RT have yielded conflicting conclusions. Hirano et al[91] concluded in their analysis that hoarseness and incomplete glottic closure were more frequently seen in patients treated with laser. McGuirt et al[92] had physicians, patients, and speech pathologists compare voice quality of patients who received RT or laser excision for early glottic cancer. They concluded that patients treated with limited excisions of tumors of the midcord had equivalent quality compared with those receiving RT. Using computerized-assisted voice analysis, Harrison et al[93] demonstrated that most of their patients irradiated for early vocal cord cancer maintained excellent voices. Mittal et al[94] reported a cost savings with radiation compared with hemilaryngectomy and thought this should be an important component in treatment decisions if other important criteria are equivalent. A recent meta-analysis performed by Higgins et al[95] of more than 7600 patients suggested a trend toward improved voice quality with RT as compared with transoral laser excision.

The outcome of RT for T2 cancers is, as expected, less favorable than that for T1 tumors. Local control rates range from 65% to 80%, and ultimate control rate is about 90% (Table 35-4). The wider range in the reported local control rates can, at least in part, be ascribed to a considerable heterogeneity of presentations within this stage, that is, varying from a superficial tumor spilling into the ventricle to a more bulky lesion transgressing the paraglottic space and impairing motion.

Oncologists have searched for prognostic determinants in this group of patients. Several reports showed that impairment in cord mobility adversely affects tumor control by RT (Table 35-5). Some physicians favor a hemilaryngectomy, if feasible, for T2b tumors.[71,72,103] However, Karim et al[97] did not find impaired cord mobility to result in a worse outcome and attributed this observation to prescribing higher radiation doses to patients with such a tumor feature. Similarly, a report from MDACC did not show a relationship between mobility and outcome, but some patients were treated with altered fractionation schedules that were theorized to have a

TABLE 35-5 Control of T2 Glottic Cancer as a Function of Cord Mobility

therapeutic advantage.[104] An update of this report reinforced the lack of impact of mobility on prognosis, independent of fractionation.[100] This was contrary to the finding of Wang,[83] who found that twice-daily radiation improved local control of T2 tumors with normal mobility but not those with impaired mobility.

Several studies were also undertaken to assess the influence of impaired cord mobility on the success rate of salvage surgery for patients who developed recurrences. Schwaab et al[77] noted difficulties in attempting salvage on a small cohort of patients presenting with T2b tumors (although, surprisingly, the initial control rate of T2b tumors in this series was better than that of T2a lesions). Wiggenraad et al[107] reported ultimate control rates of 98% for T2a and 76% for T2b tumors ($p < 0.05$). Other groups, however, have reported equivalent ultimate local control rates for tumors with normal or impaired cord mobility.[77,100,110] Ang and Peters[111] suggested that the timeliness of diagnosis and the extent of surgery, rather than the initial disease presentation, might account for the difference in the salvage results.

Anterior commissure involvement was considered a potential prognostic factor because it may carry an increased risk for unsuspected thyroid cartilage invasion. However, this feature was not found to be a prognostic determinant in most recent series. Sessions et al[112] found that anterior commissure[109] involvement was more frequently associated with larger tumors, and it was the extent of disease rather than commissure involvement per se that impacted on outcome. Le et al[84] found, in a multivariate analysis, that patients with anterior commissure involvement had a poorer local control rate but concluded that these patients also had a larger tumor burden and sometimes unsuspected subglottic disease. Modern high-resolution imaging techniques can detect clinically unsuspected thyroid cartilage invasion and eliminate the clinical significance of anterior commissure involvement.

Glottic Carcinoma in Situ

Controversies of management even exist for carcinoma in situ of true vocal cords. Although not all lesions progress to invasive cancer, Hintz et al[113] reported that with a watchful waiting policy nearly two thirds of patients developed invasive cancer that was not always suitable to voice-preserving therapies. Ferlito et al[114] polled otolaryngologists and found practices of management ranging from postbiopsy observation, vocal cord stripping, cordectomy, open partial laryngectomy, to primary irradiation.

**Ten-year actuarial larynx preservation rate*

Primary RT is an effective treatment for carcinoma in situ of the larynx. However, conservative surgical approaches such as microexcision, laser ablation,[115,116] or vocal cord stripping[117] are considered sufficient for initial treatment. Repeated biopsies, strippings, or laser excisions may be counterproductive and lead to worsening of voice quality. RT is usually reserved for recurrences or for diffuse lesions that are not suitable for limited surgery as the first therapy.

The local control rates reported in modern series of patients with carcinoma in situ treated with radiation ranges from 70% to 100% and are similar to rates described for invasive T1 disease (Table 35-6). It should be recognized that, owing to limited biopsy sampling, many radiation series may include patients with unrecognized invasive disease. For example, nearly one third of the patients in the series of Pene and Fletcher[118] diagnosed with carcinoma in situ had clinical T2 disease. Most patients developing recurrent laryngeal

TABLE 35-7 Comparison of Once-Daily versus Twice-Daily Fractionated Radiation for T2-3 Supraglottic Carcinomas

carcinoma in situ undergo salvage surgery, most often with total laryngectomy, although some series have reported salvage with voice-preserving surgery.[119,120] Although control rates after irradiation are similar to those reported for early invasive disease, recurrences in patients with carcinoma in situ take longer to manifest. Most series report median times to failure of greater than 2 years, but the majority of tumors recur within 5 years of treatment.[113,118,120-122]

T1, T2, and Selected T3 Supraglottic Tumors

Similar to glottic cancer, the optimal management of supraglottic carcinomas is still being debated. Confounding the issue even more is the necessity to manage the neck lymphatics in addition to the primary tumor. As mentioned previously, nearly one third of patients with early- to intermediate-stage supraglottic neoplasms present with palpable cervical lymphadenopathy[44,78] and another third have subclinical nodal involvement detected by elective neck dissections.[129]

Voice-preserving treatment options for early- and intermediate-stage tumors are supraglottic laryngectomy or primary RT.[44,71,74,130-134] Local control rates in most surgical series range from 80% to 90%. Bocca et al from Milan reported a local control rate of 85% in one of the largest series of more than 400 patients with predominantly T2 tumors. Of note is that postoperative RT is often given to many patients undergoing partial laryngectomy. Common indications are presence of multiple nodes, extracapsular spread of nodal disease, and close or positive surgical margins. For example, 50 of 60 (83%) patients who underwent supraglottic laryngectomy at MDACC from 1974 to 1987 had indications for postoperative RT.[44] The leading complication of supraglottic laryngectomy is aspiration, which can be morbid in heavy smokers (the majority of patients) with chronic pulmonary disease. Although preliminary data of endoscopic removal of early supraglottic lesions have been reported recently,[135,136] more experience is needed to determine its relative value.

Most surgical series selected middle-aged men who are medically fit for supraglottic laryngectomy. Hinerman et al[137] analyzed 274 patients who underwent primary RT at the University of Florida and retrospectively grouped these patients into three groups: (1) suitable for conservation surgery, (2) anatomically suitable but medically unsuitable, and (3) anatomically unsuitable. Using 1998 AJCC criteria, they reported that 45% of T1 patients, 36% of T2 patients, and 14% of T3 patients were suitable for conservation surgery. Only 14% of T1 patients were anatomically unsuitable, compared with 46% and 68% of T2 and T3 patients, respectively. Of note, results after RT for all their patients were dependent on T category but were not dependent on suitability for conservation surgery. Similar to the situation in patients with glottic carcinomas, the development of the supracricoid laryngectomy would alter the balance of patients with T2 and T3 patients thought to be anatomically unsuitable for a conservative procedure. In a small series, Laccourreye et al[138] reported on 19 patients treated with supracricoid laryngectomy. This cohort had disease in the infrahyoid epiglottis that was not suitable for more traditional conservative procedures.

In 1974, Bataini et al[139] published an overall locoregional control rate of 76% for a relatively large series of patients with T1-2, N0-2 supraglottic carcinomas treated by RT alone. Subsequent series reported control rates of 84% to 100% for T1 tumors.[79,83,140] Table 35-7 summarizes the outcome of RT in T2 and favorable T3 lesions. Fletcher and Goepfert[79] obtained a local control rate of 76% in this subset of patients by escalating the total dose of the conventional daily irradiation to 70 Gy. Application of altered fractionation regimens appear to have resulted in a trend toward further improvement in local control.[83,129,142] In the Danish Head and Neck Cancer Group (DAHANCA) randomized fractionation trials, the benefit of accelerated treatment for head and neck cancers in general was most noticeable in the subgroup of patients with supraglottic cancers.[141]

The impact of clinically positive nodal disease on local control has been evaluated in several series. Wall et al[143] found the presence of lymphadenopathy was associated with a significantly lower local control rate. Similarly, Wang et al[144] describe a marked worsening of local control in patients who were node-positive. The 5-year actuarial local control rate obtained with accelerated fractionation was 86% in patients with no adenopathy as opposed to 46% in patients with N2-3 disease. In contrast, Freeman et al[145] did not find an association between local control and the presence of lymph nodes.

The potential impact of tumor volume, estimated by CT measurements, on the results of RT was addressed by Freeman et al[146] in patients with T3 supraglottic tumors. They found a control rate of 83% for tumors of less than 6 cm^3 compared with 46% for tumors of greater than 6 cm^3. This latter group may be more suitable for surgery, particularly if voice-conserving surgery is feasible. Kraas et al[147] also studied tumor volume measurements, and although their threshold was 8 cm^3, the concept of increasing tumor volume predicting worse outcome with RT was validated in a separate cohort.

Comparative studies have been undertaken in an attempt to delineate therapy recommendations for different subsets of patients. Fein et al[134] analyzed the University of Florida experience and concluded that RT yielded a local control rate equivalent to that obtained by conservative surgery but was associated with a lower complication rate. Robbins et al[131] from MDACC compared the outcome of patients who underwent supraglottic laryngectomy with that of patients who received RT for tumors judged suitable for partial laryngectomy. They found a better tumor control rate in the surgically

TABLE 35-8 Results of Radiation Alone for Early (T1-2) Squamous Cell Carcinoma of the Hypopharynx

treated group, but the incidence of morbidity as a result of chronic aspiration was rather high. This finding contributed to the development of the current treatment policy at this institution. Briefly, supraglottic laryngectomy, with postoperative RT when indicated, is recommended for medically fit patients with bulky, infiltrative T2 and T3 tumors (e.g., invasion into the false cords or infrahyoid epiglottis). RT is selected for patients with either smaller or exophytic lesions (T2 or favorable T3) or patients with bulky lesions who are medically unfit for voice-conserving surgery.

T1 and T2 Hypopharyngeal Tumors

Although uncommon, these tumors can be treated with RT. Because of the high propensity for neck metastases, it is not unusual to see patients with small-volume primary disease suitable for RT but with large neck disease that requires multimodality treatment. In this situation, the options are to irradiate the primary tumor and neck nodes to high doses and dissect the residual neck mass about 6 weeks after RT or to perform a neck dissection followed by definitive RT to the primary tumor and with adjunctive RT to the neck. The latter approach is frequently recommended to patients who need to undergo dental extractions, requiring a delay in initiation of irradiation.[148]

Some results with primary RT for early-stage hypopharynx lesions are shown in Table 35-8. Compared with historical control data, local control rates seem to have improved with the use of hyperfractionated regimens. For example, analysis of MDACC data revealed actuarial local control rates of 86% for hyperfractionation (35 patients) and 63% for conventional fractionation (23 patients).[149] Similarly, for for T2 category piriform sinus tumors T2 piriform sinus primary tumors, Amdur et al[150] reported local control in 89% of patients treated with twice-a-day irradiation compared with 73% for those treated only once per day ($p = 0.09$). Although it is believed that hyperfractionation has improved the results, it should be realized that refinements in RT technique, including customized Cerrobend portal shaping, more generous coverage of the posterior route of spread, and the use of 6-MV x-rays with smaller penumbra, may all have contributed to the improvement of outcome. In addition, it is difficult to discern whether the rather subjective patient selection criteria have changed over the years and what impact this has on the results. Superficial and exophytic tumors, particularly in the vestibule, tend to be selected for primary RT, whereas infiltrative tumors of similar stage, especially in the apex, are chosen for multimodality treatment.

Management of Squamous Carcinoma Variants

Verrucous Carcinoma

Verrucous carcinoma is generally a well-differentiated, slow-growing, wartlike lesion. This tumor has a reputation for its relative radioresistance and a tendency for converting to a highly anaplastic neoplasm after RT.[36] However, no firm data are available to support this belief. A 5-year control rate of 66% was achieved in a series of 62 patients treated with RT at the Princess Margaret Hospital.[154] The majority of these patients had early-stage disease, although in more than half, the disease was T2 category. The majority of patients with recurrence were treated with surgery, and only 50% required a total laryngectomy, resulting in a laryngeal preservation rate of 81%. Only 3 (5%) patients died of the disease. Therefore, it is reasonable to treat patients with early verrucous carcinoma with radiation if the surgical option is a total laryngectomy. However, those with well-lateralized early tumors may be better suited for conservative surgery.

Sarcomatoid Carcinoma

Sarcomatoid carcinoma of the larynx has a similar reputation for radioresistance and for dedifferentiation after RT. In a review of 28 patients with T1-2 glottic sarcomatoid carcinoma who were irradiated, we found a 5-year actuarial control rate of 89%, which is similar to that obtained for ordinary squamous cell carcinoma.[155] Although the control rate for 7 patients with T2 tumor was only 57%, all patients with recurrences could undergo salvage surgery and only 1 patient died of the disease.

Neuroendocrine Carcinoma

Neuroendocrine carcinomas of the head and neck are extremely uncommon. They can be subgrouped into three categories. The most common is small cell undifferentiated carcinoma. Moderately differentiated and well-differentiated tumors have also been described and are sometimes referred to as atypical and typical carcinoids, respectively. The latter is extremely rare. The behavior of these three subtypes is similar to their more common counterpart in the lung.

In a report[156] describing the results of patients presenting with nonsinonasal neuroendocrine cancer, we found that the majority of patients (65%) presented with laryngeal or hypopharyngeal disease. RT was effective for locoregional control, but most patients succumb to distant metastases. The addition of chemotherapy appeared to decrease the risk of distant failure and translated into improved survival. Our current policy is to recommend neoadjuvant chemotherapy, typically with cisplatin and etoposide, followed by RT to the primary tumor and lymphatics. Concurrent chemoradiation is offered to patients who have initial large primary tumors or have a suboptimal response to chemotherapy alone.

LOCALLY ADVANCED CARCINOMAS

These tumors have been traditionally managed with total laryngectomy with or without postoperative RT. It had been

believed that although primary RT can preserve the larynx for some patients, this approach generally results in a lower survival rate than does surgery. Series describing RT alone tended to be small, retrospective, and influenced by patient selection bias, so they were not generally accepted despite reporting results similar to surgery. Additionally, data from large national databases on patient outcomes suggest that patients treated with RT alone have worse survival outcome compared with those who undergo total laryngectomy.[157] However, as opposed to Phase III data, these patients are possibly not truly comparable, and it is likely that patients treated by RT alone often have worse performance status and increased comorbidities.

Although it remains debatable whether induction chemotherapy has a role in the management of head and neck cancers, it was randomized trials using induction therapy that popularized the concept of larynx preservation. This led to the RTOG/Intergroup Phase III trial 91-11, which randomized patients between three approaches: RT alone, induction chemotherapy and local treatment based on response, and concurrent chemoradiation[158] (see later discussion). This study added to our knowledge of the role of combined-modality treatment (concurrent chemotherapy and RT) and gave further validity to nonsurgical approaches for locally advanced larynx cancers.

Although tremendous advances have been made in laryngeal preservation, progress has also been made in rehabilitation of the patient postlaryngectomy. In particular, the popularity of tracheoesophageal hands-free speech has been a tremendous advantage for patients. Thus, whereas RTOG/Intergroup 91-11 demonstrated that high larynx preservation rates can be achieved with concurrent chemotherapy and RT, patients with large-volume T4 disease were not eligible for this approach and are still usually referred for surgery and postoperative RT. Although it may be debated whether equivalent cancer control rates can be achieved with nonsurgical approaches for advanced larynx and hypopharynx disease, many of these patients have such vast destruction of their laryngeal structure that it would be unlikely to retain good laryngeal function even after successful therapy. In particular, this problem makes these patients at high risk of aspiration. Thus, a laryngectomy with rehabilitation may offer them a better quality of life than larynx preservation.

Randomized trials evaluating concurrent chemoradiation in the post–head and neck surgical setting have recently been reported. For patients deemed to be at high risk of locoregional recurrence, both the EORTC and RTOG/Intergroup[159,160] trials demonstrated that RT plus concurrent chemotherapy improve locoregional tumor control compared with RT alone. The definitions of high risk were different in the two studies. Thirty percent to 40% of patients in both studies had laryngeal or hypopharyngeal cancers. The findings of these two important trials are summarized and contrasted in Table 35-9.

T3 Glottic Cancer

Most series of primary RT for T3 glottic tumors are relatively small. The available data are summarized in Table 35-10. Initial control rates range from 44% to 70%. Various twice-a-day fractionation schedules were found to control disease in approximately two thirds of patients.[153,161] In a comparative study, Bryant et al[162] found that the disease-specific survival of patients treated with RT and surgical salvage was not significantly different from that of patients who underwent surgery and, occasionally, postoperative RT. They noted, however, that the control rate of patients requiring an emergency tracheotomy before RT was very low (18%). Mendenhall et al[161] also found similar disease-free and overall survival (OS) between patients treated with RT and those treated with total laryngectomy (occasionally with postoperative RT). The success rate of salvage surgery for radiation recurrences is on average 50% but decreases with increasing initial disease extent.

Bulky Supraglottic Cancer

Most patients with bulky, infiltrative T3 supraglottic primary tumors (often with vocal cord fixation) have been treated with total laryngectomy with or without postoperative RT. Clinical trials addressing the role of neoadjuvant chemotherapy have enrolled predominantly this subset of patients.[169-171] The Veterans Affairs study,[169] for example, randomized patients to either surgery at the outset (standard therapy arm) or neoadjuvant chemotherapy, with the responders receiving radiation and the nonresponders undergoing surgery. This trial showed that no difference in survival and larynx preservation was achieved in a substantial number of patients. However, this trial did not answer the important question of whether induction chemotherapy was more beneficial than RT alone.

Subsequently, the RTOG/Intergroup trial 91-11 tested differing larynx preservation approaches.[158] An initial report was written in 2003,[158] and an update of long-term outcomes was published 10 years later.[172] Induction chemotherapy was the control arm, and RT alone or combined with concurrent cisplatin were two experimental arms. The primary endpoint of the trial was laryngectomy-free survival, and the updated manuscript demonstrated that both induction chemotherapy and concomitant therapy showed similar efficacy with regard to this endpoint and were superior to radiation alone. The results of this trial addressed several issues. In the initial report, survival rates were equivalent for all three approaches. However, in the update, the authors noted "a possibility of worse outcome with concomitant relative to induction chemotherapy."[172] Although no difference in late effects was detected, patients who had concomitant therapy had a much higher rate of deaths not as a result of treatment or the index cancer. Locoregional control and larynx preservation were superior with concurrent chemoradiation. The addition of chemotherapy did increase the toxicity of treatment, principally acute toxicity. The suspected grade 5 toxicity rate in patients receiving concurrent chemoradiation was 5%, and the total rate of severe toxic effects was 20% in patients receiving chemotherapy.[158] The 10-year cumulative rates of grades-3 to -5 toxicity did not differ between the three arms, and ranged from 31% to 38%. However, the authors did note that in patients alive with larynx and disease free, less than 5% were limited to liquids or unable to swallow. The authors were cautious in this conclusion because of the small numbers available for long-term followup.[172]

In Europe, investigators have looked at other methods of larynx preservation. One group followed up on data demonstrating that a taxane added to the induction regimen of cisplatin and 5-fluorouracil improved outcomes in patients with head and neck cancers[173] by testing this approach for larynx preservation. Pointreau et al reported a Phase III trial for advanced laryngeal and hypopharyngeal cancers comparing the three-drug combination to the standard two-drug combination of cisplatin and 5-fluorouracil.[174] Responders received RT (with or without concurrent chemotherapy) and nonresponders underwent laryngectomies followed by RT (with or without chemotherapy). Patients receiving the three-drug combination had more infections, but despite this, these patients had a better response rate. In addition, those randomized to receive docetaxel had a 70% larynx preservation rate compared with 58% for those patients who did not receive the taxane.

A second approach investigated in Europe was to compare sequential chemoradiation to alternating chemoradiation.[175] It was hoped that the alternating chemotherapy approach, which used lower doses of chemotherapy and RT (60 Gy compared with 70 Gy in the sequential arm) would mimic results seem with concurrent chemotherapy as in RTOG 91-11. Ultimately there was no difference in either toxicity or outcomes between the two approaches.

Other than cisplatin, there is little evidence for alternative agents to be used concurrently with radiation in the treatment of larynx cancer. Cetuximab is advocated as an alternative, particularly for patients who can not receive cisplatin, but data supporting this for larynx cancer is minimal. Although the trial testing the addition of cetuximab to radiation did show a general benefit[176] an unplanned subgroup analysis only showed a benefit for patients with oropharyngeal cancer. The TREMPLIN[177] study tested concurrent cisplatin versus cetuximab for patients with advanced larynx or hypopharynx cancer. All patients were treated with induction docetaxel, cisplatin, and 5-fluorouracil (5-FU), and responders were randomly assigned to concurrent high-dose cisplatin versus weekly cetuximab. In this Phase II trial with short follow-up, the authors could not detect differences in varying outcome endpoints. Further, the study did not demonstrate better results than those seen in the GORTEC 2000-01 trial[173] using the three-drug induction regimen followed by radiation alone for responders. Although questions remain regarding cisplatin or cetuximab as the optimal concurrent agent, the RTOG recently demonstrated no benefit to combining the two drugs rather than using cisplatin alone.[178]

T4 Larynx Cancer

Patients with T4 glottic and supraglottic tumors are best treated with total laryngectomy and irradiation, especially those with nonfunctioning larynges. The larynx preservation clinical trials testing neoadjuvant chemotherapy have not yielded encouraging results for patients with T4 disease.[169,171] Only 10% of the RTOG-Intergroup trial cohort had "T4" disease, most likely with minimal thyroid cartilage invasion that has been downstaged by the criteria of the current AJCC classification. In addition, many patients with large bulky disease often will be left with dysfunctional larynges, leading to aspiration if the therapy is successful in eradicating the tumors.

In addition to general indications of postoperative RT in head and neck cancers (i.e., close or positive margins, multiple nodes, extracapsular spread of nodal disease, or extension of the primary lesion into the soft tissues of the neck), post–total laryngectomy RT is also recommended when thyroid/cricoid cartilage invasion and extensive subglottic disease are present or emergency tracheotomy is performed before RT. In a series by Klein and Fletcher,[175] stomal recurrence occurred in 13 of 54 patients (24%) with radiologic evidence of subglottic disease who did not receive postoperative RT. None of these patients was salvaged. Yuen et al[179] analyzed the data of patients with T3 and T4 glottic lesions and found that surgery alone achieved locoregional control in 90% of patients without the adverse features listed previous compared with 73% of those with some of the adverse features; with surgery and postoperative RT, locoregional control was obtained in 46 of 50 patients (92%). In patients with stage IV supraglottic cancer, Goepfert et al[180] reported a 2-year determinate control rate of 37% for surgery alone as opposed to 63% for combined surgery and postoperative RT.

Several groups have investigated chemoradiation for T4 disease. Clinicians from the University of Chicago used an aggressive concurrent regimen of paclitaxel, 5-FU, hydroxyurea, and twice-daily RT and reported 4-year locoregional control and laryngectomy-free survival rates of 71% and 87%, respectively.[181] They suggested that patients who received induction chemotherapy in addition to concurrent chemoradiation fared best. At the University of Michigan, investigators are using a strategy of chemoselection.[182] Patients with

T4 disease are treated with one cycle of neoadjuvant chemotherapy. Those with a greater than 50% response are treated with chemoradiation, whereas the remaining patients go immediately to laryngectomy. Using this approach in 36 patients, 27 underwent chemoradiation, with a 58% laryngeal preservation rate. In both the Chicago and Michigan series, there were modest rates of permanent tracheostomies and gastrostomies.[181,182]

Locally Advanced Hypopharynx Cancer

Surgery is the treatment of choice for patients with T3-4 hypopharyngeal cancer, but adjuvant irradiation is almost always indicated. Vandenbrouck et al[183] performed a randomized trial comparing preoperative and postoperative RT in the treatment of hypopharyngeal tumors. They reported a statistically better 5-year OS in patients treated postoperatively (56%) compared with those treated preoperatively (20%). Table 35-11 lists the results of postoperative RT. Analyzing a series of patients treated between 1949 and 1976, El Badawi et al found that patients who received surgery and RT had significantly higher local control and 5-year OS than those who underwent surgery alone.[184] Frank et al[185] found that, despite having higher stages, patients who received postoperative irradiation had only a 14% locoregional failure rate compared with 57% in those treated with surgery only. When adjusted for confounding variables, particularly the stage discrepancy, they also found that patients receiving postoperative irradiation had an improvement in OS.

The issue of larynx preservation in hypopharyngeal cancer has been addressed by the European Organization for Research and Treatment of Cancer (EORTC) in a multiinstitutional Phase III trial.[188] Similar to the trial of the U.S. Department of Veterans Affairs for larynx cancer, the EORTC compared induction chemotherapy, followed by RT or surgery depending on the response, with immediate total laryngectomy and partial pharyngectomy. The 5-year actuarial voice-preservation rate was 35% in patients receiving chemotherapy, and there was no difference in survival among the two arms. This trial was recently updated, and the conclusions regarding the feasibility of larynx preservation without a compromise in survival are unchanged.[189] Long-term followup suggests a poor prognosis for these patients as 10-year OS in each arm approximated 13%, with overall disease recurrence rates of approximately 50%.

Patients with locally advanced hypopharynx cancer may be suitable for therapy with concurrent chemoradiation. These patients have often been included in trials in which the eligibility has been broad and included patients with locally advanced cancers of multiple head and neck sites.[190,191] In most studies, as a subgroup, hypopharyngeal cancers represent a minority of patients. These studies have demonstrated an advantage to concurrent chemoradiation, and none of the studies has suggested that this general conclusion does not apply to locally advanced hypopharyngeal cancers. With regard to organ preservation for patients with locally advanced hypopharynx cancer, the same principles used for patient selection of larynx cancer should be applied.[192,193]

TABLE 35-11 Results of Postoperative Radiation for Piriform Sinus Tumors

Study/Author	Year	No. Pts	Failure Above Clavicle	Overall Survival

IRRADIATION TECHNIQUES AND TOLERANCE

Primary Radiation Therapy

T1-2N0 Glottic Carcinomas

T1-2N0 glottic carcinomas are typically treated with a pair of small, lateral, opposed photon fields that encompass only the larynx proper (Figure 35-5). In patients with a short neck, a 5- to 10-degree inferior tilt may be necessary to avoid irradiation through the shoulders. Other techniques include anterior wedged pairs or a four-field technique as described by Wang.[83] For T1 lesions, the field is centered on the true vocal cord and extends at or above the top of the thyroid notch superiorly to the lower edge of the cricoid cartilage inferiorly and from the anterior margin of the vertebral bodies posteriorly to approximately 1-cm falloff anteriorly. The superior and inferior borders are adjusted for T2 lesions that extend out of the glottis. When there is subglottic disease, at least one tracheal ring must be included in the fields. Typical field sizes range from 25 cm^2 (5 × 5 cm) to 36 cm^2 (6 × 6 cm). Harwood et al[78] reported better results with larger fields but acknowledged that at the time they used a free setup that likely accounted for some cases of geographic misses. Teshima et al randomized patients with stage I glottis cancers to treatment with either 25 cm^2 or 36 cm^2 fields and found that results were not different between the two field sizes. The authors emphasize that technique (appropriate coverage of the larynx and wedging to optimize the dose distribution) were critical in obtaining good outcomes, rather than field size per se.[194]

It is acceptable to use cobalt-60 gamma rays for treating glottic cancer because higher-energy beams (6 MV or greater) may underdose the anterior commissure region, particularly in thin patients. Most modern radiation oncology centers no longer have cobalt-60 units and thus rely on linear accelerators. Local control rates of more than 90% have been obtained for T1 lesions treated with 6-MV photons.[82,195] Sombeck et al[196] performed a dosimetric comparison between cobalt-60 and 6-MV beams and found a similar dose distribution except for the most anterior tissues (3 mm below the surface) where underdosing occurred with the 6-MV beam. Consequently, these authors cautioned against using the 6-MV beam for anterior commissure lesions. However, advocates of 6-MV photons for glottic cancer recommend either using tissue-equivalent bolus material for buildup or using a beam spoiler for thin patients or patients with anterior lesions.[195]

A contour or CT plan is obtained to evaluate the dose distribution and determine the need for wedges (Figure 35-6). Fifteen- or 30-degree wedges are often used and improve the dose distribution to the vocal cord, particularly for mid and posterior lesions. Some modern linear accelerators now have dynamic internal wedging to optimize the dosimetry. In the absence of wedging, optimizing the dosimetry can be achieved with "field in field" compensation. This is accomplished by using the internal multileaf collimation system built into the accelerator to create smaller fields within the larger fields to add the needed dose to areas being underdosed by the large "open" field. Some refer to this technique as intensity-modulated radiation therapy (IMRT), though this technique

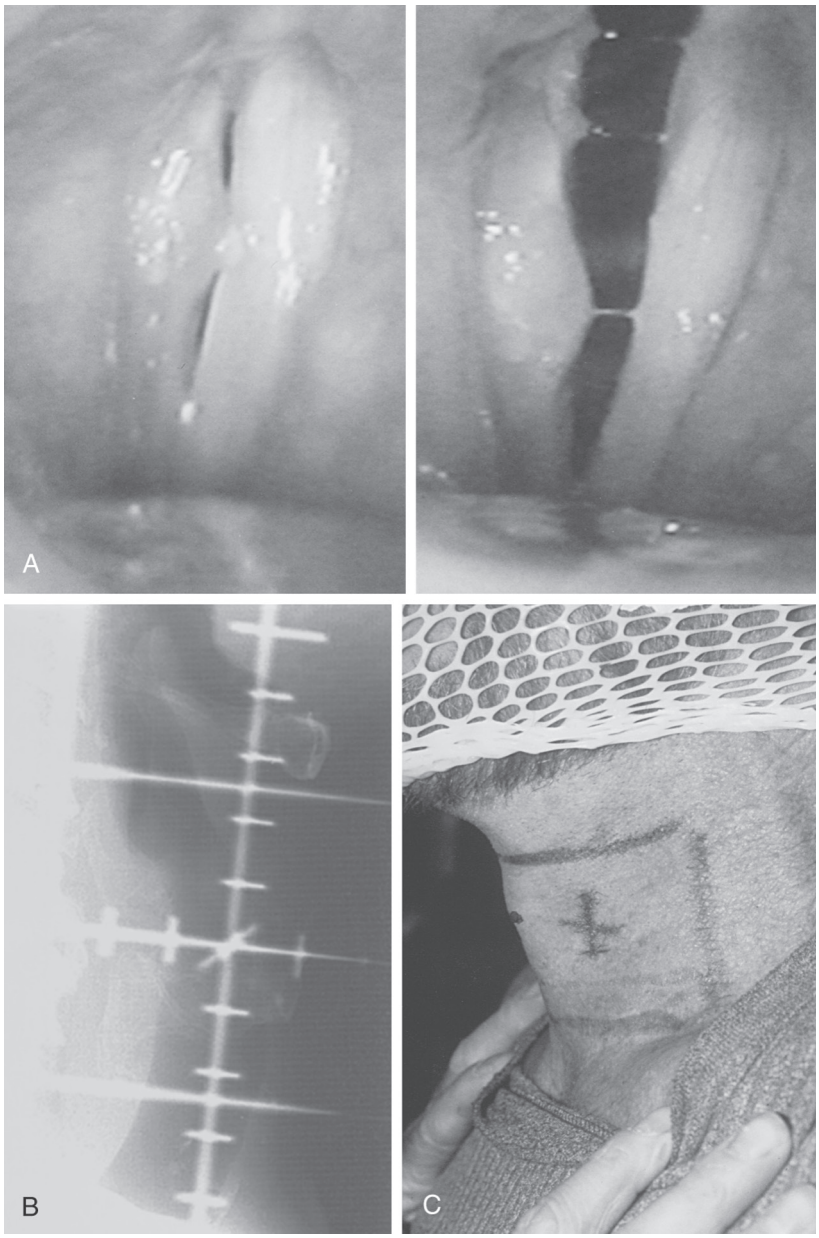

Figure 35-5 **A,** T1 glottic cancer. **B,** Simulation radiograph of a 5 × 5-cm field covering the glottis only for treatment of an early glottic tumor. **C,** Field for a T1 glottic cancer is outlined on the patient's skin.

has fewer fields than true IMRT and also is not inversed planned like true IMRT. Treating without wedges or other forms of compensation results in a less homogeneous distribution, but this may be advantageous for anterior lesions when the built-in dose differential (5% to 10%) is desirable. Unilateral lesions can be treated by unequally weighting (e.g., 3:2) the fields, favoring the side of the lesion.

Radiation doses range from 60 Gy to 70 Gy given in 2-Gy fractions. In general, a dose of 60 Gy is given to patients with no obvious clinical disease after stripping, 66 Gy to those with bulky T1, and 68 Gy to 70 Gy to patients with T2 lesions. Most centers deliver 2 Gy per day, five fractions a week. Several studies evaluating the importance of dose per fraction principally for T1 disease show that 2 Gy per fraction yields better control rates than 1.8 Gy per treatment (Table 35-12). Some centers even advocate the use of larger fraction sizes.[197] Investigators from Osaka randomized patients to either 2 Gy or 2.25 Gy per fraction and demonstrated an improvement in control in patients receiving the higher dose per fraction.[198] Many groups now treat patients with T1 glottic disease with more hypofractionated regimens, and 63 Gy in 28 fractions is a common regimen.[199]

Based on biologic rationale, it has been attempted to improve the control rate of T2 glottic carcinoma by increasing the total dose through hyperfractionation.[104] Two large retrospective studies have since been reported and both have suggested a trend ($p > 0.05$ but < 0.1) toward improved control with twice-daily treatments.[100,109] Mendenhall et al[109] compared 182 patients treated with once-daily or twice-daily treatment and reported the following 5-year actuarial local control rates: T2a, 82% and 83%, respectively; and T2b, 71% and 69%, respectively. The authors contemplated that the advantages of hyperfractionation were mitigated by selection bias. Garden et al[100] analyzed 230 patients, of whom 89 were treated with twice-daily fractionation. Local control rates were 79% and 67%, respectively, for patients treated with twice-daily or once-daily schedules. The authors hypothesized that although there may be a benefit to twice-daily treatment the data more

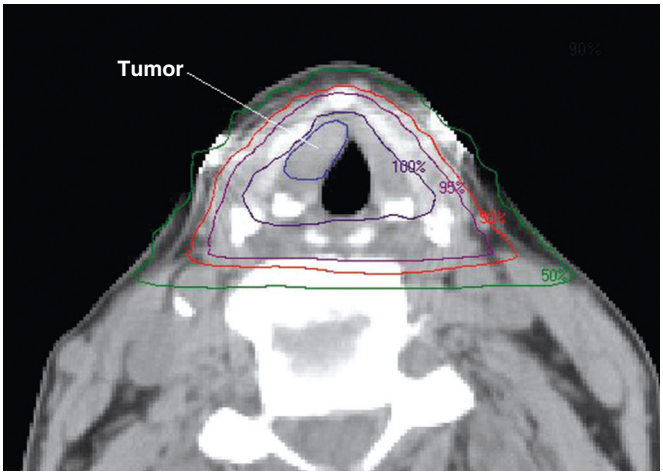

Figure 35-6 Dosimetry of parallel-opposed fields for early glottic carcinoma. Parallel-opposed, 5- × 5-cm fields were used with 30-degree wedges (heel anterior).

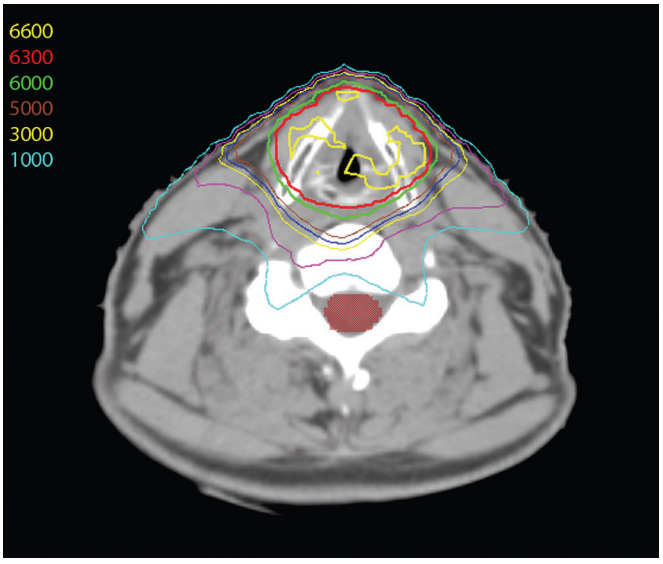

Figure 35-7 Dosimetric plan of three-field IMRT for a patient with T1 cancer of the true vocal cord. A dose of 63 Gy was prescribed in 28 fractions. Note the 3000-cGy isodose line at the anteromedial edges of the carotid vessels.

TABLE 35-12 Results of Irradiation for T1 Glottic Tumors by Fraction Size

Study/ Author	Year	No. Patients	Control Rate by Fraction Size	*p* Value
Schwaibold[200]	1988	56	1.8 Gy: 75% 2.0 Gy: 100%	<0.01
Mendenhall[201]	1988	75	2.0-2.2 Gy: 88% 2.25-2.3 Gy: 96%*	None
Kim[202]	1992	85	1.8 Gy: 79% 2.0 Gy: 96%	0.05
Rudoltz[203]	1993	91	2.0 Gy: 62% ≥2.0 Gy: 87%	0.006
Ricciardelli[204]	1994	42	1.8 Gy: 70% 2.0 Gy: 100%	<0.01
Yu[197]	1997	126	2.0 Gy: 66% 2.25-2.5 Gy: 84%	0.03
Burke[205]	1997	100†	<2.0 Gy: 44% ≥2.0 Gy: 92%	<0.01
Le[84]	1997	315	<1.8 Gy: 79% ≥1.8 Gy: 81-94%	0.05‡
Yamazaki[198]	2006	180	2 Gy: 77% 2.25 Gy: 92%	0.004

**Control in patients receiving > 60 Gy.*
†Includes T1 and T2 patients.
‡Tested continuous variable.

strongly favored a higher daily dose as a more important treatment factor because those patients treated with less than 2 Gy per day had control rates of 59% compared with an 80% control rate for those treated with more than 2 Gy per day.

The RTOG has completed accrual to a randomized trial designed to address this issue, and the results were presented in 2006. Hyperfractionation was associated with an increase in local control of approximately 9% compared with conventional RT at 5 years. Although this result was not statistically significant, it was noted that this small improvement was consistent with results seen in other hyperfractionation studies.[206]

If hyperfractionation is not feasible, daily fractions of greater than 2 Gy per day result in superior outcomes to smaller daily doses. If patients can be treated occasionally twice daily, but not for the entire course, altered schedules such as concomitant boost or those of the DAHANCA are appropriate.

RT of early glottic cancers with small fields rarely induces severe complications. Fletcher and Goepfert[79] described a 1% crude incidence of late edema in patients treated from 1962 to 1979. An analysis of late complications in 230 patients with T2 tumors revealed a 4% incidence of severe complications.[100] The complications were five cases of dysfunctional larynx or chondronecrosis requiring tracheotomy, one case of reversible laryngeal edema, and four cases of postoperative complications related to salvage.

Despite the absence of obvious complications, questions have arisen as to whether irradiation to the neck can lead to an increase in the incidence of stroke.[207] This has led several groups to assess the role of IMRT in irradiating the larynx while sparing the carotid vessels. Two recent reports[102,208] have demonstrated that IMRT can reduce the dose to the carotid arteries (Figure 35-7). A study by MDACC investigators also describes a preliminary experience using IMRT to treat 12 patients, and early data suggest local control rates equivalent to those expected for patients with stages I and II glottic cancer.[208]

T3N0 Glottic, T1-3 Supraglottic, T Any N Glottic, or Hypopharyngeal Carcinomas

T3N0 glottic and T1-3N0 supraglottic carcinomas have historically been treated with parallel, opposed, lateral portals covering the primary tumor and the subdigastric (level II) and midjugular (level III) lymph nodes. A matching anterior portal (with superior midline block to prevent overlap on the spinal cord) encompassing the lower jugular (level IV) and supraclavicular lymph nodes is also used (Figures 35-8 and 35-9). Hypopharyngeal cancers and larynx carcinomas with nodal involvement are treated with larger lateral portals covering the primary disease and the upper (level II) and midjugular (level III) nodes (under the insertion of the sternocleidomastoid muscle) and a matching anterior portal encompassing lower jugular (level IV) and supraclavicular lymph nodes. For

Figure 35-8 This 55-year-old man had squamous cell carcinoma of the right true vocal cord. The entire cord was involved, and there was subglottic extension. The cord was fixed, and the patient's disease was staged as T3N0M0. He received 70 Gy in 35 fractions with the shrinking fields shown and has been without disease for 30 months after therapy.

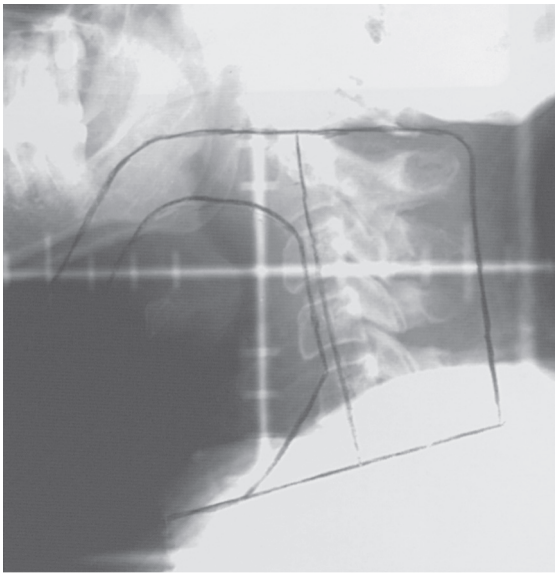

Figure 35-9 A 57-year-old woman presented with right otalgia and had a biopsy-proven squamous cell carcinoma of the epiglottis with extension of disease onto the aryepiglottic fold. The staging was T2N0M0, and she received 76.8 Gy at 1.2 Gy twice daily to the fields shown. She remains without evidence of disease.

hypopharyngeal tumors the inferior border must cover the entire piriform sinus including the apex (Figures 35-10 and 35-11). Because of the posterior location of the majority of these tumors, the off-spinal cord fields extend slightly more posteriorly than for other head and neck primary tumors. This necessitates more frequent portal verification. It is important to encompass the retropharyngeal lymph nodes generously in patients with hypopharyngeal tumors. However, supraglottic

Figure 35-10 This 74-year-old man had a biopsy-proven squamous cell carcinoma arising from the medial wall of the right piriform sinus. The lesion was 1 cm in diameter. The patient's disease was staged T1N0M0. He received 66 Gy in 33 fractions. The initial fields included draining lymphatics and retropharyngeal nodes; an off-spinal cord reduction was made at 42 Gy, and the large fields continued to 50 Gy. A final reduction was made to the total dose. The patient remained without evidence of disease until his death 8 years later.

lesions invading the medial wall of the piriform sinus only do not necessitate wide coverage of the retropharyngeal nodes.

The initial large field, on-cord RT can be accomplished with either cobalt-60 gamma rays or 6-MV photons depending on the neck diameter and the depth of the nodes. It is preferable to irradiate thick patients and those with deep-seated neck nodes with 6-MV beams. The off-cord and boost irradiations are administered with 6-MV beam with delivery of a supplemental dose to the posterior cervical nodes overlying the spinal cord with electron beams of appropriate energy.

Treatment of head and neck cancers with IMRT has rapidly increased since the early 2000s.[209,210] However, preliminary reports of IMRT have focused on treatment of nasopharynx and oropharynx cancer. In trials reporting more general head and neck results, the percentage of patients with laryngeal or hypopharyngeal cancers is extremely low.[211,212] However, particularly for hypopharyngeal cancers or patients with extensive nodal disease, the appeal of IMRT for potentially reducing xerostomia exists. The clinical target volume (CTV) for the primary tumor is the gross target volume (GTV) plus a minimum of 1 cm. In general, the entire larynx is included in the CTV. Planning target volume (PTV) expansion varies dependent on the method of treatment setup and verification; smaller PTVs can be used with image guided therapy (IGRT). However, more generous coverage is recommended in the cranial-caudal dimension, as swallowing can effect the location of the larynx in this plane. Examples of selected target delineation and isodose distributions for patients with advanced supraglottic cancer and a patient with hypopharyngeal cancer are shown in Figures 35-12 to 35-14.

Patients with T1 disease usually receive daily 2-Gy fractions to 64 Gy to 68 Gy. Patients with T2 to T3 lesions receive either daily 2-Gy fractions to 70 Gy, although preferably if they are to be treated with RT and no chemotherapy, they should be treated with either hyperfractionated twice-daily RT

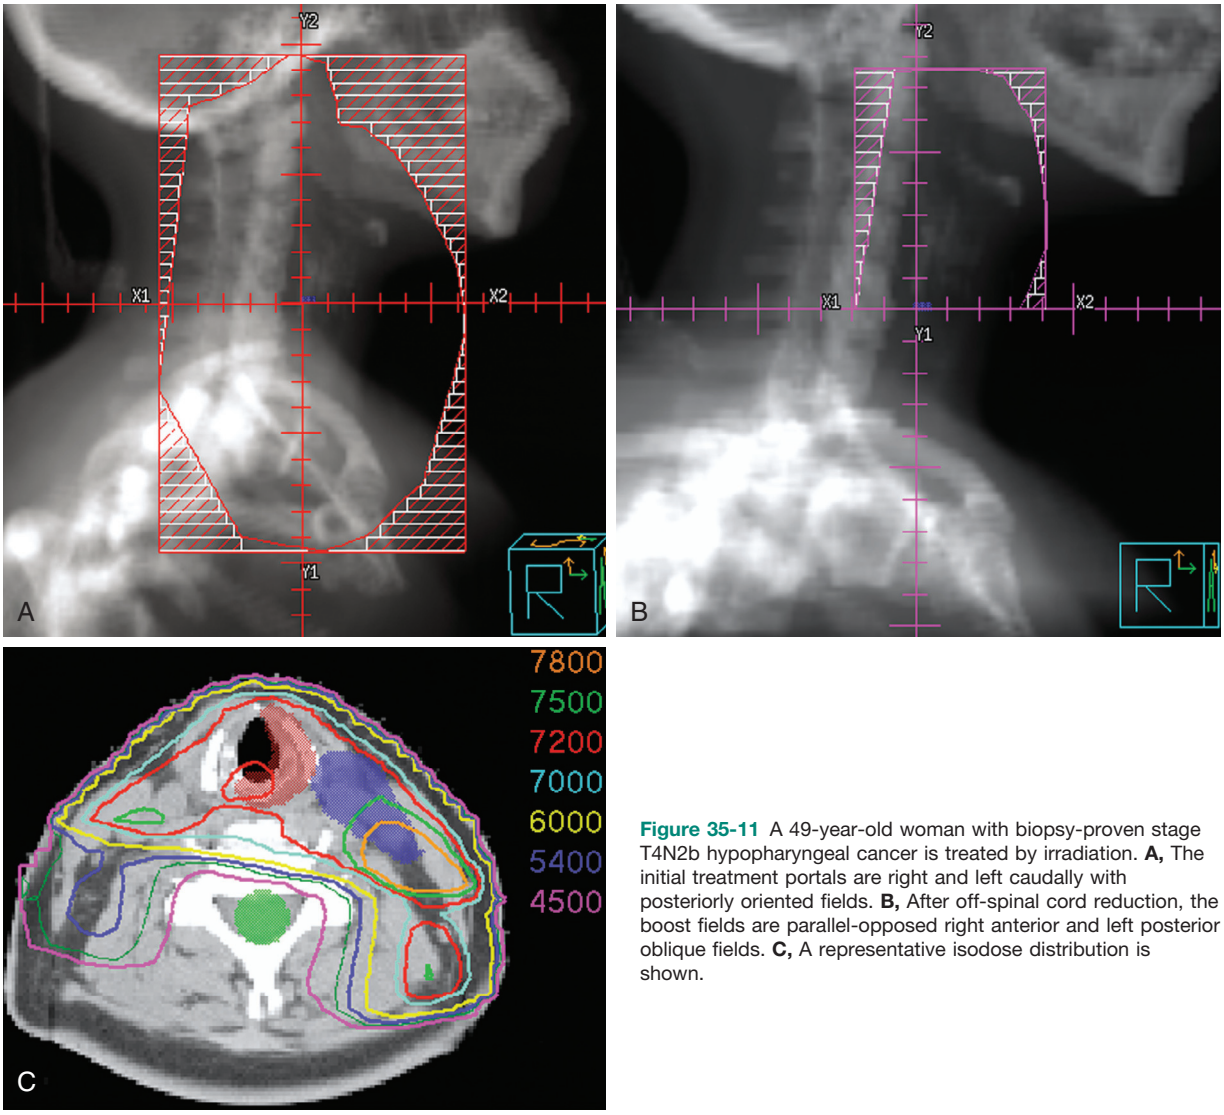

Figure 35-11 A 49-year-old woman with biopsy-proven stage T4N2b hypopharyngeal cancer is treated by irradiation. **A,** The initial treatment portals are right and left caudally with posteriorly oriented fields. **B,** After off-spinal cord reduction, the boost fields are parallel-opposed right anterior and left posterior oblique fields. **C,** A representative isodose distribution is shown.

with fraction size of 1.2 Gy to 76.8 Gy or, alternatively, are treated with an accelerated schedule such as concomitant boost or the DAHANCA schedule.[141] The concomitant boost schedule[213] treats patients to their large fields with 1.8-Gy fractions to 54 Gy and delivers the boost dose with fraction size of 1.5 Gy per fraction during the last 2.5 weeks as a second daily fraction to bring the total dose to gross disease to 72 Gy delivered in 6 weeks. The DAHANCA regimen also treats patients in 6 weeks but in 35 fractions. This is accomplished by delivering the boost as a second daily fraction once per week (for 5 weeks). Portal size is reduced to encompass the gross primary disease with 1-cm to 2-cm margins after reaching an elective dose of 50 Gy (2-Gy fractions) to 54 (1.8-Gy fractions) or 55.2 Gy (1.2-Gy fractions).

Because of larger radiation volume, RT of supraglottic and hypopharyngeal tumors induces a higher complication rate than treatment of early-stage glottic carcinomas. Mendenhall et al[140] have reported a 6% severe acute and late complication rate in 211 patients receiving primary RT for supraglottic carcinomas. In a series of 236 patients treated with hyperfractionation at MDACC, 21 patients developed grade 3 late complications; this includes two patients who died of massive hemoptysis 2 months posttherapy and tracheal necrosis after a tracheotomy, respectively, and two patients who underwent laryngectomy for necrosis.[142] However, the 3-year actuarial complication rate has decreased from 14% to 8% since increasing the interfraction interval from 4 to 6 hours. We currently maintain the 6-hour interfraction interval for twice-daily irradiation.

Postoperative Radiation Therapy

The technique for postoperative RT is similar to that for primary RT. Briefly, initial fields cover the operative and tumor bed. Patients with adverse features requiring postoperative irradiation are at increased risk for stomal failure. Patients were historically treated with a three-field technique: two lateral-opposed fields and an anterior low-neck portal (Figure 35-15). The inferior borders of the lateral fields are in close proximity or even include the superior aspect of the stoma. The stoma itself is included in the anterior low-neck field. Occasionally it is complicated to find the ideal location for the match because of the stomal location. Caudally oriented fields often provide a simple solution for this problem and obviate concerns regarding matching through the stoma or needing to block the stoma for safety reasons.[214]

IMRT is being used more often to treat these patients. This allows tailoring of the dose to high- and intermediate-risk

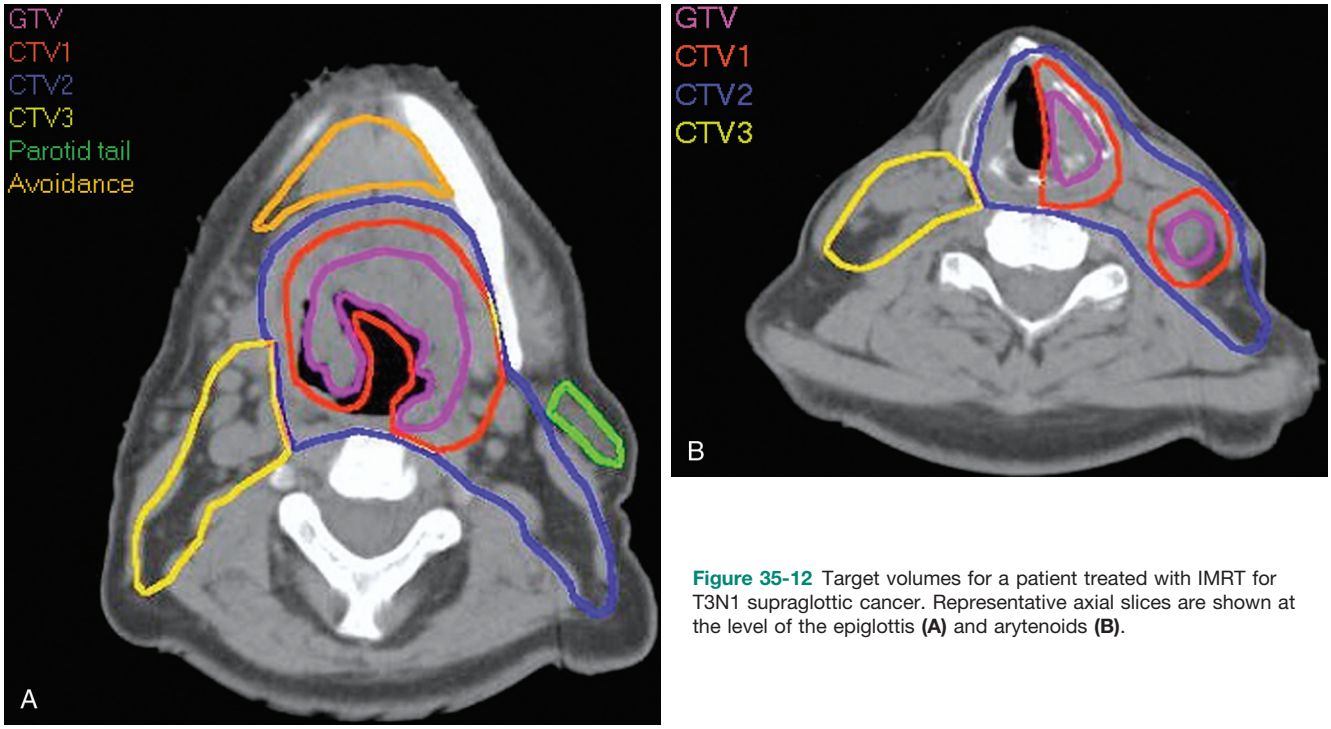

Figure 35-12 Target volumes for a patient treated with IMRT for T3N1 supraglottic cancer. Representative axial slices are shown at the level of the epiglottis **(A)** and arytenoids **(B)**.

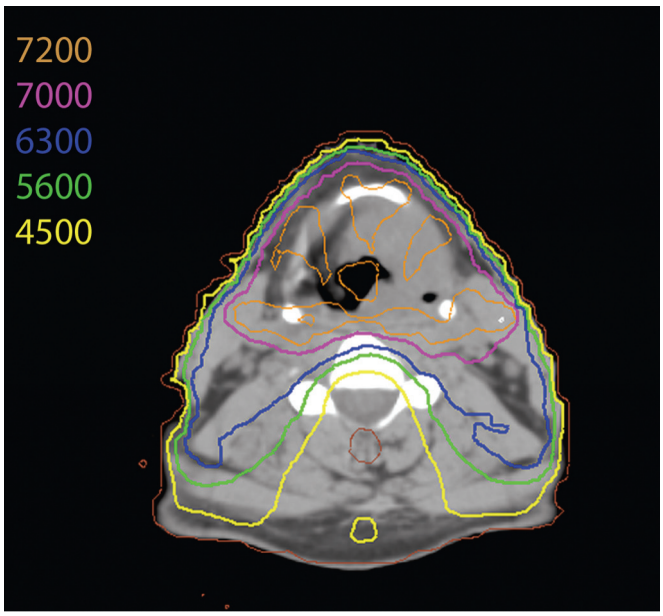

Figure 35-13 Dosimetric plan shown on an axial CT slice of a patient with T3N0 epiglottic cancer treated by IMRT. The bulky tumor can be seen at the level of the superior aspect of the hyoid. The tumor involves the epiglottis, fills the left preepiglottic space, and involves the left aryepiglottic fold and arytenoid. A dose of 70 Gy was prescribed to CTV1 (gross disease and margin). Because of concerns of larynx motion, the entire supraglottic larynx is included in CTV1. CTV2 and CTV3 are dosed to 63 Gy and 56 Gy, respectively. CTV2 included level 3 nodes, and CTV3 included level 2 and 4 nodes. The patient was treated with concurrent cisplatin.

regions, avoids a match because the entire volume can be encompassed by the fields, and, particularly in patients who are node-positive, may allow for parotid sparing (Figure 35-16).

The operative bed is treated to 57.6 Gy, and areas of increased risk are boosted to 63 Gy given in 1.8-Gy fractions[215] or 56 Gy and 60 Gy, respectively, given in 2-Gy fractions. These dose prescriptions are also applicable to targets delineated with IMRT. No dose reduction is applied for patients who have had free jejunal autograft reconstruction because no significant complications have been observed in a series of 29 patients treated to these doses.[216] The dose delivered to surgically undisturbed elective sites is 50 Gy to 54 Gy. The stoma is treated to 50 Gy to 54 Gy and boosted only if there was extensive paratracheal or soft-tissue extension in the region of the stoma.

TREATMENT ALGORITHM, CONTROVERSIES, CHALLENGES, AND FUTURE POSSIBILITIES

Treatment Algorithm

A treatment algorithm for laryngeal and hypopharyngeal cancer is shown in Figure 35-17.

Tis, T1, T2 tumors: These tumors nearly always can be treated with a single modality, either voice-sparing surgery or RT. Infiltrative T2 hypopharyngeal tumors may be considered similar to T3 disease.

T3: Options include either total laryngectomy (with pharyngectomy for a hypopharyngeal primary tumor) or a voice-preservation approach. Concurrent cisplatin and RT has been demonstrated to result in higher rates of larynx preservation than neoadjuvant chemotherapy or RT alone and is usually the treatment of choice, although it does have a modest toxicity profile. RT alone is an option for selected

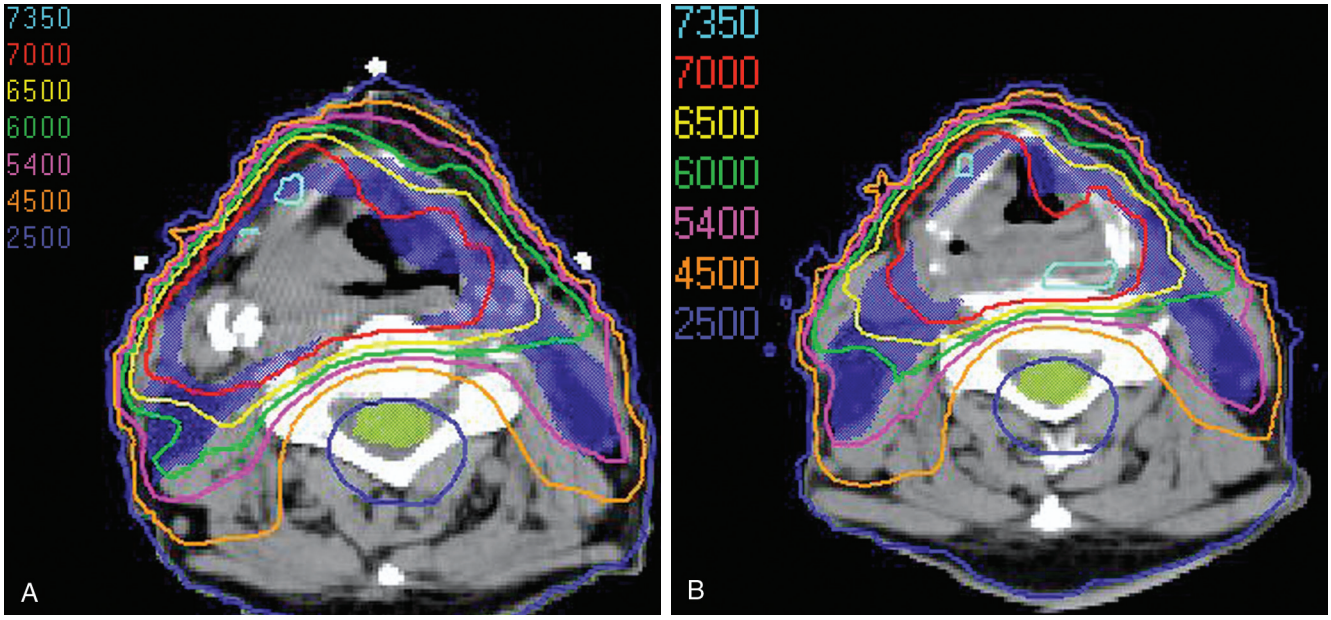

Figure 35-14 Isodose distributions on axial CT images of a patient with T3 carcinoma of the hypopharynx treated with concurrent chemotherapy and IMRT. Representative slices through the vestibule **(A)** and apex **(B)** of the piriform sinus are shown. The high-dose target volume for gross disease and the margin (CTV1) is transparent so the underlying tumor can be visualized. CTV1 was planned to 70 Gy and CTV2 *(blue)* was planned to 50 Gy. Treatment was planned with two sequential plans so that both targets would be fractionated at 2 Gy per fraction.

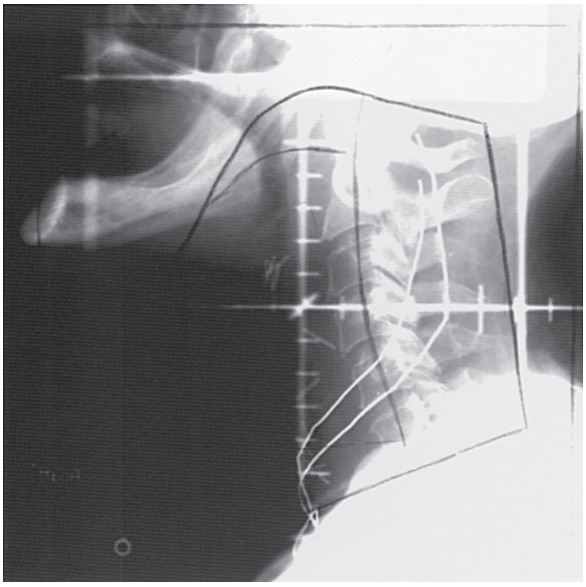

Figure 35-15 A 46-year-old man was diagnosed with squamous cell carcinoma of the right piriform sinus. He underwent a laryngopharyngectomy with jejunal autograft for repair. The tumor was 6 cm in the largest dimension, and it had invaded the soft tissues of the neck. He received postoperative radiation of 60 Gy to the fields shown. The scar and stoma are wired on the skin. One year after his therapy he developed pulmonary metastases and died with metastatic disease.

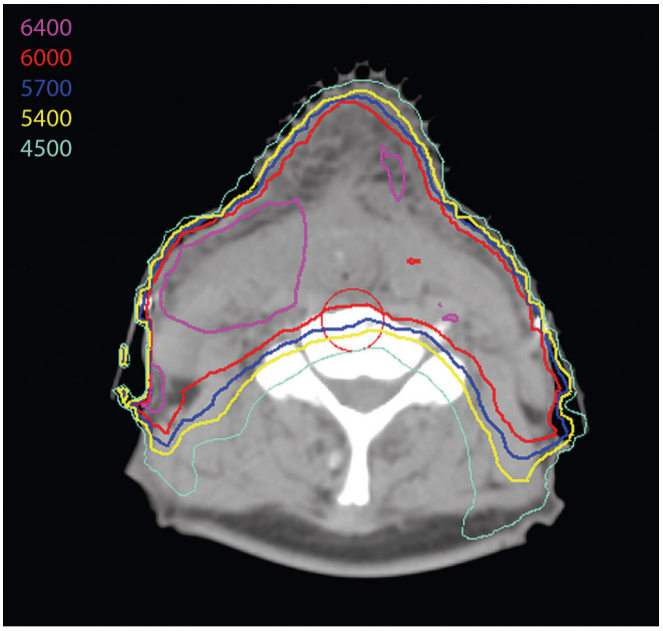

Figure 35-16 Dosimetric plan used for treatment of a patient with advanced supraglottic cancer. His disease was staged T4N2c, and he was treated initially with total laryngectomy and bilateral neck dissections. The pathology report demonstrated extracapsular spread in his right-sided levels 2 and 3 nodes. Radiation was delivered postoperatively in 30 fractions. The tumor bed was specified a dose of 60 Gy, although the area of right-sided nodal disease was specified a dose of 64 Gy. He was also treated with concurrent chemotherapy.

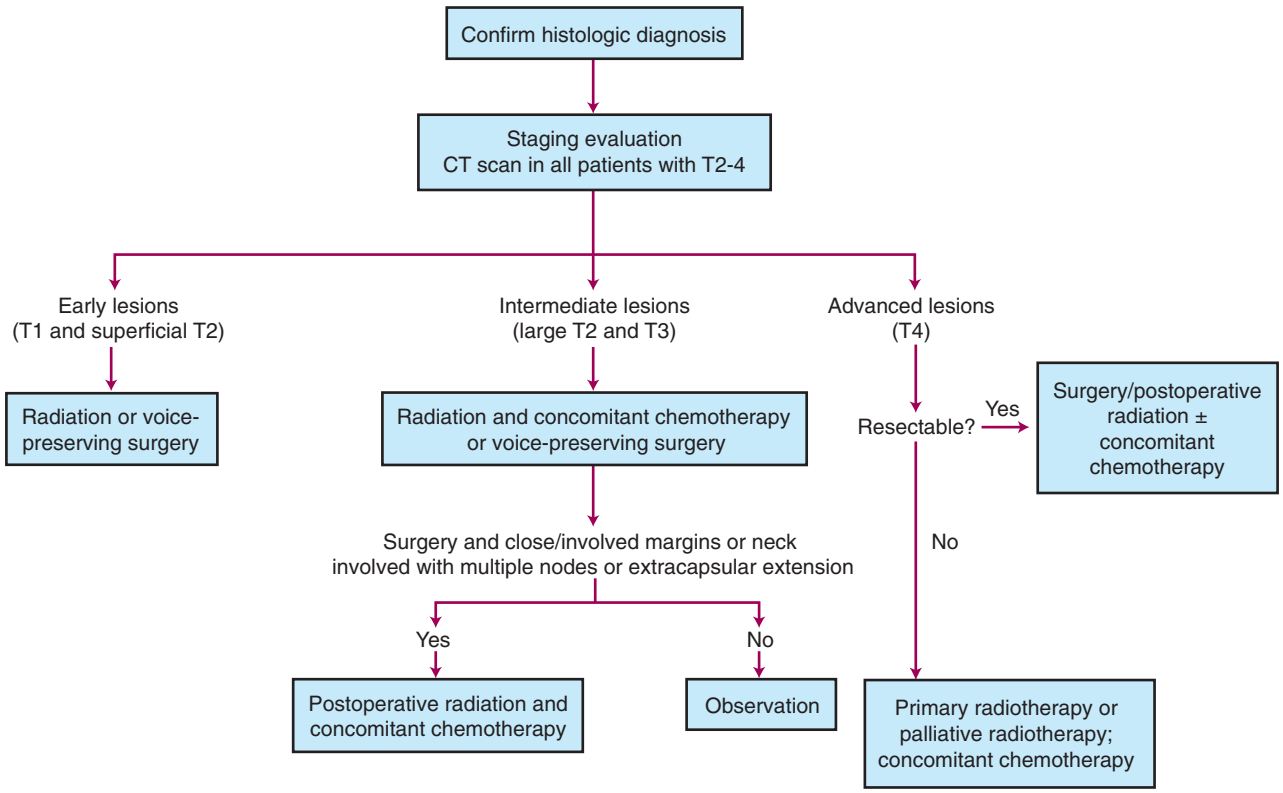

Figure 35-17 Treatment algorithm for patients with cancer of the larynx or hypopharynx.

patients who may desire larynx preservation but are deemed medically unsuitable for chemotherapy.

T4: Surgery with adjuvant postoperative RT remains the treatment of choice. Patients considered to have high-risk features (inadequate surgical margins or soft-tissue spread of disease) may require concurrent chemoradiation in the adjuvant postoperative setting. Highly selected patients with T4 disease may be treated similar to those with T3 disease using concurrent chemoradiation in an attempt at larynx preservation.

N1: If RT is used to treat the primary tumor, then surgery is reserved for any residual nodal mass. If surgery is chosen for primary treatment, then neck dissection is performed and RT is used if there is extracapsular extension or >2 pathologically involved nodes.

N2 and N3: Combined surgery and RT is used for the neck disease and sequencing chosen based on the preferred modality for treatment of the primary tumor.

M1: Systemic therapies are used for patients with good performance status; local therapies are provided for palliation if required.

Controversies, Challenges, and Future Possibilities

In the past two to three decades, we have seen seminal trials performed to maximize preservation of the larynx in patients requiring treatment for laryngeal and hypopharyngeal carcinoma. Ultimately, the concept of larynx preservation was vaguely defined. Trials designed with a primary endpoint of an intact larynx ignored the multiple functions in addition to voice that the larynx provided, particularly swallowing functions (at least with regard to the primary endpoints). Thus, although in 2014 it can be proclaimed that high-dose cisplatin delivered concurrently with radiation is the standard of care for managing locally advanced larynx cancer, this conclusion should be accompanied with caveats.

The results of RTOG 91-11 led us to conclude that most patients with laryngeal cancer can be managed without surgery except for those with T4 disease.[158] This conclusion has come under more scrutiny because SEER data have suggested that survival rates for larynx cancer have decreased in recent years.[157] However, whether this change in survival can be attributed to a greater use of larynx preservation remains moot.[80]

Future directions depend on both our continued understanding of the disease and a better understanding of the impact our therapies have on the laryngopharyngeal structures and how alterations from either disease or therapy impact quality of life. To date, several decades of investigations have not necessarily improved survival rates but have made assumptions that we have improved the quality of life in our patients because we have preserved the larynx in many patients that otherwise would have been treated with laryngectomy. What is required is developing treatments with less toxicity or better prediction models of either the efficacy (with regard to the cancer) of varying treatments in specific individuals or the impact a treatment will have in an individual with regard to function.

In cancer therapy, in general, there has been great interest in targeted therapy with the use of biologic agents. In head and neck cancers, EGFR has been attractive as a target, and preliminary results with concurrent radiation and EGFR blockade have been interesting in terms of potential enhancement of radiation response without an increase in tissue toxicity. In patients who have high levels of EGFR with larynx cancer, this approach has great theoretical appeal in lieu of concurrent RT and chemotherapy. Future directions in treatment of cancer of

the larynx may actually have a de-intensification of therapy for selected patients in whom an effective therapy can be selected with less toxicity. To date, however, in the United States, there has not been a follow-up to RTOG 91-11.

Additional directions will be in better understanding which patients will, after effective tumoricidal therapy, have a functioning larynx and which patients will be subject to chronic aspiration or swallowing dysfunction. The full integration of speech and swallowing assessments before treatment disposition is becoming a critical component in the treatment selection process.

Laryngeal carcinoma (and, to a lesser extent, hypopharyngeal carcinoma) is a curable disease. Great challenges remain, however. We still need to understand which subgroups do not benefit from their selected therapies and have disease relapse and determine if we can further improve survival rates by selecting the appropriate treatment in these patients. In the remaining patients who can be cured, we need to determine the least toxic approaches and continue to explore second primary cancer prevention because the development of less curable malignancies remains an obstacle to prolonged survival in this patient population.

CHAPTER

36 Sinonasal Cancer

Jonathan J. Beitler, Mark W. McDonald, J. Trad Wadsworth, and Patricia A. Hudgins

INCIDENCE AND EPIDEMIOLOGY

Sinonasal cancers comprise less than 1% of all malignant neoplasms and the American Cancer society estimates 2,000 Americans develop cancers of the nasal cavity and paranasal sinuses annually. Men are 50% more likely to be affected. Approximately 40% to 50% occur within the nasal cavity, 30% to 40% within the maxillary sinus, 10% in the ethmoids, and less than 5% in the frontal and sphenoid sinuses.

Sinonasal cancers are more common in carpenters, sawmill personnel, and nickel workers. These tumors are more frequently diagnosed in regions outside the United States, such as Japan and South Africa.

BIOLOGIC CHARACTERISTICS

The natural history of sinonasal cancer depends on the anatomic site, the histologic type, and the stage of the tumor. Distinct from other head and neck sites, nonsquamous cell cancers predominate. In a series of 386 patients with nasal and paranasal sinus tumors treated from 1975 to 1995, squamous cell carcinoma was the most frequent histology but was found in only one third of the patients. The incidence of squamous cell cancers of the paranasal sinuses appears to be decreasing (Annual Percentage Change –1.5% from 1973 to 2009).

Three quarters of sinonasal cancers have TP53 mutations with more than half the mutations being missense mutations.

STAGING EVALUATION

Staging includes a history, head and neck examination including fiberoptic exam, computed tomography (CT) with contrast, magnetic resonance imaging (MRI), and especially in advanced disease, positron emission tomography (PET)/CT scanning.

PRIMARY THERAPY

Radiation is generally selected for the treatment of the nasal vestibule and anterior nasal fossa and yields high locoregional control (LRC) rates with good cosmetic results. Most paranasal sinus tumors should undergo primary surgery, if resectable. Patients who are nonresectable undergo preoperative or definitive photon or proton therapy with or without concurrent chemotherapy, dependent on histology and patient suitability.

ADJUVANT THERAPY

A combination of surgery and radiotherapy (usually given in postoperative setting) is recommended for the management of more advanced resectable cancers. Because of the rarity of these cancers, as well as the varied histologies, randomized studies showing the value of adjuvant radiation therapy, with or without concurrent chemotherapy, are not available.

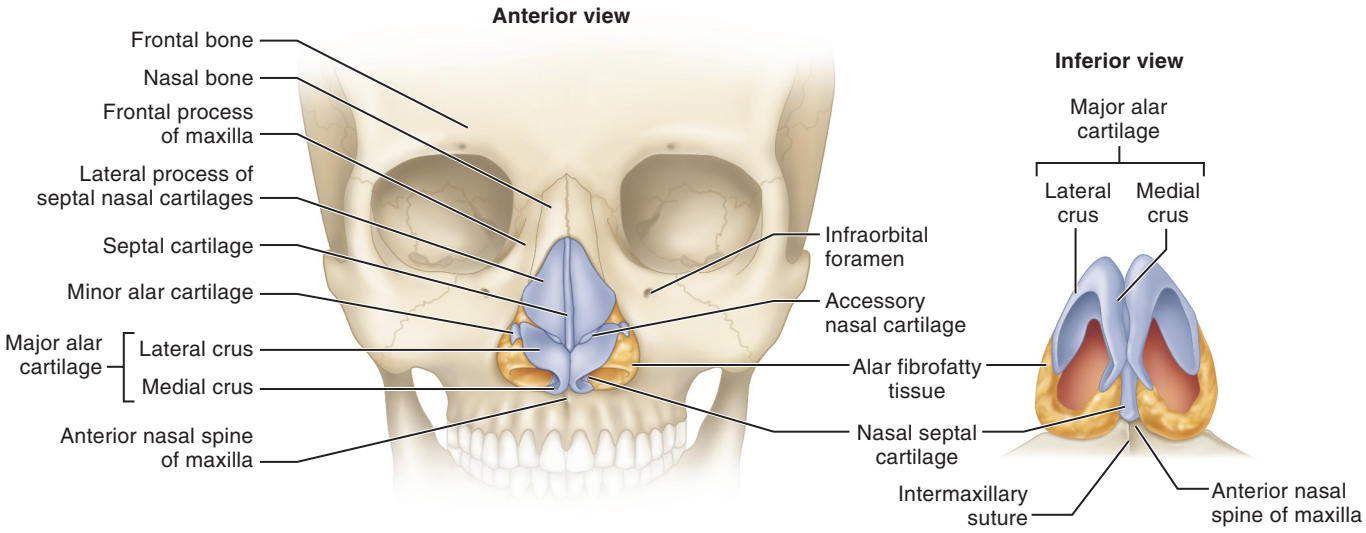
LOCALLY ADVANCED DISEASE AND PALLIATION

For squamous cell cancers, concurrent chemotherapy is frequently used with definitive radiotherapy in the management of inoperable tumors. The use of concurrent chemotherapy is based on data from other head and neck cancer sites.

Definitive radiotherapy can yield local control in a few patients with locally advanced carcinomas who are medically or surgically unresectable.

INTRODUCTION

Sinonasal neoplasms are so rare and encompass such a broad range of anatomical sites and differing histologies that obtaining clinical expertise at one center is particularly difficult. Surgery and radiotherapy are complicated because these tumors are often located close to multiple critical structures (the eye, brain, optic nerves and chiasm, brainstem, and cranial nerves). Aesthetic considerations argue for less radical surgical resection especially if cure is unlikely.



Although the American Joint Committee on Cancer (AJCC) divides the nasal cavity into four subsites[1] (the septum, floor, lateral wall, and vestibule; Figure 36-1 and eFigure 36-1) the nasal vestibule is best considered independently because cancers of the nasal vestibule remain confined until late in their course.

The treatment outcome of patients with carcinoma of the maxillary and ethmoid sinuses has improved if one compares the results, by decades from the 1960s to the 1990s.[2] Using the Danish Head and Neck Cancer Group (DAHANCA) database, the overall 5-year survival from sinonasal cancers treated from 1995 to 2004 were 20% superior to the 1982 to 1991 reference study.[3] In this review of 204 patients, treatment failures occurred in 46% with primary site being involved in 81% of failures. There was a component of nodal failure in 24% and component of distant failure in 14%. The predominant pattern of failure being local is echoed by other publications.[4] Advances have been made in methods of extirpation including skull-base surgery, reconstruction, and highly conformal proton and photon techniques that enable avoidance of adjacent critical normal tissues.[5] Many are gaining experience with endoscopic resections but long-term data on efficacy of this technique as well as radiation using protons is still lacking. The role of chemotherapy for most of these neoplasms has yet to be defined.[5]

This chapter focuses on epithelial neoplasms originating in the nasal cavity or paranasal sinuses. Other histologic types such as sarcomas, lymphomas, and melanomas are discussed in their respective chapters.

ETIOLOGY AND EPIDEMIOLOGY

Cancers of the nasal cavity and paranasal sinuses are uncommon neoplasms, with approximately 2000 Americans diagnosed per year.[6] Tumors of the maxillary sinus are twice as frequent as those of the nasal cavity and ethmoid sinus, and

eFigure 36-1 Anatomy of sinuses: Anterior/lateral and inferior views.

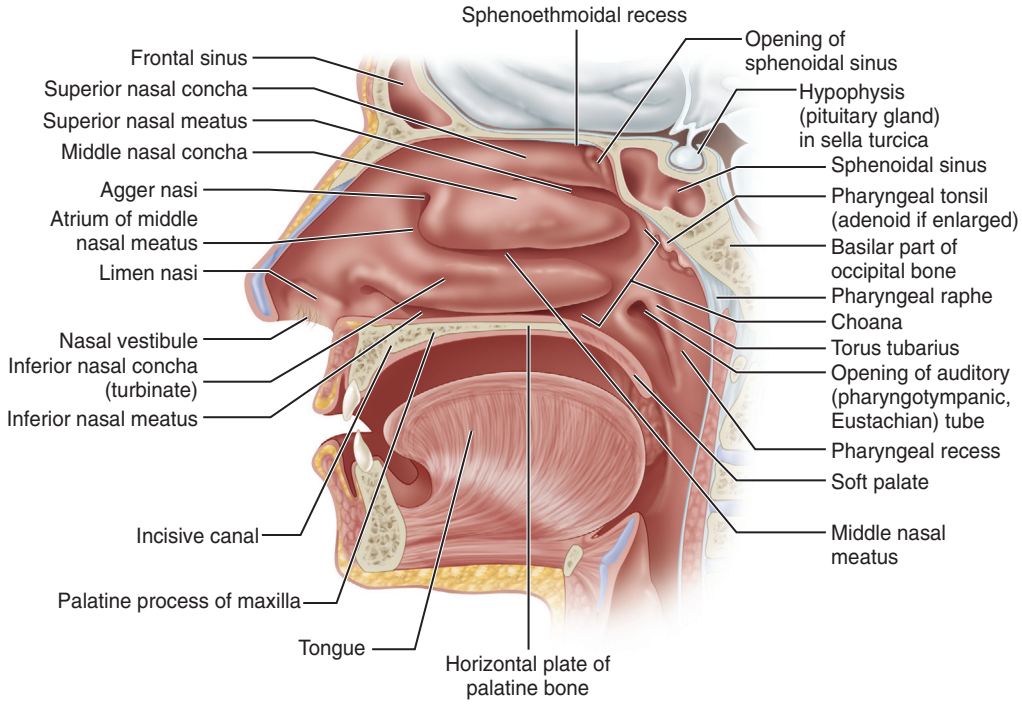


Figure 36-1 Anatomy of sinuses.

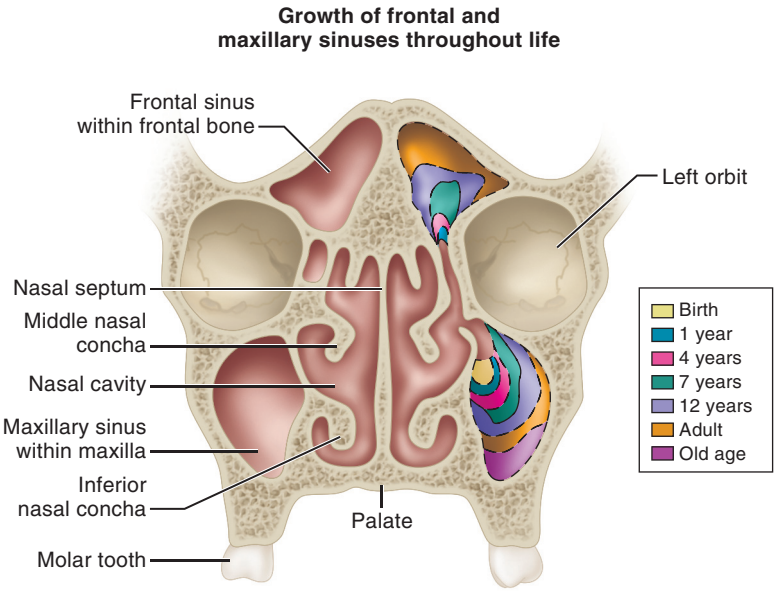
neoplasms of the frontal and sphenoid sinuses are extremely rare. Sinonasal neoplasms occur twice as frequently in men as in women. These tumors are more frequently diagnosed in regions outside the United States, such as Japan and South Africa.

A number of sinonasal cancers are relatively more common in people engaged in certain occupations or exposed to some chemical compounds.[7-12] Excessive numbers of sinonasal squamous cell cancers were seen in bakers, pastry cooks, grain millers, construction workers, carpenters and joiners with at least 15 years in the wood manufacturing industry, farm workers, and female textile workers.[13] Squamous cell carcinoma of the nasal cavity develops more often in nickel workers.[14] Adenocarcinoma of the nasal cavity and ethmoid sinus occurs more frequently in carpenters and sawmill workers who are exposed to the dust of mainly hard and exotic woods.[7,8,10,12] From a review of 358 sinonasal cancers with or without exposure to wood dust, TP53 mutations occurred in all histologies with an overall frequency of 77% but were most common in adenocarcinoma (overall rate 2.0 compared with squamous cell cancer).[15] The risk of TP53 mutations was significantly increased in association with duration, average level, and cumulative level of wood dust exposure. K-ras mutations were reported in 13% of sinonasal adenocarcinomas.[16] Synthetic wood, binding agents, and glues may also be involved as cocarcinogens.[10]

A pooled analysis of 12 case-controlled studies evaluated occupational exposure to formaldehyde, silica dust, textile dust, coal dust, flour dust, asbestos, and man-made vitreous fibers as risk factors for the development of sinonasal cancers.[17] Pooled analysis suggested that formaldehyde was a risk factor for sinonasal adenocarcinoma development but there was a strong association between wood dust and formaldehyde exposure and there were not sufficient formaldehyde only subjects to answer the question. The International Agency for Research on Cancer found that with high professional exposure to formaldehyde and limited wood dust exposure (e.g., embalmers, pathologists, chemical workers) there was no increased mortality from sinonasal cancers.[18]

Maxillary sinus carcinoma was associated with a radioactive thorium-containing contrast material, thorium dioxide (Thorotrast), which was used for radiographic study of the maxillary sinuses decades ago.[9,10] Occupational exposure in the production of chromium, mustard gas, isopropyl alcohol, and radium also increases the risk for sinonasal carcinomas.[9]

Cigarette smoking is reported to increase the risk of nasal cancer, with a doubling of risk among heavy or long-term smokers and a reduction in risk after long-term cessation. After adjustment for smoking, a significant dose-response relation was also noted between alcohol drinking and risk of nasal cancer.[12]



PREVENTION AND EARLY DETECTION

In general, carpenters, sawmill workers, and workers involved in the production of nickel, chromium, mustard gas, isopropyl alcohol, and radium should use appropriate face masks or other strategies to reduce occupational exposure to potential carcinogens. Individuals who develop persistent nasal or sinus symptoms should undergo evaluation.

PATHOLOGY, BIOLOGY, AND PATHWAYS OF SPREAD

The disease course depends on the anatomic site, the histologic type, and the stage of the tumor. The size and configuration of the paranasal sinuses change with age (eFigure 36-2).

Classifying cancers into the bins of squamous cell carcinoma (squamous cell, transitional, and verrucous), adenocarcinoma, glandular carcinoma (adenoid cystic carcinoma and mucoepidermoid carcinoma), and undifferentiated carcinoma, Dulguerov et al[2] identified 386 patients with nasal and paranasal sinus tumors treated between 1975 and 1995 and

eFigure 36-2 Paranasal sinuses: Size and configuration change with age.

TABLE 36-1 Sinonasal Cancer Histology

Histology	*n*	%
Squamous Cell	126	32.6
Sarcoma	52	13.5
Esthesioneuroblastoma	42	10.9
Glandular	39	10.1
Adenoid cystic	35	9.1
Lymphomas	38	9.8
Melanoma	34	8.8
Undifferentiated	30	7.8
Adenocarcinoma	25	6.5

Data from Dulguerov P, Jacobsen MS, Allal AS, et al: Nasal and paranasal sinus carcinoma. Are we making progress? A series of 220 patients and a systemic review. Cancer 92(12):3012–3020, 2001.

excluded nasal vestibule cancers. Squamous cell carcinoma was the most frequent histology but was only found in one third of the patients (Table 36-1).

Nasal Vestibule

The nasal vestibules are the two entry points into the nasal cavity. Each is a triangle-shaped space situated in front of the limen nasi and defined *laterally* by the lateral crus and alar fibrofatty tissue, *medially* by the medial crus of the alar cartilage and the nasal septum and the distal end of the cartilaginous septum, and columella (see Figures 36-1 and eFigure 36-1). The nasal vestibule is covered by skin and, therefore, lesions at this location are essentially squamous cell skin cancers[19] but may occasionally be basal cell carcinoma,[20] sebaceous carcinoma,[21] melanoma,[22] or non-Hodgkin's lymphoma.[23] Nasal vestibule cancers are analogous to cancers of the anal margin. Human papilloma virus has been implicated in the development of nasal septal cancers.[24]

Cancers of the nasal vestibule are said to arise preferentially on the medial wall, which is the nasal septum.[25] Nasal vestibule carcinomas can spread by invasion of the upper lip, gingiva-labial sulcus, premaxilla, or nasal cavity. Vertical invasion may result in septal (membranous or cartilaginous) perforation or alar cartilage destruction. Lymphatic spread from nasal vestibule carcinomas is usually to the ipsilateral facial (buccinator and mandibular) and submandibular nodes. The buccinators nodes[26] can be found on the buccinator muscle or in the fat of the buccinator space (Figure 36-2 *A,B*).

The buccinators nodes are divided into anterior or posterior buccinator depending on their relationship to the facial vein. The mandibular nodes[26] include the supramaxillary nodes, the supramandibular nodes, and the inframandibular nodes and lie along the external surface of the mandible adjacent to the facial artery and anterior to the masseter muscle. Large lesions extending across the midline may spread to the contralateral facial or submandibular nodes. The average incidence of nodal metastasis at diagnosis is approximately 5%.[27-31] Without elective lymphatic treatment, about 15% of patients develop nodal relapse.[27-29,31] In the intensity-modulated radiation therapy (IMRT) era, when parotid sparing is de rigueur, the 15% incidence of nodal relapse makes consideration of elective nodal irradiation mandatory. Hematogenous metastases are rare in nasal vestibule carcinomas.[31]

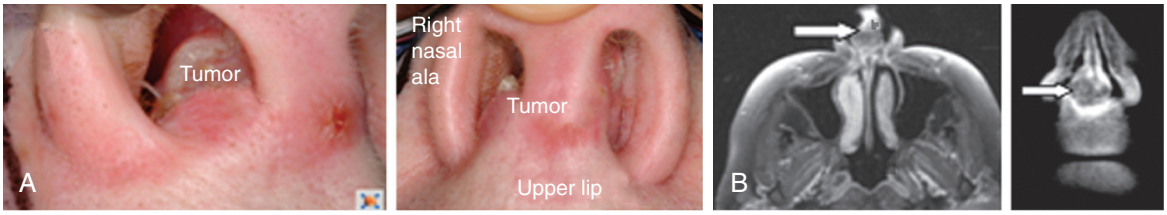
Examples of nasal vestibule tumors are shown in the photographs and magnetic resonance (MR) images in Figures 36-3 and eFigure 36-3 *A,B*.

BOX 36-1 Paranasal Sinus Drainage Pathways

SINUS	ORIFICE	DESTINATION
Posterior ethmoid	Sphenoethmoidal recess	Superior meatus
Sphenoid sinus	Sphenoethmoidal recess	Superior meatus
Anterior ethmoids	Ethmoid bulla	Middle meatus
Frontal sinus	Osteomeatal complex	Middle meatus
Maxillary sinus	Osteomeatal complex	Middle meatus
Nasolacrimal duct	Nasolacrimal duct	Inferior meatus

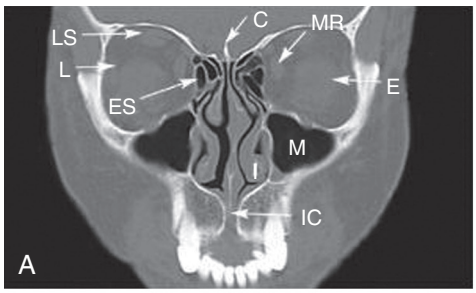
Nasal Cavity and Ethmoid Air Cells

Nasal cavity and ethmoid sinus tumors now share a common staging system.[1] The *nasal cavity proper* (nasal fossa), which excludes the nasal vestibule, begins at the limen nasi anteriorly and ends at the choana posteriorly. It extends from the hard palate inferiorly to the cribriform plate superiorly. The lateral walls consist of three thin bony structures, the superior, middle, and inferior turbinates (or concha) that project inferomedially into the nasal cavity (eFigure 36-4). The middle turbinate attaches to the cribriform plate superiorly and then posteriorly and laterally to the lamina papyracea[32] (Figure 36-4 and see eFigure 36-4).



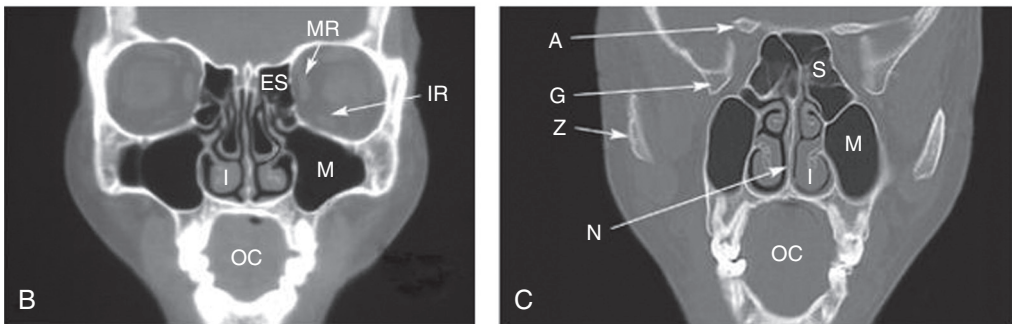
The region inferior to each turbinate is defined as the superior, middle, and inferior meati (see Figure 36-4). The superior meatus receives drainage from the posterior ethmoid air cells and the sphenoid sinus at the sphenoethmoidal recess (Box 36-1). The middle meatus is a particularly important site of drainage, taking drainage from the anterior ethmoids, the frontal sinus, and the maxilla. The anterior ethmoid air cells drain into the ethmoid bulla at the superior aspect of the osteomeatal complex, the frontal sinus drains into the middle meatus at the anterior portion of the osteomeatal complex, whereas the maxillary sinus dumps its content past the infundibulum (a valve at the superior medial aspect of the maxilla) into the middle meatus by way of the maxillary ostium at the inferior osteomeatal complex (see pink arrow in Figure 36-5). Of course, the inferior meatus receives drainage from each nasolacrimal duct.

The septum divides the nasal cavity into right and left halves (Figure 36-6). The olfactory nerves penetrate the cribriform plate and innervate the roof of the nasal cavity, superior nasal turbinate, and the upper third of the septum. This portion of the nasal cavity is referred to as the *olfactory region.* The remaining part of the cavity, the respiratory region, contains orifices connecting the nasal cavity with the paranasal sinuses.



The *ethmoid sinuses* comprise several small cavities, called ethmoid air cells, within the ethmoidal labyrinth located below the anterior cranial fossa and between the nasal cavity and the orbit (eFigure 36-5). They are separated from the orbital cavity by a thin, porous bone called the *lamina papyracea* and from the anterior cranial fossa by a portion of the frontal bone, the *fovea ethmoidalis.*

Neoplasms originating in the respiratory region of the nasal cavity and ethmoid cells are squamous cell carcinoma, adenocarcinoma, and adenoid cystic carcinoma. Carcinoma may arise from inverted papilloma.



The pattern of contiguous spread of carcinomas varies with the location of the primary lesion. Tumors arising in the upper nasal cavity and ethmoid air cells extend to the orbit through the lamina papyracea and to the anterior cranial fossa via the cribriform plate, or grow through the nasal bone to the subcutaneous tissue and skin. Lateral wall primaries invade the maxillary antrum, ethmoid airs cells, orbit, pterygopalatine fossa, and nasopharynx. Primaries of the floor and lower

septum may invade the palate and maxillary antrum. Spreading may also occur through perineural spaces especially when the histology is adenoid cystic cancer (Figure 36-7 A-I).

Lymphatic spread of respiratory region primaries is variable. Turning first to nasal cavity, where approximately 50% of the patients have a squamous cell histology,[33] a review of 23 studies with a median follow-up of 4.4 years found the weighted average regional recurrence rate for squamous cell cancers of the nasal cavity to be 18.1%.[34] At least some patients from 7 of the 23 studies received prophylactic cervical nodal irradiation, which significantly lowered the rate of neck failure.

Review of the Istituto Nazionale per lo Studio e la Cura dei Tumori of Milan experience from 1968 to 2003[35] identified 305 consecutive tumors of the ethmoid sinus. There was a striking

male predominance, 70.8% versus 29.2%. Intestinal type adenocarcinoma was the most frequent histology, 50.2%, with only 10.8% of patients with ethmoid sinus cancer having squamous cell cancer. The strong male predominance was confirmed in a 202-person study of European patients with adenocarcinomas of the ethmoid sinus.[35] Only 1.6% of 305 patients with ethmoid sinus cancer presented with adenopathy, and with a median follow-up of 109 months, the cumulative incidence of lymphatic recurrence was 4.3%.[35] It is important to note that most neck recurrences were accompanied by recurrence of the primary tumor. The 5-year cumulative incidence of metastases was just 3.6%.

The olfactory region is located at the roof of the nasal cavity. It represents a narrow strip demarcated by the lamina cribrosa and the adjoining septum and lateral walls. The olfactory region is the site of origin of esthesioneuroblastoma and, occasionally, adenocarcinomas.

Esthesioneuroblastoma is a tumor of neural crest origin first reported by Berger and Luc in 1924 as esthesioneuroepithelioma olfactif.[36] It has been given a variety of other names, including *olfactory neuroblastoma*, and *esthesioneurocytoma.* Esthesioneuroblastoma constitutes approximately 3% of all intranasal neoplasms. About 250 cases were reported in the literature between 1924 and 1990.[37] A typical histologic feature of esthesioneuroblastoma is that of a tumor comprised of round, oval, or fusiform cells containing neurofibrils with pseudorosette formation and diffusely increased microvascularity.[38] Perivascular palisading of cells can be observed in the absence of pseudorosette formation.

Esthesioneuroblastoma may be mistaken for any other "small round-cell tumor": a group of aggressive malignant tumors composed of relatively small and monotonous undifferentiated blue staining cells. These include Ewing's sarcoma, peripheral neuroepithelioma (also referred to as primitive neuroectodermal tumor or extraskeletal Ewing's), peripheral neuroblastoma ("classic-type"), rhabdomyosarcoma, desmoplastic small round-cell tumor, lymphoma, leukemia, small-cell osteosarcoma, small-cell carcinoma (either undifferentiated or neuroendocrine), cutaneous neuroendocrine carcinoma (Merkel-cell carcinoma), small-cell melanoma, and mesenchymal chondrosarcoma. Their clinical presentations often overlap but clinicopathologic features and immunohistochemistry may help in differentiation.

The route of contiguous spread of esthesioneuroblastomas is similar to that of ethmoid carcinomas. Multiple and late local and regional recurrences are the rule. Eventual development of neck disease has been reported in 21% of 110 patients[39] and in 20.2% of 678 patients,[40] with 61.7% of the cervical disease occurring more than 6 months after the diagnosis.

Maxillary Sinus

Maxillary sinuses, the largest of the paranasal sinuses, are pyramid-shaped cavities located in the maxillae. The base of the maxillary sinus forms the inferior part of the lateral wall of the nasal cavity. The roof of the maxillary sinus is formed by the floor of the orbit, which contains the infraorbital canal, and the floor is composed of the alveolar process. The apex extends toward, and frequently into, the zygomatic bone. Ohngren's line is a theoretical line passing from the medial canthus of the eye to the angle of the mandible and divides the maxillary sinus cancers into suprastructure and infrastructure tumors. Tumors superior to this arbitrary plane invade vital structures such as the orbit and middle cranial fossa earlier and thus have a worse prognosis.[41] Also of importance when understanding the anatomy of the maxillary sinus is the pterygopalatine fossa. The pterygopalatine fossa, also known as the sphenopalatine fossa, can be thought of as a box, with its anterior wall being the posterior wall of

the maxillary sinus. The posterior wall is the pterygoid plates and inferior aspect of the sphenoid bone, the roof is the inferior orbital fissure. The floor is the palantine canal and contains the greater palantine nerve. Medially it is defined by the perpendicular plane of the palatine bone. The pterygopalatine fossa contains the maxillary nerve (V2), which enters from the brain via the foramen rotundum, as well as the pterygopalatine ganglion and the distal maxillary artery, which enters via the pterygomaxillary fissure. The pterygopalatine ganglion is the largest head and neck parasympathetic ganglion and has sensory, motor, and sympathetic function.

Sixty-two percent of maxillary sinus cancers are squamous cell carcinomas.[2,42] Other histologic types and survivals are shown in Table 36-2.

The pattern of spread of maxillary sinus cancer varies with the site of origin. Neoplasms of the suprastructure tend to extend into the nasal cavity, nasopharynx, ethmoid cells, inferior or medial wall of the orbit, orbital contents, pterygopalatine fossa, masticator space, infratemporal fossa, base of the skull, parasellar region and cavernous sinus, and middle cranial fossa. Tumors of the infrastructure extend to the palate, alveolar process, gingivobuccal sulcus, soft tissue of the cheek, nasal cavity, masseter muscle, pterygopalatine space, and pterygoid fossa. It is sometimes difficult to differentiate from tumors extending from the upper alveolus and hard palate.

Overall, the incidence of clinical lymphadenopathy is relatively uncommon at diagnosis but because regional recurrence is common the presumption is that subclinical nodal disease

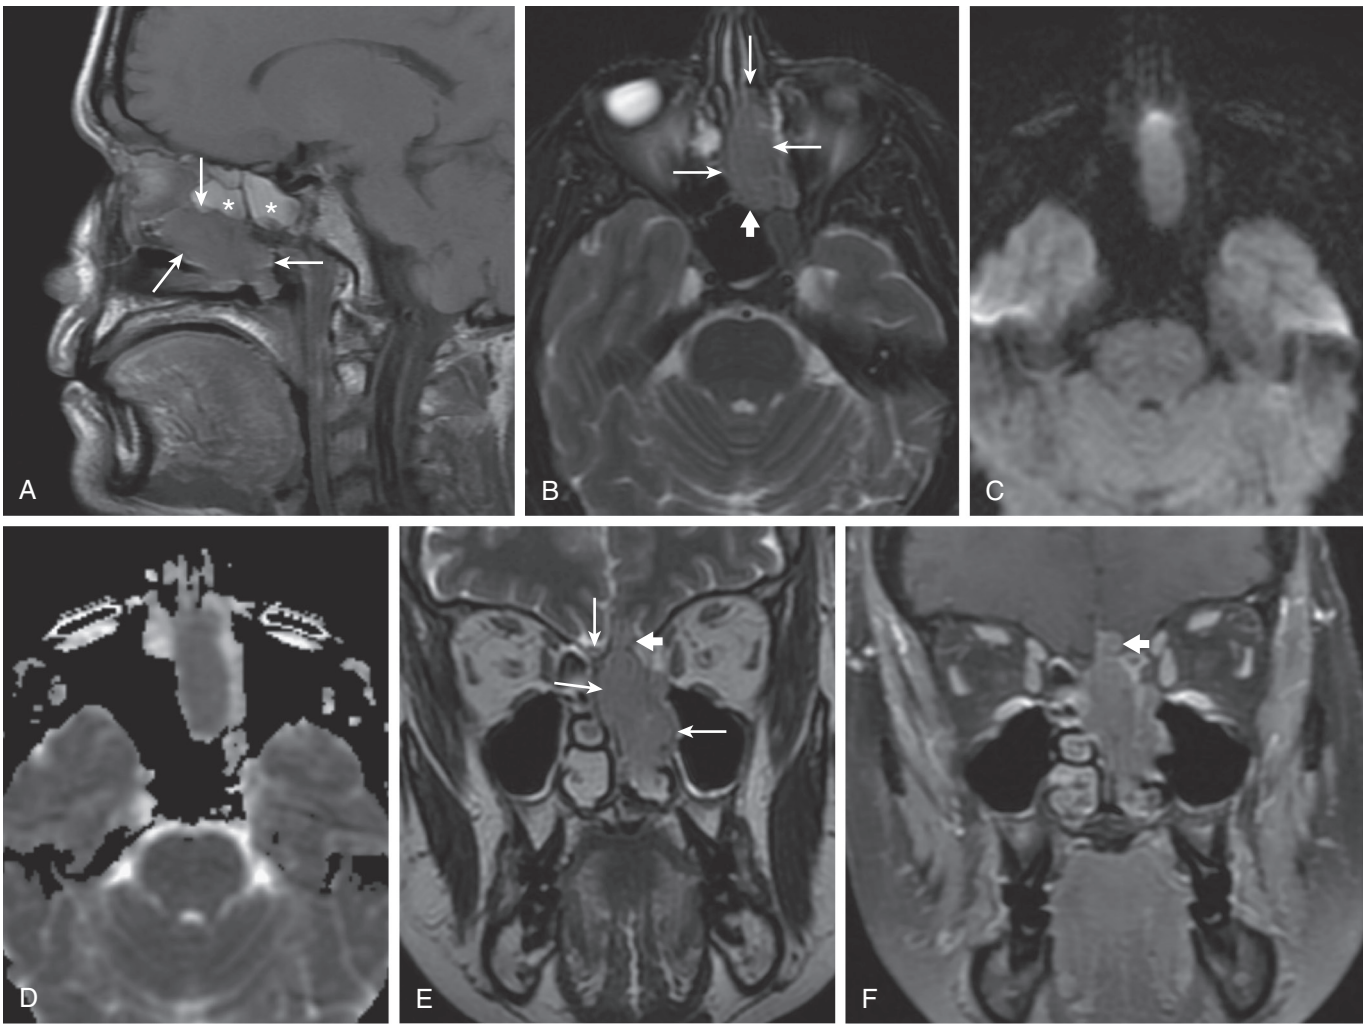

Figure 36-7 **(A-F)** Patient with nasal cavity tumor with left sphenoid sinus and intracranial extension. **A,** T1 sagittal image shows relatively low signal intensity (SI) tumor *(arrows)* in nasal cavity, extending to nasopharynx. Posterior ethmoids and sphenoid sinus are completely opacified *(asterisks)* with high SI chronic proteinaceous debris. **B,** T2-weighted fat saturated axial image shows the tumor *(arrows)* in left nasal cavity, with invasion through the anterior left sphenoid sinus wall *(arrowhead)*. Note high SI benign secretions in right ethmoid sinus. **C,** Diffusion-weighted image (DWI) shows relatively high signal in tumor. **D,** Apparent diffusion coefficient (ADC) map confirms the "restricted diffusion" because the lesion is low signal on the map. DWI can be helpful in determining whether a lesion is benign or malignant but should never be used in isolation. **E,** T2 coronal image through the left nasal cavity mass shows extension across the bony perpendicular ethmoid bone *(long arrow)*, into the right nasal cavity roof, and laterally through the medial left maxillary sinus wall *(short arrow)*. The tumor has extended across the left cribriform plate, and fills the olfactory recess, obliterating the left olfactory bulb *(white arrowhead)*. Note normal right olfactory bulb *(black arrow)*. **F,** T1 fat saturated gadolinium enhanced coronal image at same level as 3A confirms intracranial extension *(arrowhead)* on left. The smooth interface between the tumor and the gyrus rectus suggests no intradural invasion. The boundaries of the tumor are better appreciated on the T2 image, as all the normal mucosa enhances with gadolinium contrast on T1, similar to the mass.

Continued

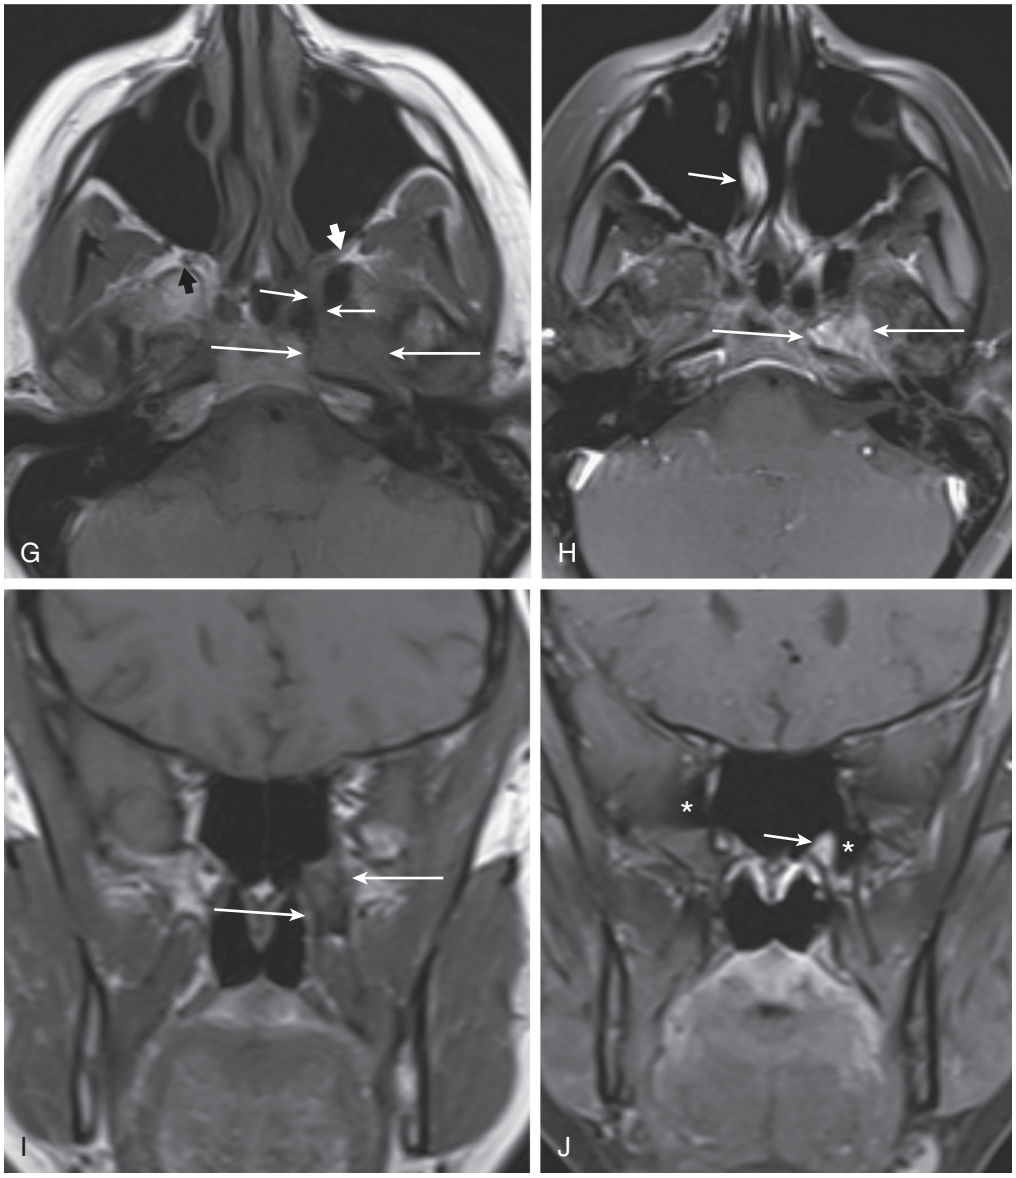

Figure 36-7, cont'd Patient with adenoid cystic carcinoma of sinus shown on axial and coronal T1 images **(G, I)** and axial and coronal T1 fat-saturated gadolinium enhanced images **(H, J)**. Imaging findings of perineural tumor are enlargement of a skull-base foramen, thickening and enhancement of the nerve, and replacement of fat that is always present at the extracranial side of the foramen. **G,** Image through the central skull base shows abnormal SI of bone *(long arrows)*, and replacement of fat in left pterygopalatine fossa *(arrowhead)*. Right pterygopalatine fossa is normal, with high SI fat *(black arrowhead)*. Note perineural tumor in left vidian *canal (short arrows)*. **H,** Robust enhancement in the abnormal bony skull base *(long arrows)* makes the tumor less conspicuous, as normal marrow is also high SI. Even perineural tumor is more difficult to appreciate, as there is normal enhancement in the nasal cavity mucosa *(short arrow)* and bright susceptibility artifact from the fat-saturation technique. **I,** T1 coronal image, without gadolinium, clearly shows abnormal SI of left pterygoid plates *(arrows)* from replacement by tumor. **J,** Gadolinium-enhanced image shows thickening and abnormal enhancement of left vidian nerve *(short arrow)* from perineural tumor spread. The osseous tumor is better seen on the precontrast image. Note band of black artifact through skull base *(asterisks)*, a limitation of fat-saturation technique at bone-air interface. Both pre- and gadolinium-enhanced T1 images are recommended to detect skull-base invasion and perineural tumor. Both sets of images must be carefully evaluated because some lesions are better seen without gadolinium and some better seen after contrast.

exists at presentation.[25] Cantu et al reported that 8.3% of 399 patients presented with lymphadenopathy, and during follow-up (median 109 months) 12.5% developed regional recurrence. Squamous cell primary cancers of the maxilla had a 10.3% incidence of nodal disease at presentation, with a 36.4% recurrence rate in patients who were N+.[35] The cumulative incidence of neck recurrence for patients with squamous cell cancer of the maxilla was 20.7%.[35] Le[43] has published the location of nodal presentation and failure and found that Levels IB, II, V, and the preauricular area can be involved ipsilaterally, and Levels II contralaterally.

Sinonasal Undifferentiated Carcinoma (SNUC)

Sinonasal undifferentiated carcinoma (SNUC) has recently been identified by the World Health Organization[44] as a distinct sinonasal neoplasm that should be differentiated from esthesioneuroblastoma and other cancers.[45] There is a male predominance and tumors typically are aggressive presenting with locally extensive disease. Etiology is unknown. Immunohistochemical studies are noncontributory and stains for epithelial mucin are negative. The nuclear to cytoplasmic ratio is high with a high mitotic rate. In 2005 there were fewer than

TABLE 36-2 Tumor Types and Survival for Maxillary Sinus Cancer

Tumor Type	No. Pts.	%	Survival	
			Median (mo.)	5-yr (%)
Squamous cell	401	61.7	18	29.2

100 cases of SNUC described, by 2008 approximately 200 cases were described,[46] and a review from 2009[45] as well as anecdotal experience suggested that the diagnosis is becoming more common. Scanty evidence ($n = 17$) reported that SNUC is one of the few ethmoid sinus cancers with a 25.5% rate of regional failure. A 13% rate of regional failure in 26 SNUCs from the maxilla was reported.[35] Mendenhall's review of the literature found 10% to 30% of patients with SNUC have clinically positive adenopathy and the cure rates varied from 20% to 50%.[47]

CLINICAL MANIFESTATION, PATIENT EVALUATION, AND STAGING

Table 36-3 summarizes the updated AJCC TNM classification (seventh edition) for cancers of the maxillary sinus, the ethmoid sinus, and the nasal cavity.[1] Significant updates in the seventh edition are as follows:

- T4 lesions are divided into T4a (moderately advanced local disease) and T4b (very advanced local disease).
- Stage IVB is defined by either T4b or N3 disease and IVC disease is defined as M1 disease.

For purposes of staging, the nasal cavity and ethmoids are considered different sites, and the maxillary sinus and ethmoid sinus are each divided into a left and right subsite. The subsites of the nasal cavity have already been identified.

Nasal Vestibule

Small carcinomas of the nasal vestibule usually present as asymptomatic plaques or nodules, often with crusting and scabbing. The septum is the most common location.[25,48] Advanced lesions may extend to adjacent structures, such as upper nasal septum, upper lip, infranasal depression (philtrum), skin of nose, nasolabial fold, hard palate, buccogingival sulcus, etc. Deep muscle and bone and nerve involvement may cause pain accompanied by bleeding or ulceration. Large ulcerated lesions may become infected, leading to severe tenderness that hinders complete clinical assessment. The contiguous spread is best assessed by bimanual palpation and examination through a nasal speculum or fiberoptic endoscopy after mucosal decongestion and topical anesthesia. Early buccinator and submandibular nodal involvement may be detected by bimanual palpation or by imaging.[26] Staging of nasal vestibule carcinoma is by the TNM classification system for the skin. However, other staging systems have been used in reporting data.[49,50]

Nasal Cavity and Ethmoid Air Cells

Carcinoma

The presenting symptoms and signs of nasal fossa tumors are similar to those associated with nasal polyps; chronic unilateral nasal discharge, ulcer, obstruction, anterior headache, and intermittent nosebleeds. This similarity often leads to delays in diagnosis. Other symptoms and signs include nasal ulcer, tenderness, facial swelling, or pain.[22] Invasion of the orbital cavity may produce a palpable medial orbital mass, proptosis, and diplopia; obstruction of the nasolacrimal duct causes epiphora (overflow of tears); involvement of the olfactory region may produce anosmia (inability to perceive odors) and expansion of the nasal bridge; and extension through the cribriform plate results in frontal headache.

The presenting symptoms and signs of ethmoid air cell tumors are sinus ache and referred pain to the nasal or retrobulbar region, subcutaneous mass at the inner canthus, nasal obstruction and discharge, diplopia, and proptosis.

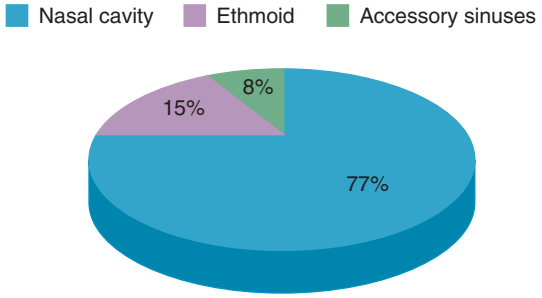
Physical assessment should include examination of the nasal cavity and nasopharynx with an endoscope after mucosal decongestion and topical anesthesia, evaluation of cranial nerves (particularly cranial nerves III, IV, V, and VI), and palpation of the nose bridge, cheek, and medial orbital cavity.

Imaging information on CT and MRI can be found on the Expert Consult website.

Primary tumors of the lateral wall and floor tend to be diagnosed in more advanced stages. Of the patients referred to the M. D. Anderson Cancer Center (MDACC) between 1969 and 1985, 3 (21%) of 14 patients with septal lesions versus 20 (65%) of 31 patients with lateral wall or floor primaries had disease extension beyond the nasal cavity (stages II and III).[52,53]

Esthesioneuroblastoma

The natural history of esthesioneuroblastomas is long and multiple recurrences are the rule. A literature review of 97 patients reported between 1969 and 1977 found that the age distribution is bimodal, with a first peak incidence occurring between 11 and 20 years and a second higher peak incidence between 51 and 60 years.[54] Surveillance, Epidemiology and End Results (SEER) analysis of 311 patients found the age distribution to be unimodal with the mean age being 53.[55] SEER analysis described the primary site as the nasal cavity in over three fourths of the cases and 12.3% presented with nodal involvement.



The most common presenting symptoms are nasal obstruction and epistaxis. Anosmia (inability to perceive odors) can precede diagnosis by many years.[56] Other symptoms are related to contiguous disease extension into the orbit (proptosis, visual field defects, orbital pain, epiphora), paranasal sinuses (medial canthus mass, facial swelling), anterior cranial fossa (headache), and manifestation of inappropriate antidiuretic hormone secretion. Most present in the nasal cavity (eFigure 36-6).

Physical evaluation and recommended staging workup procedures for esthesioneuroblastoma are similar to those for nasal fossa tumors. The commonly used staging system, proposed by Kadish et al,[38] is as follows:

- Stage A: disease confined to the nasal cavity
- Stage B: disease confined to the nasal cavity and one or more paranasal sinuses
- Stage C: disease extending beyond the nasal cavity and the paranasal sinuses, including involvement of the orbit, the base of the skull or intracranial cavity, cervical lymph nodes, or distant metastasis

The stage distribution of the 97 patients reviewed by Elkon et al[54] at diagnosis is 30% stage A, 42% stage B, and 28% stage C. Of the 22 patients who had stage C disease, 9 had orbital

CT or MRI is essential to determine the disease extent and invasion of adjacent structures (e.g., orbital cavity and anterior cranial fossa). Regarding the imaging modality, CT is best for cortical bone erosion or deossification, and the prospective use of a high-resolution bone algorithm, perhaps with dual-energy photons,[51] is recommended for assessment of the anterior and central skull base and the lamina papyracea. The coronal plane of the MRI is best for determination of intracranial extension, with fat-saturated postgadolinium–enhanced T1-weighted imaging being the "workhorse" sequence for detecting epidural disease. MRI can help differentiate tumors in the sinonasal cavity from edematous mucosa. Generally benign mucosal disease is hyperintense on T2-weighted images in distinction to malignant disease, which is less hyperintense. Tumors of glandular origin, however, tend to be exceptions and can be high signal intensity on T2-weighted images.

eFigure 36-6 Esthesioneuroblastoma, primary site of disease.

TABLE 36-3 Nasal Cavity and Paranasal Sinuses TNM Staging Classification by the American Joint Committee on Cancer[26]

PRIMARY TUMOR (T)	
Maxillary Sinus	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor limited to maxillary sinus mucosa with no erosion or destruction of bone
T2	Tumor causing bone erosion or destruction including extension into the hard palate or the middle of the nasal meatus, except extension to the posterior wall of maxillary sinus and pterygoid plates
T3	Tumor invades any of the following: bone of the posterior wall of maxillary sinus, subcutaneous tissues, floor or medial wall of orbit, pterygoid fossa, ethmoid sinuses
T4a	Moderately advanced local disease Tumor invades anterior orbital contents, skin of cheek, pterygoid plates, infratemporal fossa, cribriform plate, sphenoid or frontal sinuses
T4b	Very advanced local disease Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than maxillary division of trigeminal nerve (V_2), nasopharynx, or clivus
Nasal Cavity and Ethmoid Sinus	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor restricted to any one subsite, with or without bony invasion
T2	Tumor invading two subsites in a single region or extending to involve an adjacent region within the nasoethmoidal complex, with or without bony invasion
T3	Tumor extends to invade the medial wall or floor of the orbit, maxillary sinus, palate, or cribriform plate
T4a	Moderately advanced local disease Tumor invades any of the following: anterior orbital contents, skin of nose or cheek, minimal extension to anterior cranial fossa, pterygoid plates, sphenoid or frontal sinuses
T4b	Very Advanced Local Disease Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than V_2, nasopharynx, or clivus
REGIONAL LYMPH NODES (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, ≤3 cm in greatest dimension
N2	Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension, or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension, or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N2a	Metastasis in a single ipsilateral lymph node more than 3 cm but not more than 6 cm in greatest dimension
N2b	Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
N2c	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension. N3 Metastasis in a lymph node more than 6 cm in greatest dimension Metastasis in a lymph node more than 6 cm in greatest dimension
DISTANT METASTASIS (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
AJCC STAGE GROUPINGS	
Stage 0	Tis N0M0
Stage I	T1N0M0
Stage II	T2N0M0
Stage III	T3N0M0 or T1-3N1M0
Stage IVA	T4aN0-1M0 or T1-4aN2M0
Stage IVB	T4b any NM0 or any TN3M0
Stage IVC	Any T or any NM1

From Edge SB, Byrd DR, Compton CC, et al, editors: AJCC Cancer Staging Handbook, ed 7, New York, 2010, Springer.
Authors comment: In clinical evaluation, the actual size of the nodal mass should be measured, and allowance should be made for intervening soft tissues. Most masses more than 3 cm in diameter are not single nodes but confluent nodes or tumors in soft tissues of the neck. There are three stages of clinically positive nodes: N1, N2, and N3. The use of subgroups a, b, and c is not required but recommended. Midline nodes are considered homolateral nodes.

involvement, 6 had invasion of the cribriform plate or cranial fossa, 11 had palpable neck nodes, and only 1 had distant metastasis.

Maxillary Sinus

Because of their relatively silent presentations, maxillary cancers are often diagnosed late. Of the 73 patients referred to MDACC for treatment between 1969 and 1985, for example, symptoms and signs related to extension to the premaxillary region (facial swelling, pain, or paresthesia of the cheek) occurred in 26 (36%). Symptoms resulting from tumor spread to the nasal cavity (e.g., epistaxis, nasal discharge or obstruction) or oral cavity (e.g., ill-fitting denture, alveolar or palatal mass, or unhealed tooth socket after extraction) occurred in 20 (27%) and 19 (26%), respectively. Five patients (7%) presented with symptoms and signs of orbital invasion such as proptosis, diplopia, impaired vision, or orbital pain.[57]

Physical examination should include assessment of the oral and nasal cavities, palpation of the cheek, evaluation of the eye movement and function, and assessment of the trigeminal nerve, particularly the branches of the maxillary division (infraorbital, anterior superior alveolar, posterior superior alveolar, and greater palatine nerves). Numbness of the incisor teeth and upper lip, however, can result from biopsy through a Caldwell-Luc procedure. CT or MRI with appropriate contrast are essential to determine the disease extent and invasion of adjacent structures (e.g., orbital cavity, infratemporal, pterygopalatine, and anterior cranial fossae).

The T classification description by the AJCC staging system is shown in Table 36-3 and is based on clinical and radiologic evidence of involvement of various adjoining anatomic structures.

PRIMARY THERAPY

Nasal Vestibule

Nasal vestibule cancers are skin cancers that are in a cosmetically important location. Radiotherapy is generally preferred for carcinoma of the nasal vestibule because of better cosmetic outcome, but if local excision of a medial tumor of the nasal septum can be performed with clear margins and no cosmetic deformity, that treatment may well be more appropriate.[25] Surgery can yield a high control rate with excellent cosmetic results in selected small, superficial lesions. Depending on the location and size of the primary lesion, radiation treatment can be accomplished by external beam irradiation (EBRT), brachytherapy, or a combination of both. Cartilage invasion per se is not a contraindication for radiation therapy because the risk of necrosis is low with fractionated irradiation.[58] Rare cases of large primaries with extensive tissue destruction and distortion are best managed by resection in combination with preoperative or postoperative radiotherapy. Experienced prosthodontists can design custom-made nasal prostheses for large defects. Smaller defects can be reconstructed with a rotational or advancement flap.

Because of disagreement regarding the applicability of the AJCC staging system, some authors use the Wang staging system and some use the AJCC skin cancer staging system, which makes comparing results in a relatively rare tumor precarious. Additionally there are parochial concerns about whether nasal vestibule is a surgical disease or not. Eloquent editorials aside,[25] there is a dearth of randomized data, and endpoints such as cosmetic results are difficult to quantify.

University of Florida, Gainesville, reported that 32 of 34 patients with disease 5 cm or smaller who were treated with definitive radiation were locally controlled (Table 36-4).[59] Generally, radiation doses were high (65 Gy to 75 Gy), but techniques varied between definitive EBRT, a combination of brachytherapy and EBRT and brachytherapy alone. The authors conclude that definitive radiation gives both good local control and cosmesis for early tumors, but tumors involving bone that are more than 4 cm should be treated with a combination of surgery and radiation. The importance of both size and bone invasion are seen in Table 36-5.

Elective nodal irradiation (ENI) was only recommended for tumors involving bone that are more than 4 cm in size but the 5-year neck control and ultimate neck control were 87% and 97%, respectively, suggesting excellent follow-up because seven of the nine neck failures were successfully salvaged. The control rates of the N0 neck when the primary tumor was continuously controlled appear in Table 36-6.

DAHANCA's retrospective review[60] noted that 54 Gy in 18 fractions was more effective than 62 Gy to 66 Gy in 31 to 33 fractions for T1 lesions. However, complications were not discussed.

An overall local control of 93% was found on analysis of irradiation of 1676 carcinomas of the skin of the nose and nasal vestibule performed by the Groupe Europen de Curietherapie

TABLE 36-4 Nasal Vestibule Tumors, Local Control, University of Florida

in France.[20] Local control was dependent on tumor size (<2 cm, 96%; 2 cm to 3.9 cm, 88%; ≥4 cm, 81%), site (external surface, 94%; vestibule, 75%), and on whether a tumor was recurrent or new (88% versus 95%). Local control was independent of histology for tumors less than 4 cm, but for those larger than 4 cm, basal cell carcinomas were more frequently controlled than squamous cell carcinomas. There were few complications (necrosis, 2%). The local control rate with surgery was ~90%.

TABLE 36-6 Initial Control of the N0 Neck when the Primary Tumor Was Controlled, University of Florida

Treatment	Size	Without ENI	ENI

Other series conclude that more advanced lesions, such as Wang stage T2 or T3 are better handled by combined modality treatment.[48,60]

Table 36-7 summarizes the results of six series of patients treated by radiotherapy.[28,31,49,61,62] Patients received brachytherapy, EBRT, or a combination. A number of conclusions can be derived from these data sets. First, brachytherapy or EBRT cures, on average, about 90% of nasal vestibule lesions smaller than 2 cm. Surgery offers equivalent results.[60] Second, for tumors 2 cm to 4 cm in size, the University of Florida[59] showed 94% control for lesions less than 5 cm. Others have shown 70% to 80% local control with radiation alone with surgical salvage bringing the ultimate local control to 94%.[63] Third, occult nodal spread is extremely rare in lesions smaller than 2 cm but can be as high as about 40% in larger primary tumors. Once again surgical salvage of neck failures is high. Fourth, University of Florida[59] has documented a relatively high rate of radiation salvage for surgical failures. Finally, complications from radiation therapy alone are relatively mild. In 71 patients treated with definitive radiation at the University of Florida, there was a 21% incidence of complications with the majority being soft-tissue necrosis and no complication required hospitalization or surgical intervention. Perhaps counterintuitively, 3 of 8 patients treated with surgery and radiation developed severe complications.

Nasal Cavity and Ethmoid Air Cells

Carcinoma

Radiotherapy and surgery are effective in curing stage-I lesions of the respiratory region. The choice of therapy depends on the size and location of the tumor and the anticipated cosmetic outcome. Posterior nasal septum lesions are generally treated by surgery. In contrast, for aesthetic reasons interstitial brachytherapy (iridium-192 [^{192}Ir] wire implant) is an excellent treatment option for small anteroinferior septal lesions (1.5 cm) to avoid partial removal of the anterior nasal septum. It is preferable to treat lateral wall lesions extending to the lateral alar (eFigure 36-1) nasi with EBRT for cosmetic reasons.

Stage II and operable stage III neoplasms are best treated with surgery. In most cases, postoperative irradiation is indicated.

After excluding cancers of the nasal vestibule,[3] cancers of the nasal cavity ($n = 136$) have a far better 5-year actuarial LRC (61% versus 24%), cancer-specific survival (CSS; 74% versus 49%), and overall survival (OS; 66% versus 35%) when compared to cancers of the maxillary and ethmoid sinuses ($n = 68$), which is a trend reflected in a meta-analysis.[2] Distinct from ethmoid and maxillary cancers, looking at results from the 1960s to 1990s, there has been no improvement in survival for nasal cavity tumors through those decades.[2] The later Danish series on sinonasal cancers, which is dominated (67%) by nasal cavity tumors, documents an improvement in 5-year survival when the national experience from 1982 to 1991 is compared to the results from 1995 to 2004.[3]

Table 36-8 shows the pattern of failure in a series from MDACC. All 14 patients with carcinoma of the nasal septum had the disease controlled (10 after initial therapy and 4 after salvage therapy). Nine of 31 patients with lesions of the lateral wall and floor died of the disease, 5 of uncontrolled local disease, 2 of distant metastases, and 2 of both. The CSS rates at 5 and 10 years were 83% and 80%, respectively. The corresponding OS were 69% and 58%, respectively.

The Danish series also reflected that 81% of the failures involved the primary site with T site failure being 31%.[3] Having combined surgery and radiation therapy improved LRC.

Just as in esthesioneuroblastoma and maxillary sinus cancer, the incidence of lymphatic involvement in nasal cavity cancer is being reevaluated. A meta-analysis reviewed 23 studies of squamous cell cancers of the nasal cavity (series reporting on maxillary cancers were excluded) published between 1974 and 2002.[34] With 927 patients and a mean follow-up of 4.4 years, the regional recurrence rate was 18.1%; prophylactic irradiation was done in 7 studies. Pooled analysis of the 5 studies that reported their rates of control for the electively irradiated patients separately, suggested that the relative risk of nodal failure after elective irradiation, when compared to observation, was 0.18 or 0.16 respectively, both relative risks being statistically significant.

Nasal Cavity: Comparative Outcome by Series

Table 36-9 summarizes the results of relatively large series focusing on nasal cavity tumors. LRC rates range from 60% to 80%.[53,64-66] The incidence of isolated regional recurrence in patients who did not receive elective nodal treatment was approximately 5% in the MDACC series. Treatment morbidity was proportional to disease extent, which dictates the magnitude of surgical resection and the target volume of radiotherapy. Most frequent complications were soft-tissue necrosis, nasal stenosis, and visual impairment.

Nasal Cavity: Comparative Outcome by Histology, Stage, and Pathologic Features

The data on 783 of a total of 981 cases of nasal cavity cancer extracted from the SEER database from 1988 to 1998 were analyzed.[33] Squamous cell carcinoma was the most common tumor type (49.3%), followed by esthesioneuroblastoma (13.2%). More than half of the cases presented with a small primary tumor (T1), and only 5% had positive nodes at

diagnosis. Overall mean (median) survival was 76 (81) months, with 5-year OS of 56.7%. On multivariate analysis, male gender, increasing age, T classification, N classification, and higher tumor grade adversely affected survival independently ($p < .05$). Radiotherapy was administered in 50.5% of patients and also independently predicted poorer survival ($p = .03$), which is likely the result of the selection of patients with poor prognostic features, such as perineural invasion, positive margins, or poor performance status (medically unfit for surgery) for radiotherapy. The median and 5-year OS by histology, T classification, and differentiation are shown in Table 36-10.

Sinonasal Undifferentiated Carcinoma

With a 10% to 30% incidence of adenopathy at presentation, aggressive therapy seems appropriate.[47,67] University of Florida recommends craniofacial resection with postoperative radiation.[68] Elective nodal irradiation should be considered. Some suggest systemic therapy, and some conclude that the use of surgery has little impact on the end result.[69]

Ethmoid Sinus Cancer

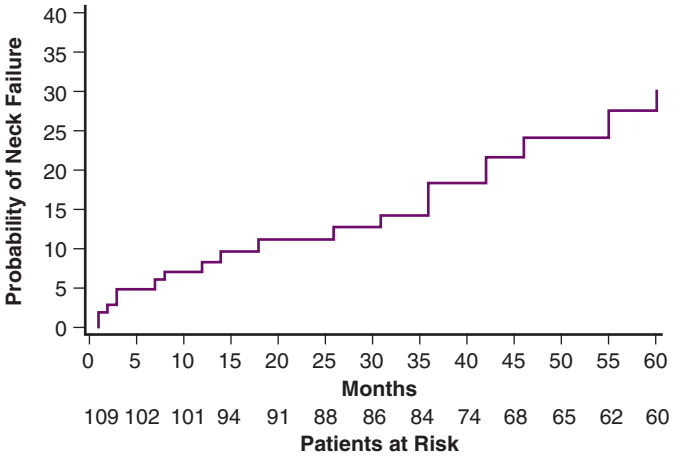
The Italian experience showed a 50.2% rate of adenocarcinomas and 5-year OS of 44.6%.[35] A review of 34 patients found 44% incidence of squamous cell cancer, with a 41% incidence of ethmoid sinus cancer patients having adenocarcinoma. Five-year OS was 44% with surgery and postoperative radiation providing good local control. Local control was one eighth with dura or brain involvement. Prophylactic neck irradiation was not recommended despite a 13% incidence of nodal involvement.[70] The European continental experience with 204 adenocarcinomas of the ethmoid sinus showed a very similar 5-yr OS of 46%.[71]

Esthesioneuroblastoma

Being especially rare, treatment recommendations for esthesioneuroblastoma are tenuous. With a mean recurrence time of 82 months,[72] any initial treatment gives early encouraging results. Whereas treatment with radiation therapy alone might be satisfactory for the uncommon Kadish stage A patient, with a mean follow-up of "only" 56.1 months, radiation therapy alone produced 58% local control for stage B disease ($n = 12$) and 18.9% local control for patients who were stage C ($n = 37$).[73]

Early in Dr Beitler's career, he noted an unexpected rate of neck failures[39,74] and attempted to publish a Kaplan-Meier meta-analysis showing that at 5 years the cumulative rate of late failure in the untreated neck was 27%.[39] At the time this was "unconventional" and the graph of the cumulative incidence of neck failure was not published (see eFigure 36-7).

Monroe[75] published a review of nine other studies and examined the rates of nodal disease. At initial presentation, 7.5% of 212 patients had nodal disease and after interval neck recurrences, the overall rate of disease in the neck was 24.3%.



SEER[55] and another retrospective analysis[76] demonstrate that survival is improved when patients receive both surgery and radiation therapy. Surgery runs the gamut from craniofacial resection to endoscopic resection.[77] Whereas a meta-analysis of 379 patients showed that endoscopic resection of esthesioneuroblastoma showed improved survival over patients treated with open surgery,[78] the authors were quite clear that their data had limitations, including patient selection. Though endoscopic surgery is comparable to open surgery for less invasive disease (which may have meant Kadish stage A and B disease), more study is needed especially regarding more invasive tumors before a definite conclusion is reached. Dr. Levine, in the Ogura Lecture to the Triological Society,[77] was more doubtful. "Despite the zeal with which endoscopic resection of esthesioneuroblastomas has been adopted, owing to limited data in terms of numbers of patients and follow-up, there is no statistically significant data at this time to support that approach."

Nishimura et al reported results of proton therapy for esthesioneuroblastoma in 14 patients, primarily with Kadish stage B and C tumors with or without surgery and chemotherapy. A dose of 65 Gy (RBE) in 26 fractions was delivered. The 5-year OS was 94% and local progression-free survival 84%. No late grade-3 or higher toxicities were observed.[79]

The role of preoperative and concurrent chemotherapy and autologous bone marrow transplant is similarly unclear.[56,80-82] Globally, surgical irradiation, or combined-modality salvage of neck recurrence is successful in approximately 30%,[40] with combined-modality salvage being more effective (71%) than either surgery (21%) or radiation alone (7%). Esthesioneuroblastoma is almost a chronic disease, requires very long follow-up, and is one of the few paranasal sinus cancers in which surgical salvage at the primary site is possible.[83]

Maxillary Sinus

The occasional patient with T1 or T2 tumors of the infrastructure can be cured by surgery alone, which may be limited to

eFigure 36-7 Cumulative incidence of neck failure.

a partial maxillectomy. However, most of these tumors present at fairly advanced stages, and the combination of surgery and radiotherapy is considered standard treatment. Nonetheless, these operations still carry significant morbidity.

A meta-analysis[2] suggested the treatment outcome of patients with maxillary sinus carcinomas has improved over the last four decades ($p = 0.02$; eFigure 36-8). However, treatment outcome is still poor, and fewer than 50% of patients survive longer than 5 years. Local recurrence at the primary site and distant metastasis are the most common patterns of treatment failure. Factors that influenced survival for maxillary sinus cancer are seen in Table 36-11.

Stratified analysis found that radiation significantly improved survival only for T4 lesions, and not for T1-T3 lesions, but slightly more than half the patients in the SEER analysis had T4 disease,[42] which limits the power of such an analysis for the patients who are T1-T3. The available literature reveals that the combination of surgery and irradiation yields a 53% to 78% 5-year local control rate and a 39% to 64% 5-year OS.[31,49,56,58,61,62,64,65,84,85]

An MDACC experience with postoperative radiation therapy for maxillary sinus cancer published in 1991 showed that (1) local recurrence was significantly higher in patients with pathologically proven nerve invasion when compared to those patients who did not have perineural invasion (36% versus 10%, $p = 0.05$); (2) the nodal relapse rate without elective nodal irradiation was >30% for those patients with squamous or undifferentiated carcinoma; and (3) complications were related to technique and fraction size >2 Gy.[57] As a result of this experience, MDACC made three modifications to their technique. (1) For patients with perineural extension, the fields included the base of skull, including the trigeminal ganglion; (2) for patients with T2-4 squamous cell or undifferentiated cancers, ipsilateral neck irradiation was included; and (3) dose homogeneity was improved. Important to the last treatment recommendation, it should be noted that of the 90 patients reviewed by Jiang et al, 88 underwent XRT using cobalt and other, now antiquated treatment techniques.

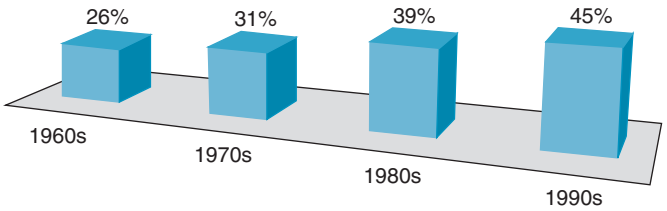
Comparing a more recent cohort of patients whom had presumably benefited from the recommendations, MDACC found that though local control and survival were not significantly impacted, there were hints of improvement.[86] Presumably because of the improved coverage of the base of skull, perineural invasion was no longer a significant predictor of local control in the newer cohort.

Elective nodal irradiation of T2-4 squamous or undifferentiated cancers reduced the risk of neck recurrence from 36% to 7% ($p < 0.001$). Of the 13 neck recurrences in the group that was not electively irradiated, 7 were in the ipsilateral level II neck, 4 in the ipsilateral Ib station, but 1 patient recurred bilaterally in the II nodal stations and 1 in the contralateral level II neck. These last two patients would not have been helped by ipsilateral elective treatment bringing the ipsilateral only neck failure rate to 30%.

Not to be forgotten was that the strongest predictor of distant disease was histopathology. Patients with squamous cell cancers had a 5-year rate of distant metastases of 11%, versus a rate of 33% to 40% for other histologic subtypes. Both nonsquamous histology and nodal disease were independent predictors of the development of an increased rate of distant metastases.

Between 1969 and 2006 the University of Florida[87] treated 54 patients with squamous cell cancer of the maxillary sinus with 96% of their patients having T3-4 disease. With a mixture of patients who were preoperative, postoperative, and received definitive radiation, the median doses to the primary site were 71.2 Gy, 67.8 Gy, and 70 Gy, respectively. The 5-year local control was 41%. Perhaps because only 1 of 54 patients had IMRT treatment, the severe complication rate was 33% ($n = 18$) with mostly ocular complications, but one fatal fistula and one fatal carotid blowout. Eight patients suffered neck failure, 3 of which were initially cN0. Three recurrences were in the contralateral neck. For the 22 patients with cN0 necks who did not receive elective neck irradiation, 2 failed in the ipsilateral neck. For the 23 cN0 patients who received either unilateral ($n = 14$) or bilateral ($n = 9$), one patient who received unilateral neck irradiation failed in the contralateral neck.

Memorial Sloan Kettering Cancer Center (MSKCC)[88] reported a postoperative sinonasal series where the median dose was 63 Gy. With more moderate dosing and one third of patients receiving IMRT there were no late grade-3 or -4 complications. The definitive-radiation MSKCC series of 39 patients[89] found that despite a median BED dose of 70 Gy, local recurrence developed in 25 of 39 (64%) patients and regional recurrence developed in 9 patients (23%). With the higher doses, more complications were seen. One patient who presented with unilateral blindness developed a corneal ulcer during radiation. One patient developed optic neuropathy and blindness 7 years after radiation; this patient received 77 Gy to the optic nerve and had been forewarned that unilateral blindness was likely. Three patients developed unilateral blindness attributable to disease progression and one patient developed radionecrosis with the dose to the temporal lobe being 77 Gy.



High dose intraarterial chemotherapy is theoretically appealing for advanced maxillary cancers. The clinical results have been disappointing.[90-93]

Conclusions

First, there is no doubt that unresectable maxillary sinus cancer has poor control despite aggressive doses of radiation, with little obvious benefit from intraarterial chemotherapy. Second, high-dose radiation therapy is prone to high complication rates, and whether an aggressive dose (70 Gy or higher) is chosen depends on the risk tolerance of the patient and the physician. Third, lymphatic spread is not trivial and ipsilateral upper nodal elective irradiation should be considered for T2 disease or higher. Fourth, contralateral upper nodal irradiation should be considered for patients who are node positive and patients with advanced disease or disease approaching or crossing the midline.

Sphenoid Sinus

Owing to the rarity of the disease, there are relatively few articles which concentrate on cancers originating in the

eFigure 36-8 Maxillary sinus cancer, survival by decade.
Dulguerov 2001.

sphenoid sinus. Their prognosis, when compared to other paranasal sites is said to be inferior but even a series of 220 patients only claims 7 cancers originating in the sphenoid sinus.[2] Headaches and visual disturbances are the most common presenting symptoms with squamous cell cancer being the most common histology.[94,95] Most series report high local failures, but the Massachusetts General Hospital (MGH) series of multimodality therapy, including proton therapy-median dose 76 Gy (RBE) showed an 86% 2-year local control rate, an 86% 2-year regional control rate, but only a 50% 2-year freedom from distant failure rate.[95] There were no cases of visual loss.

LOCALLY ADVANCED DISEASE AND PALLIATION

Primary Radiotherapy

Patients with locally advanced inoperable tumors or who are unfit for surgery are often treated with primary radiotherapy. Compilation of literature data reveals that primary radiotherapy yields a 22% to 39% 5-year local control rate and 22% to 40% 5-year OS.[96-103]

Proton therapy may have the potential to do better. In a proton series of 39 patients with unresectable malignancies of the nasal cavity and paranasal sinuses, all of whom had N0M0 disease, the 5-year OS was 55% but there were 5 patients with grades-3 to -5 late toxicity.[104] The treatment related fatality was caused by a persistent cerebrospinal fluid (CSF) leak. There were 9 (23%), 5 (12.8%), and 9 (23%) local, regional, and distant failures.

Chemotherapy: Neoadjuvant and Concurrent

Neoadjuvant Chemotherapy

Neoadjuvant chemotherapy in addition to standard radiotherapy failed to demonstrate any therapeutic advantage over radiation alone in a matched-control study from Seoul, Korea, comparing standard radiotherapy versus the combination of neoadjuvant chemotherapy and radiation.[105] Thirty-four patients with inoperable maxillary squamous cell cancer were treated with three cycles of neoadjuvant chemotherapy (cisplatin and a 5-day continuous infusion of 5-fluorouracil with or without intravenous vinblastine) followed by radiotherapy (66 Gy to 75 Gy; median, 70 Gy). The outcomes were compared with those for 34 patients treated with radiation alone who were matched for age, sex, performance status, tumor grade, and stage and local extent of tumor. Despite a higher response rate to neoadjuvant chemotherapy, the relapse rate and patterns of treatment failure were not influenced by the addition of neoadjuvant chemotherapy. Treatment-induced late complications occurred equally in both treatment groups. After a median follow-up of 48 months, there was no significant difference in 5-year OS or disease-free survival between the two treatment groups. Both groups had a 65% rate of local recurrence. The 5-year OS was 32% after radiotherapy alone and 30% after neoadjuvant chemotherapy followed by radiotherapy.

Concurrent Chemoradiation

Concurrent chemotherapy and radiotherapy using accelerated fractionation (concomitant boost radiotherapy) produced surprisingly good local control and survival in a prospective study from MSKCC.[106] Among 82 patients with unresectable cancers of the head and neck, 12 had T4 paranasal sinus cancer. Patients received 70 Gy in 6 weeks using a concomitant-boost technique with cisplatin (100 mg/m^2) given on days 1 and 22 of radiotherapy. Three-year local control rates for T4 paranasal sinus cancer was 78% and 3-year OS was 42%.

Concurrent cisplatin (single agent) or carboplatin chemotherapy is often used during EBRT to treat patients with newly diagnosed unresectable squamous cell carcinoma. The addition of chemotherapy enhances acute mucosal and cutaneous toxicity associated with radiation and brings toxicities unique to the specific systemic agent.

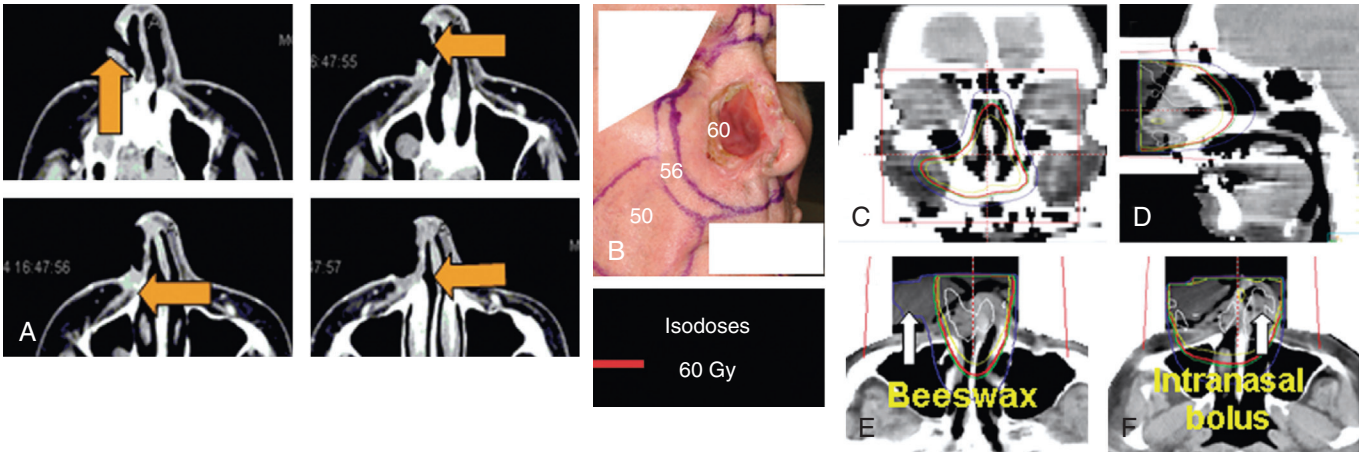
Chemotherapy can be given concurrently with radiation for patients with esthesioneuroblastoma but even the University of Virginia has questioned its efficacy.[56] Some believe that chemotherapy is of benefit for patients with high grade, stage C disease.[81] Local therapy alone with surgery and postoperative radiotherapy[40] yields excellent results at 5 years with regard to both OS (93.1%) and local control (96.2%). Concurrent chemotherapy during radiation may be considered in inoperable cases.

Palliation

The symptoms of incurable sinonasal cancer are particularly distressing. Multidisciplinary input is required even with advanced cases because palliation may involve limited surgery, palliative EBRT, investigational chemotherapy studies, or best supportive care. The morbidity of each modality has to be balanced with the benefit to symptom control and improvement in quality of life. Attention is required to

- Control of pain and discomfort as a first priority;
- Communicate the incurable status of the tumor;
- Deal with the psychological effect of incurable status;
- Help with the impact of disfigurement and dysfunction that are frequently present; and
- Collaborate with caregivers, social services, and home and hospice care, as needed.

Chemotherapy is often single agent or investigational. If radiation therapy is given, concurrent chemotherapy may be added. Although larger dose per fraction EBRT is the usual practice for palliative cases to reduce the duration of treatment, if concurrent chemotherapy is added, consideration may be given to reducing the dose to 1.8 Gy to 2 Gy/fraction to avoid severe acute effects.



Treatment with radiotherapy or chemotherapy is often effective in reduction of tumor bulk to provide relief of symptoms such as disfiguring masses, proptosis, discomfort or neuropathic pain, headache, epistaxis or other bleeding, nasal obstruction or discharge, and trismus.

IRRADIATION TECHNIQUES AND TOLERANCE

Nasal Vestibule

Target Volume

For a small, delineated, well-differentiated carcinoma measuring up to 2 cm, small fields with a 1-cm or 2-cm margin are appropriate. The initial target volume for all poorly differentiated tumors and well-differentiated primaries larger than 2 cm without palpable lymphadenopathy encompasses both nasal vestibules with at least 2-cm or 3-cm margins around the primary tumor (wider margins for infiltrative tumor) (eFigure 36-9). Bilateral facial ("Manchu mustache area"),[107] submandibular, and subdigastric node inclusion is optional and partially dependent on how reliable the patient will be for follow-up. The most recent Danish national experience of sinonasal carcinomas treated from 1995 to 2004, with no patients receiving elective neck treatment, showed 23 neck failures in their series of 204 patients.[3] For extension to "extradermal" structures such as the bone, elective nodal radiation should be more strongly considered because there was a 27%

eFigure 36-9 Adjuvant radiotherapy for a recurrent squamous cell carcinoma of the nasal cavity after partial rhinectomy. **A,** CT images show a small amount of tissue with heterogeneous enhancement. The patient had a complete resection, and pathologic analysis demonstrated invasion of bone, but the surgical section margins were negative. **B,** Fields were drawn at simulation before placing the beeswax bolus and intranasal bolus. The ipsilateral facial lymphatics (i.e., mustache field), the surgical bed with a wide margin (including the residual portion of his nostril and nasal septum), and the tumor bed with a 1.5-cm margin received 50 Gy, 56 Gy, and 60 Gy, respectively, with all doses given in 2-Gy fractions. The nostril was treated using 20-MeV electrons, and the mustache field was treated with 9-MeV electrons. A second set of skin collimation was fabricated for the reduced boost field. A wax bolus to compensate for surface obliquity was used for the whole treatment. An additional bolus was placed in the nostrils to reduce the perturbation of the electron beam with the air cavity and the air bone interfaces. **C-H,** Dose distributions.

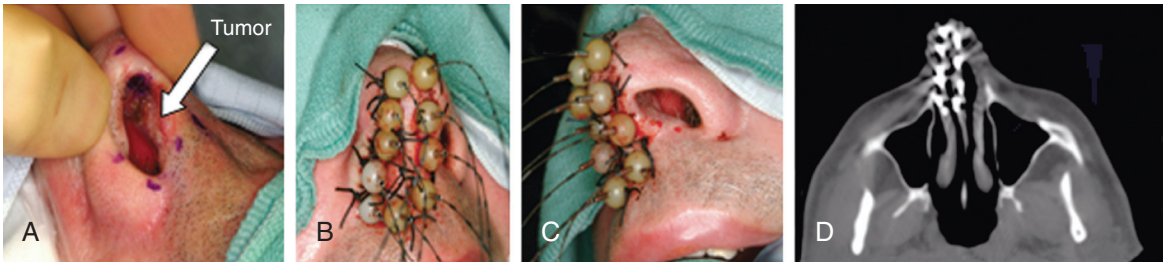


Figure 36-8 **A,** A 2.5-cm squamous cell carcinoma (T2 N0) located on the right side of the columella. **B** and **C,** The entry points are shown for the hollow stainless steel needles that are inserted for afterloading with low-dose-rate iridium-192 interstitial implants. **D,** Needle positions are seen on CT images. A dose of 60 Gy was administered at 68 cGy per hour (total treatment time was 90.6 hours).

nodal failure rate with observation and a controlled primary tumor.[59] When lymph node involvement is present at diagnosis, the lower neck nodes are also irradiated.

For postoperative radiotherapy, the initial target volume includes the operative bed plus a 1-cm to 1.5-cm margin and quite possibly elective nodal irradiation. The undissected nodal region should receive 50 Gy to 56 Gy and the primary site 60 Gy unless there were positive margins or a limited excision was done in which case the dose might be increased to 66 Gy to 70 Gy.

Setup, Field Arrangement, and Dose Fractionation Schedule

Brachytherapy

Brachytherapy for small lesions is accomplished by ^{192}Ir wire implant or, in selected cases, by intracavitary ^{192}Ir mold. Hollow needles for afterloading are inserted, often under general anesthesia, which allows good exposure of the tumor as well as protection of the airway in the event of bleeding from the vascular Kiesselbach's plexus on the anterior nasal septum or from posterior hemorrhages originating from larger vessels near the sphenopalatine artery, behind the middle turbinate. Implantation of a T2 squamous cell carcinoma of the columella is shown in Figure 36-8 and eFigure 36-10. The recommended dose for low-dose rate brachytherapy has evolved empirically and ranges from 60 Gy to 65 Gy delivered over 5 to 7 days. An example of needle placement is shown in Figure 36-8.

Brachytherapy boosts may be given to T1 or T2 nasal vestibule tumors following initial larger field EBRT. At 50 Gy, the patient is assessed, and if there is good reduction of tumor volume, a boost of 20 Gy to 25 Gy may be chosen.

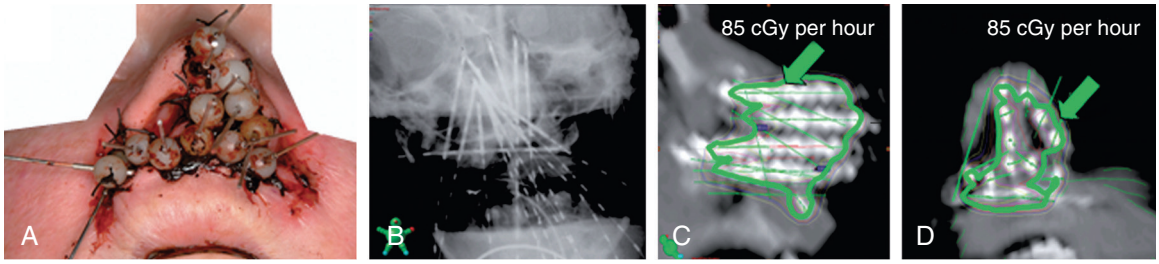
High-dose-rate (HDR) brachytherapy has also been used as a boost. A custom mold of the nasal vestibule is fabricated and tumor is marked in the mold. Two to four plastic tubes with a 1.0-cm spacing are inserted in the mold alongside the tumor. With tumors of the lateral part of the vestibule, two catheters are placed on the inner aspects of the nasal vestibule. For medially localized tumors, catheters are placed on both sides of the vestibule. Following an EBRT dose of 50 Gy in 4 weeks, HDR brachytherapy is delivered in week 6. The dose per fraction is 3 Gy (twice a day) to a total dose of 18 Gy. For tumors of the lateral nasal vestibule, dose is prescribed to a point 0.5 cm lateral to the tumor and for tumors of the septum, the dose was prescribed to the center of the tumor[49] (eFigure 36-11). With a median overall treatment time (EBRT and brachytherapy) of 36 days, this technique yielded a 2-year local control of 86% and ultimate LRC of 100%.

External Beam Irradiation

The patient lies supine and is immobilized with the head positioned (usually slightly flexed) such that the anterior surface of the maxilla is parallel to the top of the couch. This setup allows irradiation of the primary lesion through a vertical appositional field, which can be done with a combination of electrons and photons in a ratio of approximately 4:1. The position is maintained with a custom made head and neck mask. Skin collimation using a lead cut-out, is used to reduce the penumbra of the electron field and, thereby, protect adjacent structures such as the nasolacrimal duct and eye. Custom fabricated bolus material (usually beeswax) is applied to reduce the obliquity of the incident electrons at the sloping surface contour of the nose and to fill the nares for electron beam treatment to improve dose homogeneity (see eFigure 36-9). Additional bolus material may be inserted into the nasal cavity (see eFigure 36-9). The bolus is removed for photon treatments to achieve skin sparing of the dorsum and the nasal tip. Using clinical examination and any appropriate imaging the depth of the lesion is carefully assessed to select the appropriate energy. To protect the mandible, the mouth is opened and lead may be used behind the upper lips to limit dose to the upper gingiva.

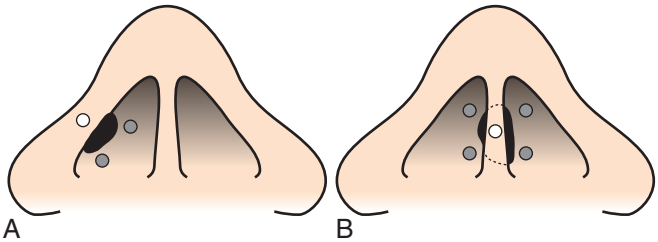
The EBRT schedule for irradiating lesions of up to 5 cm with a combination of electrons and photons is 65 Gy to 70 Gy in 1.8- to 2-Gy fractions to gross primary or nodal disease plus, if using electrons, a ≥2 cm margin. Alternatively, when accessible, it is reasonable to deliver a brachytherapy boost dose after an initial 50 Gy.

The schedule for elective nodal irradiation is 50 Gy in 25 fractions. Palpable nodes are given a boost to a total dose of 65 Gy to 70 Gy in 33 to 35 fractions, depending on the size of the nodes and IMRT techniques can be used to deliver this treatment.



Nasal Cavity and Ethmoid Air Cells

Target Volume



The technique for primary or postoperative EBRT of nasal cavity tumors depends on the depth of the tumor. A margin of at least 1 cm deep to the posterior edge should be included in the full dose volume. CT-based treatment planning is necessary for accurate target localization and dose calculation.

IMRT (Figure 36-9) or proton therapy (Figure 36-10) is recommended for tumors of the nasal cavity or for tumors of the ethmoid sinus. These techniques deliver the desired dose to the target volume while minimizing the dose to critical organs such as cornea, lens, lacrimal glands, retina, optic nerve, optic chiasm, brain, and brainstem.

For postoperative radiotherapy, the primary clinical target volume (CTV) descriptions are given in Table 36-12. CTV_1 consists of the primary tumor bed with 1.0-cm to 1.5-cm margins of normal tissue. A boost subvolume consisting of high-risk region (sites of positive margins and any gross macroscopic residual tumor) to be treated to higher dose may be

eFigure 36-10 A 2.5-cm squamous cell carcinoma (T2 N0) located on the right side of the columella treated with external beam irradiation (50 Gy/fractionated) and brachytherapy implant boost (25 Gy at 85 cGy/hr). **A,** Positions of needles, with the left nasal ala apposed to the septum by two additional sutures to close the air gap of the left nostril for optimal dosimetry. **B,** Anteroposterior radiograph taken in the operating room. **C** and **D,** Sagittal and transverse sections of the final brachytherapy plan, which shows that the 85 cGy/hr line adequately covers the tumor volume (*green line*).

eFigure 36-11 Placement of catheters (gray dots) for tumor of lateral **(A)** and medial **(B)** part of nasal vestibule. White dots indicate dose specification point. Dose specified 0.5 cm lateral from tumor for lateral tumors; for tumors of septum, dose specified in center of tumor. Catheter fixed with ColdPlast mold.

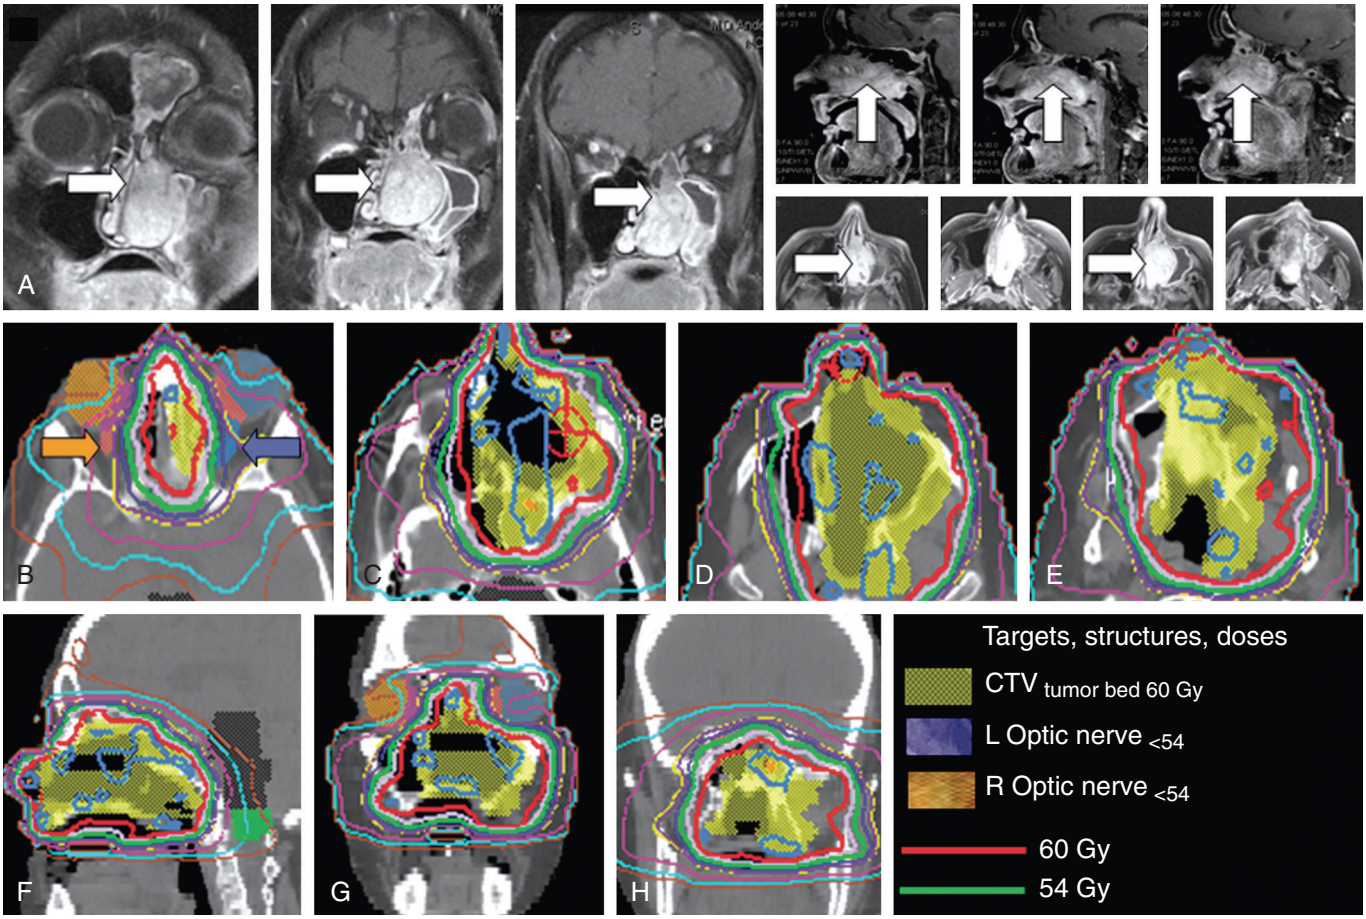

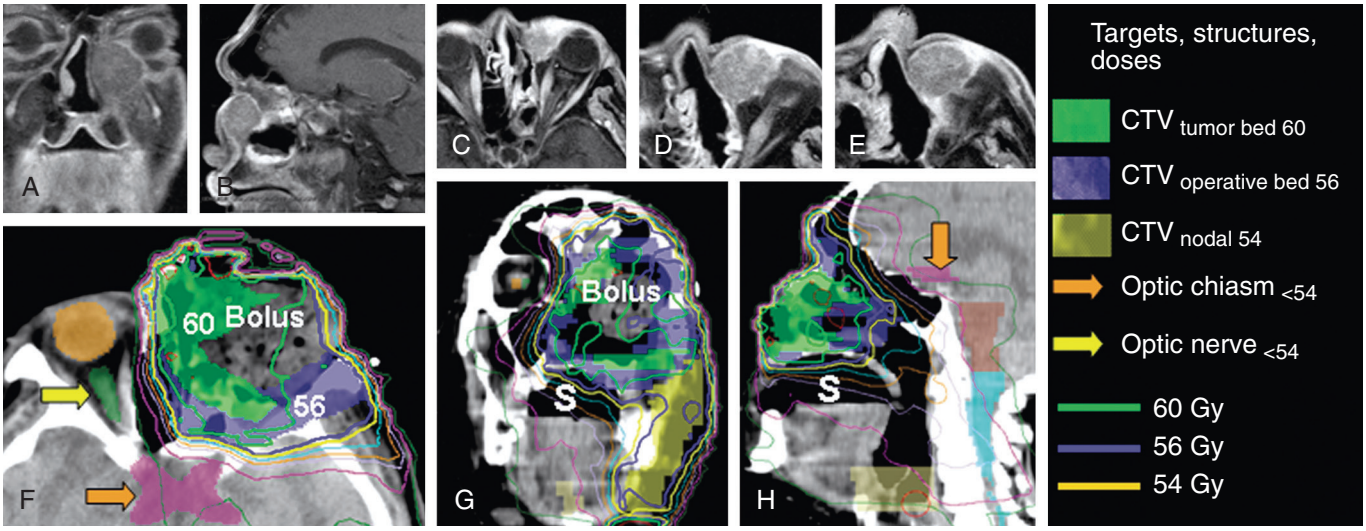

Figure 36-9 Adjuvant radiotherapy for a large tumor of the left nasal cavity after gross total resection with negative margins. **A,** In preoperative MRI, *the white arrows* indicate the primary tumor. **B-E,** Dose distributions at transverse sections. The depth of the target volume precludes the use of an electron beam. The proximity of the target volume to the optic chiasm, brainstem, eyes, and optic nerves (*arrow* in **B**) motivates the use of intensity-modulated radiation therapy. The dose limit for the chiasm and the contralateral optic nerve was set at 54 Gy and the limit for the ipsilateral optic nerve was set at 56 Gy. **F-H,** Sagittal and coronal dose distributions.

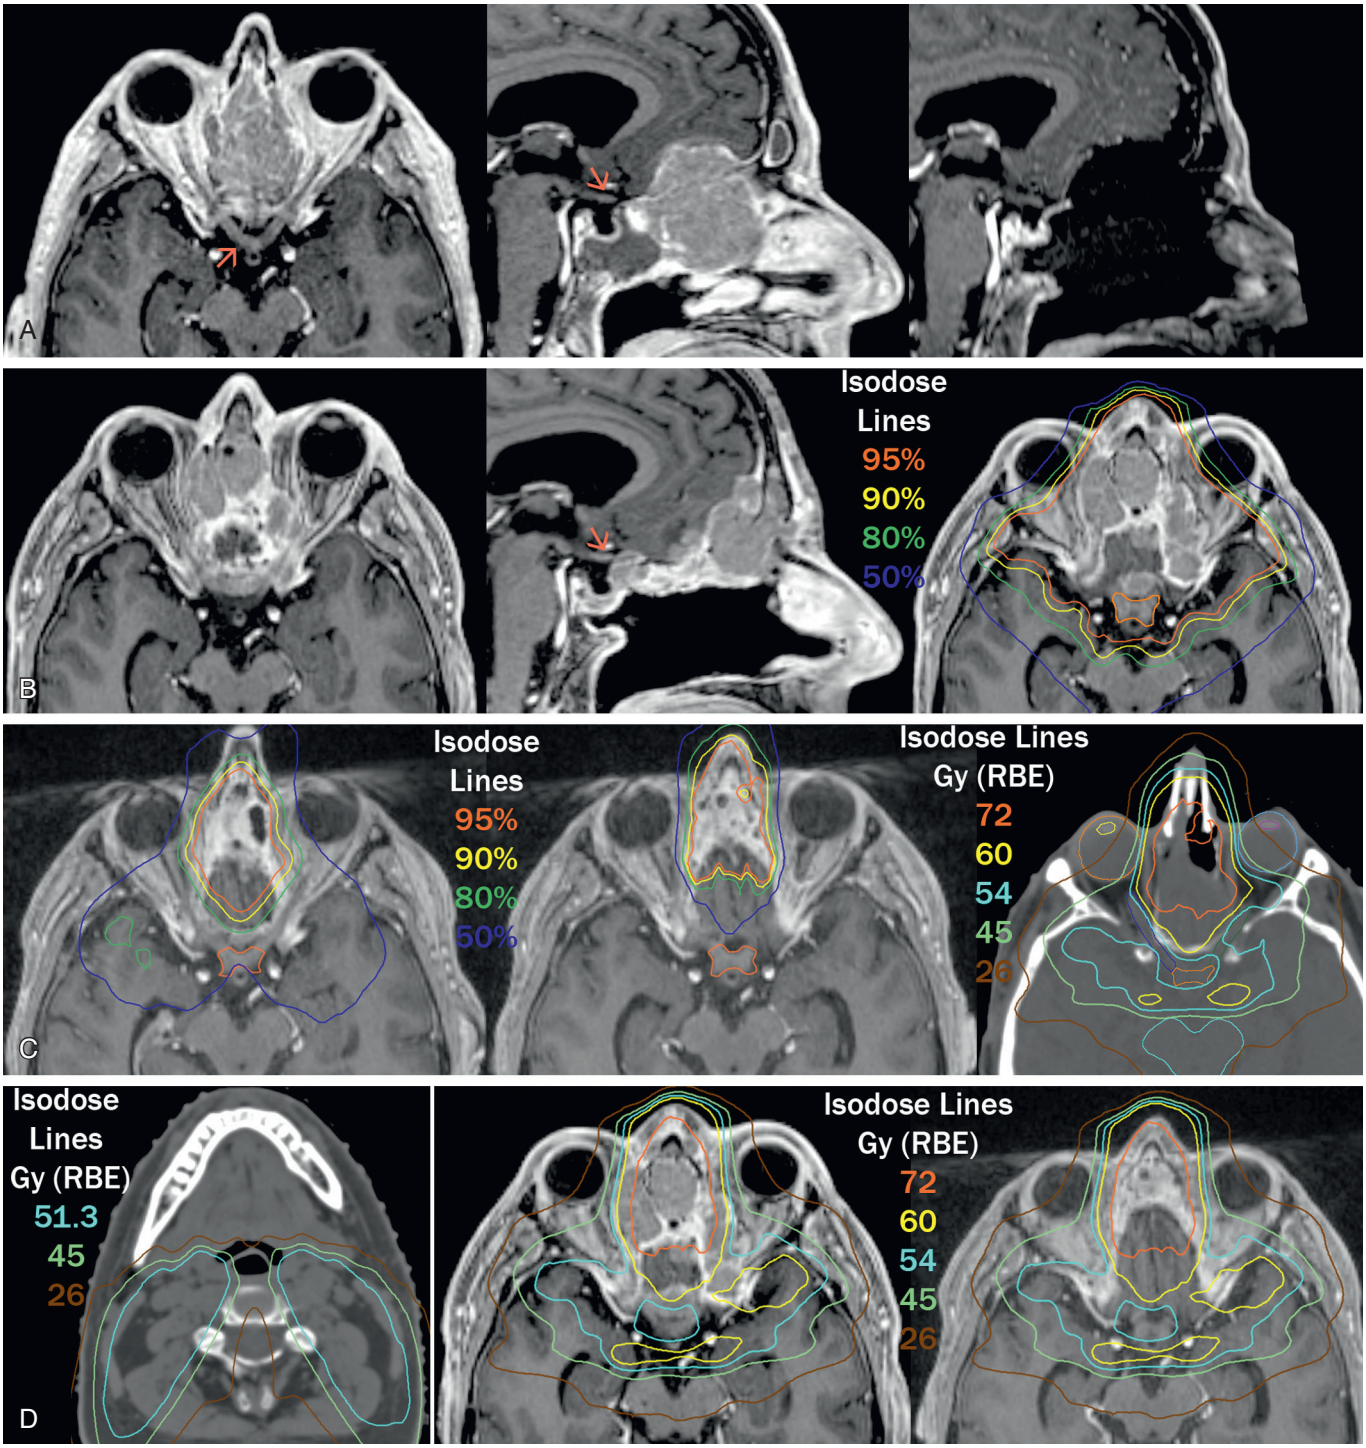
TABLE 36-12 Target Volumes for Radiotherapy of Paranasal Sinuses Using IMRT

PRIMARY RADIOTHERAPY		
Target	**Description**	**Dose (30-62 Fractions)**
GTV	Gross tumor volume (represents prechemotherapy volume)	60 Gy-74.4 Gy
CTV_1 (primary CTV)	GTV + 1.0 cm-1.5 cm	60 Gy-74.4 Gy
CTV_2 (intermediate dose)	Primary CTV + 1.0 cm-1.5 cm	59 Gy-66 Gy
CTV_3 (elective CTV)	Nodal volumes, nerve tract, and base-of-skull margin	56 Gy-57 Gy
ADJUVANT (POSTOPERATIVE RADIOTHERAPY)		
Target	**Description**	**Dose (30-35 Fractions)**
CTV_{HR} (high-risk CTV)	Sites of suspected positive margins or gross macroscopic residual tumor	66 Gy-70 Gy
CTV_1 (primary CTV)	Primary tumor bed with 1.0-cm to 1.5-cm margin	60 Gy
CTV_2 (intermediate dose)	Surgical bed	56 Gy
CTV_3 (low-dose CTV)	Tract of V2 if there is perineural invasion, additional skull-base margin, elective nodal volume if indicated	54 Gy

outlined. A secondary CTV_2 includes the entire operative bed. For ethmoid sinus tumors the frontal sinus, maxillary sinus, and sphenoid sinus may be explored during surgery; therefore, these areas are included as part of the operative bed. The bony orbit is part of the operative bed when orbital exenteration is performed as a result of tumor invasion (eFigure 36-12). A third CTV may be delineated to encompass the tract of V2 to the foramen rotundum if there is extensive perineural invasion (Table 36-12).

For primary radiotherapy using IMRT, the gross tumor volume (GTV) plus a 1-cm to 1.5-cm margin of normal appearing tissue is considered the CTV_1 to receive the full dose of 66 Gy to 70 Gy. Any neoadjuvant chemotherapy should not alter the target volumes. Other secondary CTV include the rest of the involved sinus and region around the primary target to an intermediate dose (59 Gy to 63 Gy), the tracts of nerves if there is perineural invasion, and elective nodal regions to a lower dose (56 Gy to 57 Gy) (see Table 36-12).

eFigure 36-12 The patient underwent partial rhinectomy and septectomy for a nasal cavity carcinoma. One year later, disease recurred with an irregular, fungating mass measuring 4.5 × 3.5 × 0.7 cm, which was removed en bloc with clear margins by a medial maxillectomy. **A-E,** Follow-up MRI showed a 2.3 × 2.3-cm, enhancing soft-tissue mass centered in the superior portion of the nasolacrimal duct and invading the medial inferior portion of the left orbit, displacing the globe laterally and involving the medial portion of the left inferior oblique muscle. The patient underwent left suprastructure maxillectomy with left orbital exenteration and removal of medial cheek skin. All margins were clear. Final pathologic analysis revealed an invasive schneiderian squamous cell carcinoma infiltrating the skeletal muscle. **F-H,** The intensity-modulated radiation therapy plan demonstrates target coverage and sparing of the optic nerve and chiasm. Notice the bolus material filling the orbital defect. *S* indicates the position of an intraoral stent used to depress the tongue.



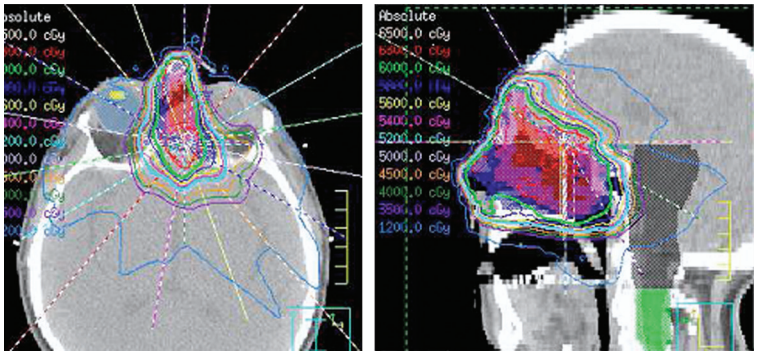


Figure 36-10 Proton therapy for a T4 N0 M0 sinonasal poorly differentiated neuroendocrine carcinoma. **A,** Preoperative axial and sagittal MRI demonstrated a large mass centered on the cribriform plate with bilateral medial orbital involvement and intracranial tumor extension, in close proximity to the optic chiasm *(arrow)*. An endoscopic craniofacial resection was performed achieving macroscopic complete resection with positive margins. **B,** Social circumstances delayed presentation for postoperative radiation for 2 months, at which time MRI demonstrated extensive recurrent disease with recurrent proptosis. An initial radiation plan was developed with delivery of concurrent cisplatin and etoposide. **C,** As the tumor responded to treatment and proptosis resolved, the plan was adapted to begin introducing a dose gradient across the optic apparatus and a smaller volume was boosted to the total dose *(middle)*. The composite plan to 75.6 Gy (RBE) on CT shows *(right)* shows generous coverage of the periorbita because of prior tumor involvement, but overestimates the dose to the globes, which were laterally displaced at onset of treatment. **D,** Elective nodal irradiation was delivered to 54 Gy (RBE), with sparing of the oral cavity. The composite plan on the preradiation MRI and the midcourse MRI is shown. A complete response was maintained at 1 year without visual complications.

Noncoplanar beam orientation					
Beam	Couch	Gantry	Beam	Couch	Gantry
1	000	220	7	000	100
2	000	260	8	000	140
3	000	300	9	090	030
4	000	340	10	300	355
5	000	010	11	090	345
6	000	060			

Figure 36-11 An example of noncoplanar beam arrangement for irradiation of an ethmoid sinus cancer. Beams 9, 10, and 11 are noncoplanar.

Setup and Field Arrangement

Treatment devices include lead skin collimation to obtain a sharp penumbra if electrons are part of the plan as well as bolus material in the nasal cavity, on postoperative defects, and on skin scars. An intraoral stent can be used to depress the tongue, provide a patent airway, and aid in immobilization. Tungsten internal eye shields may be used if the target volume approaches the orbits (when using low-energy electrons but not high-energy electrons or photons).

For EBRT, the patient is immobilized in a supine position with the head positioned such that the hard palate is perpendicular to the treatment table. Caution should be used with metal-containing shielding devices placed on the skin during simulation, which have the potential to perturb the CT images. Other devices and bolus are positioned, scars are marked with thin radioopaque wires, and transverse CT images are obtained from the vertex to the upper mediastinum.

An example of an 11-field noncoplanar arrangement is shown in Figure 36-11. The beam angle selections are based on the same principles as for three-dimensional conformal radiation therapy (3D CRT): (1) preference for the shortest path to the target; (2) avoidance of direct irradiation of the critical structures (e.g., avoidance of beam segment entry through the contralateral eye after ipsilateral exenteration); and (3) use of as large a beam separation as possible.

For 3D CRT, anterior oblique wedge-pair photon fields are most suited for lesions located in the anterior lower half of the nasal cavity. Opposed lateral fields may be applied to treat tumors at the posterior part of the nasal fossa, provided the ethmoid cells are not involved. The optic pathway can be excluded from the radiation fields with this setup. For primaries of the upper nasal cavity and ethmoidal air cells, a three-field setup allows coverage of the ethmoid cells without delivering high doses to the optic apparatus (eFigure 36-13).

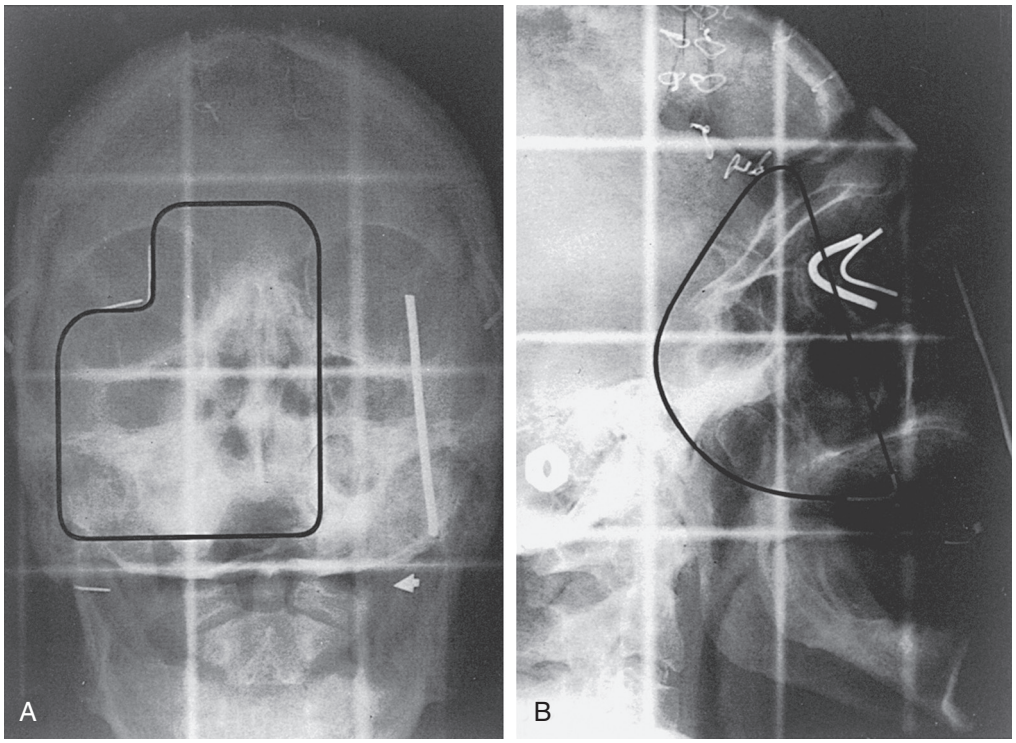
Dose Fractionation Schedule

The dose schedule of (LDR) brachytherapy is 60 Gy to 65 Gy over 5 to 7 days. The EBRT schedule for definitive radiotherapy is 66 Gy to 70 Gy in 33 to 35 fractions. For postoperative adjuvant radiotherapy, the schedule is 60 Gy to 66 Gy depending on risk factors such as close or positive surgical margins and perineural invasion. The dose regimens for primary or adjuvant radiotherapy using IMRT are summarized in Table 36-12.

Maxillary Sinus

Target Volume, Field Arrangement, and Dose Fractionation Schedule

Delineation of target volumes of *postoperative radiotherapy* is based on compilation of four sources of information (Table 36-12). These are pretreatment physical examination, pretreatment imaging, intraoperative findings (e.g., tumor extension relative to critical structures such as orbital wall, cribriform plate, cranial nerve foramina, etc., and ease of resection), and outcome of histologic examination (e.g., positive margin, perineural invasion).



IMRT or proton therapy are the preferred treatment methods because they generally yield better dose distributions in terms of tumor coverage and normal tissue sparing than 3D CRT. Nonionic intravenous contrast should be used at the time of the simulation whenever medically safe. Fusion of the PET/CT or MRI should be performed whenever this will help delineate the target volumes. For postoperative radiotherapy, CTV_1 consists of the primary tumor bed with 1.0-cm to 1.5-cm margin of normal tissue. CTV_2 encompasses the entire operative bed including the bony orbit after exenteration and the ethmoid, frontal, or sphenoid sinuses if explored during surgery. A third CTV may be delineated to encompass the tract of V2 to the foramen rotundum if there is extensive perineural invasion as shown in Figure 36-12. CTV_{HR} may be outlined, which encompasses sites of positive margins, gross macroscopic residual tumor where a higher dose may be delivered. Serious side effects from disease and treatment are common and are shown in Table 36-13. Examples of an IMRT plan for postoperative radiotherapy are shown in Figure 36-13 (an infrastructure tumor) and eFigure 36-12 (a recurrent tumor requiring left suprastructure maxillectomy and orbital exenteration).

Table 36-12 summarizes the dose regimens for IMRT. For primary radiotherapy using IMRT, the prescription doses are 66 Gy to 70 Gy to the gross tumor volume (GTV), prechemotherapy GTV for those receiving induction/neoadjuvant systemic treatment, plus a 1-cm to 1.5-cm margin of normal appearing tissue (CTV_1), 59 Gy to 63 Gy to other secondary clinical target volumes such as the rest of the involved sinus and wider region around the primary target, and 56 Gy to 57 Gy to the tracts of nerves if there is perineural invasion and elective nodal regions (Table 36-13). An example of an IMRT plan for primary radiotherapy of a sinonasal undifferentiated carcinoma is shown in Figure 36-14.

When the primary lesion invades structures adjacent to the optic chiasm, such as posterior ethmoid cells and sphenoid sinus, a dose of up to 60 Gy to the chiasm may carry a higher therapeutic ratio (potentially higher control probability with a relatively low risk for visual impairment) and thus may be acceptable after clear discussion of the therapy rationale with the patient.

Setup

The patient is immobilized in a supine position with the head slightly hyperextended to bring the floor of the orbit parallel

eFigure 36-13 A 56-year-old man sought medical attention because of nasal stuffiness and pressure discomfort below the right eye. A polypoid mass was removed from the right nasal cavity, which was diagnosed as an adenocarcinoma. CT revealed a tumor in the right ethmoid sinuses and the upper part of the right nasal cavity. The floor of the right orbit was involved. The tumor was resected through a craniofacial approach. The right antrum and the sphenoid sinus were inspected and found free of gross disease, but the mucosal lining was removed. Pathologic examination revealed an adenocarcinoma in the ethmoid sinuses spreading to the mucosa of the nasal septum. The surgical bed was treated with an anterior field **(A)** and right **(B)** and left lateral fields using 6-MV photons. The lateral orbital canthi, external auditory canals, oral commissures, and position of the cornea of the right eye were marked at simulation. The thick, straight wire indicated the slope of the face. A dose of 56 Gy was delivered to the isocenter in 28 fractions.
From Ang KK, Kaanders JHAM, Peters LJ, editors: Radiotherapy for head and neck cancers: indications and techniques, Philadelphia, 1994, Lea & Febiger.

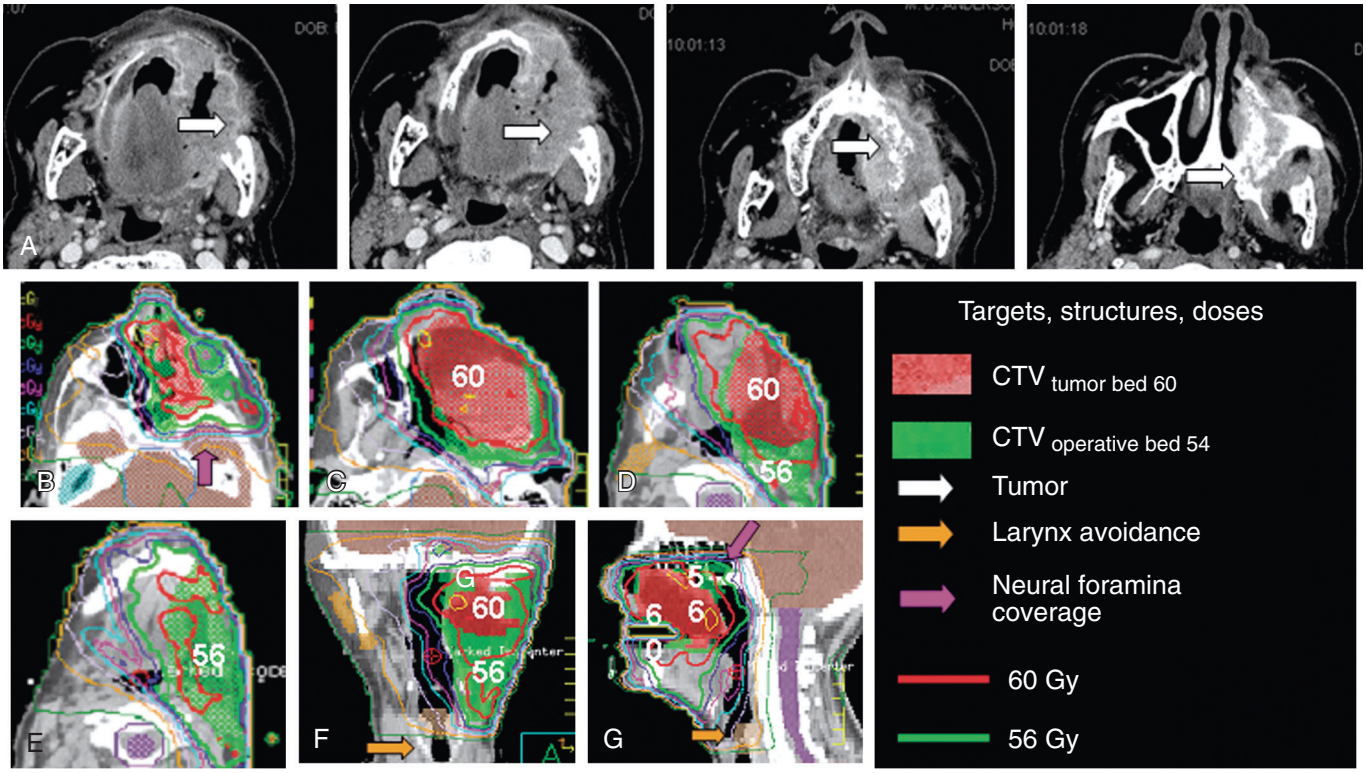


Figure 36-12 A 60-year-old woman had primary radiation therapy in 1999 to a total dose of 66.6 Gy for a left buccal cancer. In 2004, she developed a recurrence centered on the left side of the hard palate and left maxillary alveolar ridge, involving the left buccal mucosa and retromolar trigone, with gross destruction of the mandible and maxilla and the floor of the left maxillary sinus **(A)**. She underwent salvage surgery, which identified poorly differentiated squamous carcinoma with negative margins and found involvement of lymphovascular space and obvious invasion of the infraorbital nerve. She had adjuvant radiotherapy to 60 Gy using intensity-modulated radiation therapy with concurrent chemotherapy. **B-G,** Isodose distributions. The 54-Gy target volume encompasses the floor of the orbit and foramen rotundum at the base of the skull because of perineural invasion *(pink arrow)*, and the larynx was outlined for avoidance *(orange arrows)*.

TABLE 36-13 Side Effects That May Result from a Combination of Tumor, Surgery, and Radiotherapy in Patients with Paranasal Sinus Cancers

Vestibulocochlear	Vestibular dysfunction (imbalance), persistent otitis, tinnitus, hearing impairment
Ophthalmologic (lacrimal gland, eyes, lens, optic nerves, and chiasm)	Retinopathy, xerophthalmia, keratopathy, cataracts, visual impairment
Neurologic (brain, brainstem, spinal cord, temporal lobe)	Neurocognitive impairment, cranial neuropathy, myelopathy, brain necrosis
Endocrine (pituitary gland, hypothalamus, thyroid gland if neck irradiated)	Multiple endocrine dysfunction: hyperprolactinemia, syndromes associated with decreased GH, FSH, LH, T_4, TSH, ACTH, and their downstream hormones
Oral (major salivary glands, oral mucosa, mandible and temporomandibular joint)	Xerostomia, dental caries, dysgeusia, mandible exposure and necrosis, trismus
Connective tissue complications (oral cavity, soft palate musculature, pharynx, larynx, skin and subcutaneous tissues, skull bones)	Soft-tissue necrosis, skin changes, persistent lymphedema, subcutaneous fibrosis, cartilage necrosis, nasal dryness, choanal stenosis, swallowing, voice dysfunction, bone necrosis

to the axis of the anterior field. This position allows irradiation of the entire orbital floor while sparing most of the cornea and most of the globe. An intraoral stent may be considered to open the mouth and depress the tongue out of the radiation fields. Following palatectomy, a stent can be designed to hold a water-filled balloon to obliterate the large air cavity in the surgical defect and thereby improve dose homogeneity. Critical structures, including the optic chiasm, optic nerves, cochlea, parotids, superior pharyngeal constrictors, eyes (retina), brainstem, brain, and larynx should be contoured and identified as organ at risk.

Patient Care during and after Radiotherapy

Patients should be informed about the specific acute and late side effects. The keys to tolerating radiation are adequate nutrition, hydration, and hygiene. Skin and mucosal reactions as well as hydration, hygiene, and nutrition should be monitored and managed during treatment. Saline nasal rinses are initiated during the period of confluent mucositis to prevent crusting and secondary infection. Patients are instructed to use sun block with SPF greater than 15 over the irradiated area after completion of treatment. Regular follow-up examinations

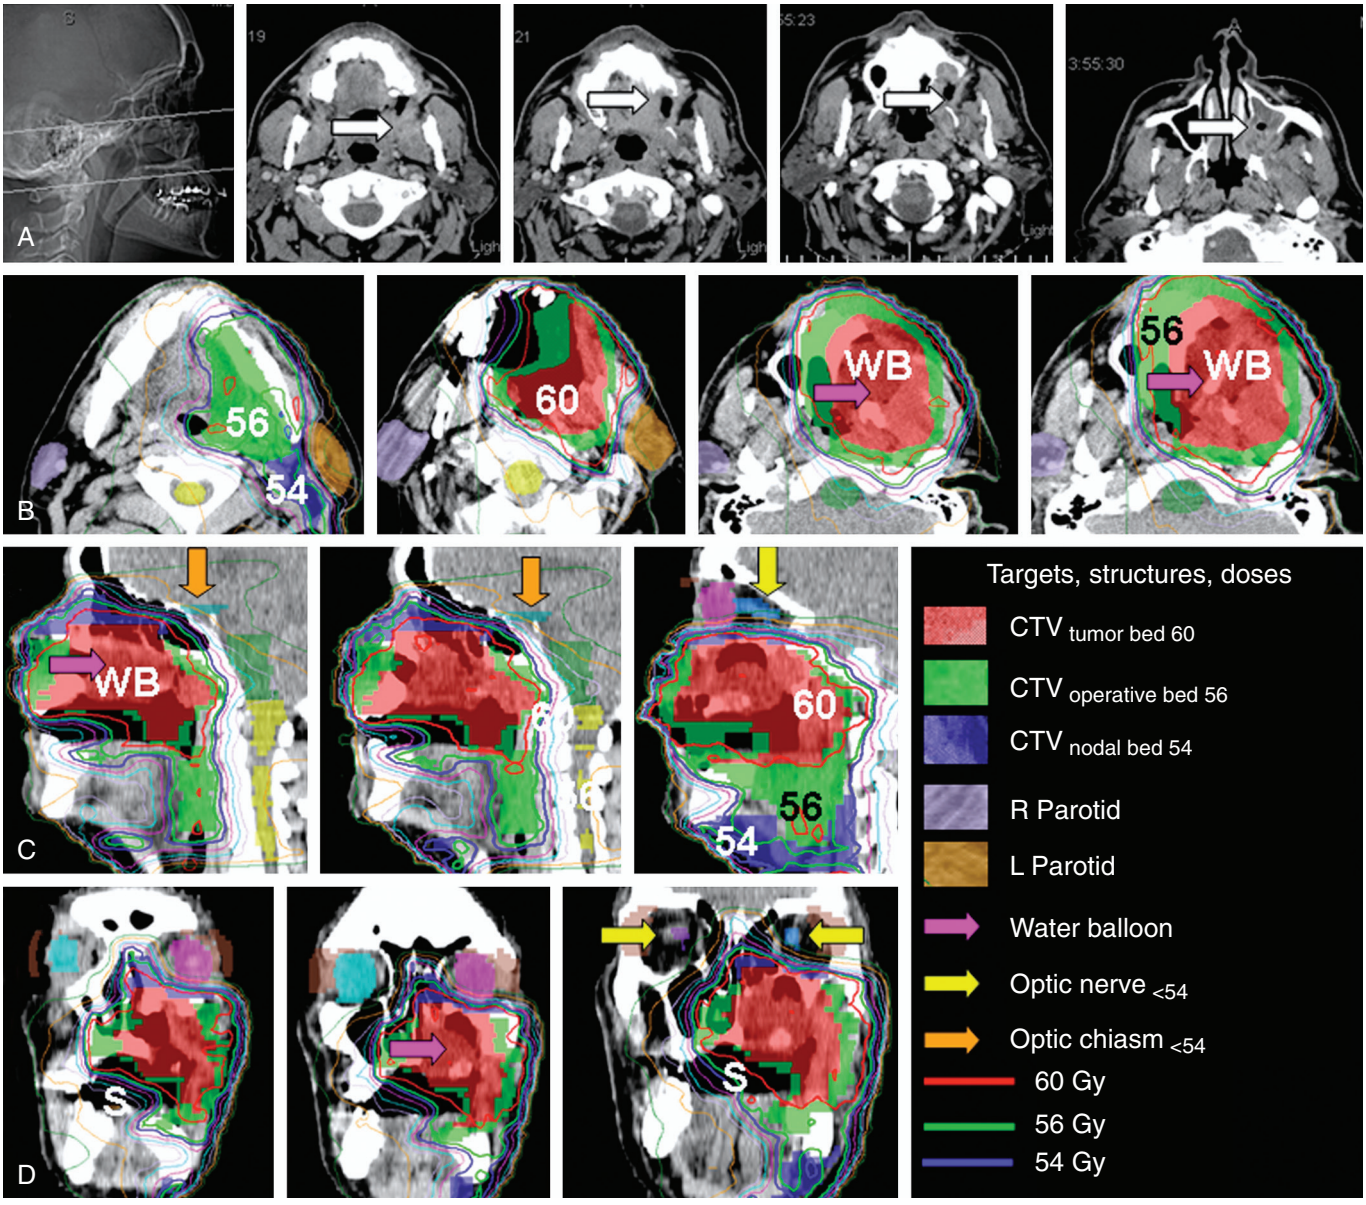

Figure 36-13 Adjuvant radiotherapy for a large, destructive T4 N0 squamous cell carcinoma centered in the left hard palate and inferior maxilla, with extension up into the left descending pterygoid canal. **A,** Tumor *(white arrows)* is demonstrated in the base of the pterygoid plates, left pterygoid musculature, and floor of the left maxillary sinus, along with destruction of the left maxillary alveolar ridge and the left soft palate. The tumor extent was confirmed at resection, and pathologic analysis showed perineural invasion (PNI). **B-D,** Transverse, sagittal, and coronal images show the dose distribution using intensity-modulated radiation therapy. The 54-Gy target volume encompasses the floor of the orbit and foramen rotundum at the base of the skull because of perineural invasion. *Pink arrows* point to a water balloon used to fill the space to provide scatter and reduce dose heterogeneity.

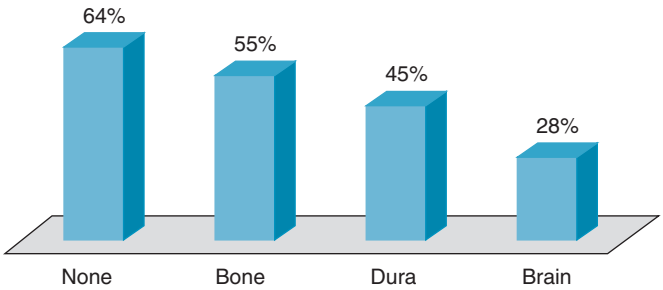

include evaluation of the treated area for late complications. A list of possible side effects is given in Table 36-13.

DIAGNOSTIC AND TREATMENT ALGORITHM AND FUTURE POSSIBILITIES

New Therapy Directions and Clinical Studies

Surgical Techniques

"It is the best of times and it is the worst of times, it was the age of foolishness, it was the epoch of belief, it was the epoch of incredulity, …"[108] Craniofacial resection and plastic reconstruction surgical techniques provide better access for complete tumor resection, while preserving and reconstructing some functionally important structures. Unfortunately, survival is not a certainty (eFigure 36-14). The International Collaborative Study[109] of 334 patients undergoing craniofacial resection for paranasal sinus tumors at 17 prestigious and experienced centers documented a not inconsiderable 4.5% operative mortality rate and a nontrivial complication rate of 33%. Esthesioneuroblastomas were excluded from the analysis as they have a far better prognosis. Surgical margins were "close" (12.9%) or positive (15.6%) in 28.5% and those patients had a 5-year CSS of only 25% versus 64% for those who had negative margins (relative risk, 2.3; $p < 0.0001$). The poor results

eFigure 36-14 5-year disease specific survival (DSS) after craniofacial resection.

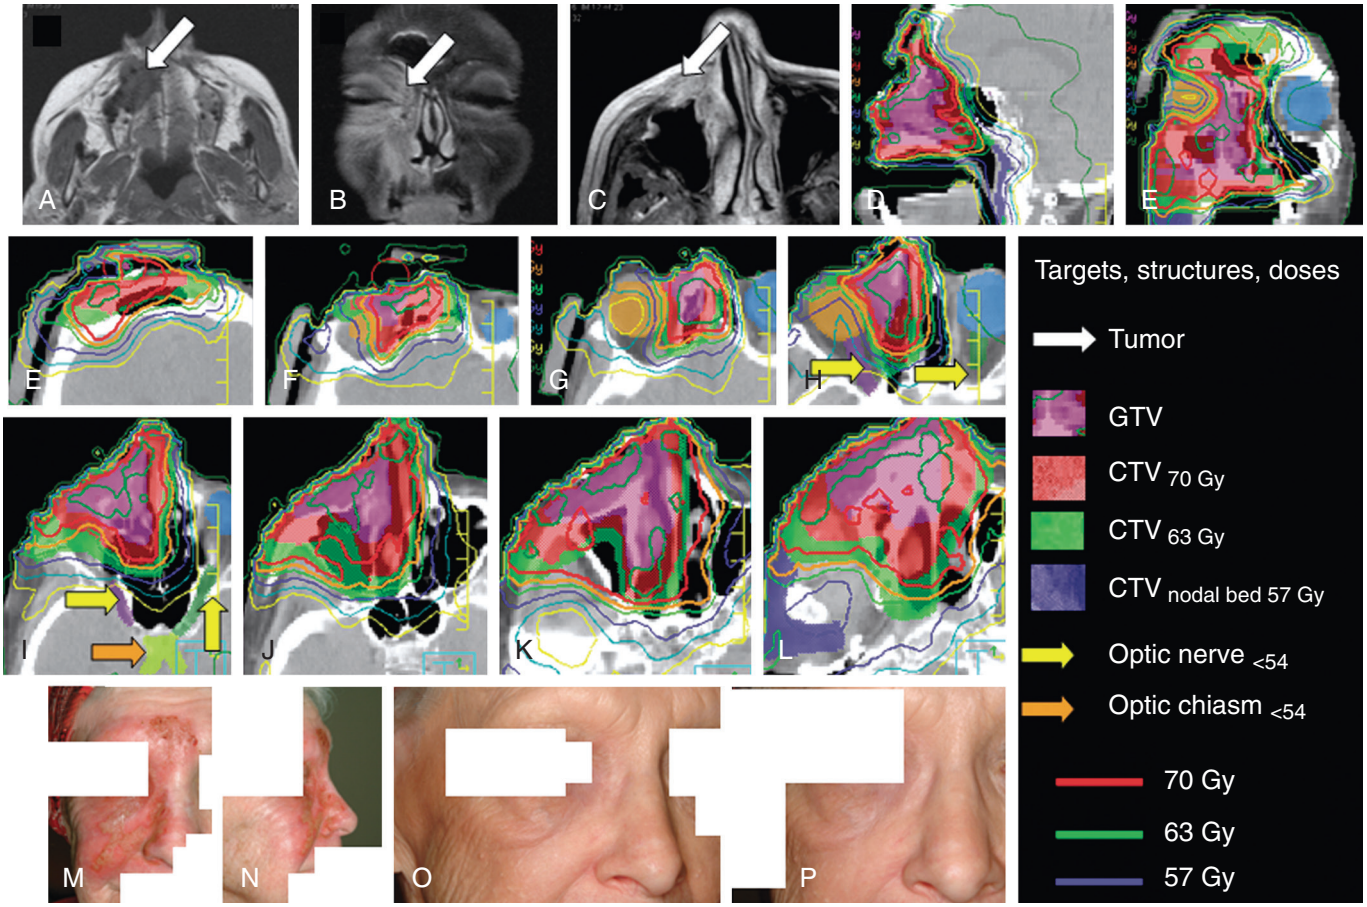

Figure 36-14 Primary radiotherapy for sinonasal undifferentiated small cell carcinoma (SNUC). **A-C,** MRI reveals an extensive infiltrating tumor that is partially enhancing and centered over the upper right nasolacrimal duct. There is penetration through the subdermal layers of the skin and spreading to the right maxillary antrum, the right ostiomeatal complex down to the hard palate, and to the inferior portion of the right frontal sinus. The patient had two cycles of induction chemotherapy consisting of cisplatin and etoposide, which had minimal effect. She received intensity-modulated radiation therapy to 70 Gy in 35 fractions with concurrent cisplatin administered during weeks 1, 4, and 7. **E-L,** The dose distribution is shown for various transverse sections. **M** and **N**, Brisk erythema can be seen on the skin of the face over the high-dose region, along with areas of moist desquamation and crusting. The patient was prescribed prophylactic antibiotic eye drops. **O** and **P**, Skin at 6 weeks after completion of therapy. The patient had no evidence of disease at the last follow-up visit.

with inadequate surgical margins bring into question the value of the surgery. Likewise, bone, dura, and brain involvement each carry a significantly worse prognosis with only a 28% 5-year disease-specific survival for those undergoing craniofacial resection, and for patients with brain involvement, the utility of the procedure must be questioned.

Endoscopic sinus surgery certainly has its practitioners but long-term evidence of its efficacy is lacking. In the largest review of endoscopic resection of sinonasal cancers with or without accompanying craniotomy, Hanna et al[110] reported on 120 patients. The local control was an excellent 85% with a median follow-up of 37 months. Practically these patients were well selected with 63% of patients treated with endoscopic resection alone having T1-T2 disease, whereas 95% of those whose treatment included craniotomy had T3 or T4 disease. As sensibly stated by the authors, endoscopic resection alone should be reserved for patients with relatively early stage disease with no, or limited, involvement of the skull base.

We seem to have the school of radical surgeons who believe in the necessity of the most complete resection possible and the minimalists who feel that considering lack of progress that less invasive surgery makes the most sense. Although opinions are plentiful, randomized data is not.

Chemoradiotherapy

In the setting of squamous cell carcinomas of the head and neck, despite a great deal of enthusiasm, the role of induction chemotherapy is unclear.[111] Based on principles[112,113] it seems reasonable to include concurrent chemotherapy for advanced squamous cell cancers of the paranasal sinuses. Unfortunately, because of the rarity of the disease, it will take many years to assess the relative value of these new developments in improving the overall outcome of patients with sinonasal cancers.

Proton Radiotherapy

Protons are charged particles with a finite, energy-dependent range in tissue. Their energy transfer increases as protons lose momentum, resulting in a large deposition of energy as the protons comes to rest in what is termed the Bragg peak. Unlike photons, the maximal dose deposition of an individual beam occurs in the target, with a slightly sharper beam penumbra[114] and small dose beyond the target ("exiting"), providing

dosimetric advantages in treatment of many disease sites. In a review of published reports of treatment planning comparisons between proton therapy and photon techniques for paranasal sinus and other head and neck cancers, proton therapy provided advantages including markedly lower doses to organs at risk (OARs), the ability to dose escalate the target without increasing dose to OARs, and the ability to maintain superior PTV coverage compared to IMRT as dose constraints to OARs became more stringent.[115]

Emerging proton techniques include active beam scanning and intensity modulation, which can further improve dose conformality, although the great majority of proton clinical results to date are based on three-dimensional conformal proton therapy (CPT). Some published clinical reports have included a component of photon therapy either because historical limited availability of proton beam time or to integrate photons for potential skin sparing and homogeneity optimization of the composite treatment plan.

Given the tremendous heterogeneity of patients with sinonasal malignancies, and institutional variation in treatment approaches, it is difficult to draw conclusions from comparison of different published series. However, most series of proton therapy have focused on patients with particularly advanced or anatomically difficult tumors, with encouraging local control and, despite delivery of aggressive doses, reported visual complications have been low.[116]

A dosimetric comparison of 3D CPT with IMRT for the treatment of a patient with maxillary sinus cancer was performed at the Florida Proton Therapy Institute.[117] The total dose to be delivered was a optimistic 74.4 Gy or 74.4 cobalt gray equivalent (CGE), to be delivered in 1.2 Gy or CGE twice-daily fractions with concurrent weekly cisplatin. The proton plan was normalized so that the CTV received 90% of the prescription dose. Both IMRT and 3D CPT covered the target volumes, but the mean and integral doses for all normal tissues were lower with 3D CPT. Both plans had maximal doses that violated normal tissue tolerances for the ipsilateral optic nerve/retina/lens, temporal lobe, pituitary, and brain. Though the protons reduced the dose to the ipsilateral optic structures, the planned dose to these normal structures was still above tolerance. 3D CPT was able to completely spare the contralateral lens, parotid, and lacrimal glands. Other centers have also reported modest benefit with 3D CPT.[118-120]

Fitzek et al reported results of a prospective study of chemotherapy, surgery, and combined photon-proton therapy in 19 patients with esthesioneuroblastomas or sinonasal neuroendocrine carcinomas, primarily Kadish stage C. Biopsy or subtotal resection was followed by two cycles of cisplatin and etoposide, followed by an aggressive hyperfractionated approach combining photons and protons to deliver a median total dose of 69.2 GyE in a median of 40 fractions. The 5-year OS was 74% and local control 88%. Both patients with local failures were salvaged by surgery. There were no late visual complications.[121]

Zedna et al reported on results of definitive proton therapy in 39 patients with unresectable tumors of the nasal cavity and paranasal sinuses, including several histologies. Approximately a quarter received induction chemotherapy. The most common dose and fractionation was 65 GyE in 26 fractions. The 3-year OS was 59% and progression-free survival 49%; 23% of patients had local progression. One patient suffered vision loss and there was one treatment related death from a CSF leak, with 13% of patients experiencing grades-3 to -5 late toxicity.[104]

Okano et al reported on 13 patients with T4b nasal and sinonasal malignancies of varied histologies treated with induction chemotherapy using docetaxel, cisplatin, and S-1, followed by concurrent cisplatin given with proton therapy to 65 GyE in 26 fractions. The 5-year OS was 75.5%, progression-free survival 34%, with three patients developing local failures. No instances of brain radionecrosis or visual loss were observed.[122]

Proton dosimetry is significantly influenced by air-tissue inhomogenities. Application of proton therapy in treatment of paranasal sinus tumors requires careful attention to dynamic changes that typically occur during radiation therapy from tumor regression and changes in mucosal thickening and filling of the sinuses with fluid. Beam arrangements are selected to provide a dosimetrically robust treatment plan, which is not reliant on the distal range of the beam to provide sparing of critical OARs.[123] When nodal irradiation is indicated, it may be incorporated with proton therapy or with matched photon fields.

TABLE 36-14 Treatment Algorithms for Cancer of the Nasal Vestibule, Nasal Cavity, and Ethmoid Sinus

Site/Extent	Preferred Treatment	Comments
NASAL VESTIBULE		
Small tumors	Brachytherapy	Suited for septal lesions
Larger tumors	EBRT	Suited for nasal floor tumors
Advanced tumors	Surgery + EBRT	—
NASAL CAVITY/ETHMOIDS		
Stage I (A)	Surgery or EBRT	Based on expected esthetic outcome
Stage II (B), III (C)	Surgery + EBRT ± chemotherapy	EBRT ± chemotherapy if high risk for anesthesia

EBRT, *External beam radiotherapy.*

Follow-Up

Although we feel ethically compelled to follow our patients, data regarding the cost-effectiveness of rigorous surveillance is lacking. The relative surveillance modalities are endoscopy for extracranial disease, multiplanar MRI with gadolinium and fat-saturation techniques for endoscopically inaccessible locations, and PET scanning for metastatic disease.

Treatment Algorithms and Conclusions

Treatment algorithms for cancers of the nasal vestibule, nasal cavity and ethmoid sinus are seen in Table 36-14 and the diagnostic and treatment algorithm for maxillary sinus in Figure 36-15. In summary, acknowledging that the literature on the subject of nasal and paranasal sinus cancers comes mostly from retrospective reviews from single institutions, "appropriate" surgery plus postoperative radiation for the aggressive sinonasal cancers is the guiding principle.[124] Especially in the IMRT era, trends toward increased use of elective nodal irradiation seem reasonable, as does the use of concurrent chemotherapy for squamous cell histologies.

CHAPTER

37 Salivary Gland Malignancies

Harry Quon, Ana Ponce Kiess, Christine H. Chung, and David W. Eisele

INCIDENCE

The overall incidence of salivary gland malignancies in the general population is about 0.9 to 4.0 new cases per 100,000 population per year.

BIOLOGIC CHARACTERISTICS

Prognostic factors relate to histology, grade, primary tumor size and extent, lymph node involvement, gender, and age.

For mucoepidermoid carcinomas, the presence of the hallmark t(11;19)(q21;p13) translocation is a key oncogenic event associated with lower rates of local and distant relapse in fusion positive malignancies.

STAGING EVALUATION

Staging includes a thorough history and physical examination, chest radiography, contrast-enhanced computed tomography (CT) scan or magnetic resonance imaging (MRI) of the head and neck region, positron emission tomography (PET) scan, and liver function tests.

PRIMARY THERAPY

Compete surgical resection is the primary therapy for major and minor salivary gland cancers. Small cancers, typically arising within minor salivary glands in cosmetically or functionally critical areas, may be treated with primary radiation therapy with moderate success in the patient who refuses surgery. New surgical options including transoral robotic surgery (TORS) now exist, offering improved function preserving surgical options especially for minor salivary gland malignancies.

ADJUVANT THERAPY

Adjuvant radiotherapy has an established role to reduce the risk of locoregional relapse in high-risk indications. These include the presence of a positive or close surgical margin, perineural invasion, high-grade histology, extraglandular extension, bone invasion, and the presence of lymph node metastasis.

EARLY STAGE DISEASE

The 10-year locoregional disease control and overall survival (OS) rates for stages I to III disease treated with surgery and postoperative radiotherapy are ≥80% and ~60%, respectively. When treated with radiotherapy alone, these are ~70% and ~65%, respectively.

LOCALLY ADVANCED DISEASE

The 10-year locoregional disease control and OS rates for stage IV disease treated with surgery and postoperative radiotherapy are ~65% and ~30%, respectively. When treated with radiotherapy alone, these are ~25% and ~20%, respectively.

When treated with neutron beam alone, the 6-year actuarial locoregional and OS rates are ~60% and ~60%, respectively. The use of neutron beam radiation can increase the rate of severe late effects including central nervous system (CNS) injury at the skull base.

PALLIATION

Combination chemotherapy regimens have poor response rates, typically less than 25%. Multiple targeted agents have been investigated, demonstrating less toxicity and the suggestion of disease stabilization but even poorer objective response rates.

The salivary glands are exocrine glands that function to produce saliva. The salivary gland unit is composed of acini of serous or mucinous cells that drain into a branching ductal system composed of cells forming the intercalated duct, striated duct, and excretory duct. Myoepithelial cells surround the acinar cells and the intercalated ducts and function by contracting and forcing saliva through the ductal system. Stem cells are present in the basal layer of the excretory and intercalated ducts that can differentiate into the different elements of the salivary glands.

There are three major paired salivary glands (parotid, submandibular, and sublingual) producing the majority of the saliva. The remaining saliva is produced from more than 600 minor simple unencapsulated tubuloalveolar glands, located throughout the lamina propria of the upper aerodigestive tract mucosa. Approximately 50% of the minor salivary glands are located within the mucosa of the hard palate. These glands are predominately mucous secreting. Minor salivary glands may also be seen in the nasal cavity and paranasal sinuses.

Benign and malignant tumors of diverse histologies may occur in a variety of anatomic sites adding to the complexity in understanding the natural history of salivary gland tumors (SGTs). This heterogeneity and the rare incidence of SGTs add to the challenge in determining the optimal management approach.

ETIOLOGY AND EPIDEMIOLOGY

The causes of SGTs, both benign and malignant, have not been clearly established. Reports consistently suggest etiologic associations with nutritional deficiencies, exposure to ionizing radiation, ultraviolet exposure, genetic predisposition, history

of previous cancer of the skin of the face, occupational exposure, viral (Epstein-Barr virus) infection, alcohol use, hair dye use, and higher educational attainment.[1-5]

Of these associations, exposure to ionizing radiation is associated with a statistically significant, though small risk of for SGTs, both benign and malignant. Radiation-induced malignant SGTs (MSGTs) may occur with higher frequency in the minor salivary glands. Studies have demonstrated not only a strong association[6] but also that the risk has a temporal latency (10 years to 25 years) and a dose-response relationship with the exposure especially for mucoepidermoid carcinomas suggesting a cause-and-effect relationship.[4,7,8] The relative risk is greater for MSGTs than benign SGTs (BSGTs).[4,8] These observations are based on several independent long-term cohort studies of victims of atomic bomb exposure[6,7,9] and patients receiving therapeutic radiation for benign[8] and malignant indications.[4] Although investigators have concluded that higher doses and repeated exposure to radiotherapy increases the develop of radiation-induced SGTs, the nature of the dose-response curve for radiation-induced SGTs is unclear beyond doses ≥4 Gy and may not necessarily always increase the risk of second malignancies.[10,11] However, the atomic bomb data does demonstrate that second malignancies are increased with single exposures up to approximately 3 Gy and that this relationship is at least linear up to 2 Gy. Unlike radiation-induced sarcomas, which appear to be primarily limited to the high doses seen within radiotherapy prescription volumes, SGTs can also be seen to occur in areas receiving low therapeutic doses of radiation with the risk increasing with higher doses.

Salivary gland tumors are regarded as rare with a reported overall incidence in the Western world of approximately 2.5 cases to 3.0 cases per 100,000 per year.[12] MSGTs account for more than 0.5% of all malignancies and approximately 3% to 5% of all head and neck cancers.[12] They comprise approximately 11% of all oropharyngeal cancers.[13] Most patients with MSGTs are in the sixth or seventh decade of life.[14]

The incidence patterns of salivary gland cancers were recently reported in a Surveillance, Epidemiology, and End Results (SEER) population-based study that offers the advantage of eliminating the inherent biases of clinical series.[15] Almost 6400 major salivary gland carcinomas were estimated to have been diagnosed from 1992 to 2006. The most common nonsquamous salivary gland cancers were mucoepidermoid carcinomas followed by adenoid cystic and acinic carcinomas of comparable incidence rates. Males had a 51% higher incidence rate compared to females. The parotid gland accounted for 80% of all major salivary gland malignancies,[15] but tumors of the parotid are in general less likely to be malignant compared to the other major salivary glands and the minor salivary glands of the palate.[12] Except for adenoid cystic carcinomas (ACCs), which were equally seen in the parotid and submandibular glands, other histologies occurred mainly in the parotid gland. Notably, squamous cell carcinomas found in the parotid region usually represent lymph node metastases from cutaneous squamous cell carcinomas rather than primary parotid gland carcinomas.[16]

Among males, the most common nonsquamous salivary gland cancers were mucoepidermoid and adenocarcinoma–not otherwise specified (NOS).[15] Among females, the most common nonsquamous salivary gland cancers were mucoepidermoid, acinic cell, and ACCs. Squamous cell, adenocarcinoma–NOS, and salivary duct carcinomas occurred with more than a twofold higher incidence among males. In contrast, females had a higher incidence of acinic cell carcinoma and ACCs.

Acinic cell carcinomas were more likely to be diagnosed at younger ages compared to other cell types.[15] Incidence ratios of salivary gland cancers were significantly lower among African Americans, Asians, and Pacific Islanders compared to whites. However, incidences of mucoepidermoid carcinoma and ACC were similar among all races.

PREVENTION AND EARLY DETECTION

The recognition that radiation exposure is a risk factor for BSGTs and MSGTs (especially mucoepidermoid carcinomas) argues that long-term surveillance is likely a prudent recommendation for patients with a known history of accidental, diagnostic or therapeutic head and neck radiation exposure. These patients should be counseled about the potential risk of late MSGTs manifesting, especially if their anticipated life span is on the order of 10 years to 25 years given the latency period noted for development of radiation-induced SGTs. It is not clear if younger patients receiving therapeutic radiation are at an increased risk,[4,8] which would necessitate more vigilant observation. Gender does not appear to be a risk factor. Issues of cost-effectiveness of various surveillance investigations and the frequency of follow-up have not been established.

Because a dose-response relationship for developing SGTs from therapeutic radiation has been described (especially for mucoepidermoid carcinomas), this raises the intriguing question of whether this risk may be mitigated with modern radiation treatment planning techniques. Modern radiotherapy techniques have the advantage that the dose and volume of normal tissue irradiated may be reduced. This includes the use of proton radiation with its favorable Bragg peak physical beam characteristic. Details of this are further discussed in considering the role of protons in the management of SGTs. At this time, the possibility that conformal radiotherapy such as protons will reduce the risk of developing SGTs remains speculative and unproven. SGTs have been demonstrated, even with low doses, including doses less than 280 cGy to the parotid glands.[8] Hence, judicious use of diagnostic and therapeutic radiation and avoidance of any unnecessary radiation exposure are currently the most effective preventive strategies that can be recommended.

BIOLOGIC CHARACTERISTICS AND MOLECULAR BIOLOGY

Significant progress has been made in the understanding of the genetics and molecular biology of salivary gland malignancies. These considerations may be organized based on biologic characteristics of the tumor cell and of the tumor microenvironment. Although many biomarkers have been evaluated and shown to have differential expression compared to normal cells, this review will highlight several that have important potential therapeutic implications especially when shown to have independent prognostic significance.

Salivary Gland Genetic and Molecular Biology

Chromosomal Rearrangements

In recent years, investigations have demonstrated recurrent, nonrandom, and hallmark chromosomal rearrangements, especially translocations that characterize both benign and malignant salivary gland tumors (reviewed in Stenman[17]). These translocations result in fusion oncogenes that affect the apoptotic threshold, cell cycle regulation, tumor angiogenesis, and growth independence. Similar rearrangements have been a common theme among leukemias, lymphomas, sarcomas, and more recently with various epithelial malignancies including thyroid, prostate, and breast carcinomas. Characterizing these recurring translocations and their clinical significance is

an active area of investigation in hopes of identifying future prognostic and therapeutic targets. Several noteworthy observations have been made to date.

In 2003, the recurrent and hallmark t(11;19)(q21;p13) translocation involving CRTC1 at 19p13 and MAML2 at 11q21 was described by several groups demonstrating it to be a key pathogenic event that underlies the development of mucoepidermoid carcinomas (MECs).[18,19] This translocation has been shown to result in the mucoepidermoid carcinoma translocated gene 1–mastermind-like gene family (MECT1–MAML2) (MECT1/TORC1/CRTC1–MAML2) fusion transcript that results in a transcription factor acting on the Notch and the CREB pathways (reviewed in O'Neill[20]).

Okabe et al have demonstrated that this fusion transcript was associated with a longer disease-free survival (DFS) and overall survival (OS) on univariate and multivariate analysis.[21] Others have reported on its favorable independent prognostic impact on survival.[22,23] Lower rates of local and distant relapses have been reported in fusion-positive MECs.[23] It is important to note that these investigations have been retrospective in nature and that prospective evaluation of the prognostic significance of MAML2 translocations remains an area of study.[24] Despite this translocation correlating with low-grade MEC, in multivariate analysis for OS, this translocation was found to be independent of tumor grading raising some to question its ultimate prognostic value.[24,25] Hence, this translocation may be of diagnostic benefit and may potentially identify a favorable cohort of high-grade MECs[26] and help identify a subgroup of high-grade MECs that may be more appropriately categorized as aggressive MEC mimics, such as adenosquamous carcinomas.[23,25] This fusion offers not only the promise of future risk stratified treatment approaches but also insights into the development of novel therapeutic targets. For example, unfavorable fusion-positive MECs are believed to have acquired further somatic mutations conferring increased invasiveness such as deletion in the *CDKN2A (p16)* gene.[27]

Deletions or translocations of the terminal regions of the long arm on chromosome 6 appear to be a consistent and unique event in the development of salivary gland ACCs.[28] Of these, reciprocal translocations involving 6q and the short arm of chromosome 9 have been frequently reported.[29,30] Persson et al have also demonstrated a recurrent and hallmark t(6:9) translocation in ACCs, resulting in the MYB–NFIB fusion oncoprotein.[31] These investigators suggest that this may also be a key oncogenic event in the pathogenesis of ACC[31] leading to the induction of high MYB oncogene expression.[28,31] MYB transcription factors regulate cell proliferation, apoptosis, and differentiation. In turn, high MYB expression can also be seen in MYB–NFIB fusion-negative ACCs as well and may be helpful for future disease stratification because it appears to have potential prognostic significance as part of a molecular prognostic profile.[32]

Mutation Analysis

With advances in massive parallel sequencing, the whole exome and genome sequences of ACCs were recently completed.[33,34] Consistent with the previous report by Persson et al,[31] the whole genome sequencing data confirms frequent t(6, 9) translocation resulting in the MYB–NFIB fusion oncoprotein and frequent chromosomal loss of 1p36, 6q24, 9p, 12q13, and 14q.[33,34] These analyses also demonstrate that ACCs have a lower somatic mutation rate (13 mutations per exome) relative to most adult solid tumors with a wide mutational diversity.[34] Many of the mutated genes encode chromatin remodeling regulators and chromatin-state modifiers (i.e., MGEA5, SMARCA2, SMARCE1, CREBBP, EP300, KDM6A, ATRX, ARID1A, ARID4B, and ARID5B) suggesting epigenetic regulation is important in the development of ACCs. Additionally, genes involved in DNA damage response (i.e., TP53, BRCA1, ATM, ERCC2, and PTPRK), protein kinase A signaling (i.e., PTPRG, PTPRH, RYR2, RYR3, and CALM2), Notch signaling (i.e., NOTCH1, NOTCH2, and SPEN), and FGF-IGF-PI3K signaling (i.e., PIK3CA, PTEN, MAGI1, MAGI2, FGFR2, and FGFR4) are shown to be mutated.[33,34] Presence of activating mutations in the FGF-IGF-PI3K pathway has a particular importance because of the existence of therapeutic agents targeting the pathway in this particularly chemotherapy resistant tumor.

Dysregulation in Growth Factor Receptors

Epidermal growth factor receptor (EGFR) and human epidermal growth factor receptor 2 (erbB2 or HER2/neu) are members of the EGFR transmembrane receptor family, and when activated, transduce mitogenic signals. Several studies have reported high immunohistochemical expression levels that may be more dominantly expressed in non-ACCs.[35-37] However, the clinical significance of EGFR protein overexpression remains controversial with some multivariate analyses demonstrating both an independent association with poor survival[38] and others demonstrating no independent association with poor survival.[37]

Similarly, erbB2 overexpression has been reported for MSGTs. These include strong overexpression in MECs and in salivary ductal carcinomas (SDCs)[39,40] but rarely for ACCs.[39] Univariate[41,42] and multivariate independent prognostic significance has been reported for erbB2 overexpression.[43,44] Agulnik et al suggest that greater clinical activity with the dual EGFR and erbB2 inhibitor lapatinib may be possible in tumors with both high EGFR and erbB2 expression and that erbB2 may be especially important.[35] Recently, patients with SDCs and erbB2 amplification treated with a trastuzumab-containing regimen containing other targeted agents based on actionable mutations were found to have improved survival compared to patients who did not have actionable mutations.[45] Identifying subgroups of patients more dependent on erbB2 signaling may be important in further defining the therapeutic benefit with erbB2 inhibition because tailoring therapies based on molecular abnormalities may be have therapeutic benefits.

c-KIT/CD117

The KIT protein is a membrane tyrosine kinase receptor, which when activated through binding to the ligands stem cell factor or mast cell growth factor, provide signals for cell survival, proliferation, and differentiation. Its overexpression has been particularly noted in ACCs[46] and has been suggested as one way in which ACCs may be distinguished from polymorphous low-grade adenocarcinomas (PLGAs),[47] though contradictory findings have also been reported.[48]

Although the independent prognostic significance for KIT overexpression has not been evaluated, it has remained an attractive therapeutic target because of the clinical success of imatinib, a small molecule tyrosine kinase inhibitor that competitively inhibits the activation of the KIT receptor and several other structurally similar receptor tyrosine kinases. However, it is clear that it is the nature of any point mutations in the protein that impacts on its response to inhibition with imatinib, a small molecule tyrosine kinase inhibitor, which competitively inhibits the activation of the KIT receptor and several other structurally similar receptor tyrosine kinases. Although several investigators have not demonstrated the presence of mutations, recent studies using more sensitive polymerase chain reaction techniques confirm the presence of multiple mutations in the *c-kit* gene in ACCs.[49] While both gain of function (activating function of the receptor) and loss of function *c-kit* mutations have been described for other malignancies, the therapeutic implications of these recently

described mutations in the therapeutic management of ACCs remains to be determined. Although the independent prognostic significance for KIT overexpression has not been evaluated, it has remained an attractive therapeutic target because of the clinical success of imatinib.

Salivary Gland Tumor Microenvironment

Neoneurogenesis

The study of perineural invasion (PNI) is an important biologic consideration for many cancers especially for MSGTs such as ACCs. The molecular determinants of this mechanism of spread have only begun to receive attention in recent years and have yielded insights to view this spread pattern as an active and reciprocal interaction between malignant cells and peripheral nerves. Observations in other cancer sites currently suggest that PNI is the result of a mutual neurotropic interaction with cancer cells characterized by the release of various paracrine growth factors.[50] As with neoangiogenesis, it is clear that the in-growth of nerve endings into a tumor may be stimulated by the tumor release of various neurotrophins such as brain-derived neurotrophic factor (BDNF),[51] nerve growth factor (NGF), and its receptor tyrosine kinase A (TrkA).[52] Neurotrophin staining has been demonstrated to be present in ACCs. NGF and TrkA have both been correlated with the presence of perineural invasion.[52] Recently, the expression of neurotrophin-3 (NT3) and its receptor TrkC/NTRK3 was demonstrated in ACCs.[53] These tumor-innervating nerve cells may release neurotransmitters that function as proliferative and pro-migratory signals for the tumor cells. Furthermore, nerve fibers are used as routes for tumor cell dissemination. For pancreatic carcinoma, detailed studies of serial sections have demonstrated that tumor cells can progress along branching nerve fascicles in a continuous fashion.[54]

Therapeutically, these insights offer the potential for the development of small molecule inhibitors such as Trk tyrosine kinase inhibitors especially for ACCs in hopes of addressing this pattern of spread.[55] Importantly, radiation has recently been shown to impair PNI not only through direct cancer cytotoxicity but also with prophylactic treatment of the nerve, disruption of paracrine signaling preventing perineural spread in an animal model system.[56] Such observations are important because they have potential radiotherapy treatment planning implications.

Hypoxia

In contrast to other solid malignancies of the head and neck, the role of tumor hypoxia has not been as extensively evaluated in MSGTs. This is an important consideration for MSGTs given their relative resistance to radiotherapy and the improved results seen with neutron radiation, which is less oxygen dependent.

Preliminary investigations using methodologies such as immunohistochemical staining for the oxygen-dependent binding of 2-nitroimidazoles suggest that salivary gland malignancies may be well-oxygenated tumors.[57] This observation would not support the hypothesis that an underlying mechanism for not only the radioresistance but also high rates of distant metastasis characterizing MSGTs is the presence of tumor hypoxia. In a study of 12 patients receiving surgery, the hypoxia-marker pimonidazole was administered preoperatively. Of the 8 patients yielding sufficient tumor specimen for analysis, immunohistochemical staining was not seen for pimonidazole and for the hypoxia inducible factor (HIF)-α or the HIF-1α regulated carbonic anhydrase (CA) IX and glucose transporters (GLUT) 1 and 3. Given that salivary gland malignancies are rare and of diverse histologies, further evaluation is needed before more generalized conclusions can be made.

PATHOLOGY AND PATHWAYS OF SPREAD

Pathology

The classification of SGTs is primarily based on morphologic patterns with two classification systems often recognized. This includes the Armed Forces Institute of Pathology (AFIP) and the World Health Organization (WHO). In 2005, the WHO further developed the classification scheme for salivary cancers originally set forth by Foote and Frazell (Box 37-1).[58] The WHO classification includes the following categories: adenomas, carcinomas, nonepithelial tumors, malignant lymphomas, secondary tumors, unclassified tumors, and tumorlike lesions. In contrast, the AFIP classification includes the following categories: benign epithelial neoplasms, malignant epithelial neoplasms, mesenchymal neoplasms, malignant lymphomas, metastatic tumors, and nonneoplastic tumorlike conditions. Speight and Barrett have reported a comprehensive summary of salivary gland histopathology.[12] Given the histologic diversity, this review will highlight histopathologies that impact the pattern of spread and its clinical manifestations.

Important prognostic factors for disease-relapse and survival are summarized in Table 37-1. Practically, histologies may be categorized as high-grade histologies with at a greater risk of nodal and distant metastases or low-grade histologies with a lower risk of nodal metastasis. The former includes high-grade MECs, high-grade adenocarcinoma–NOS, carcinoma ex-pleomorphic adenoma, salivary ductal carcinomas (SDCs), and squamous cell carcinomas. Low-grade histologies include low-grade MECs, ACCs, acinic cell carcinomas (AcCCs), and PLGAs. An intermediate group has also been described consisting of intermediate MECs.

For MECs, the histologic grading has been shown to be of prognostic significance. Several three-tiered grading schemes have been shown to be reproducible and predictive of the patient's outcome by defining low-, intermediate-, and

BOX 37-1 Classification of MSGTs

Carcinoma ex-pleomorphic adenoma
Adenoid cystic carcinoma
Mucoepidermoid carcinoma
Adenocarcinoma (NOS)
Acinic cell carcinoma
Squamous cell carcinoma
Myoepithelial carcinoma
Cystadenocarcinoma

NOS, *Not otherwise specified.*

high-grade tumors using five histopathologic features yielding a numerical score for differentiation.[59,60] High-grade MEC has a greater proportion of epidermoid cells than mucous-producing cells with a solid tumor appearance often mistaken for squamous cell carcinoma. High-grade disease also increases the risk of nodal metastasis sufficient to warrant elective management (such as a neck dissection). Despite this, the risk of nodal metastasis with low grade (LG) and especially intermediate grade (IG) can still be significant. Ozawa et al reported that, using the Goode grading schema, low- and intermediate-grade MECs had nodal metastases in 24% and 30%, respectively.[61] High grade (HG) MECs demonstrated nodal metastases in 56% of patients. In the modified Healey grading schema, lymph node involvement was 0% (LG), 22% (IG), and 72% (HG). T category also is associated with an increased risk of nodal metastasis for both major and minor salivary gland MECs.[62] T1 HG disease may be at low risk for nodal metastasis in major salivary glands, that is, anatomic sites not involving the mucosa.[62]

TABLE 37-1 Summary of Prognostic Factors

Endpoint	Prognostic Factors
Local relapse	T3 and T4 category, unresectability, and skull-base invasion
Neck metastasis	Male sex, T3 and T4 category, primary site involving the pharynx, high-grade histology especially mucoepidermoid and adenocarcinoma–NOS
Distant metastasis	Clinical perineural invasion, skull-base invasion, nodal metastasis
Survival	Stage IV, nodal metastasis

NOS, *Not otherwise specified.*

Pathways of Spread

When considering all histologies together, the risk of lymph node metastasis is increased with T3 and T4 disease, involvement of a pharyngeal site and high-grade MECs and adenocarcinoma–NOS.[63] Similar observations have been reported with T stage, anatomic site, and histology (Table 37-2).[64] For minor salivary glands, the density of the lymphatics in the anatomic site has a significant influence on the risk of nodal metastases. In general, cancers arising within the

Data from Armstrong JG, Harrison LB, Thaler HT, et al: Indications for elective treatment of the neck in cancer of the major salivary glands. Cancer 69:615–619, 1992; Byers RM, Jesse RH, Guillamondegui ON, et al: Malignant tumors of the submaxillary gland. Am J Surg 126:458–463, 1973; and Spiro RH, Koss LG, Hajdu SI, et al: Tumors of minor salivary origin: A clinical pathologic study of 492 cases. Cancer 31:117–129, 1973.

oropharynx or nasopharynx have about a 60% incidence of lymph node metastasis compared with 5% to 10% for hard palate and paranasal sinus sites. Minor salivary gland cancers arising within the tongue and floor of mouth have an approximately 40% incidence of lymph node metastasis; those arising within the gingiva have a 20% incidence of lymph node metastasis; nasal cavity, buccal mucosa, and lip have a 15% incidence or less.

ACCs at the primary site have a predilection for PNI as a unique pattern of local disease extension. ACCs occur most commonly in the palate and frequently spread by PNI. PNI may be seen in >50% of cases and spread may occur in both directions along the nerve. Growth along the nerve has been shown to have "skip" areas of involvement and noninvolvement, so that a negative nerve margin does not guarantee a final negative margin. However, a recent study of serial sections for pancreatic carcinoma suggests that PNI may in fact be contiguous along the branching nerve fascicles and that it is the branching nature of the nerve and pathologic sampling of the sections evaluated that contributes to the uncertainty in margin assessment.[65]

The risk of distant metastases is increased with the presence of lymph node metastasis, skull-base involvement, and high-grade histology.[66] Common distant metastatic sites include lung, liver, and brain and are also associated with the histologic grade.

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, AND STAGING

Clinical Manifestations

Most patients presenting with SGTs are asymptomatic and present typically with a solitary, painless mass. Low-grade SGTs tend to be slow-growing tumors that rarely invade local structures. Symptoms are largely related to the anatomic location from which it originates. Symptoms may include local pain with involvement of the parotid gland, and facial paralysis with involvement of cranial nerve VII. Local obstructive symptoms and possibly drainage from the ipsilateral ear can result from extension to involve the external auditory canal. Trismus may develop with involvement of the deeper parapharyngeal space or pterygoid muscles. Involvement of the skull base can result in other cranial nerve deficits, including symptoms of dysphagia. Minor salivary gland MSGTs commonly involve the palate where they are typically asymptomatic or cause a vague sensation of a mass. SGTs may also present with mass effect symptoms in the submandibular gland, maxillary sinus, oropharynx and larynx. Tumor involvement of functionally sensitive sites, like the larynx, is more likely to lead to symptoms and an earlier disease presentation.

PNI may result in symptoms of pain and numbness but more commonly presents as a painless mass with an indolent history of growth. Clinical symptoms are more likely to be associated with radiologic evidence of PNI (Figure 37-1). Extension through the skull base with intracranial growth can also occur and result in mass effect symptoms. Because ACCs commonly occur in the palate, spread along the palatine nerves through the greater and lesser palatine foramen is an important route of local spread.

Patient Evaluation

As with any patient with a suspected or documented malignancy, proper evaluation begins with a detailed history and physical (Box 37-2). Presence of a new mass in the face, neck, or mouth should be investigated for associated symptoms based on the surrounding anatomic structures that may be affected by disease extension. This should also include symptoms that may relate to perineural spread of the cancer. Physical examination should include a full oral cavity inspection

TABLE 37-3 Primary Tumor Staging Criteria

Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor 2 cm or less in greatest dimension without extraparenchymal extension*
T2	Tumor ≥2 cm but <4 cm in greatest dimension without extraparenchymal extension*
T3	Tumor ≥4 cm or tumor having extraparenchymal extension*
T4a	Tumor invades skin, mandible, ear canal, or facial nerve
T4b	Tumor invades base of skull or pterygoid plates or encases the carotid artery

**Extraparenchymal extension is defined as the presence of any clinical or macroscopic evidence of invasion of the adjacent soft tissues. Microscopic evidence alone does not constitute extraparenchymal extension for classification purposes.*

and bimanual palpation of structures that are or may be involved. Minor salivary gland tumors typically appear as a submucosal mass and commonly involve the palate. The proximity of the mass and any changes to the greater and lesser palatine foramina should be noted. Flexible fiberoptic nasopharyngolaryngoscopy should be performed to assess for the location and extent of any mucosal lesions in the pharynx or to assess the function of critical cranial nerves that may be suspected to be involved due to a mass at the skull base.

Fine needle aspiration or ultrasound-guided core needle biopsy of suspicious lesions may be useful to distinguish a malignant from benign processes. In a recent retrospective study of 879 patients, fine needle aspiration demonstrated a sensitivity of 83% and specificity of 99%, with overall accuracy of 93%.[67] However, other studies have demonstrated false negative rates as high as 33% and 43% for adenoid cystic carcinoma and low-grade mucoepidermoid carcinoma, respectively.[68] FNA is strongly preferred for the diagnosis of parotid gland masses as it is associated with minimal risk of tumor seeding along the biopsy tract or facial nerve injury. This is particularly important as benign tumors such as pleomorphic adenomas can be very difficult to control after local tumor seeding.

Both CT and MRI are necessary to assess the extent of the disease though the later may be particularly helpful. MRI provides better delineation of soft-tumor infiltration, PNI, and intracranial spread.[69] Bony destruction and regional lymph node metastases are better visualized with CT. CT with contrast may be complementary to MRI for minor SGTs.[69] Both pre- and postcontrast images are needed for optimal evaluation. Recently, MRI techniques such as diffusion-weighted MRI (DW-MRI), dynamic contrast-enhanced MRI (DCE-MRI), and MR spectroscopy (MR) have shown potential for discriminating malignant from benign SGTs.[70] Although the role of PET-CT imaging for salivary gland cancers has yet to be established, early studies have demonstrated an accuracy of more than 90% for detection of the primary tumor and an increased ability in identifying unrecognized local, nodal, and distant metastases.[71,72] The role of sentinel lymph node biopsy for parotid MSGTs remains a promising method to evaluate the risk of nodal metastases but warrants further evaluation before its routine recommendation.[73,74]

Staging of Major and Minor Salivary Gland Malignancies

Unlike minor salivary gland tumors, which are staged according to the anatomic site of origin, major salivary gland cancers have their own staging system. In general, tumors of the major salivary glands are staged according to the tumor size, and whether there is any extraparenchymal extension (Table 37-3). Extraparenchymal extension is described as either clinical or macroscopic evidence of invasion of the soft tissues. Microscopic extension does not constitute extraparenchymal extension. For parotid tumors, the prognostic significance of facial nerve involvement is also considered. Although tumor grade does affect outcome, the current AJCC seventh edition does not incorporate tumor grade as a component of the staging system.

Nodal staging and group staging for major salivary gland tumors follows other head and neck cancer sites and are described here.[75]

PRIMARY THERAPY

The treatment approach for SGTs continues to be based on a surgical resectability paradigm. The therapeutic dilemma occurs when there is significant involvement of a functional region in the head and neck involved in the speech or swallow function or if there is unresectable disease. Therapeutic advancements in recent years include the development of novel organ-preserving surgical approaches (Figures 37-2 and 37-3). Radiotherapy advancements include the development of more conformal radiotherapy techniques and the advent of particle beam therapy. Advancements in systemic agents have included the translation of molecular therapeutics, offering a potentially more favorable therapeutic ratio.

Surgery

The surgical treatment of salivary malignancies can be divided into categories based on the gland involved. The most common site for salivary malignancy is the parotid gland. The submandibular gland and the minor salivary glands have a lower absolute number of cancers; however, the risk of a neoplasm being malignant is higher in submandibular and minor salivary glands than it is in the parotid gland.[76]

Parotid Gland Malignancy

The mainstay of surgical management of parotid malignancies is the parotidectomy, and the extent of the surgery is dictated by the tumor extent. The gland itself is divided into superficial and deep lobes by the seventh cranial nerve (facial nerve), and tumors can exist and arise in either or both lobes of the gland. Although there is no embryologic boundary between the two components of the gland, most tumors arise from the superficial lobe.

eFigure 37-1 This demonstrates a modified Blair incision used for a surgical access for a left parotid salivary gland tumor. The incision includes a preauricular incision that transitions under the ear into a postauricular and upper neck incision.

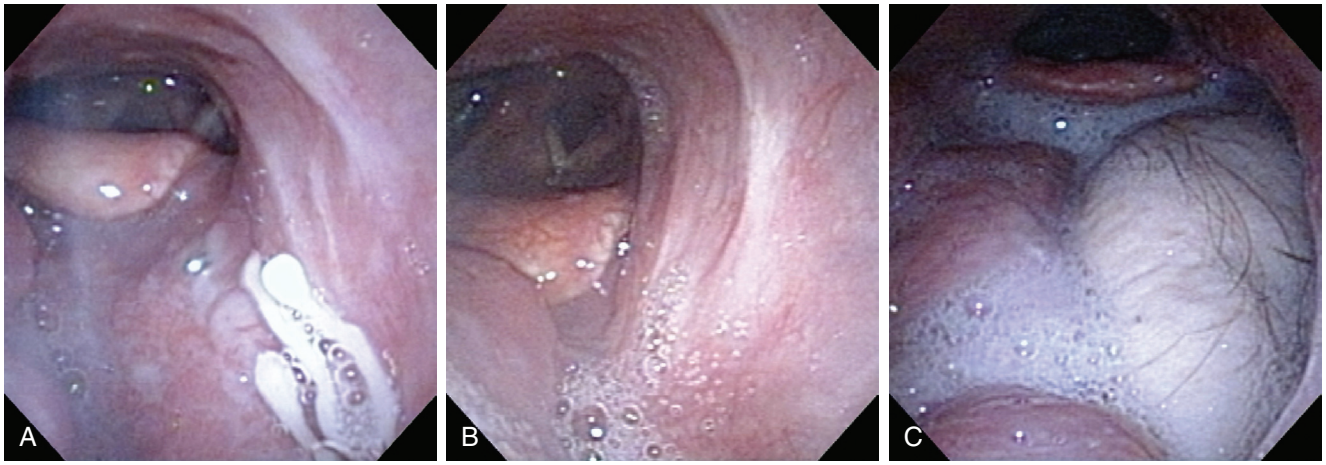

Figure 37-2 Transoral robotic resection (TORS) for an adenoid cystic carcinoma of the base of tongue. The patient was swallowing a full oral diet in the early postoperative setting **(A)** and did not require a mandibulotomy. Very good swallow function can be seen with no pooling of secretions in the vallecula with further wound healing **(B)**. In contrast, a second patient was treated with a traditional mandibulotomy and a radial forearm free-flap reconstruction in the left base of tongue demonstrating more limited swallow function with pooling of secretions in the vallecula **(C)**.

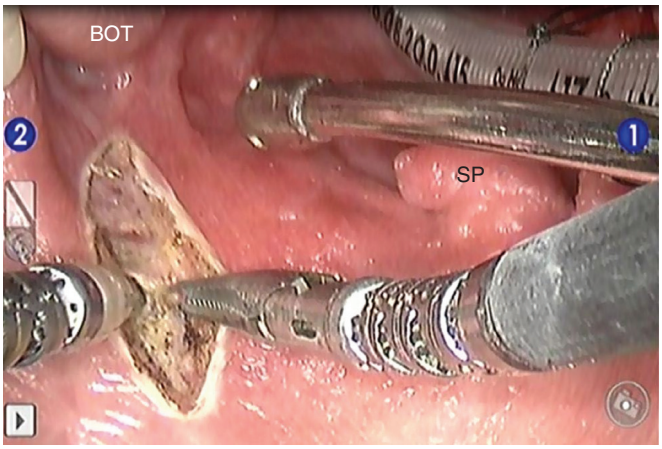

Figure 37-3 Transoral robotic surgery (TORS) of a parapharyngeal space pleomorphic adenoma. This demonstrates the robotic wristed instruments performing the early incision and dissection through the left lateral oropharyngeal wall adjacent to the base of tongue (*BOT*) and soft palate (*SP*). Excellent visualization can be demonstrated through the magnified optics.

Surgery involves an incision in the preauricular crease extending postauricularly and then into the upper neck (eFigure 37-1). This incision, known as the modified Blair incision, gives access to the facial nerve as it comes out of the stylomastoid foramen. A facelift incision is an alternative for select patients. The goal of the surgery is to identify and protect the facial nerve, trace it out along its main branches, and then manage the tumor once its relationship to the nerve has been clarified. In cases where the nerve is compromised by the tumor, or in which the tumor abuts the stylomastoid foramen, it may be necessary to identify the nerve before it comes out of the mastoid bone. This can be accomplished by drilling out the mastoid bone and identifying the nerve before it comes out of the foramen.

Once the appropriate branches of the nerve have been identified, the tumor is removed. Great care is taken to avoid entry into the tumor, and attempts are made to avoid residual positive margins as this is a known poor prognostic indicator.[77,78] Because most tumors involve only the superficial lobe of the parotid, dissecting the tumor carefully off the facial nerve is appropriate surgical care. Tumors that involve the deep lobe of the parotid gland or that involve the parapharyngeal space just medial to the parotid gland may require extended procedures to perform complete resections. These procedures are often possible through the same parotid incision but occasionally require extension of the neck incision or a mandibulotomy.[79] Excision of soft tissue, skin, muscle, and neurovascular structures in the region is appropriate if they are involved with tumor.

All attempts should be made to preserve the facial nerve during parotid surgery. Complete paralysis of the facial nerve will not only cause a significant cosmetic deficit but has the potential to affect many aspects of a patient's outcome. Corneal abrasion, nasal congestion, poor oral competence, and slurred speech are some of the common complaints after this event. Most surgeons would agree that tumor proximity to the nerve is not adequate justification for its sacrifice. However, there are circumstances under which most surgeons would agree that sacrifice of all or a part of the nerve is reasonable. Complete or partial paralysis of the face preoperatively often heralds an intraoperative finding of direct invasion of the facial nerve by tumor. If the tumor extends into the nerve, or grossly encases the nerve, then sacrifice of the nerve is warranted.

Submandibular Gland Malignancy

Although the absolute number of malignancies of the submandibular gland is far less than the parotid gland, the chance of a lesion being malignant is much higher, nearing 50%.[80] For this reason, a high level of vigilance must be in place when managing masses in the submandibular region. Most commonly, patients present with a painless mass in the region. Less commonly, painful masses or neck adenopathy may occur. Any of these presentations warrants a workup of the area, including possibly a CT or MRI and a fine-needle aspiration biopsy.

As with parotid cancers, SGT of the submandibular gland is a surgical disease. Definitive treatment often includes a combination of therapies but almost always begins with surgical excision. The surgical approach should include, at the minimum, a complete submandibular gland excision with clear margins. There is no role for enucleation of the tumor because this has been clearly associated with a higher rate of local recurrence.[81] In patients who have undergone subtotal

surgery, only to be diagnosed with cancer postoperatively, imaging studies should be performed and reoperation performed if there is residual gross tumor to obtain negative margins before considering further therapy.[54]

Sublingual and Minor Salivary Malignancy

Malignancies of the sublingual gland and minor salivary glands are rare. Minor salivary glands are present throughout the upper aerodigestive tract, and SGTs can occur at any of the sites. The oral cavity and oropharynx are the most common sites of disease, but the nasal cavity, paranasal sinuses, hypopharynx, larynx, nasopharynx, and parapharyngeal space (PPS) are all at risk for these cancers.[82]

As is the case with other salivary cancers, surgical therapy with negative margins is the mainstay of therapy. Depending on the site of the cancer, this may include a variety of surgical approaches. The challenge for these MSGTs is the functional impact that surgery can have on the speech-and-swallow function. Unlike the more common squamous carcinomas of the head and neck, the role of nonsurgical therapy has not been well established.

The role of organ-preserving surgical approaches that do not use transcervical exposure techniques are valuable in limiting the swallowing complications resulting from surgery. These include various transoral approaches including the TORS approach (Figures 37-2 and 37-3).[83] TORS has several advantages including the improved visualization of the tumor resection in three dimensions avoiding sight-line limitations with magnified optics. Its application has included function preserving resection of SGTs in the base of tongue[84,85] and in the PPS (Figure 37-3).[86]

Management of the Neck

Patients who present with clinically palpable or radiologically evident disease in the neck lymph nodes require management of this disease. This generally involves planned neck dissection at the time of the primary surgery with or without radiation.[87] What remains more controversial is the role of treatment in patients with no clinicoradiologic evidence of disease in the neck.

Some studies have demonstrated that all high-grade malignancies, (regardless of histology) would benefit from elective management of the neck.[88] Other studies have suggested elective management of the neck based on histologic type or size. This includes elective neck surgery for all squamous cell carcinomas, adenocarcinomas, high-grade MECs, undifferentiated carcinomas, and all T2 or higher tumors.[62,89,90] Still, other groups have suggested either nodal sampling of the upper neck lymph nodes at the time of the primary surgery, or including the neck in the primary treatment field for certain cancers.[91,92] What does appear clear is that high-grade, high-stage cancers benefit from aggressive multimodality therapy, including treatment of the primary site and the lymphatic drainage pathway for the tumors.

Radiotherapy

Postoperative Radiotherapy

At present no randomized studies have been conducted to establish the value of postoperative radiotherapy. Tables 37-4, 37-5, and 37-6 summarize the treatment results from modern series comparing surgery with surgery and postoperative, adjuvant radiation therapy for malignant major salivary gland, submandibular gland, and minor salivary gland cancers, respectively. These demonstrate that the addition of postoperative radiation therapy, when indicated, appears to be associated with improved local control rates and survival in patients with malignant salivary gland cancers. Frequent pathologic indications reported for the use of postoperative radiotherapy include the presence of a positive or close surgical margin (not well defined in the scientific literature), PNI, high-grade histology, extraglandular extension, bone invasion, tumor size, T category, and the presence of nodal metastases (Box 37-3). Because these pathologic indications have not been prospectively evaluated, the absolute risk of relapse and the incremental risk reduction with adjuvant radiotherapy cannot be determined. Recently, a postoperative nomogram predicting for survival in the individual patient with MSGTs of the major glands was developed further confirming the importance of these pathologic risk factors.[93]

BOX 37-3 Indications for Postoperative, Adjuvant Radiation Therapy for MSGTs

- Close or microscopically positive surgical margins or gross residual disease
- High-grade cancer
- Involvement of skin, bone, nerve (gross invasion or extensive perineural involvement), and tumor extension beyond the capsule of the gland with periglandular and soft-tissue invasion
- Lymph node metastases
- Large tumors (T3 or T4 disease) requiring radical resection
- Tumor spillage during operation
- Recurrent cancer (including benign histologies such as recurrent pleomorphic adenoma)

In general, the use of postoperative radiotherapy doses typically to 60 Gy appear to be sufficient for MSGTs with PNI of unnamed nerves.[64] In a retrospective review of 140 patients, skull-base relapses may be reduced from 15% to 5% with elective skull-base irradiation especially for T4 disease.[94] Patients with skull-base relapses had a poorer survival when compared to those who did not experience a relapse. For MSGTs with PNI of a major named nerve, elective skull-base irradiation has also been shown to be effective.[95]

Doses between 50 Gy and 60 Gy have also been used for elective irradiation of the neck with relapses less than 5%.[96] Terhaard et al observed a trend to a lower rate of neck control with elective irradiation <46 Gy compared ≥46 Gy ($p = 0.07$).[64] Again, patients with neck relapses have been associated with a poorer survival compared to those patients without neck relapses. When a higher burden of microscopic disease is suspected based on the presence of a positive margin or PNI of a major named nerve, doses <56 Gy are insufficient and doses >60 Gy may be associated with improved local control rates.[97]

With surgery and postoperative radiotherapy to the doses described, long-term locoregional control rates on the order of 80% to 90% may be expected for patients with T1-3 with N0-1 disease. With T4 or multiple nodes, locoregional control rates are significantly lower on the order of 60% to 70%.

Definitive Radiotherapy

Definitive radiotherapy is used primarily for patients with locally unresectable SGTs and will be discussed in the next section.

LOCALLY ADVANCED DISEASE AND PALLIATION

Definitive Radiotherapy: Conventional Fractionation

With locally unresectable salivary gland malignancies, the use of definitive radiotherapy on the order of 70 Gy with

conventionally fractionated schedules typically results in locoregional control rates on the order of ≤20% to 30%.[86-88] These results are also limited by the inherent biases seen with retrospective institutional reviews but are significant in their independent verification of a consistently poor outcome for unresectable salivary gland malignancies when treated with photon radiotherapy alone. These results are also consistent with the standard arm (photon) in a randomized trial of neutron versus photon radiotherapy for unresectable salivary gland malignancies.[98]

Altered Fractionation

Although RTOG 9003 demonstrated that altered fractionation improves locoregional control in other sites of the head and neck,[99] its role in salivary gland tumors is unclear. Wang and Goodman reported results using high-dose, accelerated, hyperfractionated photon beam therapy in patients with inoperable and unresectable major and minor salivary gland cancers.[100] All patients were treated with 1.6 Gy per fraction, twice a day, combined with various boost techniques to obtain a total dose of 65 Gy to 70 Gy. Local control and survival rates were promising, with a 5-year 100% local control and 65% survival rate for parotid gland lesions, and a 5-year 78% local control and 93% survival rate for minor salivary gland lesions. Late complications were minimal. However, the follow-up was relatively short, and thus far, no update has been reported.

Although this suggests a potential role for altered fractionation, it should be regarded as investigational until further data adequately addresses this issue.

Neutrons and Heavy Charged Particle Therapy

High linear energy transfer (LET) radiation from neutrons and heavy charged particles causes direct damage to DNA and is characterized by a reduced oxygen enhancement factor (OER). Compared to low LET radiation from standard photon therapy, damage from high LET radiation is less repairable, and less dependent on cell cycle state. These characteristics make high LET potentially suitable for MSGTs, which are thought to be radioresistant due to a low growth fraction and a long doubling time.

The only randomized trial comparing neutron radiation to conventional photon irradiation was conducted by the Radiation Therapy Oncology Group (RTOG) and the Medical Research Council (MRC) for patients with locally unresectable primary and recurrent MSGTs.[98] The study closed early as a result of ethical concerns because an interim analysis performed at 2 years of 25 patients demonstrated significantly better local control with neutron compared with photon irradiation (67 versus 17%, $p < 0.005$) and a trend toward improved survival (62 versus 25%, $p = 0.1$). The local control rate of 67% was consistent with prior single-institution reports associated with the use of fast neutrons.[101-103] A median survival of 2.97 years with neutrons versus 1.23 years with photons was initially reported. With longer follow-up, the overall survival curves showed no difference. The majority of failures in the neutron arm were systemic. In contrast, the major relapse pattern in the photon arm was predominantly locoregional failures. The incidence of severe or life-threatening toxicity was greater in patients treated with neutrons, with 9 patients treated with neutrons having at least one "severe or greater" complication, compared to 4 patients in the photon arm. This finding of a relatively high rate of severe complications from neutrons has been observed in another comparative series.[104]

Overall, the lack of survival difference from the randomized trial, and the high rate of severe complications coupled with the lack of institutions with available treatment capabilities, limited the broad use of fast neutron therapy. However, mature uncontrolled, single-institution studies continue to demonstrate impressive results, with lower rates of toxicity. Douglas et al published a retrospective study of 148 patients with major salivary gland tumors treated at the University of Washington with a 5-year actuarial locoregional control rate of 100% for tumors <4 cm in size, and only a 6% grade 3 or 4 complication rate.[105] An updated larger series of 279 patients from the same institution demonstrated a 6-year actuarial locoregional control rate of 59% with a grade 3 or 4 toxicity rate of 10%.[66] Neutrons have also been used in the postoperative setting for microscopic residual disease with a 100% 5-year actuarial locoregional control rate reported.[106]

In part, the increased complication rates are the result of the use of neutrons at the skull base and the adjacent CNS. The sensitivity of the CNS structures to high LET radiation often precludes safe delivery of therapeutic doses of high LET radiation to tumors with skull-base involvement. Despite this, it is interesting to observe that neutron radiation does not appear to be associated with an increased risk of facial nerve palsy as a treatment complication.[102,107] Complicating the risk of CNS injury is the recognition that skull-base involvement is associated with a poorer prognosis, local control, and survival in a group of 159 patients with unresectable ACCs.[106]

To address this technical limitation of neutrons, investigators from the University of Washington have been investigating the role of boosting the superior portion of the tumor with stereotactic radiosurgery, after reduced dose neutron beam radiotherapy, in patients with skull-base disease. In 34 patients with skull-base disease treated with a Gamma Knife boost (for details, see discussion), the 40-month actuarial local control was 82%, compared to a historical control rate of 39% in patients with skull-base disease treated with neutrons alone ($p = 0.04$).[108] Heavy charged particle radiation may also hold promise because it combines the biologic qualities of high LET with rapid Bragg Peak dose fall-off. Limited data with carbon ion radiation suggests similar tumor control as neutron beam, with less late effects.[109]

In summary, for patients with locally advanced, unresectable disease of the salivary glands, neutrons offer superior locoregional control compared to standard photon radiation, but with a potential increased risk of severe toxicity. For postoperative radiation, it is not clear that the therapeutic ratio is improved upon given the potential for increased late normal tissue toxicities. Techniques to improve the therapeutic ratio, such as those seen with stereotactic boost or with heavy charged particle radiation therapy, are warranted and are the subject of ongoing investigations.

Stereotactic Radiosurgery

Whether or not the use of hypofractionated doses of radiotherapy in the form of stereotactic radiosurgery (SRS) or fractionated stereotactic radiotherapy (SRT) can overcome the radioresistance associated with conventionally fractionated photon therapy has not been clearly established. There have been two main indications that are relevant for MSGTs and have been the subject of clinical investigations.

The first is the study of SRS at the skull base as a treatment strategy to more safely escalate the effective biologic radiotherapy dose delivered. This largely reflects the experience reported by the University of Washington as described previously. Douglas et al used a Gamma Knife radiosurgery boost as a strategy to reduce the relative biologic neutron dose to the skull base and minimize the risk of CNS injury while improving on the local control rates.[108] The median prescribed Gamma Knife dose was 12 Gy to the 50% isodose line resulting in a median neutron dose of 19.2 nGy to the isocenter. The

median number of isocenters was 17. The median target volume treated was 12.4 cm^3 (range, 1.9 cm^3 to 28.9 cm^3) with a median total volume treated of 18.3 cm^3 (range, 5.9 cm^3 to 53.9 cm^3). This resulted in a median dose of 11.98 nGy to the adjacent tip of the temporal lobe. In total, 34 patients were treated. With a median follow up of 20.5 months, the actuarial 24-month and 40-month local control rates were 82% and 82% compared to 81% and 39% in historical patients not receiving SRS boost. A total of four failures in the SRS group were described with two in-field and two out-of-field relapses. Noteworthy complications included three cases of radionecrosis with only one third of cases with symptomatic headaches responsive to steroids. Comparable risk of brain necrosis (i.e., <10%) has recently been reported by Owen et al in a retrospective analysis of 184 patients with head and neck cancers treated with SRS alone or in combination with external beam radiotherapy.[110]

The other major indication for SRS or SRT has been for *palliative indications*. The rationale for the use of an SRT approach is twofold. First, the stereotactic approach affords greater confidence in the accuracy of the target lesion to be irradiated allowing a smaller margin of uncertainty and thus reducing the volume of normal tissues that receive both unnecessary entry and exit radiation. The second is the potential greater therapeutic benefit that *may* be achieved with higher doses delivered over a single fraction or just a few fractions. To date, the reported experiences are limited and largely amount to small case reports and heterogeneous cohorts for the use of SRS or SRT for head and neck cancers including some recurrent salivary gland malignancies.[111-113] These observations limit the ability to draw any definitive generalized conclusions about the risks and benefits of SRS and SRT at this time including the optimal prescribed dose. The range in prescribed dose includes single fractions of 11 Gy to 18 Gy and hypofractionated schedules including 30 Gy in 6 fractions. In the only series reporting sole on MSGTs, effective palliation of pain was achieved with durable responses including freedom from local tumor progression ranging from 10 months to 35 months.[113] In general, the major serious but infrequent risk associated with this palliative treatment approach includes the risk of optic, facial, and trigeminal nerve injury. At this time, the use of SRS or SRT for MSGTs should be limited to treatment on a clinical protocol or treatment at institutions with a broad stereotactic experience at the skull base for other malignancies where the risks are well defined.

Proton Radiotherapy

There is limited published experience with the use of proton therapy for salivary gland tumors, although the sharp dose fall-off at depths beyond the Bragg peak may potentially allow for safer dose escalation. The Paul Scherrer Institute in Switzerland published a comparative dosimetry study of intensity-modulated photon and proton therapy in the treatment of head and neck tumors.[114] The primary endpoint was the risk of secondary cancers based on the risk estimated using the organ equivalent dose model. For proton plans, both the scatter and the neutron dose contributions were accounted for. Their modeling demonstrated that the risk of secondary malignancies may be reduced with the use of intensity-modulated proton therapy (IMPT) compared to intensity-modulated radiation therapy (IMRT) with photons. The risk was particularly reduced when the number of proton fields was limited.

Pommier et al at the Francis H. Burr Proton Center in Boston have treated 23 patients with ACCs of the skull base with a combination of proton and photon radiotherapy.[115] Only 2 of 23 patients had a complete gross resection but with residual positive margins. The mean total dose to the primary tumor was 75.9 cobalt-gray equivalent (CGE). With a median follow-up of 64 months, the 5-year actuarial local control rate was 93%. The 5-year disease-free survival (DFS) and OS rates were 56% and 77%, respectively. Multivariate analysis demonstrated that tumor involvement of the sphenoid sinus and the clivus and the presence of vision change at presentation were significant adverse risk factors for overall survival. No grade-4 or grade-5 ocular toxicities were reported. Significant grade-3 neurologic toxicities were observed in 10 patients and 2 patients developed grade-5 toxicity. These findings suggest that radiotherapy dose-escalation with protons may result in improved local control rates beyond the historic 20% to 30% local control rates with photons.[116] Recently, with a median follow-up of 25 months (7 months to 54 months), Linton et al reported similar findings using passive scatter proton radiotherapy in 26 patients with ACCs treated to a median dose of 72 Gy (CGE) with or without surgery.[117] The 2-year local control rate was 95% for previously untreated patients with two grade-3, one grade-4, and one grade-5 toxicity observed. The single case of grade-5 toxicity was observed in a patient who previously was irradiated with IMRT and SRS boost for a nasopharyngeal ACC with the prior treatment plan not archived digitally limiting reconstruction and proton planning considerations.

Chemoradiation

The data for concurrent chemoradiation (chemoRT) is scant (typically case reports and small series) and the subject of an extensive review by the French Rare Head and Neck Cancer Network. These investigators concluded that cisplatin-based chemoRT chemoradiation was the most common regimen typically used for adverse pathologic high-risk situations with low evidence to support its efficacy.[118] In the adjuvant context, a single case-control study compared 12 patients with a variety of histologies treated with chemoRT to 12 matched controls treated with radiation alone.[119] This analysis showed a significant survival and local control advantage with chemoRT, with a 3-year OS and DFS survival of 83% and 77% compared to 44% and 52% for radiotherapy alone. However, in addition to the small number of patients analyzed, several other key caveats must be noted. Performance status and comorbidity of the two groups were not reported, IMRT was used more frequently in the chemoradiation group, and a variety of histologies were treated. Thus, adjuvant chemoRT must be considered experimental. However, in the absence of level I data to support its efficacy, it is commonly used for patients with aggressive disease, positive margins, extracapsular extension, and other factors associated with a high risk of recurrence. This practice is largely based on the extrapolated experience in patients with head and neck squamous cell carcinoma (HNSCC). Hence, in the absence of established efficacy, its use should be limited to the use of chemotherapy agents in dose ranges and with schedules of administration where the toxicity spectrum and risks have been well established if it is being considered.

Much of the available literature on chemoRT for SGTs involves small single-institution series. One case report describes definitive concurrent chemoRT with intraarterial cisplatin and docetaxel in 2 patients.[120] A retrospective study of 13 patients treated with cisplatin chemoRT demonstrated complete response to initial therapy in all patients.[121] A single patient developed delayed local failure at 39 months (but achieved successful surgical salvage) and a second patient developed distant metastases; 5-year OS was 83%. Although also experimental, definitive chemoradiation is reasonable for patients who are not candidates for surgery, either based on

anatomic constraints or medical inoperability. Finally, a case series of 14 patients with recurrent MSGTs reported a 3-year locoregional control rate of 51.6% and a 3-year actuarial survival of 35.7% with 5-fluorouracil and hydroxyurea chemoRT following a median radiation treatment interval of 48 months.[122]

Palliation: Role of Chemotherapy

Data on the efficacy of chemotherapy for salivary gland malignancies is limited to case reports, retrospective reviews, and small Phase II studies.

Once metastatic, salivary gland malignancies are not curable. Nonetheless, their course can frequently be indolent, especially for ACC with metastatic disease limited to the lung. Median survival with metastatic disease with ACC is approximately 3 years[123] with some patients living substantially longer. Results with systemic agents, both chemotherapeutic and molecular-targeted agents, have been disappointing. Therefore, careful consideration must be given to administration of supportive care, with systemic therapy reserved for rapid or symptomatic progression.

Chemotherapeutic agents are of limited efficacy in salivary gland malignancies, with particularly poor responses in adenoid cystic histology. A variety of single-agent chemotherapies have been studied in the Phase II setting. Limited responses have been observed with cisplatin, vinorelbine, mitoxantrone, epirubicin, methotrexate, and paclitaxel. For example, ECOG1394 evaluated paclitaxel, given at 200 mg/m^2 every 3 weeks.[124] No responses were seen in 14 patients with ACC, whereas a 26% response rate was seen in patients with mucoepidermoid or adenocarcinoma histologies.

The best studied combination regimen is cyclophosphamide, doxorubicin and cisplatin (CAP).[125] Although CAP has demonstrated good response rates across histologies, there is no clear evidence for superior efficacy as compared to single-agent chemotherapy. Only a single randomized study compared single agent therapy to a platinum-based doublet. Airoldi et al compared vinorelbine (given at 30 mg/m^2 on days 1 and 8 every 3 weeks) to cisplatin plus vinorelbine (with cisplatin administered at 80 mg/m^2 on day 1 and vinorelbine at 25 mg/m^2 on days 1 and 8).[126] This study showed a doubling of response rate from 20% to 44% and a strong trend toward improved median survival (8.5 months versus 11 months, $p = 0.058$) with use of the doublet. Of particular note was the 44.4% response rate in the typically chemoresistant ACC. Many oncologists consider cisplatin plus vinorelbine as the standard of care when cytotoxic chemotherapy is chosen, with paclitaxel as a reasonable consideration in non-ACC disease.

Malignant salivary gland tumors commonly over express a variety of molecular targets. Given the success of targeted agents in other cancers overexpressing these markers[127-130] and the relative tolerability of the agents targeting these markers, investigators have sought to apply these agents to the MSGTs (see eTable 37-1).

Given the paucity of data, no regimen may be considered a standard of care for any histology of MSGT. Thus, when therapy is required, the authors consider a clinical trial to be the preferred option. When no Phase II trial is available, Phase I studies with agents directed at relevant targets, with low expected toxicity should be considered. In the absence of available trials and the need for therapy, it is reasonable to evaluate for molecular markers of interest (ER, EGFR, HER2, AR, and c-Kit) and consider treatment targeting any biomarker that is present. Although response rates are low for targeted agents, multiple studies suggest the possibility of prolonged stable disease. For rapidly progressive disease, especially in the patient with good functional status, good renal function, and good bone marrow function, the combination of cisplatin plus vinorelbine may be considered. Additional clinical trials are desperately needed, but the rarity of these tumors will likely require novel cooperative strategies to promote successful accrual. Ideally, studies of targeted agents aimed at promoting stable disease would be tested using creative study designs, such as a randomized discontinuation design, but the rarity of these tumors may make such definitive trials impossible.

TECHNIQUES OF IRRADIATION

Target Volume Delineation

Parotid Gland

Target volumes include the location of the primary tumor or the surgical bed for SGTs meeting the indications for radiation. The ipsilateral neck should be included in the setting of cervical lymph node metastases or high-grade primary tumor histology (especially for MEC and adenocarcinoma–NOS). It is unclear whether a primary tumor recurrence increases the risk of cervical nodal metastases. Involvement of the facial nerve requires coverage of the course of the nerve, via the facial canal, to the base of skull through the stylomastoid foramen. This should be a consideration for ACC. A boost should be considered to areas at high risk of incomplete resection.

Anatomic landmarks for the parotid should include the zygoma superiorly, styloid process medially, the soft tissues of the neck laterally, including possibly the skin and the surgical scar if there was evidence of tumor spillage or direct tumor infiltration, the masseter muscle anteriorly, the hyoid bone inferiorly, and the mastoid bone posteriorly. Careful review of preoperative imaging and the intraoperative findings are also important to consider in delineating the parotid surgical bed as is noting the location of the contralateral parotid gland.

For the cervical neck, anatomic landmarks for the N0 neck have been referenced. Briefly, cervical levels II to IV are located along the course of the sternocleidomastoid anterolaterally and the scalenus muscles posteromedially. The nodal levels at risk typically include levels II to IV but may require consideration of level V in the setting of known cervical nodal metastases or evidence of metastases to level V.

Submandibular Gland

The primary target volume includes the location of the primary tumor or surgical bed for SGTs meeting indications for radiotherapy. A boost is given to areas of unresected disease. When PNI is present, but limited to small, unnamed nerves, the target volumes are enlarged in the area of the postoperative bed, but the nerve pathways are not treated comprehensively. If named nerves are involved, such as the lingual or hypoglossal nerves, their course should be treated to the base of skull. This involves delineation of the course of the mandibular (V3) branch of cranial nerve V to the foramen ovale. The V3 branch runs from the submandibular space extending into the parapharyngeal and masseter space medial to the course of the medial pterygoid muscle to the foramen ovale (Figure 37-4). Review of preoperative imaging and intraoperative and pathologic findings are imperative in treatment planning.

Indications for treatment of the elective neck are similar to those described previously in the section for the parotid gland. However, because of the proximity of the submandibular gland to the midline of the neck, irradiation of the adjacent and contralateral upper cervical nodal regions should be a consideration when treatment of the ipsilateral neck is indicated.

eTABLE 37-1 Summary Table of Clinical Trials of Molecular Targeted Agents for MSGTs

Agent	Molecular Target	Response Rate for Adenoid Cystic Carcinoma (%)	Response Rate for Nonadenoid Cystic (%)
Imatinib mesylate	c-kit, Bcr-Abl, PDGF-R	0/16[131] 0/14[132] 0/5*[133]	N/A N/A
Trastuzumab	HER2	0/2[39,134]	1/11†

Gefitinib	EGFR	0/19[135]	0/2
Cetuximab	EGFR	0/19[136]	0/9
Bortezomib	26S proteosome NF-kappa-B (indirectly)	0/23[137]	N/A

N/A, *Not applicable.*

**Study closed early because three fifths of patients had rapidly progressive disease.*

†*One of three patients with mucoepidermoid histology had a durable response out to 45 months of follow-up.*

As c-kit is expressed by the majority of ACC, imatinib mesylate, an inhibitor of the c-kit, Bcr-Abl and PDGF-R tyrosine kinases was studied. Although responses were noted in three case reports[138,139] there were no responses in 30 patients with ACC treated in two Phase II studies.[131,132] KIT was assessed only by immunohistochemistry with no mutational analysis performed. Stable disease was common in these studies, including stable disease longer than 6 months. However, the lack of a control group and the indolent behavior of many ACC leave unclear whether this stability was the result of the activity of imatinib or the underlying indolent nature of the tumors. Pending more effective therapies, many clinicians still consider imatinib for c-kit expressing ACC because of its lack of toxicity relative to cytotoxic therapies. An ongoing Phase II study is evaluating the more potent c-kit inhibitor dasatinib.[123,140]

The anti-HER2 antibody trastuzumab and the tyrosine kinase inhibitor lapatinib have demonstrated efficacy in HER-2 overexpressing breast cancer. All histologies of MSGTs have been reported to overexpress HER2 at rates from 24% to 56%, depending on the histology, leading to a Phase II study of trastuzumab with planned accrual of 50 patients.[119,141] A total of 137 tumors were screened for HER2/neu with 17% found to be overexpressed at 2+ or 3+.[39] This result was substantially lower than previously reported in smaller series and the study was closed early with only 14 patients treated. A single patient with MEC histology achieved a long-lasting partial response (PR).[134] It is relevant to note for future investigations of HER2 as a therapeutic target, that HER2 overexpression in ACC was rare at 4%, but common in secretory duct cancers, with 21% in MEC, 83% in salivary duct, and 60% in squamous histologies.[39] A SWOG trial of trastuzumab also closed early as a result of poor accrual. In this trial, 3 patients were enrolled and treated; 1 had stable disease for almost a year and the other progressed on therapy.[129,142]

Lapatinib is an oral tyrosine kinase inhibitor (TKI) that targets both HER2 and EGFR. A Phase II study of this agent enrolled 29 patients with ACC and 28 patients with non-ACC MSGT.[35] In total, 88% of patients with ACC and 97% of patients with non-ACC expressed EGFR or erbB2. There were no responses in either group, but 47% of patients with ACC and 24% of patients with non-ACC had stable disease (SD) lasting at least 6 months. Although the indolent nature of the disease itself likely contributed to some of this stability, biologic activity of lapatinib was likely greater than that represented by the response rate. To meet response criteria, a tumor must shrink by 30%. Many patients classified as having SD experienced reductions in tumor volumes that failed to meet this threshold but nonetheless are suggestive of activity. Further, 36% of the patients with SD for more than 6 months were progressing before starting therapy, suggesting that although the therapy may not have been sufficiently active to shrink the cancer, it could at least stop its growth.

Similar results were found with the TKI gefitinib, which targets primarily EGFR. At the time of presentation, 21 patients were assessable for response, with 0 of 21 responses.[135] Thirteen of 14 patients with SD had ACC, but the median duration of SD was only 13 weeks, again raising concerns that the SD was secondary to the indolent nature of the cancer, rather than efficacy of therapy. Similarly, a Phase II study of cetuximab failed to achieve any responses. However, 20 of 23 (87%) of patients with ACC achieved SD, with 12 of these 23 (52%) achieving stability lasting at least 6 months.[136] Of note, 11 patients with ACC were actively progressing at the time of study entry; all of these patients achieved SD for at least 6 months.

Bortezomib inhibits the 26S proteosome, indirectly inhibiting NF-KB activity. A Phase II study treated 25 patients with ACC.[137] Again, no responses were seen. Patients with progressive disease were treated with the combination of bortezomib and liposomal doxorubicin based on preclinical data for synergy. Four patients were treated with this combination; one achieved a PR and 2 had SD. A Phase II study of the combination of bortezomib and doxil just closed secondary to poor accrual.[130,143]

Data for the efficacy of the hormonal agent tamoxifen is limited to three case reports of long-term SD.[144,145] Case reports also describe responses, including a complete response, to luteinizing hormone–releasing hormone analogues in patients with androgen-receptor–positive adenocarcinoma.[146]

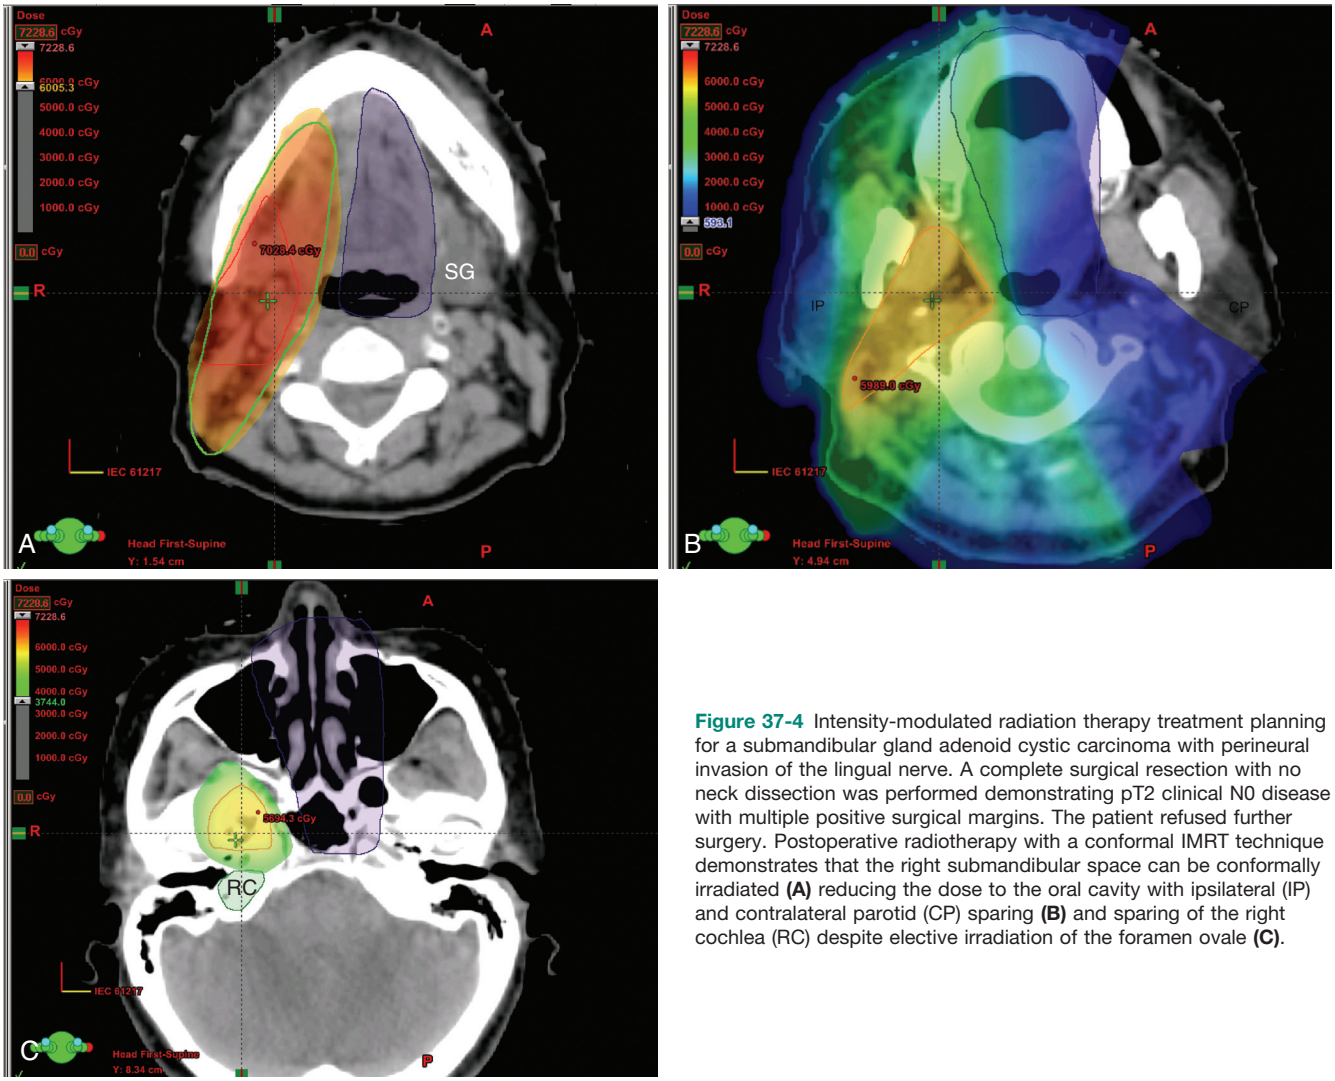

Figure 37-4 Intensity-modulated radiation therapy treatment planning for a submandibular gland adenoid cystic carcinoma with perineural invasion of the lingual nerve. A complete surgical resection with no neck dissection was performed demonstrating pT2 clinical N0 disease with multiple positive surgical margins. The patient refused further surgery. Postoperative radiotherapy with a conformal IMRT technique demonstrates that the right submandibular space can be conformally irradiated **(A)** reducing the dose to the oral cavity with ipsilateral (IP) and contralateral parotid (CP) sparing **(B)** and sparing of the right cochlea (RC) despite elective irradiation of the foramen ovale **(C)**.

Minor Salivary Glands

Target volumes include the primary tumor or surgical bed for small or low-grade cancers meeting indications for radiation therapy. These areas are determined by preoperative imaging and intraoperative and pathologic findings. Areas of unresected disease are given a boost.

Elective neck treatment varies with the histology, grade, T category, anatomic site, and nodal category.[63] Lloyd et al analyzed the SEER database identifying 2667 cases of minor salivary gland cancers with known lymph node status from 1988 to 2004. Although there are inherent limitations with SEER database analyses, the results are consistent with smaller clinical series that in turn lack the size for a multivariate analysis. Analysis demonstrated that male sex, T3-T4 category, primary site involving the pharynx and high-grade adenocarcinoma or high-grade MECs were independent risk factors for the development of nodal metastasis for minor salivary glands.

Although these findings suggest that the biology of salivary gland malignancies influences the risk of nodal metastases, they also suggest that lymphatic-rich anatomic sites may have higher rates of nodal metastases, as seen with squamous carcinomas. For ACCs, Mendenhall et al reported that this was a significant consideration in their institutional approach. They reported a 10-year neck control rate of 90% when the neck was observed compared with 98% with elective irradiation.[96] Other relevant but unestablished anatomic factors that have been well described for squamous carcinomas can also be considered during treatment planning for malignant SGTs. These include the presence of mucosal disease at the coronal midline, increasing the risk for contralateral nodal metastases,[147] and the involvement of the posterior pharyngeal mucosa, increasing the risk of retropharyngeal lymph node metastases.[148]

Simulation and Field Arrangements

A CT scan is obtained in the treatment position. Patients are typically positioned supine, with arms down, and the head and neck in the hyperextended position to move the orbits out of the radiation field. A thermoplastic face mask is used for immobilization. For cases with skull-base or intracranial involvement, a MRI can be obtained and fused to the CT to assist in target delineation. The target volumes and normal critical structures are defined on the representative CT or MRI axial images.

Traditional standard techniques used to treat parotid tumors include wedged pair or mixed beam techniques, whereas IMRT is now commonly used as well. It is our preference to use either a wedged pair technique or an IMRT

technique (allows for comprehensive coverage of the parotid bed and cervical lymph nodes, while avoiding the potential impact on the mandible of electron beam dosimetry). IMRT also allows for improved conformality at the skull base, especially when the surgical bed and scar extends superiorly above the plane of the middle and inner ear complex and may lie adjacent to the temporal lobe. Traditional radiotherapy techniques have often relied on matched fields typically with electrons to treat the course of the surgical scar if it was deemed to be at risk. This results in potential dosimetric uncertainties with a photon-electron match with the potential for a dosimetric hotspot that may lie in the temporal lobe.

IMRT may also allow for additional sparing of structures such as the cochlea, semicircular canal, mastoid air cells, and temporal lobes. Historically, hearing deficits, and soft-tissue and bone necrosis have been observed in approximately 20% of patients treated with a traditional beam arrangements especially with wedge-pair fields.[149] Using these techniques to treat the tumor bed with or without the ipsilateral neck, mean doses to the contralateral salivary glands can be effectively limited to less than 10% of the prescription dose, thereby preventing any grade-3 symptoms of xerostomia during and after treatment.

Dose, Fractionation and Pathologic Considerations

Frequent pathologic indications reported for the use of postoperative RT include the presence of a close if not positive surgical margin, PNI, high-grade histology, extraglandular extension, bone invasion, tumor size, T category, and the presence of nodal metastases. It is important to recognize that these pathologic indications have not been prospectively evaluated to determine what the absolute risk level is and the incremental risk reduction with adjuvant radiotherapy.

The typical postoperative dose to the surgical bed that has been reported has typically ranged from 60 Gy to 66 Gy with a conventional daily fractionated schedule. For a positive or close surgical margin, localization of the area of concern based on preoperative imaging and intraoperative findings for a boost dose of radiation typically of 6 Gy to a total dose of 66 Gy is an important consideration. Other risk stratified radiotherapy dose recommendations have not been clearly established. Hence, it is unclear if areas involved with extraglandular extension (i.e., T3 and T4) or nodal metastases necessitate a dose higher than 60 Gy.

PNI has been correlated with an increased risk of locoregional relapse, especially for ACCs. Recent detailed histologic studies of serial sections suggest that the mechanism in which PNI may be contributing to relapse is the result of the direct contiguous spread of cancer along the branches of the nerves.[65] Hence, a judicious clinical target volume (3 cm to 5 cm) surrounding the primary tumor bed should be created, to reflect the potential subclinical extent of cancer. The use of postoperative radiation therapy appears to be effective in reducing the risk of local relapse resulting from PNI (10-year local control rates of tumors with PNI treated with surgery compared with surgery and postoperative RT was 60% versus 88%, $p = 0.01$).[64]

For more extensive PNI resulting in clinical symptoms or radiologic nerve abnormalities, there is a further increased risk of locoregional relapse, especially with ACCs.[96] This observation is consistent with other cancer sites in which the size of the involved nerve appears to increase the risk of relapse.[150] With involvement of major named nerves, there is an increased risk of relapse including spread to the skull base and increased risk of distant relapses. Hence, elective irradiation along the course of the nerve is recommended.

For elective nodal irradiation, the anatomic draining lymphatics should be encompassed. The usual dose has ranged from 50 Gy to 54 Gy with a conventional daily fractionated schedule. However, it should be recognized that the optimal elective nodal irradiation dose for MSGTs is unknown.

Gross, unresectable disease has typically been treated to 70 Gy again with a conventional daily fractionated schedule. It is important to note that the optimal dose and fractionation schedule has not been clearly defined especially for unresectable gross disease. This is important to consider in light of evidence suggesting that radiotherapy dose escalation with photons[108] and protons[115] may offer additional improvements in local control rates. Unknown at this time is whether or not there may be incremental gains in locoregional disease control rates with the practice of a simultaneous in-field boost ("dose painting") that is now possible with the use of IMRT.

Treatment Side Effects

The side effects associated with radiation therapy are dependent on several factors: the site and volume treated, the dose fractionation regimen, and total dose delivered, whether treatment is delivered definitively or adjuvantly, the type of radiation used (low LET versus high LET), and whether concomitant chemotherapy is used.

In the treatment of salivary gland tumors, acute phase reactions (within first 90 days of completion of RT) are generally limited to rapidly proliferating tissues, such as the skin, and the oral and pharyngeal mucosa. Skin reactions can range from a mild erythema to moist desquamation, which would require aggressive skin care and antibiotic treatment. Xerostomia and dysgeusia may also occur during RT, but the risk of long-term xerostomia can be minimized with appropriate field arrangements and treatment planning, by excluding the contralateral parotid and submandibular gland. Acute mucositis is commonly observed if the oral cavity or pharyngeal mucosa is in the field. The risk of developing severe mucositis is increased with approaches such as accelerated fractionation, concurrent chemotherapy, or high LET radiation. Attention to pain control, close monitoring for the development of oral candidiasis, and aggressive nutritional support (with the placement of a percutaneous gastrostomy [PEG] tube, if needed) are required with severe mucositis.

Late complications (occurring >90 days after completion of treatment) are associated with slower proliferating tissues, with side effects limited to the particular region treated. In treatment of the base of skull, careful treatment planning is required to limit the dose delivered to critical structures, thereby minimizing the risks of side effects such as pituitary dysfunction, temporal lobe necrosis, optic neuropathy, keratitis, and hearing loss. With conventional 1.8 Gy to 2 Gy fractionation, the dose to the spinal cord should be limited to 45 Gy (maximum [max]), cochlea to 45 Gy (mean), lacrimal gland to 30 Gy (mean), optic nerves and chiasm to 54 Gy (max), temporal lobes to 65 Gy (max), and brainstem to 60 Gy (max). These doses need to be appropriately adjusted if nonstandard approaches (concurrent chemotherapy, altered fractionation, high LET radiation) are used. Every patient should undergo preradiation dental evaluation, with any necessary extractions to be done before initiation of radiation, and if dentition is to be preserved, custom fluoride trays should be applied daily using custom trays. If extractions or oral surgery needs to be done following radiation therapy, hyperbaric oxygen therapy is recommended to minimize the risk of developing osteoradionecrosis. Another common late side effect in patients receiving neck radiation therapy is hypothyroidism. In patients receiving unilateral radiation therapy, the risk of xerostomia can be minimized through conformal delivery (via

TABLE 37-7 Treatment Algorithm for Malignant Major and Minor Salivary Gland Cancers

Clinical Situation	Standard Therapy	Proposed Clinical Trial
Complete resection, adjuvant therapy	Postoperative, adjuvant EBRT when indicated (see Box 37-3)	Intergroup trial of surgical resection plus postoperative adjuvant EBRT versus surgical resection plus postoperative adjuvant EBRT with concomitant and maintenance chemotherapy
Locally advanced (primary or recurrent; unresectable or resected but residual)	1. High-dose conventional photon irradiation (consider altered fractionation) 2. Maximal surgical resection, IOERT, or brachytherapy and conventional EBRT 3. Neutron beam therapy with or without SRS boost	1. Neoadjuvant chemotherapy followed by resection (with or without IOERT or brachytherapy), and EBRT (photons or protons) with concomitant and maintenance chemotherapy 2. High-dose conventional or altered-fractionation EBRT (photons or protons) with concomitant and maintenance chemotherapy 3. Carbon ion therapy
Locally recurrent, prior irradiation	Low- to moderate-dose EBRT plus hyperthermia Palliative chemotherapy	Low to moderate dose CCRT, resection, IORT (electrons or HDR brachytherapy)

CCRT, *Concurrent chemoradiation;* EBRT, *external beam irradiation;* IOERT, *intraoperative electron beam irradiation.*

three-dimensional conformal radiation therapy, IMRT, proton therapy, or heavy charged particle therapy). Limiting the mean dose to contralateral major salivary glands to <10% of the prescription dose has commonly been recommended.

TREATMENT ALGORITHM, CONCLUSIONS, CONTROVERSIES, AND FUTURE POSSIBILITIES

In summary, SGTs are characterized by their rare incidence, diverse histology, and the potential for an indolent natural history. It is this heterogeneity that has hampered clinical progress in the management of SGTs. In recent years, progress has been made in further understanding the genetic and molecular characteristics of these tumors, but this has not yet yielded any significant therapeutic insights. However, the favorable survival associated with expression of the *CRTC1-MAML2* fusion oncogene in MECs is an important advancement toward improved classification of MECs. Therapeutic progress has been made with technical advances in surgical techniques such as the transoral robotic technique, and in radiation oncology, with the maturation of the use of fast neutron radiotherapy. The increasing study of charged particle beam radiotherapy, both protons and heavy ion beams offer the potential to further reduce toxicities with improved locoregional control rates. Although various molecular targeted therapeutics have been introduced into clinical trials, none have yet realized the goal of significantly decreasing the risk of distant metastasis. However, the toxicities associated with these systemic approaches are acceptable and manageable, and disease stabilization may be possible with several targeted agents.

In conclusion, the treatment options for patients with SGTs have significantly improved in recent years offering the potential for more effective function preserving locoregional therapy. Our preferred treatment algorithm is seen in Table 37-7. Major survival gains will likely only be realized with the development of more effective systemic therapy.

CHAPTER

38 Thyroid Cancer

Juan P. Brito, Ian D. Hay, and Robert L. Foote

INCIDENCE

In the United States the incidence of well-differentiated thyroid cancer increased from 4.9 per 100,000 to 14.3 per 100,000 between 1975 and 2009. It was estimated that 62,450 new cases would occur in the United States in 2015. Carcinomas are of follicular or parafollicular cell (C cell) origin, and 95% are well differentiated.

BIOLOGIC CHARACTERISTICS

Prognostic factors include patient age, histology, grade, tumor size, neoplastic extent, and completeness of initial surgical resection. Reliable prognostic scoring systems permit accurate outcome prediction.

Only a few patients with thyroid carcinoma are at risk for cause-specific mortality.

STAGING EVALUATION

Staging includes the patient's history, physical examination of the neck, fine-needle aspiration (FNA) biopsy, ultrasound neck examination, and a chest radiograph.

Additional studies may include vocal cord examination, chest computed tomography (CT), skeletal magnetic resonance imaging (MRI), and 18F-fluorodeoxyglucose (18F-FDG) positron emission tomography with CT (fused PET/CT).

PRIMARY THERAPY

Surgical resection is the primary therapy for resectable, well-differentiated thyroid carcinomas. Most are treated by near-total or total thyroidectomy with excision of involved regional nodes. Cause-specific survival (CSS) rates exceed 90% at 20 years.

ADJUVANT THERAPY

Thyroxine-suppressive therapy of thyroid-stimulating hormone (TSH) is standard postoperative management of papillary and follicular cancers.

Radioactive iodine (RAI) therapy is used for treating distant metastasis, unresectable or residual papillary thyroid carcinoma (PTC), and most cases of follicular thyroid carcinoma (FTC) or Hürthle cell carcinoma (HCC). Radioiodine remnant ablation (RRA) is widely used in high-risk follicular cell–derived cancers (FCDCs) but may not benefit patients with low-risk tumors.

External beam radiotherapy (EBRT) is reserved for selected patients with locally advanced disease and with high-risk surgical pathologic features and patients with recurrent or metastatic disease nonresponsive to RAI therapy.

UNDIFFERENTIATED TUMORS AND PALLIATIVE THERAPY

Anaplastic cancer is preferably treated by resection, EBRT, and chemotherapy.

Thyroid lymphomas typically are diffuse, large cell lymphomas of B-cell origin. These tumors are best controlled with combination chemotherapy (rituximab, cyclophosphamide, hydroxydaunomycin, Oncovin [vincristine], and prednisone) and involved field EBRT.

Thyroid tumors are the most common endocrine neoplasms. They usually manifest as anterior neck nodules, which in most cases can be localized to the thyroid gland by palpation. Most nodules are benign hyperplastic (or colloid) nodules, but 5% to 20% of nodules that come to medical attention are true neoplasms: benign follicular adenomas or carcinomas of follicular or parafollicular cell (C cell) origin. Differentiating true neoplasms from hyperplastic nodules and distinguishing benign from malignant tumors are major diagnostic challenges for clinical endocrinologists. High-resolution ultrasound studies assessing large groups of normal volunteers suggested that the prevalence of incidentally discovered nodular thyroid disease in healthy adults is more than 60%.[1] In the United States during 2015, 62,450 new cases of thyroid cancer were expected. It has been estimated that a half-million people are currently living with thyroid cancer in the United States.[2]

In the current era, when patients are increasingly being advised on the advantages of self-examination to detect cancer at an early stage, the finding of a palpable mass in such a superficial and visibly obvious location as the thyroid gland can be disconcerting, and the patient is likely to seek prompt medical evaluation. At the conclusion of an appropriate investigation, the patient can usually be reassured that the nodule is benign. If the discovered lesion is suspected to be malignant, the patient can be advised that the management of typical thyroid cancer is effective[3] and usually consists of surgical resection,[4] followed by medical therapy[5] and regular postoperative surveillance.[6] In recent years, a degree of consensus has been achieved with regard to the initial evaluation of nodular thyroid disease[7,8] and the management of differentiated thyroid cancer,[7,9,10] but important biologic and clinical questions remain unanswered.[11-13]

From a radiation oncologic standpoint, FCDC of the thyroid has some historic interest. In 1940, Hamilton et al[14] at the University of California–San Francisco, first reported evidence of uptake of RAI in FCDC. In 1942 at Columbia University, Keston et al[15] gave a patient with an iodophilic femoral metastasis a 10-mCi therapeutic dose of RAI. Since that time, RAI therapy has become the primary treatment for iodophilic distant metastases in the papillary or follicular histologic type of FCDC.[16] The concept of RRA to "complete" a thyroidectomy

in FCDC, which was derived from pioneering work by Blahd et al[17] at the University of California–Los Angeles, in the late 1950s, has been increasingly employed in the routine management of FCDC.[18] The use of EBRT in managing thyroid cancer has its origin in the 1960s.[19] Subsequently, the role of EBRT generally has been restricted to the treatment of locoregional advanced FCDC, but it has also been employed as primary therapy in the management of two rare malignancies: anaplastic (undifferentiated) thyroid carcinoma and primary malignant lymphoma of the thyroid.[20] In this chapter, we discuss the more common FCDCs, but where indicated, less common tumors derived from nonfollicular cell origin are considered.

ETIOLOGY AND EPIDEMIOLOGY

The annual incidence of thyroid cancer is 0.5 to 10 per 100,000 people in the general population in most countries. Between 1975 and 2009, the incidence of thyroid cancer increased from 4.9 to 14.3 cases per 100,000 individuals in the United States; with a more pronounced increase in women (from 6.5 to 21.4 cases per 100,000 women).[21] In South Korea the incidence of thyroid cancer has increased from 10.6 per 100,000 per year in 1996 to 111.3 per 100,000 per year in 2010.[22]

Clinical thyroid malignancy is relatively uncommon, accounting for only about 2% of human malignancies.[23] Nonetheless, it was estimated that thyroid cancers would account for 96% of endocrine malignancies in the United States in 2014.[2] It was estimated that 1890 patients with thyroid cancer would die during 2014, accounting for 67% of deaths from endocrine malignancies.[2]

Most thyroid cancers are derived from follicular epithelium. In most countries, incidence rates for PTC generally exceed the incidence rates for FTC, and either PTC or FTC is far more common than the usually lethal anaplastic (undifferentiated) thyroid carcinoma.[24,25] Similar data on the frequency of the various histologic types are contained in two large series of thyroid cancer cases reported from the United States and Japan.[26,27] These data are summarized in Table 38-1.

Anaplastic carcinomas and FTCs tend to be relatively more common in areas endemic for goiter, and numerous case-control studies have strongly suggested that dietary iodine content is responsible for the increased incidence rates in these areas.[28] This hypothesis is supported by the fact that dietary iodine supplementation has been shown to increase the relative proportion of PTC and to decrease the frequency of FTC.[29]

PTC and FTC are more than twice as common in women as men and tend to occur much more commonly in middle age and later, although patients with PTC are younger than patients with FTC.[24,25] The preponderance of women with FCDC has led to speculation about the role of estrogen as a risk factor. Other putatively estrogen-dependent tumors, particularly breast cancer, and thyroid cancer occur more frequently in the same individual than expected by chance.[30] Case-control studies have suggested a correlation between pregnancy, a high estrogen state, and the onset of thyroid cancer.[31] Other studies have suggested that pregnancy per se, rather than the associated estrogen levels, may be associated with increased thyroid cancer risk.[32] The role of female sex hormones as a risk factor for thyroid cancer development must still be considered unresolved.

The most firmly established risk factor for development of thyroid cancer is prior exposure to ionizing radiation, particularly to the head and neck region during childhood, which used to be a common problem in some exposed populations in Japan and the Pacific during the 1960s and 1970s in the aftermath of atomic bomb use at the end of World War II and in areas exposed to atmospheric nuclear bomb tests during the 1950s and 1960s.[33,34] In most other countries, radiation treatments for benign medical conditions, such as acne vulgaris, thymic enlargement, tinea capitis, or inflammatory connective tissue disorders, contributed to increasing numbers of patients with thyroid cancer.[35,36] These practices have largely been abandoned, and radiation exposure as a risk factor for the most part has ceased to be of significant importance.[36] Exceptions are areas of high natural background radiation; radiotherapy used for malignant conditions[37]; and areas where radioactive contamination of the environment from military or civilian sources is a notable problem, particularly in many countries in the southern part of the former Soviet Union that were heavily contaminated in the wake of the Chernobyl nuclear reactor accident.[38] The contamination in parts of Belarus and Ukraine was significant and prolonged, and there is mounting clinical evidence that this contamination has led to increased rates of thyroid malignancies, often of an unexpectedly aggressive nature.[39-41] In the United States, it has been disclosed that a significant segment of the U.S. population was exposed to radioiodine during a series of nuclear bomb explosions at the Nevada test site in the 1950s.[42] Predictions of excess relative risk of thyroid cancer vary but may prove to be significant. However, it is impossible to determine whether individual thyroid cancers arose as a result of radiation exposure or as sporadic events.[42,43] It has been also suggested that the surge of cases of thyroid cancer is not as a result of a new risk factor but rather, because of the exponential increase in the use of diagnostic imaging.[43] This argument is supported by the steady incidence of mortality from thyroid cancer despite a large increase in thyroid cancer incidence; many of which are small and papillary in nature. Additionally, many autopsy studies, conducted around the world, have demonstrated that thyroid cancer is common, occurring in 24% to 36% of patients who died from nonthyroid related causes.[44]

Although most cases of thyroid cancer are sporadic occurrences, a small proportion of thyroid cancers may be familial, and in the case of C cell–derived malignancy, medullary thyroid carcinoma (MTC) may be associated with multiple endocrine neoplasia (MEN) type II (MEN-II) syndrome and its associated adrenal medullary tumors (pheochromocytomas). In patients with the MEN-II syndrome, a strong and typical family history can often be obtained. PTC may also be associated with other nonthyroid malignancies and with premalignant conditions such as Cowden's syndrome and familial adenomatous polyposis coli (i.e., Gardner's syndrome).[45] Several cases of familial PTC have been described.[46] No such distinct associations exist for FTC, but aggregation of FTC cases in families with dyshormonogenesis has been described.[47]

PREVENTION AND EARLY DETECTION

Most thyroid cancers are sporadic and not caused by an avoidable environmental agent. Prevention of thyroid malignancy is impossible.

Nodular thyroid disease generally can be detected early by careful neck palpation in the course of routine physical examinations. High-resolution ultrasound can readily detect impalpable thyroid nodules 2 mm to 3 mm in diameter. There is no evidence, however, that population screening for nodular thyroid disease using ultrasound is warranted because 70% to 90% of diagnosed thyroid malignancies are of the papillary histologic type. In such incidentally discovered papillary tumors, 85% to 90% are deemed low risk and are associated with mortality rates close to rates predicted by actuarial curves and comparable to rates for nonmelanoma skin cancer.

In contrast, early detection of the often more aggressive, familial MTC is possible when there is evidence within the family of an inherited mutation of the *RET* proto-oncogene in the pericentromeric region of the short arm of chromosome 10. Such mutations have been found in more than 90% of familial MTC cases, and since the successful cloning and sequencing of the *RET* gene, asymptomatic members of affected families can be tested for the presence of a mutation at this locus.[48] A positive test result obviates the need for any further testing. The present recommendation for persons shown to harbor the mutation is to undergo prophylactic total thyroidectomy, which completely prevents the development of the invariably multicentric MTC associated with these conditions.[10,49] If such a mutation is found in infancy, the current practice is to perform a total thyroidectomy when the child is 3 to 5 years old.[10,50]

PATHOLOGY AND PATHWAYS OF SPREAD

Most thyroid cancers are well-differentiated tumors derived from follicular cells. PTC accounts for 40% to 90% of cases, and 15% to 40% are classified as FTC, which includes the so-called oxyphilic or Hürthle cell variant. Anaplastic thyroid cancer (ATC), also derived from the follicular cell, is the least common FCDC, typically constituting 1% to 5% of most series. The frequency of C cell–derived MTC depends on the diligence with which reporting centers pursue the early diagnosis of patients with familial MTC and MEN-II, but it may account for 2% to 8% of thyroid cancers. Nonepithelial thyroid tumors include sarcomas, malignant hemangioendotheliomas, and malignant lymphomas. Lymphomas may involve the thyroid as the only manifestation of the disease or as part of a systemic disease; such tumors may rarely complicate Hashimoto's (autoimmune) chronic lymphocytic thyroiditis, which in the United States is the most common cause of goiter and noniatrogenic hypothyroidism. Blood-borne metastases to the thyroid are common at autopsy in patients with widespread malignancy, but they rarely cause clinically detectable thyroid enlargement.

PTC most often occurs in patients 30 to 50 years old; the mean age at diagnosis is about 45 years. Most primary tumors are 1 cm to 4 cm in diameter; the average is about 2 cm to 3 cm in the greatest dimension. Of tumors, 95% are classified on the basis of degree of differentiation as histologic grade 1 (of 4); 80% of primary PTC tumors are assessed to be DNA diploid by flow cytometry.[51] Extrathyroidal invasion of adjacent soft tissues is present in about 15% (range 5% to 34%) at primary surgery, and about one third of patients with PTC have clinically evident lymphadenopathy at presentation.[52] About 35% to 50% of excised neck nodes have histologic evidence of involvement, and in patients 17 years old or younger, nodal involvement may be present in up to 90%.[53] The primary disease is confined to the neck in 93% to 99% of patients with PTC at diagnosis.[51,52] Spread to superior mediastinal nodes is usually associated with extensive neck nodal involvement. Distant metastases are diagnosed in only 1% to 7% of patients with PTC before or within 30 days of primary treatment.[51,54]

FTC occurs in older patients, and the mean age in most studies is more than 50 years, about 10 years older than for typical PTC.[25,55] Women affected by FTC outnumber men by more than 2:1. Patients with FTC rarely (4% to 6%) have clinically evident lymphadenopathy at presentation.[56] In most series, the average tumor size in FTC is larger than in PTC.[55] When tumor grading is performed, higher grade tumors are more common than with PTC.[55] DNA aneuploidy is present in about 60% of FTC tumors and in up to 90% of patients with oxyphilic or Hürthle cell variant tumors.[25,57] Direct extrathyroidal extension into adjacent soft tissues does not occur in the common "minimally invasive" FTC, but it is not unusual in the rare patient with "widely invasive" FTC. Of patients with FTC, 5% to 20% may have distant metastases at presentation, and the most common sites of distant spread are lung and bone.[25,58]

MTC arises from the C cells of the thyroid rather than the follicular epithelium; secretes a characteristic hormone, calcitonin; is frequently associated with one or more paraendocrine manifestations; and provides an early biochemical signal (i.e., hypersecretion of calcitonin) that permits its early detection, treatment, and cure.[10,59] The tumor occurs in sporadic and familial forms, with the latter constituting about 20% of the total. The familial variety usually appears at a younger age, is almost invariably bilateral, is less likely to have associated cervical metastases at presentation, and has a better prognosis.[10,59] Most importantly, the familial variety is preceded by a premalignant C-cell hyperplasia that can be cured by total thyroidectomy.[60]

ATC is the least common FCDC and typically constitutes less than 5% of most reported series.[61] It usually occurs after age 60 years, and it is only slightly more common in women than men (1.3:1 to 1.5:1). It is highly malignant, rapidly invading adjacent structures and metastasizing throughout the body. Pathologic examination of tumor biopsy specimens may reveal evidence of PTC or FTC, which may represent a precursor of ATC. Thorough biopsy sampling may be necessary to detect residual well-differentiated thyroid tissue. On histologic examination, the tumor is usually composed of atypical cells that exhibit numerous mitoses and form a variety of patterns. Spindle-shaped cells and multinucleated giant cells usually predominate, but in a third histologic pattern described as squamoid, the cells are undifferentiated but retain an epithelial appearance. It was formerly thought that there was a small cell ATC, but most of these tumors have been classified as malignant thyroid lymphomas.

BIOLOGIC CHARACTERISTICS, PROGNOSTIC FACTORS, AND STAGING

It has long been recognized that prognosis in thyroid cancer largely depends on the age of the patient, the histology of the tumor, and the anatomic extent of disease at presentation. Although head and neck cancer is staged entirely on the basis of anatomic extent, thyroid cancer staging is unique in that the histologic diagnosis and the age of the patient are included because of their prognostic importance.

The seventh edition of the TNM (primary tumor, regional nodes, metastases) staging scheme for thyroid carcinoma, approved in 2009 by the International Union Against Cancer[62] and in 2010 by the American Joint Committee on Cancer (AJCC),[63] is presented in Table 38-2. The primary tumor status

**T-category definition:* T1, *greatest dimension ≤2 cm, limited to the thyroid;* T2, *>2 cm but ≤4 cm, limited to the thyroid;* T3, *>4 cm, limited to thyroid or any tumor with minimal extrathyroid extension;* T4a, *tumor of any size extending beyond thyroid capsule to invade subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve;* T4b, *tumor invades prevertebral fascia or encases carotid artery or mediastinal vessels.*

is defined in this scheme on the basis of the size of the primary lesion (diameter in centimeters) and the presence of extrathyroidal extension. A T1 tumor is 2 cm or smaller and limited to the thyroid. T1a refers to tumors of 1 cm or less, and T1b refers to a tumor more than 1 cm but not more than 2 cm in greatest dimension. A T2 tumor is 2.1 cm to 4.0 cm in diameter and limited to the thyroid. A T3 tumor is larger than 4 cm and limited to the thyroid or any tumor with minimal extrathyroidal extension (i.e., to sternothyroid muscles or perithyroidal soft tissues). A T4a tumor represents moderately advanced disease, which extends beyond the thyroid capsule and invades subcutaneous soft tissue, larynx, trachea, esophagus, or recurrent laryngeal nerve, and a T4b tumor represents locally advanced disease, typically invading prevertebral fascia or encasing carotid artery or mediastinal vessels.

When tumor spreads to lymph nodes, it is classified as N1. N1a refers to metastasis in level VI (e.g., pretracheal and paratracheal nodes, including prelaryngeal and Delphian nodes), and N1b describes metastasis to other unilateral, bilateral, or contralateral cervical or superior mediastinal lymph nodes. M1 refers to the presence of distant metastasis involving nonregional lymph nodes, internal organs, or bones.

To make this TNM information clearer, several of these TNM descriptions can be grouped together into stages I through IV. For the seventh edition of the TNM/AJCC staging system, the grouping for MTC is the same as for PTC or FTC in patients older than 45 years with one exception. A T3 N0 M0 MTC patient is considered stage II, whereas such a patient with papillary and follicular cancers is considered stage III. All patients with ATC are considered stage IV, reflecting the poor prognosis of this type of cancer.

For patients younger than 45 years with a diagnosis of PTC or FTC, the TNM stage is I (any T, any N, M0) if there is no distant spread and stage II (any T, any N, M1) if there are distant metastases beyond the neck or upper mediastinal lymph nodes. For patients with MTC or who are 45 years or older with PTC or FTC, the seventh edition of the TNM/AJCC staging system is more complicated than before.

In patients with PTC or FTC who are 45 years of age or older, stage I (T1 N0 M0) cancers are 2 cm or smaller and have not spread to lymph nodes or distant sites. Stage II (T2 N0 M0) cancers are more than 2 cm in diameter but not bigger than 4 cm, and they are localized to the thyroid. Stage III (T3 N0 M0 or T1-3 N1a M0) encompasses tumors larger than 4 cm or with minimal extrathyroidal extension and tumors of any size that have spread to central neck nodes.

In former TNM/AJCC classifications, stage IV referred only to patients who had distant spread, but the later editions (since 2002) define these patients as IVC (any T, any N, M1), and the designations IVA and IVB define more aggressive tumors that have not spread to distant sites. Stage IVB (T4b, any N, M0) refers to the unusual situation of a tumor that has grown back to the spine (e.g., prevertebral fascia) or into nearby large blood vessels (e.g., carotid artery or mediastinal vessels). The new stage IVA (T1-4a, N0-1b, M0) was formerly considered to be stage III, and it encompasses locally invasive T4a tumors (i.e., with or without nodal involvement [any N]) and node-positive N1b tumors (with primary tumors of any size but localized or showing only minimal extrathyroidal extension [T1-3]).

Because of significant differences in the tumor biology displayed by the four principal types of thyroid carcinomas, the remainder of this discussion of tumors is divided according to histologic type.

Papillary Thyroid Carcinoma

Most patients with PTC present with localized, node-negative disease.[51,64,65] Patients 45 years old or older with nodal metastases or extrathyroidal extension account for less than 20% of cases.[51] Only about 1% to 3% of older patients with PTC present with distant metastases. Figure 38-1, *A* shows CSS according to pathologic TNM (pTNM) stage in a cohort of 1851 patients who underwent surgical treatment at Mayo Clinic during the period 1940 to 1990.[66]

Three types of tumor relapse may occur with PTC: postoperative regional nodal metastasis, local recurrences, and postoperative distant metastases. Local recurrence has been defined as "histologically confirmed tumor occurring in the resected thyroid bed, thyroid remnant, or other adjacent tissues of the neck (excluding lymph nodes)" after complete surgical removal of the primary tumor.[67] Nodal or distant spread is considered postoperative if the metastases are discovered within 180 days or 30 days, respectively. In a cohort of 2370 patients with PTC who did not have initial distant metastases and had complete surgical resection of their primary tumors during treatment at Mayo Clinic from 1945 to 2000, relapse rates at nodal, local, and distant sites were 9.8%, 5.5%, and 4.6%, respectively, after 25 years of follow-up.[65] In a larger cohort of 2512 PTC patients treated during the period 1940-1990 at Mayo Clinic, the CSS rates at 5, 10, and 20 postoperative years were 98%, 96%, and 95%, respectively.[65]

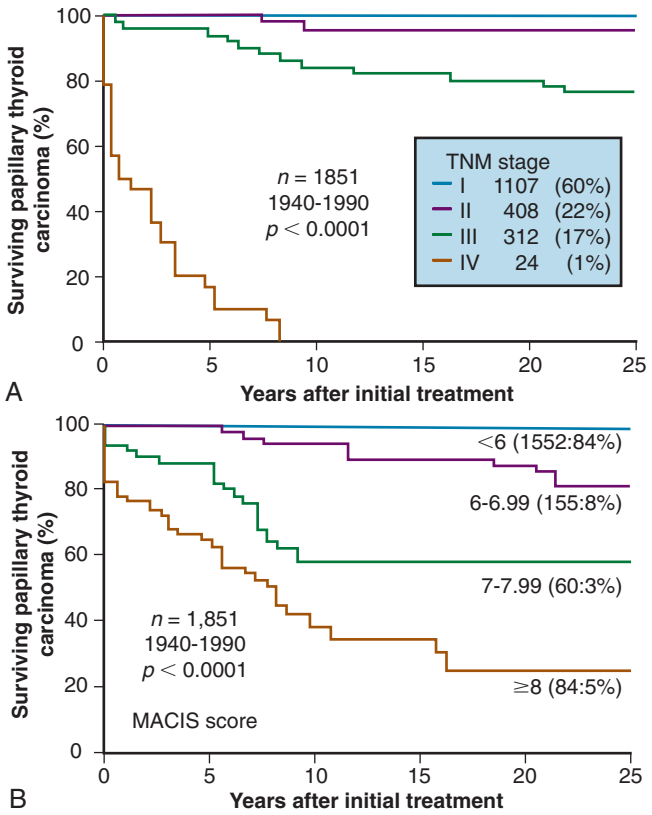

Figure 38-1 Cause-specific survival (CSS) for a cohort of 1851 patients with papillary thyroid carcinoma treated at the Mayo Clinic during the period 1940 to 1990. **A,** CSS by pathologic TNM (primary tumor, regional nodes, metastases) stage; numbers in parentheses are the percentages of patients in each pathologic TNM stage grouping. **B,** CSS by MACIS (metastasis, age, completeness of resection, invasion, and size) scores of <6, 6-6.99, 7-7.99, and ≥8; numbers in parentheses are the numbers and percentages of patients with PTC in each of the four risk groups.
From Larsen PR, Davies TF, Hay ID: The thyroid gland. In Wilson JD, Foster DW, Kronenberg HM, et al, editors: Williams Textbook of Endocrinology, ed 9, Philadelphia, 1998, WB Saunders, pp 389–515.

Of patients with lethal PTC, 20% of deaths occurred within the first year after diagnosis, and 80% of the deaths occurred within 10 postoperative years.[51,52,65]

Only a fraction (≈15%) of patients with PTC have relapse of disease, and even fewer (≈5%) have a lethal outcome.[51-53,65] The exceptional patient who experiences an aggressive course tends to relapse early, and the rare fatalities usually occur within 5 to 10 years of initial diagnoses.[51,52,65]

Multivariate analyses have been used to identify variables predictive of cause-specific mortality.[68-71] Increasing patient age and presence of extrathyroidal invasion are independent prognostic factors in all such studies.[68-71] The presence of initial distant metastases and large size of the primary tumor are also significant variables in most studies,[68,70] and some groups[51,64,68,69,72] have reported that histopathologic grade (i.e., degree of differentiation) is an independent variable. The completeness of initial tumor resection (i.e., postoperative status) is also a predictor of mortality.[51,71] The presence of initial neck nodal metastasis, although relevant to future nodal relapse, does not apparently influence cause-specific mortality.[51,52,71]

From a multivariate analysis of more than 14,200 patient-years of experience, a prognostic scoring system was devised and named the AGES system after five independent variables: patient's *a*ge, tumor *g*rade, tumor *e*xtent (e.g., local invasion, distant metastasis), and tumor *s*ize.[51,68] With the use of such a scoring system, 86% of patients with PTC were in the minimal-risk group (AGES score <4), and they had a cause-specific mortality rate of only 1%.[51] In contrast, patients with AGES scores of 4 or greater (i.e., high-risk group is 14% of the total) had a 20-year cause-specific mortality rate of 40%. Based on the description of the Mayo Clinic–derived AGES system,[68] Cady and Rossi,[73] working at the Lahey Clinic, devised a simplified version of the AGES system, which they called the AMES multifactorial system. The AMES system disregarded tumor grade because this information was not readily available to the authors, but they took advantage of the other four variables: *a*ge, *m*etastasis, *e*xtent, and *s*ize. The details of the AMES system are presented in Table 38-3. Of the 1961 to 1980 cohort of patients studied by Cady and Rossi, 89% were deemed low risk and had a death rate of 1.8%; outcome results virtually identical to results defined by the AGES prognostic scores.[51,68]

TABLE 38-3 Classification of Risk Group Categories According to the AMES System

LOW RISK
1. Younger patients (men <41 years; women <51 years), no distant metastasis
2. Older patients with (a) minor tumor capsule involvement *and* (b) primary cancers <5 cm in diameter *and* (c) no distant metastasis
HIGH RISK
1. All patients with distant metastasis
2. All older patients with (a) major tumor capsule involvement *or* (b) primary cancers ≥5 cm in diameter

Data from Cady B, Rossi R: An expanded view of risk-group definition in differentiated thyroid carcinoma. Surgery 104:947–953, 1988.
AMES, *Age, metastasis, extent, and size.*

Although the AGES scheme had the potential for universal application, some academic centers could not include the differentiation variable (tumor grade [G]) because their surgical pathologists did not recognize higher grade PTC tumors.[74] Another prognostic scoring system for predicting PTC mortality rates was devised with the use of candidate variables that included completeness of primary tumor resection but excluded histologic grade.[71] Cox model analysis and stepwise variable selection led to a final prognostic model that included five variables: *m*etastasis, *a*ge, *c*ompleteness of resection, *i*nvasion, and *s*ize (MACIS). The final score was defined as MACIS = 3.1 (if age is ≤39 years) or 0.08 × age (if age is ≥40 years), +0.3 × tumor size (in centimeters), +1 (if tumor not completely resected), +1 (if locally invasive), +3 (if distant metastases are present). As illustrated by Figure 38-1, *B*, the MACIS scoring system permitted identification of patient groups with a broad range of risk of death from PTC. Twenty-year CSS rates for patients with MACIS scores of less than 6, 6 to 6.99, 7 to 7.99, and 8 or more were 99%, 84%, 56%, and 24%, respectively. When cumulative mortality from all causes of death was considered, approximately 85% of patients with PTC (who had AGES scores <4 or MACIS scores <6) experienced no excess mortality over rates predicted for control subjects.[51,65,68,71]

Follicular Thyroid Carcinoma

When more than 75% of cells in an FTC exhibit Hürthle cell or oncocytic features, the tumor is classified as an HCC, oncocytic carcinoma, or oxyphilic variant FTC.[25] Most patients with FTC or HCC present with tumors that are 2 cm or larger and confined to the neck. Patients 45 years old or older with nodal

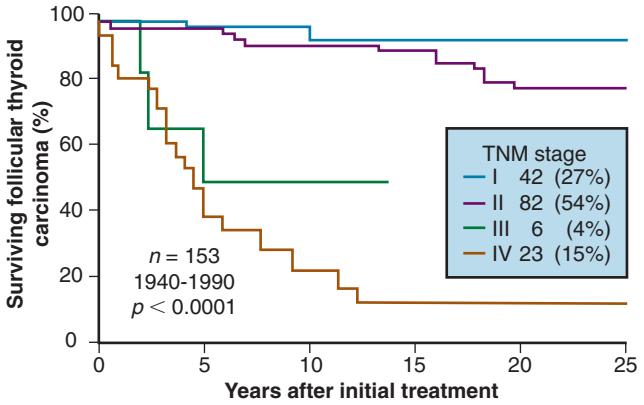

Figure 38-2 Cause-specific survival according to pathologic TNM (primary tumor, regional nodes, metastases) stages for a cohort of 153 patients with nonoxyphilic follicular thyroid carcinoma treated at the Mayo Clinic during the period 1940 to 1990. Numbers in parentheses are the percentages of patients in each pathologic TNM stage grouping. *From Larsen PR, Davies TF, Hay ID: The thyroid gland. In Wilson JD, Foster DW, Kronenberg HM, et al, editors: Williams Textbook of Endocrinology, ed 9, Philadelphia, 1998, WB Saunders, pp 389–515.*

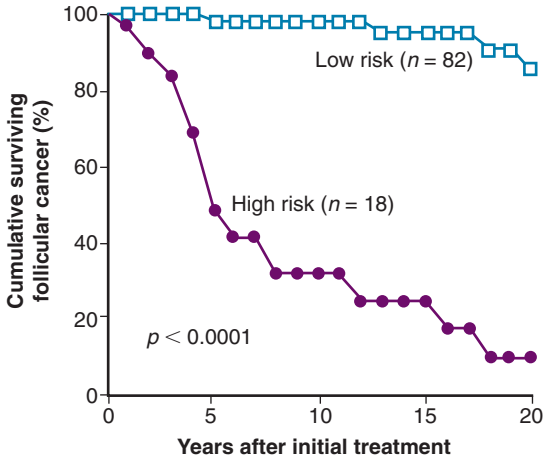

Figure 38-3 Cause-specific survival among 100 patients with nonoxyphilic follicular thyroid carcinoma treated at the Mayo Clinic during the period 1946-1970 and plotted by high-risk and low-risk categories. High risk is characterized by two or more of the following factors: age older than 50 years, marked vascular invasion, and metastatic disease at the time of initial diagnosis.
From Brennan MD, Bergstralh EJ, van Heerden JA, et al: Follicular thyroid cancer treated at Mayo Clinic, 1946 through 1970: initial manifestations, pathologic findings, therapy, and outcome. Mayo Clin Proc 66:11–19, 1991.

metastases or extrathyroidal extension account for only about 4% to 7% of FTCs and 8% to 10% of HCCs.[64,66] In contrast to patients with PTC, among whom only 1% to 3% present with distant metastases, about 4% to 6% of patients with HCC and 7% to 15% of patients with nonoxyphilic variant FTC have distant metastases at the time of initial diagnosis.[25,64,66] Figure 38-2 shows CSS according to pTNM stage in a cohort of 153 patients with nonoxyphilic FTC surgically treated at Mayo Clinic during the period 1940-1990.[66]

Nodal metastases are rare in typical FTC, and nodal relapse rates at 10 and 20 postoperative years are 1% and 2%, respectively. About 6% of patients with HCC have nodal involvement at presentation,[56] but at 20 and 30 years after primary surgery, 18% and 24%, respectively, of these patients have nodal relapse.[25] When relapse at neck or distant sites is considered, patients with HCC have the highest rates of tumor relapse after 10 or 20 years. Local recurrences account for most of these postoperative events because the numbers of distant metastases in patients with HCC are comparable with the numbers of metastases found in nonoxyphilic FTC (i.e., about 20% after 20 postoperative years).[25]

Cause-specific mortality rates vary with the presenting TNM stage for patients with FTC or HCC. The death rates tend to parallel the curves for development of distant metastases. In five decades of Mayo Clinic experience, the mortality rate for FTC initially exceeded that of HCC, but by 20 and 30 postoperative years, there were no significant differences in CSS rates between FTC and HCC,[25] with both survival rates about 80% at 20 postoperative years and 70% at 30 postoperative years.

The risk factors that predict outcome of patients with FTC are largely the same as for patients with PTC: distant metastases at presentation, increased patient age, large tumor size, and presence of local (extrathyroidal) invasion.[25] To a lesser degree, increased mortality is associated with male sex and higher grade tumors. Vascular invasiveness, lymphatic involvement at presentation, DNA aneuploidy, and oxyphilic histology are potential prognostic variables unique to FTC.[25] The importance of vascular invasion is underscored by a study showing that patients with FTC with minimal capsular invasion and no evidence of vascular invasion had 0% cause-specific mortality after 10 years of postoperative follow-up.[75]

Prognostic scoring systems for FTC allow stratification of patients into high-risk and low-risk categories.[25,76] A multivariate analysis at the Mayo Clinic found that distant metastases, patient age older than 50 years, and marked vascular invasion predicted a poor outcome.[55] As illustrated by Figure 38-3, if two or more of these factors are present, the 5-year survival rate is 47%, and the 20-year survival rate is 8%. If only one of these factors is present, the 5-year survival rate is 94%, and the 20-year survival rate is 86%.[55]

Systems developed to predict outcomes for PTC or FTC have been applied to patients with FTC. Specifically, the AMES risk-group categorization by Cady and Rossi has proved useful in FTC.[64,73] From a multivariate analysis of 228 patients with FTC treated at Memorial Sloan Kettering Cancer Center, the independent adverse prognostic factors were identified as age older than 45 years, Hürthle cell histologic type, extrathyroidal extension, tumor size exceeding 4 cm, and presence of distant metastasis.[77] The prognostic importance in FTC of histologic grade has also been confirmed[77,78] by the Memorial Sloan Kettering group, who have included this factor in their assignment of risk groups to low-risk, intermediate-risk, and high-risk categories, with 20-year survival rates of 97%, 87%, and 49%, respectively.[77] The AGES and MACIS prognostic scoring systems, originally developed for PTC, have also been successfully applied to FTC.[79,80] It seems that scoring systems used in PTC can be cautiously applied in FTC as long as some of the unique features of this tumor, such as vascular invasiveness and the remarkable significance of DNA aneuploidy in HCC, are considered.[25]

Medullary Thyroid Carcinoma

In reported studies of treated MTC, the proportion of patients with intrathyroidal node-negative tumors of 2 cm in diameter or smaller (TNM stage I) varies, depending on the number of familial cases detected by biochemical testing or DNA screening. The number of patients who present with TNM stage I MTC ranges from 5% to 25%, with the lower numbers

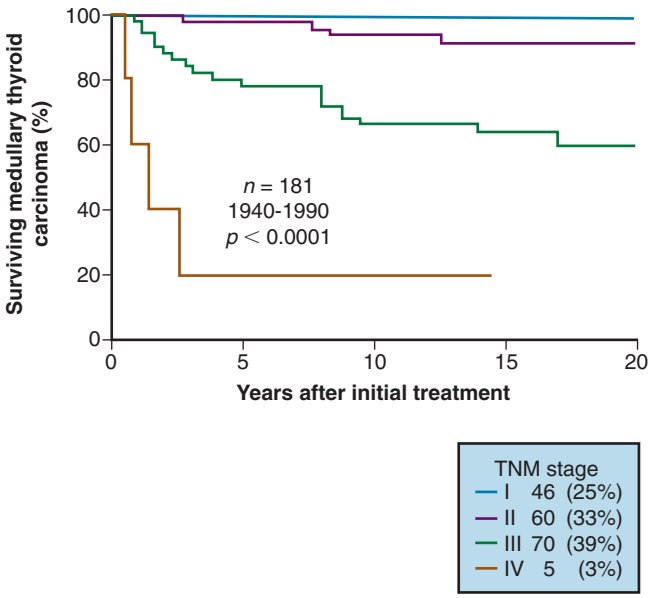

Figure 38-4 Cause-specific survival according to pathologic TNM (primary tumor, regional nodes, metastases) stage for a cohort of 181 patients with medullary thyroid carcinoma treated at the Mayo Clinic during the period 1940 to 1990. Numbers in parentheses are the percentages of patients in each pathologic TNM stage grouping.

representing the older series. Of patients, 25% to 50% present with positive neck nodes; the proportion of patients presenting with distant metastases usually exceeds the proportion with PTC but is typically less than the proportion with FTC. Stage IV cases constitute 3% to 10% of most MTC series. Figure 38-4 illustrates cause specific survival according to pTNM stage in a cohort of 181 patients with MTC surgically treated at Mayo Clinic during the period 1940-1990.[66]

Other prognostic factors relevant to outcome in MTC include age at diagnosis, male gender, vascular invasion, calcitonin immunoreactivity, amyloid staining, presence or absence of postoperative gross residual disease, and abnormal postoperative plasma calcitonin levels.[10,81-83] In a multivariate analysis from Toronto, only the presence of extrathyroidal invasion and postoperative gross residual disease were significant in the prediction of CSS.[83] In another multivariate study from Mayo Clinic, however, the only factors remaining in the final Cox model were pTNM stage III or IV disease, negative Congo red staining for amyloid, and postoperative gross residual disease.[82] Based on these three independent prognostic variables, a scoring system was devised to define four risk groups with 10-year mortality rates ranging from 5% to 100%.[82]

Anaplastic Carcinoma

Patients with ATC have a poor prognosis, and survival beyond 1 year is rare. There is no real use for an elaborate staging system for these patients, although distant and lymphatic spread at presentation, advanced age, and extremely poor differentiation have been identified as factors that make an already grim picture worse.[61,84] Figure 38-5 shows survival curves for 82 patients with ATC, stratified by extent of disease at presentation.[61]

CLINICAL MANIFESTATIONS AND PATIENT EVALUATION

At initial assessment, most patients with thyroid cancer have a palpable neck mass, which may represent the primary intrathyroidal tumor or metastatic regional lymphadenopathy. In some patients, the tumor may be clinically occult, and the impalpable lesion may first be recognized on high-resolution neck imaging[85] or during the course of a neck exploration for presumed benign thyroid disease. In patients with a family history of MTC or MEN-II syndrome, the finding of an *RET* oncogene mutation (identical to the proband) or abnormal calcitonin (or stimulated calcitonin) levels, or both, may necessitate elective prophylactic thyroidectomy in a patient who may prove to have early MTC visible only under the surgical pathologist's microscope.[49,50]

Features of the history and physical examination rarely provide convincing evidence for a diagnosis of thyroid malignancy.[7,8] The diagnosis of thyroid cancer necessitates pathologic confirmation from cytologic or histologic material. It is generally recognized that FNA biopsy is the most effective method available of preoperatively distinguishing between benign and malignant thyroid nodules.[7,8] All cancer diagnoses should be verified, however, by careful examination of histologic material after surgical excision of affected tissues. This approach is particularly relevant to the problem of the cellular follicular lesions described by cytologists as "suspicious" for follicular or Hürthle cell neoplasm. The diagnosis of FTC or HCC depends on the demonstration of invasion of the thyroid capsule or the adjacent blood vessels (i.e., angioinvasion), a process that typically necessitates careful evaluation of serial sections from the excised specimen for the presence or absence of such microinvasion. Even if FTC or HCC is apparently excluded at intraoperative frozen section, the resected specimen must be carefully reviewed in multiple sections from paraffin-embedded material.[25]

FNA biopsy can usually allow a confident diagnosis of PTC, which typically represents more than 75% of clinically recognized thyroid cancers in most contemporary series.[11,51,64,72]

Some authorities claim that the characteristic nuclear abnormalities diagnostic for PTC may be best seen in cytologic preparations from an FNA biopsy specimen, rather than in frozen sections or in paraffin-embedded histologic material. MTC may be readily diagnosed by FNA biopsy, but in equivocal cases, amyloid stained by Congo red or immunoperoxidase labeling of intracytoplasmic calcitonin may allow a definitive preoperative diagnosis.[10,59] ATC may often be diagnosed by FNA biopsy, but it sometimes may be difficult to distinguish from carcinoma metastatic to the thyroid.[61] When the biopsy specimen is found to be suspicious for ATC, immunostaining for thyroglobulin can help confirm the diagnosis of ATC. FNA diagnosis of thyroid lymphoma is difficult to make, and verification may necessitate examination of open biopsy material and specific immunostaining for clonal B-cell and T-cell populations.[86]

The evaluation of a patient with thyroid cancer requires obtaining a thorough history and performing physical examination with particular attention to signs and symptoms associated with local (extrathyroidal) invasion, involvement of regional (neck) nodes, and distant spread. Historical features suggesting a possible thyroid cancer include growth of a thyroid nodule over weeks or months; changes in speaking, breathing, or swallowing; and systemic symptoms of malignancy, such as weight loss, fatigue, and night sweats. On thyroid palpation, typical signs may include firm consistency of the dominant nodule, irregular shape, and fixation to underlying or overlying tissues. Evidence of suspicious regional lymphadenopathy may be present in up to one third of patients with PTC and MTC, but it is absent in most patients with FTC.

Patients with thyroid cancer are typically euthyroid, and when measured, the serum TSH level is usually normal. FNA biopsy can provide a confident diagnosis of PTC, MTC, and usually ATC. Diagnosing follicular cancer preoperatively remains a problem because capsule or vascular invasion cannot be shown in cytologic material. When FCDC is suspected and the decision is made for surgical exploration, it is often advisable to draw blood for a baseline serum thyroglobulin. This thyroid-specific protein can be used as a tumor marker to assess the efficacy of future therapies. Similarly, for patients with MTC, baseline measurements of calcitonin and carcinoembryonic antigen may permit a more accurate subsequent assessment of tumor control.

A preoperative vocal cord examination may permit the demonstration of unilateral vocal cord paralysis, which may raise suspicion about pressure or invasion of the ipsilateral recurrent laryngeal nerve. Particularly with PTC, MTC, and HCC, in which initial nodal involvement is common, high-resolution, real-time ultrasound examination of the neck can provide a surgeon with valuable information regarding the extent of disease within the thyroid gland and in adjacent regional lymph nodes. With extensive nodal disease or suspected locally invasive thyroid cancer, examination of the lower central neck with CT may delineate the presence of an intraluminal tumor or show more subtle evidence of tracheal or esophageal involvement with invasive disease. A high-resolution spiral CT scan of the chest or a whole skeleton isotopic bone scan is not routinely performed before initial neck exploration, but it can be useful postoperatively to exclude metastases in the mediastinum, lung, or bone, especially in patients without gross residual disease but with persistently elevated tumor markers.

Scanning with RAI has little role to play in the preoperative evaluation of thyroid malignancy. However, a postoperative whole body scan has become the gold standard for identification of iodophilic distant metastasis in patients with PTC or FTC.[7,9]

PRIMARY THERAPY

Surgery

Surgery is the standard primary treatment for differentiated thyroid cancers, but the extent of initial surgery is an area of considerable controversy.[4,68,87,88] Various investigators have advocated ipsilateral thyroid lobectomy with isthmectomy, bilateral subtotal thyroidectomy, and near-total or total thyroidectomy. Most institutions favor the initial resection of both lobes of the thyroid. Clinical guidelines promote near-total or total thyroidectomy as the recommended operative procedure for FCDC and total thyroidectomy for MTC.[7,9,10] Even thyroid carcinomas that are locally extensive, involving extrathyroidal structures, may be most effectively treated by a more aggressive surgical approach.[89,90] Most studies that have evaluated the impact of surgical treatment in thyroid cancers have compared total or near-total thyroidectomy with less aggressive surgical procedures.[4,67,68,91] These reports suggest that survival rates in higher risk cases are significantly improved after the more extensive surgery.[4,68]

An often-cited reason for removing all or nearly all of the thyroid gland is reducing the risk of future recurrence of FCDC in the contralateral thyroid lobe. This approach may be most appropriate in cases of PTC, in which multicentricity is a frequent phenomenon. Some investigators claim, however, that a subsequent local recurrence in the contralateral lobe also can be managed with a secondary operative procedure.[92] Such "completion" thyroidectomies carry a higher morbidity except in the hands of highly skilled surgeons.[67,93] One advantage of initial resection of the entire gland is the subsequent ability to follow serum thyroglobulin levels and to perform meaningful radioiodine scanning more easily.[6,7,9] Whole body scans may be difficult to interpret in the setting of residual thyroid remnant, as would be found after unilateral or bilateral subtotal resection.

In addition to the initial resection of the thyroid, the question of the extent of neck node removal remains controversial. When clinically evident nodal metastases are identified by palpation or ultrasound examination, surgical removal is performed. The role of prophylactic or prognostic lymph node dissections is unclear. For patients undergoing total or near-total thyroidectomy, removal of the central compartment lymph nodes may not add significantly to the morbidity of the procedure and should be included routinely with the primary resection.[7,93-96] Modified radical neck dissection is indicated for gross nodal metastases found before or during surgery, and it may improve the outcome of older patients with PTC with larger tumors or evidence of extrathyroidal invasion.[97,98]

The advantage of total thyroidectomy over near-total thyroidectomy may be nonexistent or limited to patients with more advanced malignancies.[67,68,99] The use of more limited surgery, such as unilateral total lobectomy, is probably appropriate only for a selected population of low-risk patients, such as patients with papillary microcarcinoma.[7,9,100]

Adjuvant Therapy

Thyroid Hormone

Postoperative thyroid suppression therapy for FCDC is based on administration of supraphysiologic oral doses of levothyroxine. This therapy has been widely used for more than 40 years, and it is assumed that suppression of endogenous TSH deprives TSH-dependent differentiated FCDC cells of an important growth-promoting influence. Traditionally, the goal of thyroxine therapy has been complete suppression of pituitary TSH secretion, as indicated by undetectable levels of serum TSH when measured in sensitive immunometric assays.

Uncertainty surrounds the level to which the serum TSH level must be suppressed to maximize benefit while avoiding potential long-term complications.[3,5,7,9]

With the increasing availability of sensitive TSH assays, meticulous titration of the level of TSH suppression has become possible. If patients with FCDC are deemed to be at high risk for relapse or mortality on the basis of scoring or staging systems,[63,71,73] or if they have persistent or recurrent carcinoma that cannot be eradicated by surgery, RAI, or other therapeutic measures, the goal would be to maintain the TSH level at less than 0.1 mU/L indefinitely in the absence of specific contraindications. In most patients with PTC who would be classified as low risk by prognostic scoring systems,[68,71,73,78] it is generally accepted that the degree of TSH suppression would be less stringent, and the goal for basal serum TSH should be in the readily detectable, barely subnormal range of 0.1 mU/L to 0.5 mU/L.[5,7,9,66,99]

Radioactive Iodine Therapy

Similar to the use of thyroid hormone for TSH suppression, the concept of adjuvant RAI therapy originated from treatment approaches to metastatic thyroid carcinoma and was based on an equally compelling physiologic premise. Because most FCDC cells retain some architectural and functional features of normal thyrocytes, iodine trapping and sometimes organification may be preserved in the tumors. It seemed appropriate to take advantage of this trapping by trying to eradicate microscopic residual postoperative tumor foci with RAI.

RRA has been defined as "the destruction of residual macroscopically normal thyroid tissue after surgical thyroidectomy."[99,101] Typically, RRA is used to complete the initial therapy in a patient whose FCDC has been completely resected (i.e., no gross residual disease is reported at the conclusion of the primary neck exploration). RRA is a procedure that is offered to patients with FCDC who have undergone "potentially curative" surgical treatment, and it should not be confused with RAI therapy, in which larger doses of iodine-131[102] (^{131}I) are used in an attempt to destroy persistent neck disease or distant metastatic lesions.[86,99,101,103,104]

Proponents of RRA describe at least three advantages for this adjunctive therapy. First, by being actively trapped by normal thyroid cells, RRA is thought to destroy occult microscopic carcinoma cells within the thyroid remnant. Second, the later detection of persistent or recurrent disease, particularly in the neck by RAI scanning, is facilitated by the destruction of remaining normal tissue. Third, the performance of RRA is thought to increase the value of serum thyroglobulin measurement during follow-up. This last benefit has convinced many physicians to consider RRA in patients with FCDC who are, by prognostic scoring or staging, deemed to be at low risk for tumor relapse or cause-specific mortality.[18,101] Other physicians have not advocated RRA in these low-risk patients, however, because of a lack of evidence of improved outcome.[98,99,101,103]

Investigators have reported benefit and a lack of benefit from the use of RRA. It is unclear from these reports whether outcome is improved with the routine use of RRA in the initial therapy of all patients with differentiated thyroid carcinoma, largely because of difficulties obtaining a comparable control group and the potential for selection biases, which may account for the outcomes reported. Sawka et al[101] systematically reviewed 1543 English references to determine whether RRA decreases the risk of thyroid cancer–related death or relapse after bilateral thyroidectomy for PTC or FTC. In 18 cohort studies not adjusted for prognostic factors or interventions, the benefit of RRA in decreasing thyroid cancer–related mortality and any relapse by 10 years was inconsistent among centers. However, pooled analyses suggested a statistically significant treatment effect of RRA in terms of 10-year outcomes for locoregional recurrence (relative risk, 0.31) and distant metastases (absolute decrease in risk, 3%). The conclusion of this meta-analysis was that RRA might be beneficial in decreasing relapse of well-differentiated thyroid cancer; however, Sawka et al[101] said that "the incremental benefit of remnant ablation in low-risk patients treated with bilateral thyroidectomy and thyroid hormone suppressive therapy is unclear."

The National Thyroid Cancer Treatment Cooperative Study Group (NTCTCSG) was founded in 1986 and has maintained over more than two decades a registry contributed to by 11 North American institutions prospectively following a large nonrandomized cohort of patients with FCDC, with the objective of assessing the effects of initial and longitudinal management on outcomes. By June 2001, 2936 patients were registered, and the more recently published results of outcome showed that "no treatment modality, including lack of radioactive iodine, was associated with altered survival in stage I patients." Jonklaas et al[3] "were unable to show any impact, positive or negative, of specific therapies in stage I patients." These authors concluded that "postoperative RAI (RRA) therapy does not provide significant benefit in stage I patients, and could even be harmful," and suggested that "further evaluation of the potential risks and benefits of treatment in stage I patients is, therefore, indicated."[3]

Use of prognostic scoring schemes may help to define patients at significant risk for relapse and who are more appropriate for consideration of remnant ablation. At the Mayo Clinic, patients with PTC who have MACIS scores greater than 6.0 or are found to have persistent elevation of serum thyroglobulin levels after 6 to 8 postoperative weeks are considered for an ablative procedure. Use of such a scheme is applicable only if the patient undergoes a near-total or total thyroidectomy. If the goal is to minimize the use of RAI, more extensive surgery such as near-total or total thyroidectomy is more appropriate in low-risk patients. However, if RRA is planned, more extensive surgery may not give any advantage. In high-risk patients, the use of RAI in addition to more aggressive surgery seems warranted.[98,103,105]

After determining the need for remnant ablation, the question of dose after the primary surgical procedure is also an important consideration. In the United States, low-dose regimens of less than 30 mCi have been used when the amount of residual thyroid tissue is small. Higher doses of 75 mCi to 150 mCi may be appropriate when microscopic residual is present or when the initial scan suggests an unsuspected metastatic site. Use of low-dose RAI in such a patient may decrease the ability of the tumor subsequently to concentrate sufficient radioiodine and should be avoided.

Further treatment with RAI ideally should reflect the local or distant uptake of iodine in residual differentiated thyroid cancer tissue. Adequate ability of thyroid cancer cells to concentrate radioiodine is variable, and this approach may not be appropriate in all patients. Patients with FTC may concentrate RAI better than patients with PTC.[104] In a multicenter Canadian study, Simpson et al[104] reviewed the outcomes of more than 1500 patients with PTC or FTC and studied 321 patients who were treated with RAI. The use of RAI resulted in significantly improved local control in patients with microscopic residual disease. CSS was also significantly better for patients with PTC with microscopic residual disease who received RAI. Most patients received only thyroid remnant ablation doses (50 mCi to 125 mCi), but total (cumulative) therapeutic doses given in one to seven treatments ranged from 75 mCi to 1000 mCi.

The definitive role of RRA continues to evolve.[105,106] Multiple studies have suggested that RRA be used routinely in

high-risk patients. Although the definition of "high risk" varies, most investigators favor using RAI in patients with large tumors or extensive extrathyroidal invasion and in patients with incompletely resected disease or distant metastases. Robbins and Schlumberger[105] recommended RRA for "any individual with a carcinoma larger than 1.5 cm or with a thyroid carcinoma of any size with obvious lymph node involvement, extrathyroidal extension, or multicentricity." The clinical guidelines proposed by the European Thyroid Association and the American Thyroid Association should allow some greater uniformity of treatment approach.[7,9,106]

External Beam Radiation Therapy (EBRT)

The appropriate application of EBRT in PTC and FTC is controversial, and this modality is not uniformly used.[106,107] A better understanding of prognostic factors that are specific to local recurrence may help identify an appropriate population of patients who would be candidates for EBRT. Most prognostic schemes consider only the overall risk of relapse and CSS.

Historically, indications for EBRT have included residual macroscopic or microscopic disease, extrathyroidal extension, multiple lymph node involvement, Hürthle cell histology, older age of patients, large tumor size, and residual disease that does not take up RAI. Several investigators have retrospectively reviewed their experience with EBRT and suggested improved local control or survival benefit or both. The patient populations in these studies are not uniform with respect to other treatments that also effect local control, making interpretation difficult.

Most series support the use of adjuvant EBRT for patients with microscopic residual disease or narrow surgical margins of resection. An early Canadian study of follicular and papillary carcinomas evaluated the role of EBRT according to completeness of surgical resection.[108] Table 38-4 summarizes these findings. Although the overall numbers are small, they suggest that patients with surgically narrow or microscopically positive margins may benefit from the addition of EBRT in moderate doses. These results were achieved with minimal morbidity.

A larger synopsis of 13 Canadian institutions in which EBRT was used predominantly in patients with high-risk features, such as extrathyroidal invasion, high-grade malignancies, and older age, revealed a significant improvement in local control for patients who had microscopically positive or narrow surgical margins.[106] In this study, the overall survival (OS) of patients with PTC with presumed or microscopic residual was significantly improved with the addition of adjuvant EBRT. These improvements were seen with or without the use of RAI. Results from Germany for patients with pathologic T4 disease (based on the older staging system) with or without lymph node involvement also suggest a benefit from EBRT with respect to local control and distant failure rates, especially in patients older than 40 years.[109] However, in a review from Princess Margaret Hospital in Toronto of 207 patients with microscopic residual, the addition of EBRT did not significantly improve the CSS or the local control ($p = 0.38$ and $p = 014$).[110] A more recent review with a larger number of patients and longer follow-up revealed an improved 10-year CSS in high-risk patients (age >60 years, extrathyroid extension, microscopic residual disease, no gross residual disease) with the addition of EBRT.[111,112] A review from Mount Sinai Hospital in Toronto found that the use of EBRT was the only predictor of significantly improved disease-specific survival and OS in patients with well-differentiated thyroid cancer with extrathyroidal extension.[113]

Benker et al[114] described 932 patients with differentiated thyroid malignancies and found no OS benefit with the addition of EBRT. On subset analysis, however, patients older than 40 years with T3 or T4 disease experienced improved survival that approached statistical significance ($p = 0.09$). All patients in this series received thyroxine-suppressive therapy and RAI.

The role of EBRT in the setting of gross residual disease has been evaluated by multiple investigators, with a wide range of outcomes. A study from the Royal Marsden Hospital showed complete response in 37% of patients and partial response in an additional 25%.[115] The Princess Margaret Hospital study had 33 patients with macroscopic disease treated with EBRT with or without RAI; the 5-year local recurrence-free rate was 62%.[110] Tubiana et al[116] from Institut Gustav-Roussy evaluated 97 patients with macroscopic residual based on the surgeon's clinical assessment. Local recurrence after EBRT was only 15% compared with 32% in a similar surgical category without postoperative EBRT. None of these patients received RAI. With the ability to deliver higher doses of EBRT using techniques such as intensity-modulated radiotherapy (IMRT) or proton beam therapy (IMPT), it may be feasible to give higher doses than were used in these studies and perhaps increase the long-term control of disease in this difficult patient population.

Although the definitive role of EBRT for differentiated thyroid carcinoma remains controversial, retrospective data support its use in a selected population of patients who have microscopic or presumed microscopic residual cancer.[117] Evidence exists not only for PTC and FTC but also for HCC and MTC.[118-120] The only randomized trial evaluating the role of EBRT was initiated in 2000 in patients with pathologic T4, N0-1, M0 disease after surgical resection and ablative ^{131}I therapy.[121] The study closed because of inadequate accrual in March 2003 despite acceptable toxicity.[122] The study authors indicated that at early follow-up, there are lower than expected relapse rates in the nontreatment arm. The improvements in surgical management of these patients and the appropriate application of RAI may have accounted for the decreased relapse and mortality rates compared with historical studies.

The use of EBRT for patients with differentiated thyroid cancer needs to be carefully tailored to the specific patient and applied after use of RAI. Although efforts to improve on surgical outcome have focused mainly on RAI treatment in patients with a high risk of relapse, there seems to be an evolving role for EBRT in their management. The rationale for inclusion of EBRT upfront in the management of this subset of patients is to (1) treat tissues that are known to take up less RAI (areas of extrathyroidal or extranodal extension, which are known poor prognostic indicators); (2) treat carcinomas that fail to concentrate and retain RAI (20% of all differentiated thyroid cancers, patients with Hürthle cell tumors, and patients >40 years old who commonly have less sodium iodide symporter); (3) spare some of the systemic toxicity of RAI treatment (when adequate treatment of residual disease entails excessive doses of radioiodine or when repeated treatments are likely to be

necessary, increasing cumulative systemic toxicity); and (4) spare some of the morbidity associated with uncontrolled locoregional cancer, such as obstruction of the esophagus or trachea or both, neurovascular compromise, pain, hemorrhage, need for laryngectomy, and need for repeated surgical procedures.

The current American Thyroid Association and National Comprehensive Cancer Network guidelines suggest that EBRT should be considered in patients older than age 45 with grossly visible extrathyroid extension at the time of surgery and a high likelihood of microscopic residual disease and patients with gross residual tumor in whom further surgery or RAI would likely be ineffective.[123] Changes in the staging of locally advanced thyroid cancers in 2002 by categorizing minimal extrathyroidal extension as T3 disease and creating two T4 categories should help delineate further the highest-risk population. In the clinical setting of T4b disease, it is unlikely that complete surgical resection can be achieved, and use of EBRT in addition to RAI seems to help control gross disease. For patients with locally recurrent disease, early use of EBRT as a component of treatment should be considered.

Treatment of the thyroid bed or gland and its draining lymph node areas has historically been a challenging undertaking. Advances in treatment modalities include three-dimensional conformal multiple-beam treatments, IMRT, and IMPT treatments. Although there is no definitive evidence of a dose-response relationship between radiation dose and local control probability, there is some suggestion that higher doses are associated with lower local recurrence rates.[116,124] With the increasing availability of IMRT and IMPT, dose escalation may be more readily achievable in the adjuvant setting without increasing toxicity.[125-127] Stereotactic body radiotherapy (SBRT) has been proposed as a highly targeted technique that is efficient (one to three treatments) and effective in controlling cervical lymph node recurrence of nonanaplastic thyroid cancer (100% tumor control) with no serious adverse events.[128]

Chemotherapy

Although most thyroid cancers, FCDC, and medullary cancers respond to historical therapeutic approaches, radioiodine-refractory metastatic differentiated thyroid cancer (FDTC) and advanced medullary thyroid cancer (MTC) have, until recently, had few treatment options. The role of systemic therapies, such as cytotoxic chemotherapy in the treatment of these advance thyroid cancers is limited. Most agents have low response rates. The most active single agent reported in the treatment of thyroid cancers is doxorubicin (Adriamycin). Other reportedly active agents include cisplatin, carboplatin, and etoposide (VP-16).

The Eastern Cooperative Oncology Group (ECOG) reported the only randomized study of the use of chemotherapy in advanced thyroid cancer.[129] Patients with locally advanced or metastatic FTC, PTC, MTC, and ATC were eligible. In this study, patients were randomly assigned to chemotherapy with doxorubicin alone or doxorubicin with cisplatin. Of the 84 eligible patients, the investigators reported a complete response rate of 6% and a partial response rate of 15%. A partial or complete response to chemotherapy occurred in 8 (23%) of 35 patients with advanced differentiated thyroid carcinomas. Overall, there was no advantage to the combination-drug regimen over doxorubicin alone. All five complete responders were in the combination arm, however.

Targeted Therapy for Advanced Thyroid Cancer

The most promising targeted therapies for advanced thyroid cancer are tyrosine kinase inhibitors (TKIs). TKIs are oral therapies that inhibit various altered intracellular metabolic pathways. In clinical trials these therapies induce significant regression in differentiated and medullary thyroid cancer without improvement in survival (Table 38-5). The only TKI approved for advanced FDTC is sorafenib. Among patients with well-differentiated thyroid cancer that has metastasized, recurred, or has not responded to radioactive iodine, this therapy increased the length of progression-free survival (PFS) by 41% and led to a median PFS of 10.8 months.[130] Vandetanib and Cabozantinib are two TKIs approved for progressive and metastasized medullary thyroid cancer. Both therapies are associated with improvements in mean PFS and reduction in tumor size compared to patients receiving placebo. At Mayo Clinic, two recently published multicenter Phase II studies described a initial experience with pazopanib in both FDTC[131] and, more recently, MTC.[102] Among patients with metastatic, rapidly progressive, and radioiodine-refractory FDTC, pazopanib induced a partial response (30% decrease in the sum of the longest diameter of target lesions) in about 49%; with an estimated 66% likelihood of having responses longer than 1 year's duration. Promising results were also observed for patients with progressive and metastatic medullary thyroid cancer, where pazopanib induced a partial response in 14.3% of patients with median PFS of 9.4 months.

TABLE 38-5 Tyrosine Kinase Inhibitors for Advanced Thyroid Cancer

	Tumor Type	Target	Partial Response (%)	Progression-Free Survival (Months)	Most Frequent Adverse Effects (%)
FDA APPROVED					
Sorafenib	PTC	BRAF, RET, other TKRs	13-41	10-18	Hand-foot-skin reaction (30%), diarrhea (43%), fatigue (37%)
Vandetanib	MTC	RET, other TKRs	16-45	20-27	Hypertension (33%), rash (53%), diarrhea (57%)
Cabozantinib	MTC	RET, other TKRs	28	11.2	Diarrhea (15.9%), hand-foot-skin reaction (12.6%), and fatigue (9.3%)
NON-FDA APPROVED					
Axitinib	PTC, FTC	Other TKRs	26-40	NA	Diarrhea (55%), increased creatinine (55%), hypertension (40%)
Pazopanib	PTC, FTC	RET, other TKRs	49	11.7	Liver enzymes elevation (53%), weight loss (52%), diarrhea (52%)
Sunitinib	PTC, FTC	RET, other TKRs	28	10-21	Diarrhea (61%), liver enzymes elevation (56%), fatigue (54%)

BRAF, *v-Raf murine sarcoma viral oncogene homolog B;* RET, *rearranged during transfection;* FTC, *follicular thyroid cancer;* MTC, *medullary thyroid cancer;* NA, *not assessed;* PTC, *papillary thyroid cancer,* TKR, *tyrosine kinase receptor.*

The most common side effect of these TKIs is fatigue, hand-foot skin reaction, gastrointestinal and abdominal pains, and hypertension. It has been estimated that TKIs cause mortality in about 1.5% of patients.[132] Also important to consider is that even in the presence of radioiodine-refractory disease, advanced thyroid cancer does not always progress to cause symptoms or result in decreased quality of life.[133] Therefore, it is important to offer these treatments to those patients where the benefits may outweigh the potential harm. A potential subgroup, where this is true, are patients with radioiodine-refractory, previously irradiated disease and nonsurgical, non-EBRT candidates with progressive or threatening symptoms.

THYROID LYMPHOMA AND ANAPLASTIC THYROID CARCINOMA

The most common poorly differentiated tumors of the thyroid, lymphoma and ATC, are treated differently from well-differentiated FCDC and MTC. For that reason, these two tumors and their treatment plans are considered separately.

Primary Thyroid Lymphoma

For a thorough and in-depth review of lymphoma, please refer to Chapters 76 and 77 "Hodgkin's Disease" and "Non-Hodgkin's Disease.

Most thyroid lymphomas are diffuse, large B-cell lymphomas (DLBCLs), but significant numbers are in the category of lymphomas known as mucosa-associated lymphoid tissue (MALT) lymphomas or mixed tumors containing elements of DLBCL and MALT. Rarely, other types of lymphoma, including follicular lymphomas and Hodgkin's lymphomas, have been reported.[134,135] Thyroid lymphomas usually manifest with a rapidly enlarging mass that is sometimes associated with respiratory and esophageal symptoms. These lymphomas typically occur in middle-aged and older women and are often associated with chronic thyroiditis.[134,135] MALT lymphomas have a more indolent natural history, whereas DLBCLs tend to be more aggressive.

In general, early stage, indolent, low grade lymphoma (including MALT lymphoma) is treated with EBRT alone to a dose of 24 Gy in 12 fractions to an involved-field. Stages III-IV disease (indolent follicular lymphoma, marginal zone lymphoma) is also treated with radiation therapy alone to 24 Gy in 12 fractions to involved-fields.[136-139] In cases where the treatment intent is palliative, 4 Gy in 2 fractions may be sufficient.[139] For early stage (I, II) diffuse aggressive (large B-cell) lymphoma, the treatment is typically 8 cycles of Rituximab, Cyclophosphamide, Doxorubicin Hydrochloride, Vincristine Sulfate, Prednisone (R-CHOP) usually followed by 30 Gy in 15 fractions EBRT to the involved field if there has been a complete response to chemotherapy. The addition of EBRT to chemotherapy in this situation has been reported to improve disease free or PFS and OS when compared to chemotherapy alone.[137,138,140-143]

In stages III-IV DLBCL involving the thyroid gland, the treatment would generally be R-CHOP alone. Further improvement in outcomes for DLBCLs has been shown with the addition of monoclonal antibodies, especially rituximab, to combination chemotherapy.[144,145] Other immunologic and radiolabeled agents are being evaluated.

Anaplastic Thyroid Carcinoma

The treatment of ATC is frustrating because of the rapidly progressive nature of this disease and its high fatality rate. Most patients are women presenting in the sixth to seventh decade of life, typically with a mass rapidly enlarging over a short time interval. Symptoms of hoarseness, dyspnea, dysphagia, and pain are common in this form of thyroid malignancy. Persistent or recurrent local disease is often the cause of death. Distant metastases are present in almost half of patients at presentation.

The optimal role of surgery has not been well defined. Surgery may be performed initially in some patients, but this probably reflects the selection of a favorable population of patients. The M. D. Anderson Cancer Center reported that more extensive surgery by itself did not provide a survival advantage.[84] Overall, most patients present with unresectable or metastatic disease, and the initial surgery in these situations is primarily for diagnostic purposes. In most reports, however, the only long-term survivors were patients who had undergone surgical resection.[61,146-149] For this reason, surgery should be strongly considered as a component of treatment. Surgery has been performed before or after EBRT, chemotherapy, or both.[84,150] The sequence of surgery relative to EBRT and chemotherapy may be primarily a reflection of the extent of disease at time of patient presentation to the treating physicians.[151]

EBRT has been used in the treatment of these advanced tumors, but because of the high metastatic rate and high rate of local failure with EBRT alone, the investigation of chemotherapy in addition to EBRT is warranted.[152] Multiple studies have investigated the use of multimodality therapy.[146,147,150,153] The use of hyperfractionated EBRT has been examined because of the rapid proliferation rate of these malignancies.[147,150,153,154] Various approaches have been reported, but most studies use doxorubicin-based chemotherapy given concurrently with local EBRT.[129,147,153,155]

In approaching ATC, we view two issues to be paramount: (1) the eradication of localized disease in the neck, with protection of the airway, esophagus, and neurovascular structures, and (2) the control of metastatic disease, which almost always contributes to the death of patients with ATC. It follows that a strategy combining locoregional and systemic therapy may offer the greatest promise in ATC.

Although long-term survival (>1 year) after combined-modality therapy in ATC has been so rare as to provoke reports of single cases,[156] subsequent series support the benefit of combined-modality approaches. Swaak-Kragten et al[157] conducted a study of 30 patients with ATC treated with an adjuvant approach combining surgery, EBRT, and single-agent chemotherapy with doxorubicin administered concurrently with EBRT and continued after EBRT completion and reported an encouraging improvement in 1-year survival from 9% (historical controls) to 23% (new patient cohort). Haigh et al[158] reported a 75% 2-year survival in 8 patients undergoing complete surgical resection and adjuvant EBRT and chemotherapy. Tan et al[159] reported an estimated 5-year survival of 60% for 5 patients who underwent complete resection. Four patients had received postoperative EBRT, 3 with post-EBRT doxorubicin-based chemotherapy. Pudney et al[160] reported a median OS of 13 months for 5 patients with stage IVB ATC treated with either EBRT concurrent with doxorubicin or induction docetaxel, doxorubicin, and cyclophosphamide. Three patients developed progression of local disease, and 1 developed distant metastases. Higashiyama et al[161] reported a 12-month survival rate of 44% in 9 patients with stage IVb ATC treated with induction paclitaxel. This survival rate compared favorably with a historical control group of 50 patients treated without induction paclitaxel; their 12-month survival was just 5.9%. A retrospective review of 10 consecutive patients with stage IVA and IVB ATC from Mayo Clinic who were treated with aggressive combined modality therapy (surgery if feasible, early initiation of docetaxel and doxorubicin, with the addition of concurrent EBRT followed by adjuvant

chemotherapy as tolerated) had an unexpectedly long median OS of 60 months, compared to a 5- to 6-month median OS among an analogous historical group of patients.[162] NRG Oncology is currently studying such aggressive combined modality therapy in a randomized Phase II clinical trial (RTOG 0912) using surgery when possible, concurrent IMRT and paclitaxel with or without pazopanib.

The optimal EBRT fractionation schedule has not yet been determined. Of patients treated with a moderate dose (57.6 Gy) slightly accelerated radiotherapy, given twice daily 3 days per week, combined with concurrent weekly doxorubicin, 70% required a 1-week interruption in treatment because of pharyngoesophagitis and tracheitis.[153] Moderate-dose (60.8 Gy) accelerated fractionation even without concurrent chemotherapy may be too toxic with a median OS of just 10 weeks.[163] Low-dose (40 Gy) hyperfractionated accelerated radiotherapy with sequential but not concurrent chemotherapy (doxorubicin) seems to be well tolerated with 1-year and 3-year OS of 50% and 35%, respectively.[155] Moderate-dose (60 Gy) hyperfractionated accelerated radiotherapy without concurrent chemotherapy seems to be well tolerated with a median OS of 13.6 months and 1-year and 5-year OS of 66.7% and 0%, respectively.[164] However, others have reported less than 10% 1-year survival with hyperfractionated accelerated radiotherapy to a median dose of 57 Gy in patients with nonmetastatic disease.[165] In the current NRG Oncology clinical trial, IMRT is being used with conventional daily fractionation to a total dose of 66 Gy in 33 fractions of 2 Gy each over a 6.5 week period of time.

In a report of the Surveillance, Epidemiology and End Results (SEER) database from the National Cancer Institute, the only factors predicting for lower cause-specific mortality were age younger than 60 years, intrathyroidal tumor, and combined use of surgery and EBRT.[166] However, the overall cause-specific mortality rate was 80.7% at 1 year. The use of multimodality therapy, including surgery, EBRT, and chemotherapy, is appropriate and offers the best chance for long-term survival, but more active systemic agents need to be found to improve survival significantly.

IRRADIATION TECHNIQUES AND TOLERANCE

EBRT Treatment Volumes and Doses

Treatment of the thyroid bed or gland and the regional lymph nodes is challenging because of the contour of the body in this anatomic area; the potential extension of disease to the upper mediastinum; involvement of lymph nodes in the central and lateral neck and mediastinum; and the close proximity of the lungs, spinal cord, esophagus, larynx, pharyngeal constrictors, and brachial plexus. Historically, several approaches have been reported for the initial extended fields, including a single anterior electron field,[110] an anterior field with a posterior supplemental field for the mediastinum, and lateral fields.[116]

For optimal treatment in an adjuvant setting or for locoregionally advanced or recurrent disease treated with curative intent, the clinical target volume should include the thyroid bed (including gross disease if present), lymph nodes of the central and lateral neck (typically bilateral levels II through VI, consider adding level VII when level II is involved or in the case of bulky adenopathy), and upper mediastinum. When treating for palliation, it is reasonable to consider treating only the gross tumor volume plus margin. Treatment planning should be image based (CT simulation) and incorporate CT, ^{18}F-fluorodeoxyglucose (^{18}F-FDG) fused PET/CT, and MRI.

At Mayo Clinic, we have chosen to use IMRT or intensity-modulated arc therapy (VMAT) in the treatment of these patients, which allows us to quickly administer a more conformal high dose (60 Gy to 70 Gy) with improved homogeneity to the thyroid bed or gross disease and high-risk areas (lymph nodes and tracheoesophageal groove), while lowering the dose to normal organs at risk, including the salivary glands, epiglottis, false vocal cords, true vocal cords, arytenoids, central and posterior aspects of the pharyngeal constrictors and esophagus, brachial plexus, and spinal cord. The use of IMRT and VMAT has allowed for more elegant treatment of this disease site compared with conventional two-dimensional and three-dimensional treatment planning (Figure 38-6). IMRT improves the minimum and mean dose to the planning tumor volume and significantly reduces the dose to the spinal cord.[125,127,167,168] This is true for treatment of the thyroid tumor bed and locoregional nodal sites.

The radiation dose used in the postoperative setting for microscopic residual disease should be 60 Gy in 6 weeks. However, some centers have suggested 40 Gy given over 3 to 3.5 weeks is adequate.[108] For known gross residual disease, dose escalation to 66 Gy to 70 Gy is reasonable. One retrospective study from the United Kingdom suggested a possible dose-response effect at greater than 50 Gy for patients treated with curative intent.[107] The use of higher doses without added morbidity may be feasible with IMRT, VMAT, and IMPT. Although there is no definitive evidence of a dose-response relationship between radiation dose and local control probability, there is some suggestion that higher doses are associated with lower local recurrence rates.[116,124]

Treatment Tolerance

With the increasing availability of IMRT, VMAT, and IMPT, dose escalation may be more readily achievable in the primary setting without increasing toxicity while lowering toxicity in the adjuvant setting.[125-127] Ideal planning target volumes and dose remain inadequately characterized, however. Early experiences with IMRT seem to suggest that escalation of dose to subclinical sites of possible involvement (nodal regions outside the thyroid bed to 54 Gy), the margin-negative thyroid bed (60 Gy-63 Gy), margin-positive regions (66 Gy), and gross disease (70 Gy) is technically feasible without increasing toxicity.[125,127] One treatment is given each day, 5 days a week, 1.8 Gy to 2.0 Gy per treatment. Acute radiation reactions include dermatitis, laryngitis, pharyngitis, tracheitis, and esophagitis. Late sequelae are uncommon but may include laryngeal edema, cartilage necrosis, esophageal stenosis, myelitis, brachial plexopathy, and pulmonary fibrosis.

TREATMENT ALGORITHM, CONCLUSIONS, AND FUTURE POSSIBILITIES

Treatment Algorithm

The initial approach to a potentially malignant thyroid mass is to perform FNA biopsy. This technique permits the identification of patients with definite cancer or for whom there is a high degree of suspicion for malignancy. At initial operation (i.e., open biopsy, thyroid lobectomy, and near-total or total thyroidectomy), the surgeon can assess tumor size, determine the presence or absence of gross local invasion or regional lymph nodal metastasis, and define the postoperative status (i.e., presence or absence of gross residual disease). The surgical pathologist can identify the degree of tumor differentiation (i.e., histologic grade); the tumor histologic type; and, if requested, the DNA ploidy.

Typically, FCDC is treated by near-total or total thyroidectomy unless the primary tumor is 1 cm or less in diameter. MTC is treated by total thyroidectomy, whereas ATC and lymphoma probably require only an open biopsy for verification

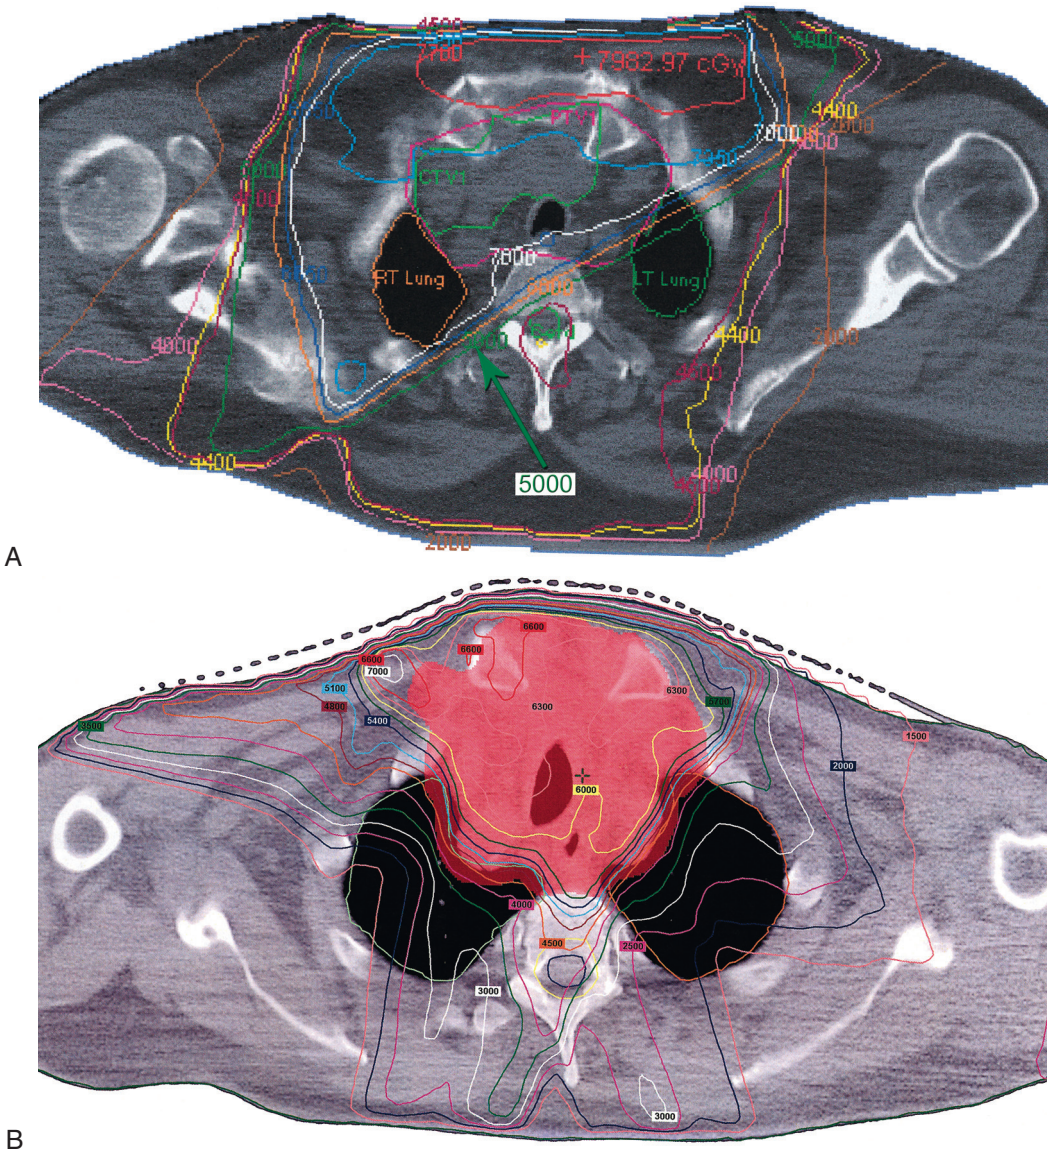

Figure 38-6 **A,** Three-dimensional treatment planning isodose curves for a patient with locally recurrent and progressive papillary thyroid carcinoma, deemed unresectable. Treatment uses anteroposterior fields followed by oblique fields to the left neck for a total dose of 70 Gy. **B,** Intensity-modulated radiotherapy (IMRT) treatment plan for a patient with resected recurrent Hürthle cell carcinoma. Treatment uses nine IMRT fields delivering 60 Gy to central lower neck and 54 Gy to lateral upper neck and mediastinum.

of diagnosis. Postoperatively, all patients undergoing more than a lobectomy require thyroid hormone therapy, but only patients with FCDC should receive TSH-suppressive doses of thyroxine.

Knowledge of patient age, cell type, pTNM stage, and postoperative status permits classification of patients into risk groups, which may influence the selection of subsequent postoperative adjuvant therapy. The treatment of patients with different tumor histologies is outlined in the following paragraphs and summarized as four steps in the accompanying treatment algorithm (Table 38-6).

Papillary Thyroid Carcinoma, Follicular Thyroid Carcinoma, and Hürthle Cell Carcinoma

Patients with FCDC with documented distant metastases (e.g., lung, bone) at presentation undergo RAI scanning 6 to 8 weeks postoperatively and are treated with ^{131}I therapy; the dose depends on the extent of metastases and avidity for RAI. Subsequent repeat whole body scans are performed at 3- to 6-month intervals until no further uptake is observed in the neck or distant sites. Serum thyroglobulin levels are obtained before RAI therapy and are closely monitored while on and off thyroxine to gauge progress in terms of tumor control.

Patients with unresectable or resected but residual FCDC are typically given the opportunity of whole-body scan and possible RAI therapy. If a whole-body scan reveals no significant uptake after therapy, a course of EBRT is considered.

Patients 45 years old or older with locally invasive disease usually are given RAI therapy. Some authorities consider the addition of EBRT, especially if serum thyroglobulin levels continue to be elevated despite apparently adequate treatment with RAI.

The role of remnant ablation in patients with intrathyroidal or node-positive PTC remains controversial. Use of the AGES,

TABLE 38-6 Treatment Algorithm

Step I	*Initial neck exploration/thyroid resection* FCDC: usually near-total or total thyroidectomy MTC: total thyroidectomy ATC: open biopsy or subtotal thyroidectomy Lymphoma: FNA or open biopsy Lymph nodes: removal of central compartment nodes in FCDC and MTC; modified radical neck dissection for involved lateral nodes
Step II	*Thyroid hormone therapy* Replacement doses for MTC, ATC, lymphoma TSH-suppressive doses for FCDC except microcarcinoma
Step III	*Outcome prediction by risk-group classification* Gauged according to age, stage, histologic type, and cancer type-specific scoring systems (e.g., AMES, MACIS)
Step IV	*Patient selection for RAI therapy, EBRT, chemotherapy, or combinations* FCDC: RAI therapy indicated for distant spread, unresectable or residual neck tumor, possibly invasive disease in PTC and most cases of FTC or HCC; EBRT for local or metastatic tumor nonresponsive to RAI therapy; almost no role for chemotherapy in differentiated FCDC MTC: residual or recurrent neck disease considered for EBRT; octreotide or chemotherapy considered for palliation only ATC: postbiopsy EBRT and concurrent chemotherapy Lymphoma: CHOP chemotherapy plus EBRT

AMES, *Age, metastasis, extent, and size;* ATC, *anaplastic thyroid cancer;* CHOP, *cyclophosphamide, hydroxydaunomycin, Oncovin (vincristine), prednisone; EBRT, external beam radiotherapy;* FNA, *fine-needle aspiration,* FCDC, *follicular cell–derived cancer;* FTC, *follicular thyroid carcinoma;* HCC, *Hürthle cell carcinoma;* MACIS, *metastasis, age, completeness of resection, invasion, and size;* MTC, *medullary thyroid carcinoma;* PTC, *papillary thyroid carcinoma;* RAI, *radioactive iodine;* TSH, *thyroid-stimulating hormone.*

AMES, or MACIS prognostic classifications may permit a more selective use of RAI. Generally, most patients with FTC or HCC undergo postoperative whole-body scans and are considered candidates for RRA. This may be an overaggressive position because the prognosis is excellent for minimally invasive FTC after surgery alone, and HCC usually does not avidly uptake RAI.

Medullary Thyroid Carcinoma

Because MTC may be bilateral and multicentric and because nodal metastases are common at presentation, most authorities recommend an initial surgical approach of total thyroidectomy, central compartment node removal, and possible modified radical neck dissection if the lateral neck is involved with disease. There is no role for TSH-suppressive or RAI therapy in this condition. Recurrent disease in the neck or mediastinum is typically treated by repeat surgical exploration. EBRT may have a role in local control if disease becomes unresectable, and it can be usefully employed in the treatment of osseous metastases, especially when vertebral deposits threaten the spinal cord. Combination chemotherapy has been used in stage IV MTC, as has subcutaneous octreotide therapy. These treatments have not been shown to improve CSS in disseminated, symptomatic MTC.

Anaplastic Thyroid Cancer

Usually only an open biopsy is performed at surgery when ATC is first diagnosed. More extensive initial resection should be considered if it can be achieved without significant morbidity. Most patients with ATC are given EBRT postoperatively, and many are given the option of concurrent chemotherapy during EBRT. There is no generally approved efficacious chemotherapeutic program available to patients with ATC.

Primary Thyroid Lymphoma

In contrast to the outlook for ATC, much greater optimism is expressed in managing primary thyroid lymphomas. There has been a gradual shift from subtotal thyroidectomy to open biopsy and FNA biopsy in diagnosing this condition. Recognition of the probably systemic nature of the disease led initially to an acceptance of the role of EBRT to the involved thyroid gland and regional nodes. More definitive data point to the use of combined-modality therapy in the management of this disease, typically combining R-CHOP chemotherapy with EBRT.

CHAPTER

39 Unknown Head and Neck Primary Site

William M. Mendenhall, Anthony A. Mancuso, and John W. Werning

INCIDENCE
Approximately 3% of head and neck squamous cell carcinomas metastasize to the neck from an unknown head and neck primary site.

BIOLOGIC CHARACTERISTICS
Biologic characteristics are similar to head and neck mucosal squamous cell carcinomas with known primary sites.

STAGING EVALUATION
Evaluation includes history and physical examination, computed tomography (CT) of the head and neck, chest radiography, direct laryngoscopy with ipsilateral tonsillectomy, and directed biopsies. Optional studies include chest CT and positron emission tomography (PET).

PRIMARY THERAPY AND RESULTS
Therapy consists of neck dissection to the involved neck or radiotherapy (RT) to the neck, oropharynx, and nasopharynx if RT is indicated for treatment of neck disease. The 5-year survival is approximately 50%.

ADJUVANT THERAPY
Concomitant cisplatin chemotherapy is administered for N2 and N3 neck disease and for close and positive margins or extracapsular extension following an initial neck dissection.

LOCALLY ADVANCED DISEASE
RT is administered to the oropharynx, nasopharynx, and both sides of the neck with concomitant chemotherapy followed by evaluation for a neck dissection.

PALLIATION
Moderate dose RT (30 Gy/10 fractions or 20 Gy/2 fractions with a 1-week interfraction interval) is administered to the involved neck.

In a small percentage of patients with squamous cell carcinoma metastatic to the cervical lymph nodes, the primary lesion cannot be found, even after an extensive evaluation. Patients with metastatic adenopathy in the upper neck have a good prognosis when treated aggressively, compared with those with metastatic lymph nodes in the level IV nodes or supraclavicular fossa.[1] The latter group is more likely to have a primary lesion located below the clavicles and the probability of cure is remote. Most patients have either squamous cell carcinoma or poorly differentiated carcinoma. Patients with adenocarcinoma almost always have a primary lesion below the clavicles, although if the nodes are located in the upper neck, one must exclude a salivary gland, thyroid, or parathyroid primary tumor.

This chapter addresses the management of patients presenting with squamous cell or poorly differentiated carcinoma in the upper or middle neck. Squamous cell carcinoma presenting in a parotid area lymph node is almost always metastatic from a cutaneous primary site and will not be addressed.[2]

DIAGNOSTIC EVALUATION

Patients should be evaluated with a thorough physical examination including careful evaluation of the head and neck by multiple examiners. A needle biopsy of the lymph node should be performed; fine-needle aspiration (FNA) is preferred to a biopsy because it is less traumatic, and there is a lower likelihood of seeding tumor cells along the needle track.[3-7] Evaluation of the neck node biopsy for Epstein-Barr virus (EBV) DNA, via polymerase chain reaction, may be useful in detecting a nasopharyngeal primary tumor in geographic areas where this malignancy is prevalent.[8] Similarly, evaluation of the biopsy for high-risk human papilloma virus (HR-HPV) may be useful for detecting an oropharyngeal carcinoma.[9] Most occult primary cancers that are detected in the United States are in the oropharynx so that, depending on the situation, testing in the biopsy for HR-HPV may be useful for determining the aggressiveness of the treatment plan.[10] HPV-positive oropharyngeal cancers have a better prognosis, and it may be possible to eliminate concomitant chemotherapy or use a lower RT dose. The necessity of adding a neck dissection may also be lower.

After chest roentgenography, CT or magnetic resonance imaging (MRI) of the head and neck is obtained to detect an unknown primary lesion arising from the mucosa of the head and neck. We use CT initially and follow with MRI only in cases with equivocal findings in which MRI might yield additional useful information, such as a suspected primary site in the nasopharynx. A complete blood count is obtained to evaluate the patient for anemia, which may reduce the likelihood of local regional control after irradiation alone. A chest CT should be considered for patents with N3 neck disease, as well as those with N2b to N2c disease and bulky adenopathy in the low neck, to assess the lungs for pulmonary metastases.[11] The recommended diagnostic algorithm is depicted in Box 39-1.[12]

Preliminary evidence suggested that fluorodeoxyglucose (FDG) single-photon-emission computed tomography (SPECT) or PET scans may identify primary lesions that would not otherwise be identifiable.[13,14] Theoretically, tumor cells have a higher metabolic rate than normal tissues, and therefore, take up more FDG so that they appear "hot" on a PET or SPECT scan. If an FDG-SPECT or PET scan is obtained as part of the workup, it should be performed before panendoscopy so that any suspicious areas of increased uptake can be biopsied.

BOX 39-1 Diagnostic Algorithm

GENERAL

History
Physical examination
Careful examination of the neck and supraclavicular regions
Examination of oral cavity, pharynx, and larynx (indirect laryngoscopy with a flexible endoscope)

RADIOGRAPHIC STUDIES

Chest roentgenogram
Computed tomography (CT) or magnetic resonance imaging (MRI) scans of head and neck (special attention to nasopharynx, pharynx, and larynx)

LABORATORY STUDIES

Complete blood cell count
Blood chemistry profile

DIRECT ENDOSCOPY AND DIRECTED BIOPSIES

Nasopharynx, both tonsils, base of tongue, both pyriform sinuses, and any suspicious or abnormal mucosal areas
Ipsilateral tonsillectomy
Fine needle aspirate (FNA) or core-needle biopsy of the cervical node

Limited data pertaining to the usefulness of FDG-SPECT and FDG-PET scans suggest these procedures may identify the primary site in a relatively small subset of patients.[15-17] The FDG-SPECT scan was the sole procedure that correctly identified the occult primary site in only 1 of 26 patients (4%) at our institution (Table 39-1).[10] Similarly, FDG-PET was the only means of detecting a primary site in none of 21 patients at the University of Florida (Table 39-2).[10] Currently, FDG-PET-CT scans are not routinely obtained at our institution as part of the diagnostic evaluation of these patients. When obtained, they may be useful in detecting distant metastases in patients with advanced neck disease and for evaluating suspicious cervical lymph nodes in areas that would otherwise not receive definitive RT, as opposed to a moderate dose employed for suspected subclinical disease.

Direct laryngoscopy with fiberoptic endoscopic visualization under general anesthesia is performed with directed biopsies of the nasopharynx, tonsils, base of tongue, and pyriform sinuses, and of any abnormalities noted on CT or MRI or suspicious mucosal lesions observed during endoscopy. A subset of patients will have the primary tumor site discovered at direct laryngoscopy. The likelihood of discovering the primary site is related to whether or not a suspected (but not definite) primary site is discovered on physical examination or radiographic evaluation (Table 39-3).[10] Most suspected primary sites are detected by pretreatment radiographic workup as opposed to physical examination.

An ipsilateral[10,15,18] tonsillectomy should be performed in patients who have not had a prior tonsillectomy and who have adequate lymphoid tissue remaining in the tonsillar fossa. Although some authors recommend a bilateral tonsillectomy,[19] the likelihood of finding the primary site in the contralateral tonsil for patients with ipsilateral neck nodes is probably quite low. Lapeyre et al[18] reported 87 patients who were evaluated between 1969 and 1992 and underwent a unilateral tonsillectomy; 26% of patients were found to have a tonsillar cancer. Seventy-nine of 236 patients who were evaluated as the University of Florida underwent a tonsillectomy at the time of direct laryngoscopy; the primary site was detected in the tonsil in 35 patients (44%).[10] The likelihood of detecting the primary site was related to whether there were suspicious findings on physical examination or radiographic evaluation (Table 39-4).[10]

Fifty-eight primary head and neck cancers were found in 126 of 236 patients (53%) in the University of Florida series.[10] The most common primary sites were tonsillar fossa (59 patients, 45%) and base of tongue (58 patients, 44%).[10] The reason for the decreased likelihood of detecting cancers in other sites may be that they are found on physical examination with fiberoptic endoscopy and on radiographic evaluation.[7,20,21] In contrast, it is still difficult to discern a small primary cancer hidden in the lymphoid tissue of the tonsillar fossa or tongue base.

PRIMARY THERAPY AND RESULTS

Treatment Techniques and Algorithm

Treatment options range from treatment of the involved neck alone with a neck dissection or RT to irradiation of the suspected primary site and both sides of the neck followed by evaluation for a planned neck dissection.[22-24] Although treatment of the potential mucosal primary site and contralateral neck appears to reduce the risk of a local regional recurrence, the impact on survival is modest at best. Therefore, patients with a single positive node without extracapsular extension may be treated with a neck dissection alone and followed closely, provided that the neck was not violated with an open procedure prior to surgery.[25-27]

If RT is indicated to treat the involved neck, we usually irradiate the nasopharynx and oropharynx, as well as both sides of the neck (Figure 39-1, *A*).[1] Although it may be tempting to irradiate the involved neck alone or combined with RT to the ipsilateral mucosal sites deemed to be at risk, the base of tongue is a midline structure that probably harbors the undetected primary site as often as the tonsillar fossa, so it has been our policy to treat the entire oropharynx.[28] Failure to do so is likely associated with an increased risk of a local regional recurrence and further RT would be complicated by the initial treatment.[29] It is not necessary to irradiate the oral cavity unless the patient has submandibular (level I) adenopathy, in which case we either do a neck dissection and observe the patient or irradiate the oral cavity and oropharynx. At one

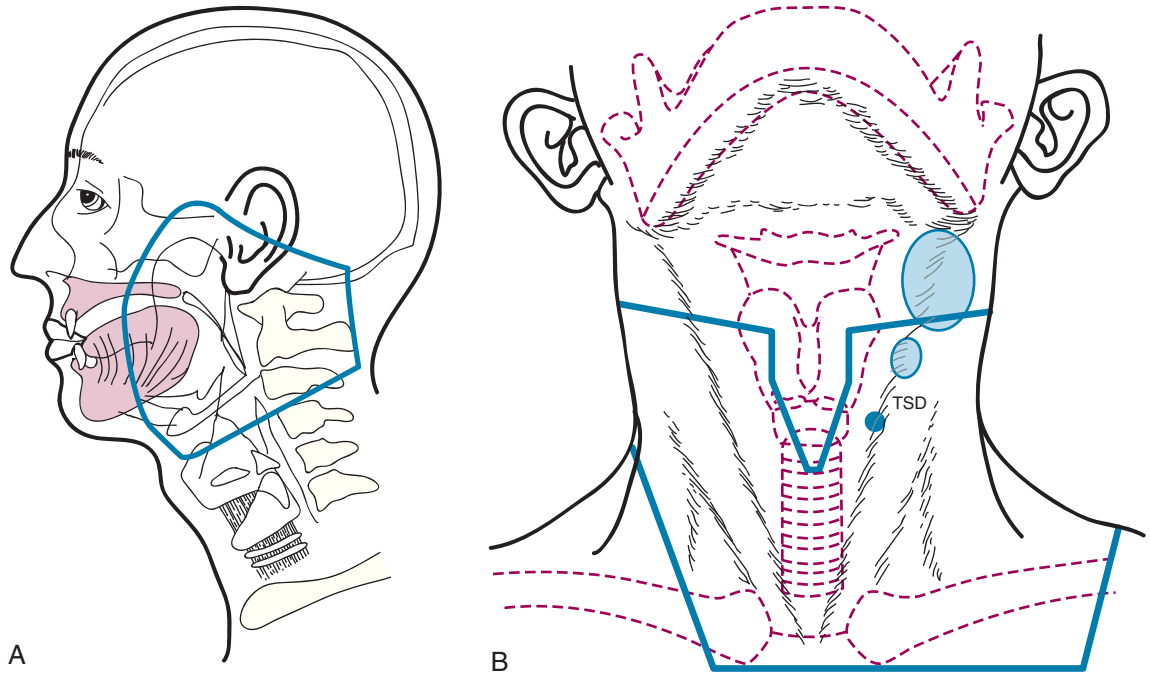

Figure 39-1 **A,** Radiation treatment technique for carcinoma from an unknown primary site. Superiorly, the portal treats the nasopharynx and the jugular (level II) and spinal accessory (level V) lymph nodes to the base of skull. The posterior border is behind the spinous process of C2. The inferior border is at the thyroid notch. Antero-inferiorly, the skin and subcutaneous tissues of the submentum are shielded, except in the case of advanced neck disease. The anterior tongue margin is set so as to obtain a 2-cm margin on the base of tongue and tonsillar fossa, as well as the nasopharynx. One portal reduction is shown (reduce off spinal cord). **B,** Fields for bilateral lower neck radiotherapy. The larynx shield should be carefully designed. Because the internal jugular vein lymph nodes (level III) lie adjacent to the posterolateral margin of the thyroid cartilage, the shield cannot cover the entire thyroid cartilage without producing a low-dose area in these nodes. A common error in the treatment of the lower neck is to extend the low neck portal laterally out to the shoulders, encompassing lateral supraclavicular lymph nodes that are at negligible risk while partially shielding the high-risk midjugular lymph nodes with a large rectangular laryngeal block. The inferior extent of the shield is at the cricoid cartilage or first or second tracheal ring; the shield must be tapered because the nodes tend to lie closer to the midline as the lower neck is approached. Lateral borders of the low-neck portals are set to cover only the lymph nodes in the root of the neck when the risk of low-neck disease on that side is small (i.e., stage N0 or N1 disease). If there are clinically positive lymph nodes in the lower neck or if major disease is present in the upper neck, the lateral border of the low-neck field is widened on that side to cover the entire supraclavicular region out to the junction of the trapezius muscle with the clavicle. *TSD,* Target-to-skin distance.
***A,** From Mendenhall WM, Mancuso AA, Amdur RJ, et al: Squamous cell carcinoma metastatic to the neck from an unknown head and neck primary site. time, it was our policy to irradiate the larynx and hypopharynx, but because the likelihood of a primary tumor in these sites is low, and because the morbidity of irradiating these areas is significant, we modified our technique in approximately 1997.[28] It could be argued that the nasopharynx should also be eliminated from the primary treatment volumes. However, the incidence of positive retropharyngeal nodes is relatively high in patients presenting with advanced neck disease[30] so that the volumes must include the skull base (jugular foramen and retropharyngeal nodes) and at least part of the nasopharynx. It is our belief that a modest increase in the size of the treatment volumes to adequately irradiate the nasopharynx does not significantly increase morbidity.

Patients are treated with parallel-opposed fields at 1.8 Gy per fraction to a midline dose of 64.8 Gy with reduction off the spinal cord at 45-Gy tumor dose (see Figure 39-1, *B*).[31] The lower neck is treated through a separate en face anterior field. Treatment is administered with cobalt-60, 4-MV x-rays, or 6-MV x-rays. Dosimetry is obtained at the level of the central axis (which usually corresponds to the oropharynx) and the nasopharynx. The dose to the nasopharynx is usually 3 Gy to 5 Gy lower than the central axis. Currently, the majority of radiation oncologists obtain a multilevel three-dimensional dosimetric analysis to evaluate the dose delivered to the clinical target volume (CTV), planning target volume (PTV), and organs at risk (OARs). Patients with ipsilateral nodes may be treated with intensity-modulated radiotherapy (IMRT) to reduce the dose to the contralateral parotid (≤26 Gy mean dose) to reduce the likelihood of long-term xerostomia. Patients with bilateral-positive nodes are better treated with parallel-opposed fields to reduce the risk of a marginal miss.[32] Patients with advanced, fixed adenopathy undergo a boost to the involved part of the neck using anteroposterior wedged beams to a total dose in the range of 70 Gy to 75 Gy. Concomitant chemotherapy should be considered for patients with N2 and N3 neck disease. Our preference is to use weekly cisplatin (30 mg/m^2) or cisplatin 100 mg/m^2 every 3 weeks for two cycles.[33]

Treatment of the neck depends on the extent and location of the adenopathy. Patients with N1 and early N2B neck disease located in the high-dose fields may be treated with irradiation alone if the nodes have resolved completely.[34-36] Similarly, if the patient has undergone an excisional biopsy of a single positive node, the neck may be treated with radiation alone with a 95% likelihood of neck control.[37] Patients undergo a CT scan of the neck 1 month after completing RT at our institution and the decision whether to proceed with neck dissection depends on the likelihood that viable tumor remains in the neck.[38-40] The criteria employed for determining whether a neck dissection should be performed are outlined in Table 39-5.[38,40] Because the likelihood of cure is low if a regional recurrence develops in a clinically positive neck after treatment with radiotherapy alone, we usually proceed with a modified neck dissection if the risk of residual disease exceeds 5%.[41] In practice, patients with N2-N3 neck disease and those with gross disease neck disease after an open neck biopsy often undergo a planned neck dissection after radiation therapy.[36,42]

The treatment algorithm is depicted in Figure 39-2.

Results

One hundred thirty-six patients were treated at the M. D. Anderson Hospital between 1968 and 1992 and had a median duration of follow-up of 8.7 years.[43] Both sides of the neck and potential head and neck mucosal primary sites were irradiated. A mucosal head and neck cancer developed in 14 patients (10%); 6 of the 14 cancers were located in unirradiated sites. Recurrent disease in the neck developed in 12 patients (9%). The 5-year cause-specific survival rate was 74%.

The incidence of subsequent mucosal primary lesions was compared by Erkal et al[44] for patients with a known primary site and a series of 126 patients treated for an unknown primary site at the University of Florida. The incidence for both groups was similar at 5 years, suggesting either that mucosal irradiation significantly reduced the risk of primary site failure or that patients with unknown primary sites have a much lower risk of a second primary head and neck cancer developing subsequently (Figure 39-3).[44] The 5-year absolute and cause-specific survival rates for the 126 patients with an unknown primary were 47% and 67%, respectively. The 5-year outcomes stratified by N-category are shown in Figures 39-4, *A-D*.[44]

Reddy and Marks[29] reported 52 patients treated to the neck alone (16 patients) or to the neck and potential head and neck primary sites (36 patients). Failure in the head and neck mucosa occurred in 44% of those who underwent treatment to the neck alone, compared with 8% in those who underwent irradiation of the head and neck mucosa ($p = 0.0005$). The 5-year survival rates were similar for the two treatment groups.

Grau et al[45] reported 273 patients treated with curative intent at five cancer centers in Denmark between 1975 and 1995 with surgery alone (23 patients), RT to the ipsilateral neck alone or combined with surgery (26 patients), and RT to the neck and head and neck mucosa alone or combined with

From Erkal HS, Mendenhall WM, Amdur RJ, et al: Squamous cell carcinomas metastatic to cervical lymph nodes from an unknown head-and-neck mucosal site treated with radiation therapy alone or in combination with neck dissection. Int J Radiat Oncol Biol Phys 50(1):55-63, 2001.[44]

surgery (224 patients). The ipsilateral oropharynx unintentionally received some irradiation in patients treated to the ipsilateral neck alone, depending on the treatment technique.[45] The 5-year rates of freedom from failure in the head and neck mucosa were as follows: surgery alone, 45%; RT with or without surgery to the ipsilateral neck, 77%; and RT to the head and neck mucosa with or without surgery 87%. Failure in the oropharynx, particularly the base of tongue, was the most common location of mucosal site failure.

Complications

The main complication of radiation therapy for patients treated for an unknown head and neck primary tumor is xerostomia. The likelihood of long-term problems with altered taste or difficulty swallowing is relatively low. IMRT may be used to reduce the dose to the contralateral parotid gland so long as the patient does not have bilateral clinically positive neck nodes. It is difficult to limit the dose to the parotid if there are positive nodes in the same side of the neck without risking underdosing the adenopathy and increasing the risk of a marginal miss.[32] The risk of bone exposure, radiation myelitis, or radiation-induced malignancy is low.

The complications of neck irradiation include subcutaneous fibrosis and lymphedema of the larynx and submentum. The latter complications may be minimized by sparing an anterior strip of skin when designing the parallel-opposed lateral portals used to encompass the suspected primary site. This will also reduce the risk of desquamation, particularly in patients who receive concomitant chemotherapy. A 5-mm-wide midline block in the en face low-neck field may also diminish the likelihood of postirradiation edema. The probability of complications is directly related to radiation dose and volume.

Complications of neck dissection include hematoma, seroma, lymphedema, wound infection, wound dehiscence, chyle fistula, damage to cranial nerves VII, X, XI, and XII, carotid exposure, and carotid rupture. The incidence of complications after neck dissection is probably higher when the operation follows a course of radiation therapy.

The incidence of postoperative complications in a series of 143 patients treated with radiation to the primary lesion and neck followed by unilateral neck dissection was 23%.[36] Seventeen patients (12%) required a second operation and four patients (3%) experienced fatal complications.[36] The incidence of complications was higher for maximum subcutaneous doses higher than 60 Gy. Taylor et al[46] updated the University of Florida experience with an analysis of the incidence of moderate (2+) and severe (3+) wound complications in a series of 205 patients who underwent a planned unilateral neck

dissection after radiation therapy. Radiation therapy was given once daily in 123 patients, twice daily in 80 patients, and with both techniques in the remaining 2 patients. The incidence of wound complications tended to increase with total dose and dose per fraction.

CONCLUSIONS

The diagnostic evaluation of patients with squamous cell carcinoma of the head and neck from an unknown primary site includes multiple head and neck examinations by experienced examiners, FNA of the neck node, CT from the skull base to the clavicles, direct laryngoscopy and biopsies, and an ipsilateral tonsillectomy. The primary site will be detected in approximately 40% to 50% of patients and will be located in the oropharynx in more than 80% of patients. The management of these patients is controversial. Treatment usually includes irradiation of both sides of the neck (levels II, III, IV, and V) and the potential mucosal primary sites. The likelihood of 5-year survival is approximately 50% and is related to the extent of disease in the neck.

ACKNOWLEDGMENTS

The authors thank the research support staff of the Department of Radiation Oncology for their preparing the manuscript for publication.

CHAPTER

40 Management of the Neck

Vincent Grégoire, Thierry P. Duprez, Benoît Lengelé, and Marc Hamoir

Assessment and treatment of regional lymph nodes in the neck are of utmost importance in the management of patients with head and neck squamous cell carcinoma (HNSCC). The philosophy of treatment of the neck has evolved over the past several decades. Radiation oncologists and head and neck surgeons progressively realized that extensive treatments were associated with more morbidity but not always with a better oncologic outcome than less extensive procedures. Today, a comprehensive approach to the treatment of the neck needs to be multidisciplinary, taking into account the patient's quality of life without jeopardizing cure and survival. A better understanding of the patterns of lymph node metastasis promoted the use not only of selective dissection but also of selective irradiation in selected patients. Concepts are still evolving; for example, the need and extent of postconcomitant chemoradiation neck node dissection continues to be evaluated.

In this chapter, the discussion will be limited to management of the neck for oral cavity, oropharyngeal, hypopharyngeal, and laryngeal squamous cell carcinoma.

ANATOMY OF THE LYMPHATIC SYSTEM OF THE NECK

The head and neck region has a rich network of lymphatic vessels draining from the base of the skull through the jugular nodes, spinal accessory nodes, and transverse cervical nodes to the venous jugulosubclavian confluence or the thoracic duct on the left side and the lymphatic duct on the right side.[1,2] A comprehensive anatomic description of this network was made by Rouvière more than 50 years ago.[1] The whole lymphatic system of the neck is contained in the celluloadipose tissue delineated by the aponeurosis enveloping the muscles, vessels, and nerves (Figure 40-1). The lymphatic drainage is mainly ipsilateral, but structures such as the soft palate, tonsils, base of the tongue, posterior pharyngeal wall, and especially the nasopharynx have bilateral drainage. On the other hand, sites such as the true vocal cord, paranasal sinuses, and middle ear have few or no lymphatic vessels at all. The nomenclature of head and neck lymph nodes has been complicated by various confusing synonyms that are still in use in major textbooks and articles. Several expert bodies have proposed the adoption of systematic classifications aimed at standardizing the terminology. Following the description by Rouvière, the TNM (primary tumor, regional nodes, metastases) atlas proposed a terminology that divides the head and neck lymph nodes into 12 groups.[3] In parallel to this classification, the Committee for Head and Neck Surgery and Oncology of the American Academy for Otolaryngology–Head and Neck Surgery has been working on a classification (the so-called Robbins classification), dividing the neck into six levels, including 8 node groups.[4] This classification is based on the description of a level system that has been used for a long time by the Head and Neck Service at the Memorial Sloan Kettering Cancer Center (MSKCC).[5] Because one of the objectives in developing the Robbins classification was to create a standardized system of terminology for neck dissection procedures, only the lymph node groups routinely removed during neck dissection were considered. The terminology proposed by Robbins was recommended by the International Union Against Cancer (UICC).[6] Recently a task force comprising worldwide opinion leaders in the field of head and neck radiation oncology reviewed and updated the previously published guidelines on nodal level delineation, and came up with a proposal corresponding more closely with the TNM atlas (Table 40-1).[7] The major advantage of this new proposal (the so-called modified from Robbins classification) over the TNM terminology is the definition of the boundaries of the node levels. The delineation of these boundaries is based on anatomic structures such as major blood vessels, muscles, nerves, bones, and cartilage that are easily identifiable on computed tomography (CT) or magnetic resonance (MR) axial imaging sections. The anatomic boundaries are oriented to a patient lying in a supine position with the neck in a neutral position.

Level Ia is a unique median region that contains the submental nodes. The lymph nodes are located in a triangular region limited anteriorly by the platysma muscle, posteriorly by the mylohyoid muscles, cranially by the symphysis of the mandible, caudally by the hyoid bone, and laterally by the anterior belly of the digastric muscle. The medial limit of level Ia is virtual because the region continues into the contralateral level Ia. Nodes in level Ia drain the skin of the chin, mid lower lip, tip of the tongue, and anterior floor of the mouth. Level Ia is at greatest risk for harboring metastases from cancer arising from the floor of the mouth, anterior oral tongue, anterior mandibular alveolar ridge, and lower lip. *Level Ib* contains the submandibular nodes located in the space between the inner side of the mandible laterally and the digastric muscle medially, from the symphysis menti anteriorly to the submandibular gland posteriorly. The submandibular nodes receive efferent lymphatics from the submental lymph nodes, lower nasal cavity, hard and soft palate, maxillary and mandibular alveolar ridges, cheek, upper and lower lips, and most of the anterior tongue. Nodes in level Ib are at risk for developing metastases from cancers of the oral cavity, anterior nasal cavity, soft-tissue structures of the mid-face, and submandibular gland.

Level II contains the upper jugular lymph nodes located around the upper one third of the internal jugular vein (IJV) and upper spinal accessory nerve. It extends from the insertion of the posterior belly of the digastric muscle to the mastoid cranially to the carotid bifurcation (a surgical landmark) or the caudal border of the body of the hyoid bone (a clinical landmark) caudally. Level II can be further subdivided into level IIa and IIb by the posterior edge of the internal jugular vein. Level II receives efferent lymphatics from the face, parotid gland, and submandibular, submental, and retropharyngeal nodes. Level II also directly receives the collecting lymphatics from the nasal cavity, pharynx, larynx, external auditory canal, middle ear, and sublingual and submandibular glands. The nodes in level II are therefore at greatest risk for harboring metastases from cancers arising from the nasal cavity, oral cavity, nasopharynx, oropharynx, hypopharynx, larynx, and major salivary glands. Level IIb is more likely associated with primary tumors arising in the oropharynx or nasopharynx and

TABLE 40-1 Comparison between the TNM Atlas for Lymph Nodes in the Neck and the Guidelines of the Lymph Node Levels Modified from Robbins

TNM Atlas Terminology		Robbins–Modified Node Levels	
Group No.	**Terminology**	**Level**	**Terminology**
1	Submental nodes	Ia	Submental group
2	Submandibular nodes	Ib	Submandibular group
3	Cranial jugular nodes	II	Upper jugular group
4	Middle jugular nodes	III	Middle jugular group
5	Caudal jugular nodes	IVa IVb	Lower jugular group Medial supraclavicular group
6	Dorsal cervical nodes along spinal accessory nerve	V Va Vb	Posterior triangle group • upper posterior triangle nodes • lower posterior triangle nodes
7	Supraclavicular nodes	Vc	Lateral supraclavicular group
8	Prelaryngeal and paratracheal nodes	VI VIa VIb	Anterior compartment group: • anterior jugular nodes • prelaryngeal, pretracheal, and paratracheal nodes
9	Retropharyngeal nodes	VII VIIa VIIb	Prevertebral compartment group • retropharyngeal nodes • retrostyloid nodes
10	Parotid nodes	VIII	Parotid group
11	Buccal nodes	IX	Buccofacial group
12	Retroauricular and occipital nodes	X Xa Xb	Posterior skull group • retroauricular and subauricular nodes • occipital nodes

No., *Number.*

is less frequently involved in tumors of the oral cavity, larynx, or hypopharynx.

Level III contains the middle jugular lymph nodes located around the middle third of the IJV. It is the caudal extension of level II. It is limited cranially by the caudal border of the body of the hyoid bone and caudally by a plane in which the omohyoid muscle crosses the IJV (a surgical landmark) or by the caudal border of the cricoid cartilage (a clinical landmark). Level III contains a highly variable number of lymph nodes and receives efferent lymphatics from levels II and V and some efferent lymphatics from the retropharyngeal, pretracheal, and recurrent laryngeal nodes. It collects the lymphatics from the base of the tongue, tonsils, larynx, hypopharynx, and thyroid gland. Nodes in level III are at greatest risk for harboring metastases from cancers of the oral cavity, nasopharynx, oropharynx, hypopharynx, and larynx.

Level IVa contains the lower jugular lymph nodes located around the inferior third of the IJV from the caudal limit of level III to a limit set arbitrarily 2 cm cranial to the sternoclavicular joint, caudally. Level IVa receives efferent lymphatics primarily from levels III and V, some efferent lymphatics from the retropharyngeal, pretracheal, and recurrent laryngeal nodes, and collecting lymphatics from the hypopharynx, larynx, and thyroid gland. Level IVa nodes are at high risk for harboring metastases from cancers of the hypopharynx, larynx, thyroid, and cervical esophagus. Rarely metastases from the anterior oral cavity may manifest in this location with minimal or no proximal nodal disease. *Level IVb* contains the medial supraclavicular lymph nodes located in the continuation of level IVa down to the cranial edge of the sternal manubrium. Level IVb receives efferent lymphatics primarily from levels IVa and Vc, some efferent lymphatics from the pretracheal, and recurrent laryngeal nodes, and collecting lymphatics from the hypopharynx, esophagus, larynx, trachea, and thyroid gland. Level IVb nodes are at high risk for harboring metastases from cancers of the hypopharynx, subglottic larynx, trachea, thyroid, and cervical esophagus.

Level Va and Vb includes the lymph nodes of the posterior triangle group. This group includes the lymph nodes located along the lower part of the spinal accessory nerve and the transverse cervical vessels. It extends from a plane crossing the cranial edge of the body of the hyoid bone to a plane crossing the cervical transverse vessels caudally. The distinction between the upper posterior triangle (level Va) and the lower posterior triangle (level Vb) allows lymph node involvement of the lower two thirds of the spinal accessory nerve chain to be differentiated from that of the transverse cervical vessel chain.[8,9] A horizontal plane defined by the caudal edge of the cricoid cartilage separates these two compartments. The demarcation between the posterior end of level IIb and the uppermost part of level Va has still not been clearly defined. From an anatomic point of view, the uppermost part of level Va includes lymph nodes belonging to the occipital region (see level Xb).[10] Thus, it was proposed to use the hyoid bone as a radiological landmark to define the cranial limit of level Va. Level Va and Vb receives efferent lymphatics from the occipital and postauricular nodes and from the occipital and parietal scalp, skin of the lateral and posterior neck and shoulder, nasopharynx, oropharynx (tonsils and base of the tongue) and the thyroid gland. Level Vb lymph nodes are at high risk for harboring metastases from cancers of the nasopharynx, oropharynx, and thyroid gland. Nodes in level Va are more often associated with primary cancers of the nasopharynx, oropharynx, or cutaneous structures of the posterior scalp, whereas those in level Vb are more commonly associated with tumors arising in the thyroid gland.

Level Vc contains the lateral supraclavicular nodes located in the continuation of the posterior triangle nodes (level Va and Vb) from the cervical transverse vessels down to a limit set arbitrarily 2 cm cranial to the sternal manubrium, that is,

a similar limit than the caudal border of level IVa. It corresponds partly to the area known as the "the supraclavicular fossa" also called the *triangle of Ho*, which was clinically defined in the mid-1970s before the era of CT for the neck staging of nasopharyngeal carcinoma.[11] Level Vc receives efferent lymphatics from the posterior triangle nodes (level Va and Vb) and is more commonly associated with nasopharyngeal tumors.

Level VI lymph nodes contains the anterior compartment nodes including superficially, the anterior jugular nodes (level VIa), and in the deep previsceral space, the prelaryngeal, pretracheal and paratracheal (recurrent laryngeal nerve) nodes (level VIb). *Level VIa* is contained between the anterior edges of the sternocleidomastoid muscles. It is limited cranially by the caudal limit of level Ib, caudally by the cranial edge of the sternal manubrium, anteriorly by the platysma, and posteriorly by the anterior surface of the infrahyoid muscles. These nodes mostly drain the integuments of the lower face and anterior neck. Consequently, their treatment should only be addressed in lower lip tumors and in advanced gingivomandibular carcinomas invading the soft tissues of the chin. Level VIb is contained between the two common carotid arteries. Its most cranial part comprises two to three inconstant infrahyoid nodes, which rest on the thyrohyoid membrane and drain the anterior floor of mouth, tip of the tongue, and lower lip. Consequently, for all other primary tumor locations, it is proposed to set the cranial limit of level VIa at the caudal edge of the body of the thyroid cartilage. *Level VIb* is limited caudally by the cranial edge of the sternal manubrium. Level VIb receives efferent lymphatics from the anterior floor of mouth, the tip of the tongue, the lower lip, the thyroid gland, the glottic and subglottic larynx, the hypopharynx, and the cervical esophagus. These nodes are at high risk for harboring metastases from cancers of the lower lip, the oral cavity (floor of mouth and tip of the tongue), the thyroid gland, the glottic and subglottic larynx, the apex of the piriform sinus, and the cervical esophagus.

Level VIIa contains the retropharyngeal nodes, which lie within the retropharyngeal space, extending cranially from the upper edge of the first cervical vertebrae to the cranial edge of the body of the hyoid bone caudally. Typically, retropharyngeal nodes are divided into a medial and a lateral group. The lateral group lies medial to the internal carotid artery and lateral to a line parallel to the lateral edge of the longus capiti muscle. The medial group is an inconsistent group of one to two lymph nodes intercalated in or near the midline. Retropharyngeal node receives efferent lymphatics from the mucosa of the nasopharynx, the Eustachian tube, and the soft palate. These nodes are at risk of harboring metastases from cancers of the nasopharynx, the posterior pharyngeal wall, and the oropharynx (mainly the tonsillar fossa and the soft palate). *Level VIIb* contains the retrostyloid nodes, which are the cranial continuation of the level II nodes. They are located in the fatty space around the jugulo-carotid vessels up to the base of skull (jugular foramen). Retrostyloid nodes receive efferent lymphatics from the nasopharyngeal mucosa and are at risk of harboring metastases from cancers of the nasopharynx and from any other head and neck primary with massive infiltration of upper level II nodes through retrograde lymph flow.

Level VIII contains the parotid node group, which includes the subcutaneous preauricular nodes, the superficial and deep intraparotid nodes, and the subparotid nodes. These nodes extend from the zygomatic arch and the external auditory canal down to the mandible. The parotid group nodes receive efferent lymphatic from the frontal and temporal skin, the eyelids, the conjunctiva, the auricle, the external acoustic meatus, the tympanum, the nasal cavities, the root of the nose, the nasopharynx, and the Eustachian tube. They are at risk of harboring metastasis from cancers of these regions but especially from tumors of the frontal and temporal skin, the orbit, the external auditory canal, the nasal cavities, and the parotid gland.

Level IX contains the malar and buccofacial node group, which includes inconsistent superficial lymph nodes around the facial vessels on the external surface of the buccinator muscle. The buccofacial nodes receive efferent vessels from the nose, the eyelids, and the cheek. They are at risk of harboring metastases from cancers of the skin of the face, the nose, the maxillary sinus (infiltrating the soft tissue of the cheek), and the buccal mucosa.

Level Xa contains the retroauricular (also called *mastoid*) and subauricular nodes, which include superficial nodes lying on the mastoid process from the cranial edge of the external auditory canal cranially to the tip of the mastoid caudally. The retroauricular nodes receive efferent vessels from the posterior surface of the auricle, the external auditory canal, and the adjacent scalp. They are at risk of harboring metastases mainly from skin cancers of the retroauricular area. *Level Xb* contains the occipital lymph nodes, which are the cranial and superficial continuation of the level Va nodes up to the cranial protuberance. Level Xb nodes receive efferent vessels from the posterior part of the hair-bearing scalp and are at risk of metastases from skin cancers of the occipital area.

IMAGING OF THE NECK

The armamentarium available for the imaging workup of the metastatic cervical lymph nodes includes CT, magnetic resonance imaging (MRI), ultrasonography, and positron emission tomography (PET).[12] Nodal imaging is mandatory in a pretreatment workup because clinical assessment of the nodal status in patients with a thick or small neck has a low sensitivity and because deeply located nodes remain inaccessible in all patients.[13]

CT and MRI are standard cross-sectional imaging modalities through which anatomic "slices" of the entire neck depict the contours and internal structure of the nodes (Figures 40-2 and 40-3). MRI may have an advantage over CT scanning because of the higher spontaneous contrast it distinguishes between fatty and non-fatty tissues. The multiplanar capability of MRI has been an advantage of this technique since its introduction into clinical use in the early 1980s. However, the multirow detector technology and the spiral acquisition modality of newer-generation CT systems have boosted the multiplanar reformatting capabilities of CT scans, which now equal those of MR images. The major criteria for nodal malignancy using CT or MRI include the size of the nodes (a short axis longer than 10 mm) and the presence of a central necrosis (hypodensity on CT images; hypointensity on T1-weighted MR images and hyperintensity on T2-weighted MR images). Central necrosis is well highlighted by intravenous contrast agent perfusion, which enhances nodal areas with arterial blood supply on both CT and MR images (see Figures 40-2, *A*, and 40-3, *C*). However, the two techniques share common weaknesses: the inability to detect micrometastatic deposits within normal-sized nodes (false-negative results) and the risk for inappropriate classification of malignancy in nodes that are enlarged by benign reactive changes (false-positive results). Thus far, neither MRI nor CT can provide perfect diagnostic accuracy for nodal metastatic workup. It has been shown in a large series of patients that the two techniques have an almost similar and unsatisfactory performance.[14]

Ultrasonography has long been regarded as a low-cost, widely available, and innocuous alternative to CT/MRI, with the additional advantages of color Doppler flow–encoded

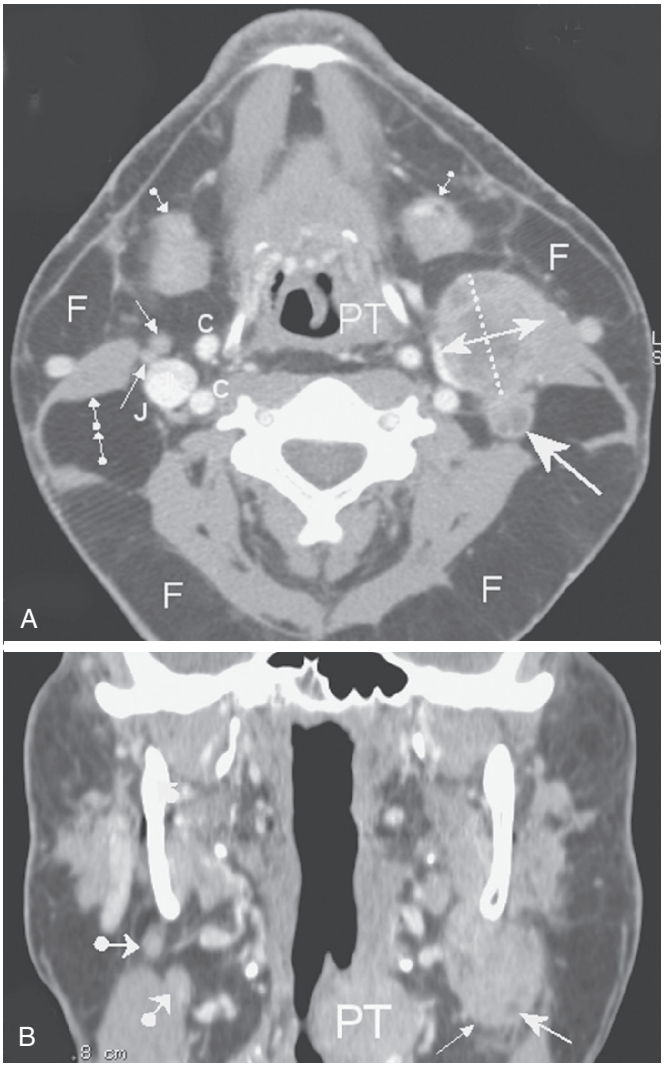

Figure 40-2 CT nodal display in a patient with left oropharyngeal squamous cell carcinoma (SCC). **A,** Native contrast-enhanced slice in the axial transverse plane using multislice multirow detector (MSMD) spiral acquisition technique. Hypodense fatty (F) environment allows clear delineation of the neck structures. Left oropharyngeal SCC (PT) is present. Abnormal nodes are seen within the left level II region, with anterior adenomegaly (long axis of 26 mm is shown as *dotted line*; short transverse axis of 18 mm is shown between the *double-ended arrow*) and a posterior, normal-sized node showing necrotic hypodensity *(thick arrow).* Normal-sized contralateral nodes are indicated *(thin arrows).* Observe the isodensity of the submandibular glands *(ball-arrowhead)* and of the muscles *(double ball-arrowhead).* Jugular veins (J) and carotid arteries (C) are strongly opacified at this early second phase of biphasic iodinated contrast agent perfusion. Notice the lamination of the left internal jugular vein by adenomegaly. **B,** Reformatted image in the coronal plane from the same three-dimensional data set shows the primary tumor (PT), left metastatic adenopathy, and contralateral, normal-sized nodes *(ball-arrowhead).* Observe the irregularities of the inferior aspect of the enlarged node, suggesting extranodal spread *(thin arrow)* and hypodense foci corresponding to necrotic areas within adenomegaly *(thick arrow).*

vascular architecture depiction and fine-needle aspiration guidance. However, time demands and operator skill requirements are limiting factors, as well as the unresolved technical difficulties of fusing two-dimensional ultrasound data and three-dimensional CT/MRI data for radiotherapy planning. Ultrasound is also less efficient than CT and MRI at detecting nodal necrosis,[15] and deeply located nodes may be poorly accessible to the technique.

Research is under way to improve the diagnostic accuracy of MRI, including experimental lymphophilic contrast agents, magnetization transfer imaging (MTI), free water diffusion-weighted imaging (DWI), magnetic resonance spectroscopy (MRS), and bolus tracking perfusion-weighted imaging (PWI).[16-18] Currently, only the DWI MR technique has made a definite breakthrough in clinical routine by yielding fast-to-acquire and easy-to-process accurate quantitative data that significantly add to pretherapeutic nodal staging attempts,[19-21] early prediction of therapeutic response,[22] and posttreatment early detection of residual/recurrent tumor.[23] Many think that molecular imaging probes targeting either specific membrane antigens or metabolic pathways of tumor cells could be the definitive contributors to perfect diagnostic accuracy in nodal metastatic workup, in which case MRI and PET will be competitors.

PET using fluorodeoxyglucose (FDG) as a tracer has become the most available technique for "metabolic imaging" by enhancing foci of increased glucose uptake. However, PET alone provides only restricted diagnostic accuracy. The limitations of PET can be offset by coregistering the information on anatomic CT or MR images[24] (Figure 40-4). Integrated PET/CT combines the poor anatomic localization of PET with the accurate morphologic data provided by CT. The results of a recent large, prospective study showed that FDG-PET significantly improved the staging of HNSCC because of its detection of metastatic or additional disease.[25] However, a recent meta-analysis totaling 1236 patients demonstrated that the accuracy of FDG-PET was only marginally superior to that of CT or MRI. This study calls into question the routine value of FDG-PET for nodal staging.[26] In addition to research on dedicated tissue-specific MR contrast agents, research is under way on PET radiopharmaceutical tracers that would allow the assessment of hypoxia, angiogenesis, apoptosis, and receptor status. These studies make up the second main field of research in oncology imaging.[27] Using anatomic imaging studies to detect tumor recurrences in previously treated primary sites is unsatisfactory because extensive unspecific posttherapeutic changes may mask small foci of neoplastic recurrence.[28] On the other hand, promising data have been reported with the use of FDG-PET in this setting.[29] Similar concepts apply to nodal metastases, and it may be possible that molecular and metabolic imaging methods will also become standard in nodal relapse detection. The key imaging concept for the radiation oncologist's day-to-day practice is the capability of superimposing PET/MRI metabolic and molecular mapping onto CT/MRI anatomic images to improve the delineation of the irradiation target.[30] PET-CT and PET-MRI fusions are the founding paradigms that have now emerged into the clinical routine[31] (see Figures 40-3 and 40-4).

STAGING OF NECK NODE METASTASES

The seventh edition (2009) of the American Joint Committee on Cancer (AJCC) staging for neck node metastases[32] is presented in Table 40-2. This classification does not apply to nasopharyngeal, thyroid, or skin cancers. The classification for nodal staging applies whether the modality used for neck assessment is clinical examination or imaging. The routine use of CT or MRI and—in expert hands—ultrasound is recommended especially for assessing nodes not clinically identifiable (e.g., retropharyngeal, intraparotid, or superior mediastinal nodes) or for patients for whom clinical palpation of the neck is less sensitive (e.g., those who have a thick or small neck).[33] Last, it should be emphasized that the Nx

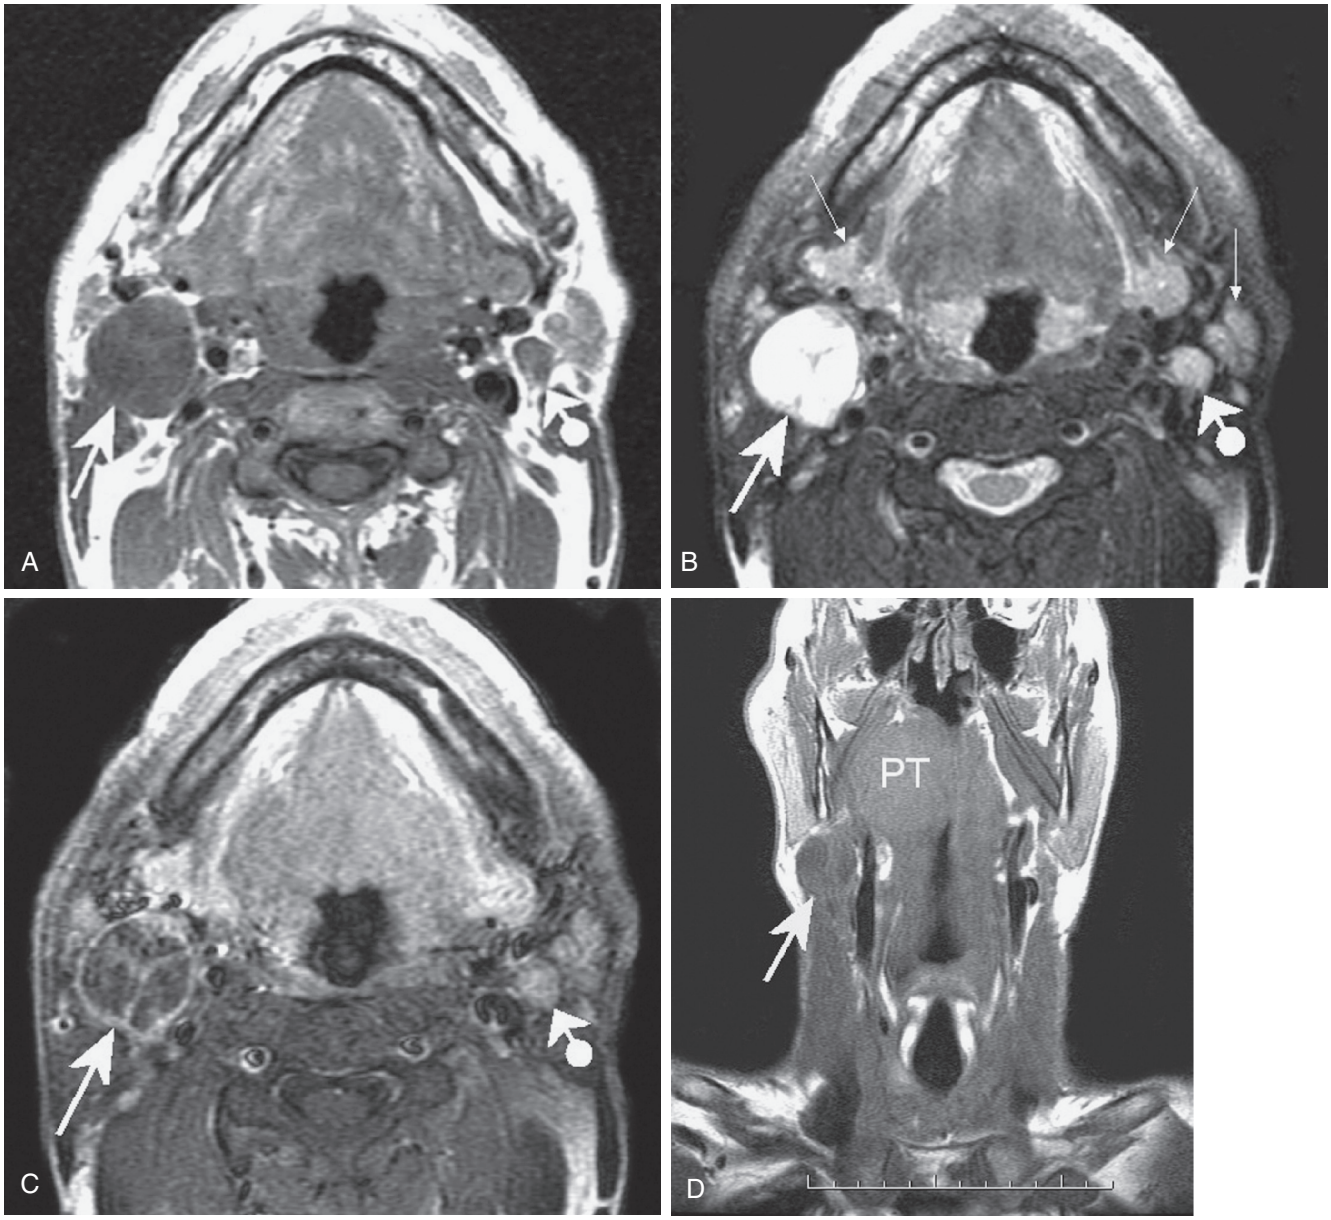

Figure 40-3 Magnetic resonance nodal display in a patient with right oropharyngeal squamous cell carcinoma (SCC). **A,** Transverse, unenhanced, T1-weighted spin-echo (SE) image showing a left level II hypointense necrotic adenopathy *(arrow)* with a normal contralateral node in level II *(ball-arrowhead).* **B,** Transverse, T2-weighted fast spin-echo (FSE) image with fat suppression option in a similar slice location discloses strong hyperintensity of the necrotic node due to fluid-like content *(arrow)* compared with the normal contralateral node, which displays the usual intermediate to high signal intensity *(ball-arrowhead).* Observe the almost similar signal intensity of the normal node and of the parotid and submandibular glands *(thin arrows).* **C,** Transverse, contrast-enhanced, T1-weighted SE image with fat suppression option in a similar slice location as in **A** and **B** shows only peripheral ring-like enhancement of the margin of the necrotic adenomegaly *(arrow).* The normal contralateral node enhances slightly and homogeneously *(ball-arrowhead).* **D,** Coronal view, precontrast, T1-weighted MR image shows a primary tumor *(PT)* and hypointense necrotic adenopathy *(arrow).*

classification applies only when the neck has not been assessed or could not be assessed.

INCIDENCE AND DISTRIBUTION OF NECK NODE METASTASES

Clinical and Radiologic Assessment

The metastatic spread of head and neck tumors into the cervical lymph nodes is rather consistent and follows predictable pathways, at least in the neck that has not been violated by previous surgery or radiotherapy. In Table 40-3, the frequency of metastatic lymph nodes is expressed as a percentage of patients who are node-positive.[34,35]

The frequency of neck node metastases and the distribution of clinically involved nodes depend to a major extent on the primary tumor site. Typically, hypopharyngeal tumors have the highest propensity for nodal involvement, which occurs in 70% of cases. Cranial and anterior tumors (e.g., oral cavity tumors) mainly drain into levels I, II, and III, whereas more caudally located tumors (e.g., laryngeal tumors) mainly drain into levels II and III and, to a lesser extent, levels IV and V.

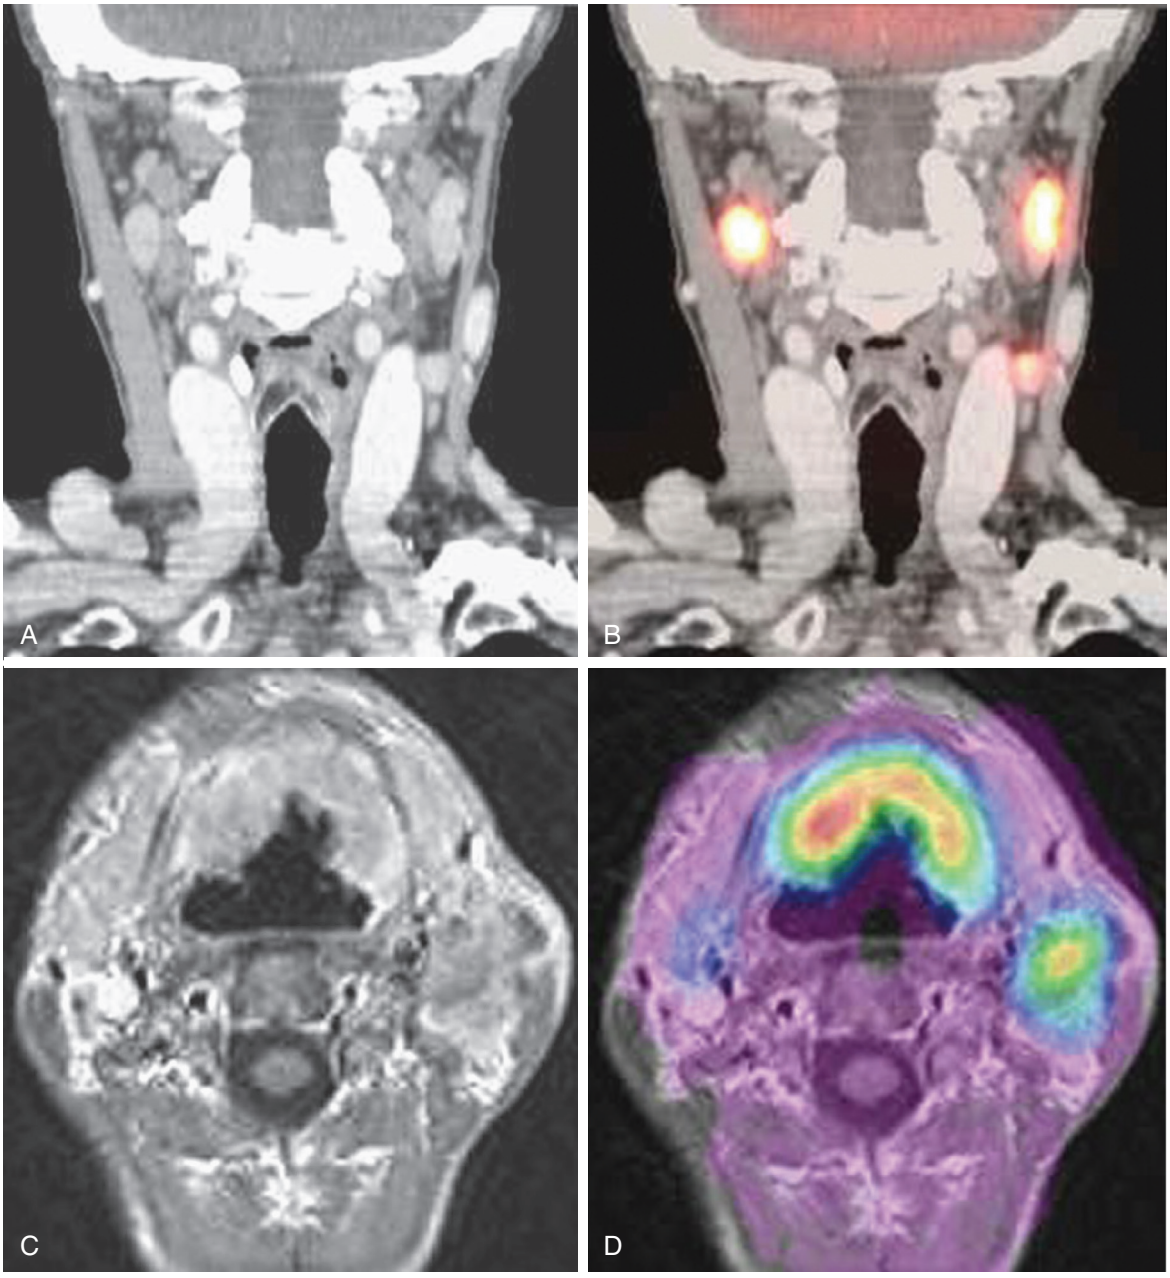

Figure 40-4 CT-MRI-PET image fusion. **A,** Postcontrast, reformatted CT image in the coronal plane shows bilateral, mildly enlarged metastatic nodes in the carotid-jugular chains. Tumoral involvement of the nodes remains speculative because of the borderline short-axis diameter and absence of obvious necrotic changes. **B,** Superimposition of ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) data on a CT image demonstrates increased glucose uptake within the nodes. **C,** Postcontrast, T1-weighted, axial transverse MR image from three-dimensional gradient-echo acquisition using spoiled gradients (SPGR) shows bilateral anterior, horseshoe-sized oropharyngeal tumor and metastatic left-sided nodes in level II. **D,** Superimposition of FDG-PET data on an MR image demonstrates increased glucose uptake within the primary tumor and metastatic nodes. *Courtesy M. Lonneux, MD, PhD.*

Contralateral nodes are rarely involved except for midline tumors or tumors in sites where bilateral lymphatic drainage has been reported, such as the soft palate, base of the tongue, and pharyngeal wall. Even in these tumors, the incidence of contralateral involvement is much lower; in base-of-tongue tumors with clinically positive nodes, the rate is 31% in the contralateral level II nodes compared with 73% in the ipsilateral level II nodes (data not shown). Node distribution follows the same pattern in the contralateral neck as in the ipsilateral neck. Except for nasopharyngeal tumors, involvement of ipsilateral level V nodes is rather rare, occurring in less than 1% of oral cavity tumors, in less than 10% of oropharyngeal and laryngeal tumors, and in about 15% of hypopharyngeal tumors. It almost never occurs in contralateral level V nodes.

Metastatic lymph node involvement in the neck depends on the size of the primary tumor, increasing with the T category. In the series reported by Bataini et al,[34] 44% of patients with a T1 tumor had clinical lymph node involvement; this increased to 70% for patients with T4 lesions. There are, however, no data suggesting that the relative distribution of involved neck levels varies with the T category.

Retropharyngeal lymph nodes represent a special entity because they are usually not clinically detectable. The incidence of retropharyngeal lymph node involvement can be estimated only from series in which CT or MRI of the retropharynx has been systematically performed as part of the diagnostic procedure. Retropharyngeal node involvement occurs in primary tumors arising from (or invading) the mucosa of the occipital and cervical somites, such as the nasopharynx, pharyngeal wall, and soft palate (Table 40-4). The incidence of retropharyngeal lymph node involvement is higher in patients in whom involvement of other neck node levels has also been documented.[18,36,37] However, in patients with clinical stage N0 nasopharyngeal tumors and, to a lesser extent, in patients with pharyngeal wall tumors, the incidence of retropharyngeal node involvement is still significant—between 16% and 40%. Also, as already described for the other lymph node levels, involvement depends on the T category and is typically lower for T1 tumors.

TABLE 40-2 American Joint Committee on Cancer Staging for Neck Node Metastasis

Category	Definition
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral node, ≤3 cm in greatest dimension
N2a	Metastasis in a single ipsilateral node, >3 cm but ≤6 cm in greatest dimension
N2b	Metastasis in multiple ipsilateral nodes, ≤6 cm in greatest dimension
N2c	Metastasis in bilateral or contralateral nodes, ≤6 cm in greatest dimension
N3	Metastasis in a lymph node >6 cm in greatest dimension

Pathologic Lymph Node Metastases

The distribution of pathologic lymph node metastasis in patients with primary tumors of the oral cavity, oropharynx, hypopharynx, and larynx can be derived from retrospective series in which a systematic radical neck node dissection was proposed as part of the initial treatment procedures.[41-44] Retrospective series are essentially biased regarding patient and treatment selection, but these series from the Head and Neck Department at MSKCC are the largest and most consistent data ever published on that matter. The results of these retrospective studies are shown in Tables 40-5 and 40-6. The data are presented in terms of the number of neck dissections with positive lymph nodes divided by the total number of neck dissection procedures and expressed as a percentage. Most patients (>99% for patients with N0 tumors and 95% for patients with N+ tumors) had unilateral treatment only, and

no distinction between the ipsilateral and contralateral neck was made.

Overall, metastatic disease was detected in 33% of the prophylactic neck dissections and in 82% of the therapeutic neck dissections. In these series, the overall sensitivity and specificity of the clinical examination reached 85% and 62%, respectively. As already observed with the pattern of clinical metastatic lymph nodes, the distribution of pathologically confirmed metastatic lymph nodes depended on the primary tumor site. Typically, in patients with clinical stage N0 oral cavity tumors, metastatic lymph nodes were observed in levels I to III, and in patients with clinical stage N0 oropharyngeal, hypopharyngeal, and laryngeal tumors, in levels II to IV. This pattern of node distribution is similar to that determined from the clinical palpation of the neck. It should be noted that the T-category distribution was different in the various groups. Of patients with laryngeal tumors, 54% (42 of 79) had stage T3 to T4 tumors (mainly, supraglottic lesions) compared with 27% of patients with oral cavity tumors (52 of 192), 25% of patients with hypopharyngeal tumors (6 of 24), and 17% of patients with oropharyngeal tumors (8 of 47). Such a difference in T category presumably explains the high incidence of microscopic node metastases in the group with laryngeal tumors.

The pattern of metastatic node distribution in patients who underwent therapeutic neck dissection was similar to that observed in patients with N0 tumors, with the difference that significant pathologic infiltration of an additional nodal level was typically observed—level IV for oral cavity tumors and levels I and V for oropharyngeal, hypopharyngeal, and, to a lesser extent, laryngeal tumors. Overall, this observation illustrates the gradual infiltration of node levels in the neck. This concept is well illustrated by the prevalence of metastases in level V. In the MSKCC series,[45] the prevalence of pathologic infiltration in level V was quite low, averaging 3% in 1277 neck dissections in patients with oral cavity, oropharyngeal, hypopharyngeal, and laryngeal tumors. The prevalence peaked at 11% for hypopharyngeal tumors with pathologically positive nodes (see Table 40-6). A thorough analysis of level V infiltration showed that for all tumor sites pooled together, infiltration of level V without metastases in levels I to IV was observed in only one patient (0.2%). This patient had a hypopharyngeal

tumor. Infiltration in level V remained below 1% when a single pathologically confirmed positive node was also observed in levels I to III, but reached 16% when a single pathologically confirmed positive node was also observed in level IV. When more than one level was infiltrated, the probability of level V involvement progressively increased, reaching 40% when levels I to IV were all involved. The pattern of involvement of level I is also a good illustration of the concept of gradual node infiltration. In the MSKCC series, pathologic involvement of level I was found in only 2% of patients with clinical N0 oropharyngeal tumors and was not observed in patients with clinical N0 hypopharyngeal tumors (see Table 40-6). On the other hand, in patients with clinically positive nodes, metastases in level I were reported in 15% and 10% of patients with oropharyngeal and hypopharyngeal tumors, respectively.

Incidence of Skip Metastases in the Neck

Skip metastases are metastases that do not progress in an orderly manner from one level to the next (e.g., from level I to level II). Depending on their frequency, skip metastases in patients with clinical stage N0 tumors may have a profound implication for the therapeutic management of the neck. In the series from the MSKCC,[44] 8 of 343 patients with clinical stage N0 tumors (2.5%) developed skip metastases. Seven of these patients had oral cavity tumors that metastasized in level IV or V only. One patient had a laryngeal tumor. These low figures are in good agreement with a rate of neck failure outside the dissected levels of 3% (2 of 64 lesions) observed in patients with pathologic N0 lesions treated at the same institution by supraomohyoid neck dissection.[46] Most of these patients had tumors of the oral cavity. None of them received postoperative radiation therapy because they were all free of metastases. Byers et al[47] carefully evaluated the frequency of skip metastases in 270 patients primarily treated by surgery at the M. D. Anderson Cancer Center (MDACC) from 1970 to 1990 for squamous cell carcinoma of the oral tongue. Of these patients, 12 had metastases in level III only, 9 had metastases in level IV only, and 2 had metastases in level IIb (i.e., nodes that are far enough posterior to the internal jugular vein). In addition, in 90 of the patients who had pathologic stage N0 tumors after selective neck dissection of levels I to III and who did not receive postoperative radiation therapy, 9 subsequently developed recurrence in level IV. Altogether (in levels IIb, III, and IV), the frequency of skip metastases reached 12% (32 of 270 lesions). If one excludes the skip metastases in level IIb and III, the frequency reached only 7% (18 of 270 lesions).

Incidence and Pattern of Node Distribution in the Contralateral Neck

There are few data available on the pattern of pathologic node distribution in the contralateral neck. Bilateral neck dissection was performed only when the surgeon thought there was a high risk of contralateral node involvement (e.g., with tumors of the oral cavity or oropharynx reaching the midline or extending beyond it or with hypopharyngeal and supraglottic tumors). Obviously, in such cases bilateral radical neck dissection was never performed, so an accurate estimate of the pattern of node involvement in levels I to V of the contralateral neck is not possible. Furthermore, in almost every study, data on both sides of the neck were pooled for presentation. Kowalski[48] presented data on 90 patients who underwent bilateral supraomohyoid neck dissection and in whom the pattern of node distribution in each side of the neck was reported separately. Most of these patients had squamous cell carcinoma of the lip or oral cavity. In the ipsilateral neck, pathologic infiltration in levels I, II, and III reached 20%, 15%, and 15%, respectively. In the contralateral neck, corresponding values reached 13%, 11%, and 0%, respectively. These figures are in good agreement with data on clinical node distribution showing that both sides of the neck exhibited a similar pattern of node distribution but with a lower incidence in the contralateral neck.

Foote et al[49] reported the rate of contralateral neck failure in a limited series of 46 patients with clinical stage N0 base of the tongue tumors treated by some form of glossectomy and ipsilateral neck dissection. None of these patients received postoperative radiation therapy. Ten patients (22%) had contralateral neck recurrence, and the most common sites were levels II, III, and IV. It appears that in two of these patients, recurrence was also observed at the primary site. The development of delayed contralateral neck metastases was not related to the clinical or pathologic extent of the base of the tongue tumor. O'Sullivan et al[50] reported a retrospective series of 228 patients with tonsillar carcinoma who were treated for the primary tumor and in the ipsilateral neck only with radiation therapy. The vast majority of these patients had T1 to T2 and N0 to N1 disease. Contralateral recurrence in the neck was observed in only 8 patients (2%), including 5 patients with local recurrence as well. No neck failures occurred in the 133 patients with N0 neck classification. Although not significant because of the small number of events, involvement of a midline structure (i.e., soft palate and base of the tongue) appeared to be a prognostic factor for contralateral neck recurrence. Similar results were reported in a series of 101 node-negative tonsil carcinoma (mainly, stage T1 to T3) cases treated unilaterally.[51] Only two neck recurrences were observed in the contralateral neck.

RECOMMENDATIONS FOR SELECTION OF TARGET VOLUMES IN THE NECK

Metastatic lymph node involvement of primary squamous cell carcinoma of the oral cavity, pharynx, and larynx typically follows a predictive pattern. Data on clinical and pathologic neck node distribution as well as on neck recurrence after selective dissection procedures support the concept that not all neck node levels should be treated as part of the initial management strategy of head and neck primaries of squamous cell origin.[52,53] However, the data on which such a concept is based have come from retrospective series and so may include possible biases (e.g., in patient selection, use of a series from the preimaging area, and so on) that could limit their validity.

Tables 40-7 and 40-8 present recommendations for the selection of clinical target volumes in the neck for pharyngolaryngeal squamous cell carcinomas. These guidelines can be applied whether the treatment modality is surgery or radiotherapy. A complete discussion on choosing between these two modalities is beyond the scope of this chapter, but factors to consider include the neck classification, the treatment option for the primary tumor, human papillomavirus (HPV) and Ebstein-Barr virus (EBV) status, the performance status of the patient, and the institutional policy agreed on by a multidisciplinary head and neck tumor board.

Selective treatment of the neck is appropriate for patients with clinical N0 HNSCC of the oral cavity, oropharynx, hypopharynx, and larynx.[46,53,54] Typically, levels Ia to III nodes should be treated for oral cavity tumors, and levels II to IV nodes should be treated for oropharyngeal, hypopharyngeal, and laryngeal tumors. Robbins[8] suggested that elective treatment of level IIb nodes is probably not necessary for patients with clinical N0 primary tumors of the oral cavity, larynx, or hypopharynx. Byers et al[47] suggested that level IV nodes be

included in the treatment of the mobile tongue because of the high incidence (10%) of skip metastases. Retropharyngeal nodes should be treated in tumors of the posterior pharyngeal wall. For subglottic tumors, tumors with subglottic or transglottic extension, or hypopharyngeal tumors with esophageal extension, level VI nodes should also be included in the treatment volume.

As proposed by Byers,[54] similar guidelines could be recommended for patients who have N1 tumors without radiologic evidence of extracapsular infiltration. For hypopharyngeal tumors, however, because of their high lymphophilicity, comprehensive treatment of levels Ib to V may be advisable. When an involved lymph node is located at a boundary of a level that has not been selected for the target volume, it is recommended to extend the selection to include the adjacent level.[55] Typically, this applies only for oropharyngeal tumors with a single lymph node involved in level II at the boundary with level Ib or for an oral cavity tumor with an N1 node in level III at the boundary with level IV.

For patients with multiple nodes (N2b), the available data suggest that adequate treatment should include nodes in levels Ib (Ia for oral cavity) to V. Level Ib nodes could, however, be omitted for laryngeal tumors, and level V nodes omitted for oral cavity tumors with neck involvement limited to levels I to III. Prophylactic treatment of the retropharyngeal nodes should be systematically performed for oropharyngeal and hypopharyngeal tumors. Patients with N0 disease should have level VI nodes treated for subglottic tumors, tumors with subglottic or transglottic extension, or hypopharyngeal tumors with esophageal extension. It has been proposed that patients

with nodes in the upper neck (i.e., upper level II nodes) have the upper limit of the target volume extended to include the retrostyloid nodes (level VIIa).[55] Similarly, the supraclavicular nodes (level IVb) should be included in the target volume in cases of lower neck involvement (i.e., level IV or Vb nodes).[55]

There are no data available on the distribution of pathologic metastatic neck nodes in patients presenting with a single ipsilateral large node (N2a or N3) or with bilateral or contralateral nodes (N2c). For patients with a single large node—in the absence of data—it appears safe not to recommend selective treatment. For N3 disease, the type of treatment of the neck is also likely to be dictated by the local extension of the node into the adjacent structures (e.g., paraspinal muscles, parotid gland, blood vessels). For N2c tumors, one proposal is to consider each side of the neck separately, such as selective treatment on both sides for a small single node on each side, selective treatment for a small single node on one side, and more extensive treatment on the other side in the case of multiple nodes.

Prophylactic treatment of the contralateral neck for N0 disease lack consensus and is likely to be based on clinical judgment rather than on strong scientific evidence. Typically, patients with midline tumors or tumors originating from or extending to a site that has bilateral lymphatic drainage (e.g., the base of the tongue, vallecula, posterior pharyngeal wall) are thought to benefit from bilateral neck treatment, whereas well-lateralized tumors (e.g., the lateral border of the tongue, retromolar trigone, tonsillar fossa) can be spared contralateral treatment. It has also been reported that the risk of contralateral neck metastases increased with involvement of the ipsilateral neck in patients with tumors of the pharynx and larynx.[56] Putting all these data together, it would seem advisable to restrict treatment to the ipsilateral neck for tumors of the lower gum (not approaching the midline), lateral floor of the mouth, lateral border of the mobile tongue, upper gum, cheek, retromolar trigone, tonsillar fossa (without extension to the base of the tongue, soft palate, or posterior pillar), and lateral wall of the piriform sinus. In other situations in which prophylactic contralateral neck treatment is recommended, selection of the node levels to be treated should follow rules similar to those for the ipsilateral neck.

In principle, a similar approach should apply for the definition of the node levels to be irradiated postoperatively. However, if the selection criteria for postoperative radiotherapy are capsular rupture, a metastatic node more than 3 cm in diameter, or more than one metastatic node, then irradiation of levels I to V will typically be performed. As for primary irradiation, the retrostyloid space and supraclavicular fossae should be included in the target volume, depending on the location of the metastatic nodes.[55] For laryngeal tumors, level I nodes could be omitted. For oral cavity tumors with metastatic nodes located in level I or II only, postoperative irradiation of level V could be omitted. Retropharyngeal and paratracheal nodes should be treated as mentioned previously.

NECK NODE DISSECTION PROCEDURES AND SENTINEL NODE BIOPSY

In 1991, based on the definition of the neck level, the Committee for Head and Neck Surgery and Oncology of the American Academy for Otolaryngology–Head and Neck Surgery made several recommendations for neck dissection terminology. The main objective was to develop standardized terminology limited to the use of a few defined procedures in which the lymphatic and nonlymphatic structures removed were unambiguously described. Such recommendations had to correlate with the biology of neck metastases and meet the standards of oncologic principles. The goal of each type of neck dissection is to remove the lymphatic structures (nodes and vessels) that are poorly individualized in the fatty tissue of the neck. When it is oncologically sound, some or all nonlymphatic structures of the neck—such as the internal jugular vein, spinal accessory nerve, sternocleidomastoid muscles, and submandibular glands—may be preserved. Since the 1991 classification, revisions have been proposed; the current neck dissection terminology and definitions[8,9,57-59] are summarized in Table 40-9.

Radical neck dissection (RND), previously considered to be the standard basic procedure, is defined as the resection of lymph node levels I to V, including removal of the sternocleidomastoid muscles, IJV, and spinal accessory nerve.

Modified RND refers to the removal of all lymph nodes routinely resected by RND but sparing one or more nonlymphatic structures (i.e., spinal accessory nerve, IJV, sternocleidomastoid muscles) usually removed during RND (Figure 40-5). Medina[60] subclassified modified RND into three types: type I preserves the spinal accessory nerve only; type II preserves the spinal accessory nerve and sternocleidomastoid muscles; and type III preserves the spinal accessory nerve, sternocleidomastoid muscles, and IJV. Type III is also called by European authors "functional neck dissection," as first described by Suarez[61] and popularized by Bocca et al.[62,63] However, in their classic description, the submandibular gland was not removed.

Selective neck dissection (SND) is dissection with preservation of one or more lymph node levels routinely resected in RND (Figure 40-6). To avoid confusion in terminology for the different subtypes of SND, the 2002 revision of the node

TABLE 40-9 Classification of Neck Dissection: Definitions and Terminology

Type of Neck Dissection	Lymph Node Levels Resected	Nonlymphatic Structures Removed
Radical neck dissection	I, II, III, IV, V	SCM, IJV, SAN
Modified radical neck dissection	I, II, III, IV, V	Preservation of one or more of the following: SCM, IJV, SAN
Selective neck dissection	Preservation of one or more of the following: I, II, III, IV, V. Parentheses are used to denote levels or sublevels removed: SND (I-IV)	None
Extended neck dissection	Resection of one or more or additional lymph node group not routinely removed by radical neck dissection (e.g., parapharyngeal, paratracheal nodes)	Resection of one or more nonlymphatic structures not routinely removed by radical neck dissection (e.g., carotid artery, hypoglossal nerve, overlying skin)

Adapted from Robbins KT: Classification of neck dissection. Current concepts and future considerations. Otolaryngol Clin North Am 31:639–656, 1998.
IJV, *Internal jugular vein;* SAN, *spinal accessory nerve;* SCM, *sternocleidomastoid muscle.*

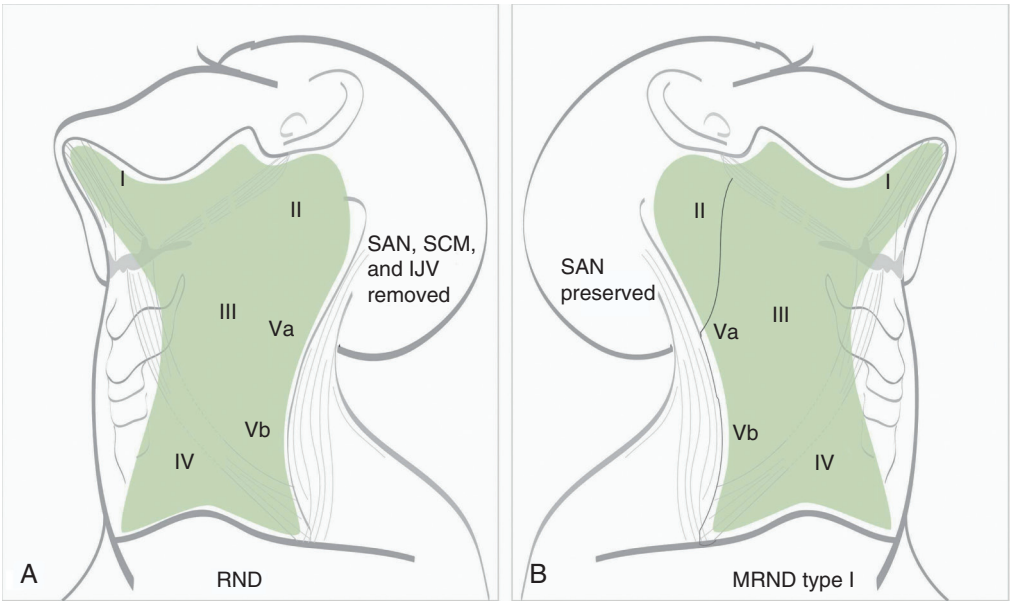

Figure 40-5 Lymph node levels and nonlymphatic structures removed in radical neck dissection **(A)** and modified radical neck dissection type I **(B).** In radical neck dissection for levels I to V, the spinal accessory nerve (SAN), sternocleidomastoid muscle (SCM), and internal jugular vein (IJV) are resected. In a modified radical neck dissection type I for levels I to V, the sternocleidomastoid muscle and internal jugular vein are resected. The spinal accessory nerve is preserved.

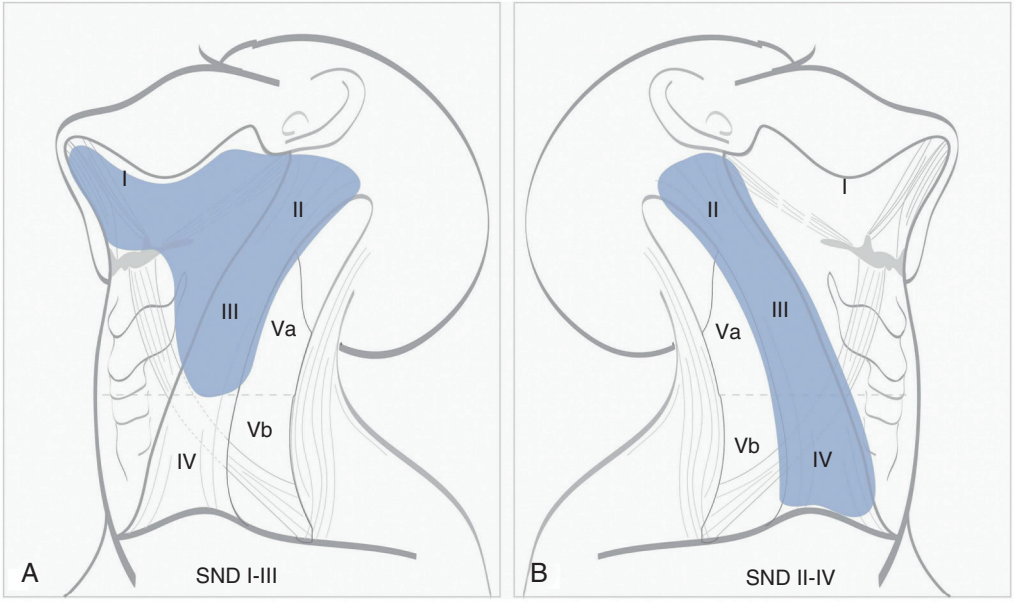

Figure 40-6 Examples of selective neck dissection (SND). In SND I to III or supraomohyoid neck dissection **(A)**, only levels I, II, and III are removed. In SND II to IV or lateral neck dissection **(B)**, only levels II, III, and IV are removed.

dissection classification excluded "named" node dissections (e.g., supraomohyoid node dissection, posterolateral node dissection) and proposed that the term *selective neck dissection* (SND) be followed in parentheses by the node levels or sublevels removed, for example, SND (I to III).[57] Super-selective neck dissection (SSND) is a SND limited to the dissection of two or fewer contiguous neck levels. The feasibility of SSND for residual lymph node disease after chemoradiation was first reported by Robbins et al.[64]

Extended RND is defined by the removal of one or more additional lymph node groups (e.g., parapharyngeal or paratracheal lymph nodes) or nonlymphatic structures (e.g., carotid artery, paraspinal muscles, vagus nerve), or both, nonroutinely resected during a RND. Any additional structures removed should be identified in parentheses.

A method recently introduced in HNSCC for detecting occult micrometastases in the neck is lymphoscintigraphy associated with sentinel lymph node biopsy (SLNB). The concept is based on identification of the primary echelon of lymphatic drainage followed by the harvest of the sentinel lymph node within this basin only, assuming that if the sentinel lymph node is negative, there is no need for a comprehensive neck dissection. The technique was initially proposed for the detection of lymph node invasion in cutaneous melanoma,

and thereafter in various sites.[65-67] SLNB of cervical lymph nodes was introduced as a minimally invasive diagnostic procedure, able to predict more accurately the nodal status in patients who are node-negative with oral and selected oropharyngeal squamous cell carcinoma.[68]

SLNB has been shown to improve staging of clinical N0 (cN0) tumors in patients with early squamous cell carcinoma of the oral cavity and oropharynx by identifying micrometastases.[70,71] Several centers have now adopted SLNB alone as a staging tool for early clinical N0, oral and selected oropharyngeal squamous cell carcinomas.[70] In experienced teams, it is now acknowledged that SLNB is a reliable diagnostic procedure for staging the cN0 neck and identifying patients with occult nodal metastatic disease.[71,72] A recent meta-analysis including 21 prospective studies and 847 patients showed a pooled estimate of sensitivity of 93% and the negative predictive value (NPV) ranged from 80% to 100%. The rate of detection of occult metastases ranged from 14% to 60% (median, 34%). The vast majority of the patients had early oral squamous cell carcinomas.[73] Moreover, it was recently reported in a study including a limited number of patients, that SLNB was associated with significantly less postoperative morbidity as compared to elective neck dissection.[74]

There is evidence supporting further treatment to the neck in patients with micrometastases in sentinel lymph nodes.[77] Regarding isolated tumor cells only, a watchful waiting policy could be warranted, although there is a low risk for metastases in nonsentinel lymph nodes. Larger series are required to establish the importance or significance of micrometastases and isolated tumor cells and to define an acceptable level of incorrectly downstaged isolated tumor cell disease in patients who have other metastases in the neck.

NECK NODE DELINEATION AND IRRADIATION TECHNIQUES

Delineation of the Clinical Target Volume

Several authors have proposed recommendations for the delineation of the neck node levels.[59,78-81] Detailed comparison of these guidelines revealed a few important discrepancies, preventing uniform target volume delineation in the neck among radiation oncologists. A critical review of the two proposals was undertaken in the early 2000s in collaboration with representatives of the major European and North American clinical cooperative groups to generate an international set of guidelines for the delineation of the neck node levels in a node-negative neck.[82] The correspondence between these guidelines and neck dissection procedures was further validated.[83] In the late 2000s, a few amendments were proposed to take into account the specific situation of a node-positive and postoperative neck.[55,84] Most recently, in 2013, a task force comprising opinion leaders in the field of head and neck radiation oncology from European, Asian, Australian/New Zealand, and North American clinical research organizations (DAHANCA, EORTC, HKNPCSG, NCIC CTG, NCRI, RTOG, TROG) was formed to review and update the previously published guidelines on nodal level delineation.[7]

The updated 2014 consensus guidelines for neck node delineation are presented in Table 40-10 and Figure 40-7. The volumes delineated in Figure 40-7 correspond to the clinical target volume (CTV) and do not include margins for organ motion or setup inaccuracy. The boundaries are based on a patient lying supine with the head in a "neutral" position. The terms *cranial* and *caudal* refer to structures closer to the cephalic and pedal ends, respectively. The terms *anterior* and *posterior* were chosen to be less confusing than the terms *ventral* and dorsal, respectively.

It is beyond the scope of this chapter to discuss in depth these recommendations. The reader is referred to the original publication.[7] A few specific issues, however, merit attention.

The proposal for the node level delineation is valid irrespective of the nodal status of the patient, that is, node-negative or node-positive. However the translation from the node levels to CTV delineation may need some adjustments as a function of the nodal status setting. In patients who are node-negative and in patients with a single small lymph node or with several small lymph nodes not abutting one of the surrounding structures (e.g., muscle, salivary gland), the CTV will be defined by the association of one or several of the node levels.

For larger lymph nodes abutting or infiltrating one of the surrounding structures (e.g., sternocleidomastoid muscle, the paraspinal muscles, or the parotid gland), CTV delineation may need to take account of macroscopic and microscopic tumor infiltration outside of the node. Based on experts' opinion, an isotropic expansion by 10 mm to 20 mm into these structures from the visible edge of the node (i.e., the nodal GTV) appears reasonable, excluding bone and airway.[84]

Last, the proposal for the node level delineation still holds for the postoperative situation, at least from a conceptual point of view.

Irradiation Techniques

With the use of three-dimensional conformal radiotherapy (3D-CRT) and intensity-modulated radiotherapy (IMRT), there is no longer a standard recipe for setting up field sizes and borders according to bony landmarks. Instead, the irradiation technique should be selected and adapted so that the entire planning target volume (PTV) receives the prescribed dose within the adopted dose-volume constraints and in full consideration of the International Commission on Radiation Units and Measurements (ICRU) recommendations.[85]

The dose prescription depends on various factors, such as prophylactic versus therapeutic irradiation, or the use of combined-modality treatment, planned neck node dissection, and postoperative irradiation, and so on, which are beyond the scope of this chapter for comprehensive review. For primary radiotherapy, a typical prophylactic dose of about 50 Gy, 54 Gy, or 56 Gy in 2, 1.8, or 1.6 Gy per fraction is given over 5 to 7 weeks, and a therapeutic dose of about 70 Gy in 2 Gy per fraction is given over 7 weeks. For postoperative irradiation, depending on the risk factors, doses usually range from 60 Gy to 66 Gy in 2-Gy fractions over 6 to 6.5 weeks.

CONTROL OF THE N0 NECK

Guidelines generally recommend performing prophylactic treatment of the neck in patients with primary HNSCC clinically staged at N0 but having a probability of 20% or more of occult lymph node metastases.[86] Elective neck dissection and elective neck irradiation are equally effective in preventing disease occurrence in the cN0 neck. The choice between these two procedures generally depends on the treatment modality chosen for the primary tumor and many other factors. However, the basic rule that should govern the choice between surgery and radiotherapy (RT) is to favor a single-modality treatment if possible, avoiding overtreatment. For example, supraglottic laryngectomy with selective neck node dissection is just as effective as primary radiation therapy of the larynx and neck for treating a T1 or T2N0 supraglottic laryngeal tumor. For such a disease stage, the need for postoperative RT quite low. Conversely, for a T3N0 supraglottic laryngeal tumor, a conservative treatment approach with primary RT or concomitant chemoradiation should be favored because of the

The sentinel lymph node can be identified by peritumoral injection of a radioactive tracer. The tracer mimics lymph spread and accumulates in the first-echelon node. With the help of lymphoscintigraphy and a gamma probe, the sentinel lymph node is localized and selectively excised. Histologic evaluation of the sentinel lymph node allows for pathologic staging of the neck. Additionally, lymphoscintigraphy and SLNB provide information on the presence of atypical basins or lymphatic flow that is not predictable and would typically not be addressed by a selective node dissection.[69]

Because sentinel lymph nodes are worked up thoroughly, a high number of occult metastases are revealed. Occult metastases are, by definition, clinical stage N0 neck metastases detected by histologic testing. They are further divided into macrometastases (>2 mm in largest dimension), micrometastases (<2 mm in greatest dimension), and isolated tumor cells.[75-77] Isolated tumor cells are recognized as a separate entity and are single tumor cells or small clusters of tumor cells not more than 0.2 mm in greatest dimension. Such cells are typically detected after immunohistochemical or molecular biologic testing only, and they do not show evidence of metastatic activity (e.g., proliferation or stromal reaction) or penetration of vascular or lymphatic sinus walls.[76] The debate continues whether patients with micrometastases or isolated tumor cells in sentinel lymph nodes have a risk similar to that for patients with metastases in the neck who have clinically invaded lymph nodes.

In conclusion, with a high detection rate and a high sensitivity, SLNB seems clearly an accurate and safe diagnostic modality to detect occult lymph node metastases in early oral cavity squamous cell carcinoma clinically N0. The conclusions of the meta-analysis gathering many studies with a small number of patients need to be validated by large multicenter studies with long-term follow-up. Also, prospective studies are needed to determine whether the implementation of SLNB alone would reduce patient morbidity but still be as effective as SND. In particular, the effect of SLNB on at least one third of patients with a positive SLNB remains an issue because the pathologic status of the SLN is only known a few days after the surgical procedure. Those patients require two surgical interventions instead of one to complete the neck dissection.[72] Some of those patients could have some delay before starting postoperative radiotherapy, when indicated. Furthermore, the morbidity in those patients should be compared with the morbidity in a group of patients who underwent SND electively. Development of rapid analysis of the SLN using molecular biology techniques could solve this issue.

TABLE 40-10 Consensus Boundaries, Node Levels I-X

Level	Boundaries					
	Cranial	**Caudal**	**Anterior**	**Posterior**	**Lateral**	**Medial**
Ia, submental	Mylohyoid m.	Platysma m. (caudal edge of ant belly digastric m.)	Symphysis menti	Body of hyoid bone/ mylohyoid m.	Medial edge of ant. belly, digastric m.	n.a.
Ib, submandibular	Cranial edge, submandibular gland; ant, mylohyoid m.	Plane through caudal edge hyoid bone and mandible; alternatively caudal edge submandibular gland (most caudal); platysma m. Figure 40-7 Head and neck CT sections performed on a 32 year-old volunteer immobilized with a head-neck-shoulder thermoplastic mask. The head was set in a "neutral" position. Sixty mL of iodinated contrast medium (Omnipaque 350, HealthCare, Diegem, Belgium) was injected intravenously at a rate of 1 mL/s, then after a 3-minute gap, another 50 mL were injected at a rate of 1.5 mL/s. The examination was performed on a Toshiba (Toshiba Aquilon LB, Toshiba Medical Systems Corporation, Japan) helicoidal CT (300 mAs and 120 keV) using a slice thickness of 2.0 mm, an interval reconstruction of 2.0 mm and a helicoidal pitch of 11. CT sections were reconstructed using a 512 × 512 matrix. Sections were taken at the level of the top edge of the first cervical vertebra (**A**), the bottom edge of the second cervical vertebra (**B**), midfourth cervical vertebra (**C**), the bottom edge of the sixth cervical vertebra (**D**), midfourth thoracic vertebra (**E**), and top edge of the second thoracic vertebra (**F**). Each node level corresponds to node groups, and thus does not include any security margin for organ motion, patient motion or set-up inaccuracy. 1: common carotid artery; 2: internal carotid artery; 3: external carotid artery; 4: internal jugular vein; 5: external jugular vein; 6: anterior jugular vein; 7: right brachiocephalic trunk; 8: right brachiocephalic vein; 9: left subclavian artery; 10: left subclavian vein; 11: facial vessels; 12: masseter muscle (m.); 13: pterygoid m.; 14: longus capitis m.; 15: longus colli m.; 16: sternocleidomastoid m.; 17: digastric (anterior belly) m.; 18: digastric (posterior belly) m.; 19: platysma m. 20: trapezius m.; 21: splenius capitis m.; 22: scalenus m.; 23: levator scapulae m.; 24: serratus anterior m.; 25: thyrohyoid m.; 26: sternohyoid m.; 27: parotid gland; 28: submandibular gland; 29: thyroid gland; 30: mastoid; 31: styloid process; 32: mandible; 33: maxilla; 34: hyoid bone; 35: odontoid process; 36: second cervical vertebra; 37: fourth cervical vertebra; 38: sixth cervical vertebra; 39: thyroid cartilage; 40: cricoid cartilage; 41: clavicle; 42: first thoracic vertebra; 43: second thoracic vertebra; 44: rib; 45: lung apex; 46: esophagus; 47: Bichat's fat pad; 48: prestyloid parapharyngeal space.

necessity of postlaryngectomy RT and the non-superiority of the surgical approach (Figure 40-8).

Neck Control after Neck Node Dissection

SND has become more widely used despite some concerns that it may not be as effective as a more comprehensive form of neck dissection, such as a modified RND. Anticipating the conclusions that could be drawn from the MSKCC data with regard to the extent of the neck dissection, several groups have been performing SND since the 1950s.[46,48,54,87-97] Such selective neck procedures were initially proposed for patients who were clinically node-negative and later extended to patients who were clinically node-positive. These studies are biased because the patients treated by a selective procedure were probably highly selected with regard to the tumor site, tumor stage, and nodal status. In addition, in most of these patients, postoperative RT was usually performed in the presence of high-risk features for primary tumor or neck recurrence, such as close or positive resection margins, multiple node involvement, large node infiltration, or extracapsular spread. It is likely that the irradiated field encompassed the node levels that were not dissected but that could be at risk for microscopic infiltration.

Originally, SND was typically considered a method for accurately staging neck disease but not one that could affect regional control and survival rates. A retrospective review of 359 patients with stage T1 to T2 N0 squamous cell carcinoma of the oral cavity and oropharynx treated at the University of Pittsburgh showed significant improvement in regional control, disease-free survival (DFS), and regional recurrence-free survival rates for the group of patients who underwent SND along with primary tumor excision as compared with another group of patients who underwent excision of the primary tumor only.[90] The patients who underwent SND were three times more likely to receive postoperative RT, most likely because of identification of adverse prognostic factors in the pathologic specimen. In a prospective randomized trial comparing modified RND and SND (I to III) (supraomohyoid

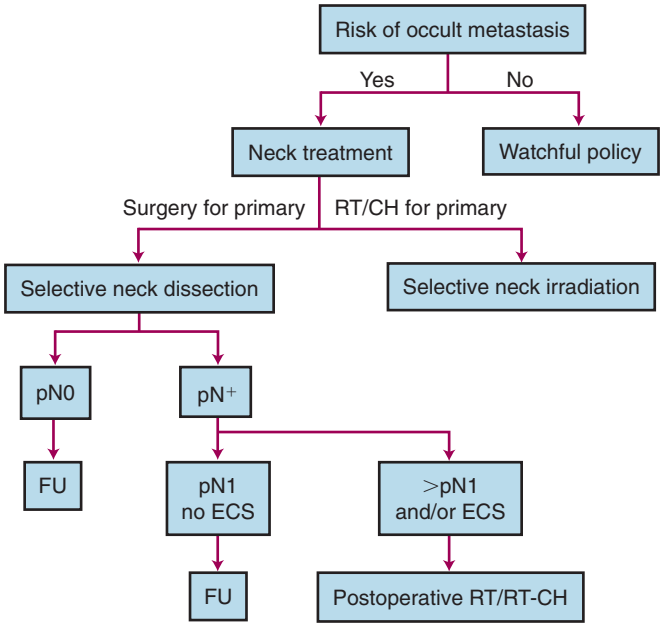

Figure 40-8 Treatment algorithm for clinically negative neck (N0) disease. *ECS,* Extracapsular spread; *FU,* follow-up; *RT,* radiotherapy; *RT-CH,* concomitant chemoradiation.

nodes) for patients who were clinically node-negative with T2 to T4 tumors of the oral cavity, the Brazilian Head and Neck Cancer Study Group was unable to show any difference either in 5-year actuarial overall survival (OS) or in the rate of neck failure.[87] Postoperative irradiation was delivered in cases with a positive margin of the primary tumor or positive lymph nodes. This study is however biased by the fact that patients included in the SND group and found to have a positive lymph node (on frozen section) during the neck dissection were offered a modified RND.

With these limitations in mind, in some of these studies the level of the neck recurrence was reported, allowing an estimate of the failure rate in the neck inside and outside the dissected levels (Table 40-11). In most of these studies, neck recurrence was reported only in patients in whom the primary tumor had been controlled, excluding neck recurrence as a result of reseeding from the recurrent primary tumor. After SND (I to III) or SND (II to IV), the rate of neck failure in nondissected levels was low, typically below 10%. Consequently, SND can be considered the optimal procedure for surgically managing N0 neck disease in patients with a high risk of occult lymph node metastasis.

Neck Control after Radiotherapy

Table 40-12 presents the percentage of neck recurrences in large retrospective series of pharyngolaryngeal squamous cell

TABLE 40-11 Neck Failure after Selective Neck Dissection for Squamous Cell Carcinomas of the Oral Cavity, Oropharynx, Hypopharynx, and Larynx

Author	Year	Site	Clinical Category (AJCC 1980)	Dissected Levels	Neck Failure (Percentage of Patients with Primary Tumor Controlled)		
					Total	Dissected Levels	Undissected Levels
Byers[81]	1988	Oral cavity, oropharynx, hypopharynx, larynx	T1-4 N0	I, I-III, II-IV, I-V	45/299 (15%)[a]	31/299 (10%)	14/299 (5%)[b]

carcinomas treated with conventional fractionated RT.[98-100] Some of the patients reported in these series were treated in the late 1950s, so the data must be interpreted with caution because of the likelihood of large uncertainties about the absolute dose calculation and dose distribution. Altogether, the neck control rates reached more than 92% after radiotherapy. After salvage surgery, the ultimate neck control rate reached a range of 94% to 100%. As expected, because of the high probability of regional control obtained with standard fractionation regimens, altered fractionation regimens or combined chemoradiation regimens did not improve the neck control rates.[101,102] All of these studies were performed using two-dimensional irradiation techniques, that is, with target volumes extending typically from the base of the skull to the clavicles.

With the introduction of 3D-CRT, IMRT, and selective neck irradiation, one important issue is the potential risk of geographic miss outside of the irradiated volumes. Eisbruch et al[103] reported a series of 135 patients treated bilaterally from 1994 to 2002 with 3D-CRT or IMRT for primary tumors located mainly in the oropharynx ($n = 80$) and without node metastasis in the contralateral neck. Of these, 73 patients received postoperative RT, but none had neck node dissection on the contralateral neck. In the contralateral neck, the CTV typically included the levels II to IV and retropharyngeal nodes. For the contralateral level II nodes, the upper limit was set at the junction between the posterior belly of the digastric muscle and the jugular vein. The median prophylactic dose was 50.4 Gy or 50 Gy in fractions of 1.8 Gy or 2 Gy. With a median follow-up of 30 months (range, 6 to 105 months), 15 patients had a regional recurrence (of these, 6 also had a primary tumor recurrence), 11 on the ipsilateral side and 4 on the contralateral side. Only 1 of the 15 patients presented a retropharyngeal node recurrence marginal to the CTV. Using a similar treatment philosophy, Bussels et al[104] did not report any recurrence on the ipsilateral side of the neck with N0 disease treated with parotid-sparing 3D-CRT in a series of 72 patients with oral cavity and pharyngolaryngeal squamous cell carcinoma. Chao et al[105] also looked at the pattern of recurrence in a series of 126 patients treated postoperatively ($n = 74$) or primarily ($n = 52$) for HNSCC by IMRT from 1997 to 2000. In this series, the lower neck (below the thyroid notch) was treated with a "traditional" anterior field. With a median follow-up of 26 months, 17 recurrences (13%) were observed. Six of these patients had recurrence outside of the target volumes, of which only one was in the lower neck of a patient with N0 disease.

CONTROL OF THE N1 TO N3 NECK

Neck Control after Surgery Alone

The surgical management of N1 neck tumors is more controversial (Figure 40-9). Traditionally, a comprehensive neck

dissection (RND and modified RND) has been the surgical standard for patients presenting with neck disease. Andersen et al[106] reported that the rates of regional recurrences in the dissected neck following RND or modified RND type I for N1 or N2 disease were similar. Selective procedures have, however, gained popularity. In the retrospective study by Byers et al,[89] including 517 SND procedures mainly for patients with N0 or N1 neck disease, 50 patients had pathologic N1 disease. Of these patients, 36 received postoperative RT for the presence of risk factors associated either with the primary tumor or the nodal site and only 1 (3%) presented with a regional recurrence. In patients who did not receive irradiation despite the presence of risk factors, 5 of 14 (36%) had neck failure. In a large retrospective review of 296 selective node dissections in levels I to III, Spiro et al[96] reported a rate of regional failure of 6.5% in patients staged with a pathologically positive neck. Most patients with pathologically invaded lymph nodes had postoperative RT. Recently, Schmitz et al[97] reported a regional failure rate of 8% in neck disease of pathologic N1 without better regional control in the necks treated with postoperative irradiation, suggesting that postoperative irradiation is not justified in pathologic N1 neck disease without extracapsular spread. With the inherent limitation of retrospective studies, it appears that SND for patients with limited neck disease is a safe procedure, providing that postoperative irradiation is given in the presence of risk factors for regional relapse.

Despite the use of aggressive single and combined treatment protocols, patients with locally advanced metastatic neck disease still have a poor prognosis because of the high risk of regional failure and distant metastases.[107,108] However, the concept of using a less than radical procedure has gained acceptance even for advanced regional disease. Khafif et al[109] reported the results of 118 patients with N2 to N3 disease treated with RND or modified RND and was not able to find any difference in OS between the two groups. The recurrence rate in the modified RND group increased significantly in comparison with the group of patients treated with standard RND (52% versus 33%), but some modified RND procedures were not really comprehensive. In a study comparing RND and modified RND (type I) in 212 patients with N2 and N3 lesions, the MSKCC group reported an overall 5-year neck control rate of 86% and a 5-year actuarial survival rate of 61%.[106] No difference was found between the two groups. Adjuvant postoperative RT enhances regional control but does not seem to significantly improve survival rates.[110] Investigators of the Royal Prince Alfred Hospital in Sydney, Australia, reported the outcome of 181 patients who had 233 neck dissections for N2 to N3 disease (163 extended RND, RND, or modified RND and 70 SND).[111] Postoperative RT to the neck was given in 82% of the patients. At 5 years, control of disease in the treated neck was achieved in 86%. Adjuvant RT significantly improved neck control rates ($p = 0.004$) but did not alter survival rates.

The utility of extended RND depends on whether acceptable control rates are attainable without prohibitive morbidity. Shaha[112] described the results in 40 patients with N2 to N3 tumors treated by extended RND combined with postoperative RT. The regional control rate reached 70% at 2 years, with one perioperative death. The morbidity of extended RND depends on the additional structure or structures removed. If a common carotid artery is removed, the perioperative mortality rate ranges from 6% to 58%.[113,114] However, when the structures sacrificed are of no major neurovascular significance (e.g., parotid gland lymph nodes, paraspinal muscles), the additional morbidity is minimal.

Neck Control after Primary Radiotherapy

The lower probability of regional control of the positive neck with RT has been documented by several retrospective series performed in the pre-HPV era.[98,100,115] In a series from the Institut Curie in Paris,[98] 1646 patients with squamous cell carcinoma of the oropharynx and pharyngolarynx had a 3-year regional control probability of 98%, 90%, 88%, and 71% for N0, N1, N2, and N3 lesions (AJCC 1976 classification), respectively. The nodal size was an even more discriminating factor, with nodal failure rates of 6%, 14%, and 39% for nodes below 3 cm, between 4 cm and 7 cm, and more than 7 cm, respectively.[115] In this series, 75% of the neck nodes were treated by a form of concomitant boost approach with total doses in the range of 70 Gy to 85 Gy in 5 to 6 weeks. In the series of 458 patients who were node-positive with squamous cell carcinoma of the larynx and pharynx treated at Aarhus University Hospital from 1963 to 1991, the 5-year neck node control rate reached 68%, 68%, and 56% for N1, N2, and N3 lesions (UICC 1982 stage), respectively.[100]

An important issue in the management of positive neck disease by RT is whether these results can be improved by hyperfractionated or accelerated regimens, or concomitant chemoradiation. In randomized studies comparing a standard fractionated regimen with an altered fractionated regimen, no improvement was observed between the two arms[116-118] (Table 40-13). In the European Organization for Research and

Treatment of Cancer (EORTC) 22791 study, only patients with N0 or N1 neck disease were included, and because of the good control of neck disease in the standard arm, it was not surprising that the hyperfractionated regimen did not bring any benefit.[116] In the Danish Head and Neck Cancer Group (DAHANCA) 6 and 7 trials, no significant regional improvement was observed with the accelerated regimen in patients who were node-positive.[117] Similarly, despite a benefit in OS, the Toronto trial did not observe any increase in the control of the neck with an accelerated hyperfractionated regimen.[118] Contrary to results achieved with altered fractionation regimens, concomitant chemoradiation regimens appear to have an impact on the control of disease in the neck[119,120] (Table 40-14). In the study by Calais et al,[119] all neck stages were analyzed together. However, because 75% of the patients were node positive, it is unlikely that the 12% improvement rate resulted only from a beneficial effect in the patients with N0 lesions. In the study by Lavertu et al,[120] which included fewer patients, the improvement in node control was observed for all positive neck categories.

Indications for Postoperative Irradiation or Chemoradiation

The benefit of postoperative RT in HNSCC progressively emerged in the 1970s and 1980s as a standard of care for patients at high risk of locoregional relapse after surgery.[121-124] Prognostic indicators for locoregional relapse after surgery include the primary disease site, surgical margins at the primary site, presence of perineural invasion, number of metastatic lymph nodes, and presence of extracapsular rupture.[125,126] Based on the clustering of these pathologic factors, MDACC proposed to stratify patients into three risk categories, conditioning the need for postoperative RT[127] (Table 40-15). In the absence of any risk factor, the need for postoperative RT could not be shown. Patients with extracapsular rupture or a combination of two or more risk factors were identified as being at high risk of locoregional relapse, and for these patients a randomized study showed the benefit of a radiation dose of 63 Gy (in 35 fractions) as compared with 57.6 Gy (in 32 fractions). For patients with only one risk factor other than extracapsular rupture, a dose of 57.6 Gy was shown to be optimal. A subsequent study from the same group further validated the use of these categories of risk factors and also documented the time between surgery and the start of postoperative RT and the total treatment time (from surgery to the end of RT) as additional risk factors.[128] In this study, it was also shown that patients with a high risk of relapse benefited from accelerated treatment (63 Gy in 5 weeks versus 63 Gy in 7 weeks) in terms of both locoregional control and survival.

With the need to further improve locoregional control rates after surgery and postoperative RT, a few trials combining

TABLE 40-15 Prognostic Factors for Locoregional Relapse after Surgery

postoperative concomitant chemotherapy and RT were reported in the 1990s.[129,130] Although the results favored the combined approach, these studies did not really influence the pattern of care of patients primarily treated with surgery. The European Organization for Research and Treatment of Cancer (EORTC) and the Radiation Therapy Oncology Group (RTOG) conducted similarly designed studies aimed at assessing the benefit of postoperative RT (60 Gy to 66 Gy) combined with cisplatin (100 mg/m^2) given on days 1, 22, and 43 for patients with a variety of risk factors that were slightly different between the two trials.[131,132] In the EORTC study, a highly statistically significant benefit in favor of the combined treatment was observed for both locoregional control and OS (Table 40-16). In the RTOG study, the benefit in locoregional control probability did not translate into a statistically significant difference in survival rates. Combined-modality treatment did not decrease the incidence of distant metastasis in either of these studies. In both studies, the concomitant use of chemotherapy significantly enhanced the acute local toxicity of radiotherapy, and only half the patients could actually receive the full treatment as planned. A meta-analysis of these two studies demonstrated a statistically significant benefit of combined chemoradiation but only in patients who had positive surgical margins or extracapsular spread, that is, patients with the highest risk of relapse after surgery.[133] For the other patients, RT alone can still be considered as a standard of care.

Indications for Postradiotherapy Neck Node Dissection

Advances in chemoradiation for advanced head and neck carcinoma have shown that organ preservation is feasible without compromising DFS and OS.[134,135] This strategy has led to

TABLE 40-16 Efficacy of Concomitant Chemotherapy and Postoperative Radiotherapy

controversial issues concerning the role of node dissection after RT or chemoradiation for patients with N2 to N3 disease at initial diagnosis. A residual neck mass may be present in as many as 30% to 60% of patients after completion of chemoradiation. For these patients, irrespective of the neck category, there was a consensus in the literature favoring an immediate neck node dissection because of the low probability of achieving neck control with salvage surgery when recurrence develops.[136]

Whether a neck dissection should be proposed for all patients with N2 to N3 disease at diagnosis or only for those without a complete response is still a matter of debate.[137-147] That neck dissection could be avoided following complete nodal response to irradiation is a consequence of a better response assessment using imaging,[148] and improved regional control with chemoradiation[119,134,149,150] and with hyperfractionated or accelerated RT.[151,152] There are currently many arguments supporting the position that systematic planned neck dissection is no longer justified in patients without clinically residual disease in the neck,[153] and many institutions have switched to neck dissection for residual disease in the neck only.[137,144,147,154] Improvement in assessing the neck status with imaging (CT, MRI, FDG-PET) has contributed enormously to this change in paradigm.[155-164]

Optimum timing of PET after chemoradiation is crucial and could explain discordant results between series.[163,164] A prospective study conducted by the Ontario Clinical Oncology Group assessing the use of FDG PET-CT at 9 weeks post-RT to detect recurrence following treatment showed that PET-CT yielded high rates of false-negative results.[165] Conversely, studies on postchemoradiation PET performed at 12 to 13 weeks posttreatment showed NPV values of 97% to 100%, and PPV values of 62.5% to 71%, respectively.[166,167] Investigators from the MSKCC confirmed that after chemoradiation, FDG PET-CT reached an NPV of 94% for clinically residual enlarged lymph nodes (≥1 cm), and an NPV of 98% in clinically negative necks.[168] Based on these findings, patients with residual lymphadenopathy and absence of abnormal FDG uptake have a low probability of residual viable tumor cells.

Last, a cost-effectiveness analysis on the use of CT and PET/CT for assessing the need for adjuvant neck dissection was reported comparing three strategies: dissection in all patients, dissection in patients with residual disease on CT scanning, and dissection in patients with residual disease on PET/CT scanning.[169] Probabilistic sensitivity analyses confirmed that the PET/CT strategy was more cost-effective than the other two options. A definite answer on the issue of post-RT neck dissection should come from ongoing prospective studies.

To summarize, balancing the benefit with the increased morbidity of postchemoradiation surgery, current evidence suggests that neck node dissection be restricted to those patients with a noncomplete response after organ-preservation protocol.[153] In this situation, there is a growing evidence to support the approach of using SND even in patients with initial advanced nodal disease and with clinically persistent disease, with less than 5% of subsequent neck failure.[38-40,170,171] More, it has been recently demonstrated that SSND was a reliable surgical option for patients with residual disease confined to a single neck level.[172] In all studies reporting on postconcomitant chemoradiation SND, the rate of major postoperative complications was less than 10% and comparable to the rate of complications observed after primary surgery.[38,141,173-175] Despite the absence of a prospective study comparing SND and SSND with comprehensive node dissection after organ preservation protocols, one would intuitively expect less fibrosis, shoulder dysfunction and neck deformity in patients who underwent limited surgery.

LATE COMPLICATIONS AFTER NECK TREATMENT

Complications of Neck Node Dissection

In addition to the medical complications inherent in any surgical procedure, neck dissection may potentially be associated with some specific perioperative complications and late complications or sequelae. The description of perioperative complications is beyond the scope of this chapter. Readers interested in such topics will find detailed information in a textbook dedicated to head and neck surgery.[176]

Recognized complications after neck dissection include numbness or burning of the neck and ear, neck pain, shoulder discomfort, neck tightness, lower lip weakness, decreased range of motion of the head, neck, and shoulder, lymph edema, cramping and spasms of the neck musculature, and cosmetic disfigurement. In 2001, Shah et al[177] proposed a neck dissection–specific quality-of-life questionnaire used in a series of patients who had undergone neck dissection as part of their treatment.[177] Some of these patients had been previously treated by chemotherapy (25%) or RT (50%). Neck tightness and shoulder discomfort had the greatest effect on quality of life. Advanced tumor stage, often requiring more radical surgery and use of chemotherapy or RT, was associated with a worse quality of life after neck dissection. Overall, the quality of life after neck dissection tends to improve with time.[177]

The most noticeable sequela induced by spinal accessory nerve resection is the decreased ability to abduct the shoulder above 90 degrees. However, any type of neck dissection may result in impairment of shoulder function.[178] Studies reported that preservation of the spinal accessory nerve in modified RND and SND was associated with a better quality of life and fewer shoulder disorders in both the short and long term.[177] Using the University of Washington quality-of-life questionnaire, the Liverpool group reported that little morbidity associated with shoulder dysfunction was observed in patients

Investigators from the University of Florida reported negative predictive value (NPV) of CT scan of 94% to 97% for the detection of residual or recurrent neck metastasis, providing that strict criteria were used.[155-157] In a large Canadian study (n = 363), a NPV of 100% was reported for CT scan using a regression of the initial diameter equal or more than 80% at 6 to 8 weeks postconcomitant chemoradiation.[158] In a previously reported study, the same group has showed that CT assessment of patients with N3 nodes was not adequate.[159] Also, in the studies mentioned previously, the specificity (thus, the positive predictive value) of CT scan was found to be low, around 28%. In this framework, could MRI outperform CT examinations? A meta-analysis showed that CT and MRI were equivalent for the detection of pretreatment lymph node metastases in HNSCC.[160] Diffusion-weighted MRI was recently reported as a better tool than conventional MRI for initial regional staging and for assessment of treatment response early after the end of chemoradiation.[161,162]

The use of FDG-PET scanning has gained growing interest in this setting. In a 2004 study including 41 patients treated with definite RT (with or without concomitant chemotherapy), a negative PET scan after RT was highly correlated with a negative pathologic finding after neck node dissection or fine-needle aspiration, or with the absence of neck relapse (NPV of 100% for maximum standardized uptake values <3.0).[163] In another study including 24 patients staged with FDG-PET after induction chemotherapy followed by chemoradiation, the NPV of a PET scan reached only 73%.[164]

following a unilateral levels I to III or I to IV neck dissection in comparison with patients undergoing primary surgery without neck dissection.[179] However, unilateral neck dissection extending to level V and bilateral SND (I-III or I- IV) were associated with statistically significantly worse shoulder dysfunction. Adjuvant RT seemed to have a detrimental effect on shoulder dysfunction, whether or not the patient had a unilateral SND.

In another series, assessment of patients who underwent neck dissection with or without RT at least 1 year previously revealed that neck pain was present in one third of patients, shoulder pain in 37%, and loss of sensation in 65% (related to the number of dissected levels and to RT).[180] A prospective study on objective assessment after treatment concluded that adjuvant RT had no effect on shoulder joint function and that shoulder disability was inevitable in all types of neck dissections, whether or not the spinal accessory nerve was spared. However, shoulder function was better after SND and modified RND than after RND, although electromyographic findings were similar after either RND or modified RND and SND.[181] The benefit of postoperative physical therapy has been stressed, and it should be started in the early postoperative period after all types of neck dissections.[182]

Complications of Neck Irradiation

Late complications after head and neck irradiation were discussed in the previous chapters. In the following section, only specific complications arising in the soft tissues of the neck will be reviewed. They mainly concern subcutaneous fibrosis, thyroid dysfunction, and carotid artery stenosis. Typically, late complication probability depends on the total dose, dose per fraction, time interval between fractions, volume of normal tissue receiving a high dose, and use of concomitant chemotherapy or a biologic modifier.

The probability of grades-3 to -4 (RTOG late morbidity scale) subcutaneous fibrosis in the neck is rather low after standard RT. From randomized studies performed in the 1990s, it can be estimated at around 3%.[119,152,183,184] After accelerated or hyperfractionated treatments, no increase in grades-3 to -4 subcutaneous toxicity was observed, providing that enough time was allowed between fractions.[152] In an EORTC trial with only a 4-hour interfraction time, a 50% risk of fibrosis was documented at 5 years after treatment.[185] After concomitant chemoradiation, randomized trials reported a substantial increase in late skin morbidity, reaching figures of around 10%.[119]

Clinically indolent hypothyroidism in patients with lower neck irradiation has been reported at rates of up to 24%.[186,187] Most patients usually develop hypothyroidism within 1 year after treatment. Postoperative RT—especially after laryngeal surgery—including partial thyroidectomy, has been shown to be a risk factor. Yearly thyroid function testing (i.e., thyroid-stimulating–hormone level) is advised in the follow-up of patients with irradiation to the neck.

Carotid artery stenosis after neck irradiation has been reported by several authors, but few studies have investigated the incidence, disease patterns, and risk factors including tobacco use, hypertension, hyperlipidemia, diabetes, etc. Matched control Doppler ultrasound examinations have reported significant carotid stenosis in 30% to 50% of patients with previous irradiation to the neck.[188] Compared with the general population, a relative risk of stroke of 5.6 has been reported in patients with previous irradiation to the neck.[189] This relative risk was further increased for patients older than 60 years and with follow-up longer than 10 years. Increased attention to the clinical signs of carotid stenosis together with proper management of the other risk factors (e.g., diabetes, hypertension, hypercholesterolemia, smoking, obesity) should contribute to a decreased incidence of stroke and neurologic sequelae in this patient population.

All of the published data on late complications are from the era before IMRT was available. With the use of modern RT techniques (IMRT), a major reduction in late complications is anticipated, mainly through a reduction in the volume of normal tissue irradiated at a high dose and a reduction of the "uncontrolled" hot spot within or outside of the PTV. More fatigue, headache, and nausea and vomiting have also been reported with IMRT, likely resulting from the irradiation of the posterior fossa.[190] The introduction of IMRT has, however, raised the controversial concern of an increased risk of radiation-induced secondary neoplasms because a larger volume of normal tissue might be irradiated at a lower dose in comparison with standard two-dimensional techniques. Also, depending on the radiation technique used, the delivery of a specified dose to the isocenter from modulated fields may require a longer beam time compared with the same dose delivered to a nonmodulated field. The IMRT treatment plan then results in an increase in the number of monitor units by a factor of two to three, thus increasing the dose outside the boundary of the primary collimator caused by leakage and scattered radiation.[191] As a consequence, the total body dose received may be substantially increased. It is estimated that an additional 0.5% of surviving patients will develop a secondary malignancy as a result of an increased volume of normal tissue receiving a small radiation dose. This number needs to be added to the 0.25% of surviving patients who subsequently develop a radiation-induced malignancy. In all, it is estimated that about 0.75% of surviving patients may develop a secondary malignancy as a result of the switch to IMRT, which is approximately twofold greater than the incidence observed after more conventional RT.[192] Whatever the contribution of IMRT in the induction of secondary cancers may be, we should bear in mind that even if IMRT increases the probability of locoregional control and the potential for increased cause-specific survival, this group of patients experiences comorbidities and increased risk for a second primary tumor associated with their lifestyle. This may decrease the relative importance of radiation-induced secondary malignancies.

MANAGEMENT OF RECURRENT NECK DISEASE

Whether treated by RT, surgery, chemotherapy, or a combination of all three, the prognosis of patients with recurrence of disease in the neck remains abysmal. Recurrent neck disease is quite invariably associated with unfavorable prognostic factors. Extracapsular spread is almost always reported and multiple lymph node levels are frequently involved.[193] Neck disease recurrences are often unresectable because of involvement of the wall of the common carotid artery or the internal carotid artery, the paraspinal muscles, and the cranial nerves. Even when salvage surgery is attempted, the inability to achieve a complete resection with clear margins is generally the rule.

Few studies have specifically addressed the problem of recurrent neck disease following curative treatment in HNSCC. Godden et al[193] retrospectively reviewed the charts of 35 patients with recurrent neck disease after either primary surgery (80% of patients; 50% had postoperative RT and 18 had neck dissection) or primary RT. Recurrence in the neck was managed by neck dissection in 25 patients of whom 18 had postoperative RT. Ten patients (29%) were considered inoperable. Nine of the 18 patients with an initial neck dissection recurred in previously dissected level II. This high rate of level-II recurrence stresses the necessity of adequate training

for surgeons performing neck dissection procedures. In this series, ultimate control of neck disease was obtained in only 5 of the 35 patients and 4-year OS did not exceed 20%.

The likelihood of successful salvage treatment in patients with neck recurrence after primary RT is low. Bernier et al[98] reviewed 116 patients with isolated nodal failure after RT alone for oropharyngeal, hypopharyngeal, and laryngeal carcinoma. Fourteen patients had salvage neck dissection and 18 were reirradiated. Only one patient (1%) was successfully salvaged. In 1999, the University of Florida reviewed the medical records of 51 patients who experienced recurrent disease in the neck only.[194] Of the 18 patients (35%) who underwent salvage treatment, all had subsequent relapse of disease (locally, regionally, or distantly). Control of the neck at 5 years was only 9% for the patients who underwent salvage treatment, which was similar to the rate of neck control for the whole population. For the whole group of patients, absolute and cause-specific survival rates reached 10% at 5 years for both endpoints. However, at 3 years, patients who received salvage treatment had absolute and cause-specific survival rates of 44%. In comparison, none of the 33 remaining patients was alive at 3 years.

More recently, in a series of 540 patients, investigators from two institutions in the Netherlands reviewed the effectiveness of salvage neck dissection for regional pathologic lymphadenopathy after chemoradiation.[195] Patients with neck dissection for residual (persistent lymph node metastases diagnosed within 3 months after treatment) and recurrent regional disease (recurrent lymph node metastases diagnosed at least 3 months after treatment) were included. Sixty-eight patients were considered as unresectable. Salvage neck dissection was performed in 61 patients, 45 for regional residual disease and 16 for recurrent regional disease. In the group of patients who had salvage neck dissection, the 5-year regional control and OS rates were 79% and 36%, respectively. Interestingly, patients with recurrent disease had a better outcome than patients with residual disease. The 5-year regional control was 77% for residual disease and 86% for recurrent disease, but the difference was not statistically significant. In multivariate analysis, recurrent disease and negative surgical margins were shown as significant independent predictors for a better OS. Of note, only 8 of 16 patients who had salvage neck dissection for recurrent disease had histologically positive tumor in the specimen. These results confirm that salvage neck dissection may benefit selected patients with limited recurrence in the neck.

In 2010, the Institut Gustave Roussy reported a series of 93 patients who had recurrence after chemoradiation.[196] Salvage surgery was performed in 40% of these patients, and in this group 2-year OS was 43.4%. Univariate analysis demonstrated that initial stage IV disease and concurrent local and regional failure were significant prognostic factors for poor OS. In the group of patients without initial stage IV disease who had either an isolated regional or tumor recurrence, the 2-year OS reached 83%, whereas it was 0% in the group of patients with initial stage IV and concurrent local and regional failure. These results confirm that salvage surgery should only be proposed to selected patients with isolated resectable treatment failure in the neck.

Few institutions have evaluated salvage treatment with aggressive combined modality approaches that include low-dose reirradiation (preoperative or postoperative with or without concurrent chemoradiation) combined with an attempt at gross resection plus intraoperative radiotherapy (IORT) with either electrons (IOERT) or high-dose-rate brachytherapy (HDR-IORT).[197] Although the series involve small numbers of patients, early results suggest potential improvements in both locoregional control and survival rates compared with those of standard salvage approaches, and further evaluation is warranted.

In summary, most of the patients with regional recurrence are unable to undergo salvage treatment, and when salvage treatment with standard approaches (surgical resection, external beam radiation therapy) is attempted, control of neck disease remains poor. Salvage neck dissection alone should be restricted to patients with limited recurrence of disease in the neck.

CHAPTER

41 Cutaneous Carcinoma

Michael J. Veness and Julie Howle

INCIDENCE

Cutaneous basal cell carcinomas (BCCs) and squamous cell carcinomas (SCCs) are the most frequent cancers worldwide. White populations residing in locations with high level exposure to ultraviolet (UV) radiation, such as Australia and New Zealand and the southern United States, have a particularly high lifetime risk for developing skin cancer.

BIOLOGIC CHARACTERISTICS

The natural history of skin cancers varies widely with the histologic type ranging from tumors with an indolent course and a high cure rate of 90% to 95% (e.g., BCC) to aggressive tumors with high (30% to 50%) mortality rates (e.g., Merkel cell carcinoma [MCC]).

STAGING EVALUATION

After biopsy confirmation, patients should be staged with history and physical examination and, when indicated, blood chemistry, chest radiographs, contrast-enhanced computed tomography (CT), magnetic resonance imaging (MRI), or positron emission tomography (PET)/CT scans.

PRIMARY TREATMENT

Surgery is the primary treatment for most skin cancers. Nonsurgical treatment such as radiotherapy (RT) may be preferable for treating select BCCs and SCCs, particularly on and around the midface (e.g., nose, lower eyelids), lips, and ears because it may result in better functional and cosmetic results than surgery. Topical and locally destructive treatments may also be effective in cases of superficial (1 mm to 2 mm) skin cancer.

ADJUVANT TREATMENT

In patients with BCCs and SCCs, the indications for postoperative (or adjuvant) RT include the presence of close or positive surgical margins, perineural invasion, invasion of bone or cartilage, and extensive skeletal muscle infiltration. Most patients with MCC should be considered for wide-field adjuvant RT. Patients with a high incidence of occult nodal spread may benefit from elective nodal treatment, often wide-field RT that may also encompass the primary site (e.g., high-risk SCC, MCC).

No effective systemic adjuvant therapy is currently available for nonmelanoma skin cancers (NMSCs). The addition of concurrent chemotherapy with RT in select high-risk cases may be considered but is not supported by high-level evidence.

LOCALLY ADVANCED DISEASE AND PALLIATION

Surgery with adjuvant RT is the standard treatment for locally advanced and operable tumors. In certain patients, definitive RT can still offer a reasonable possibility of achieving local control in patients with locally advanced carcinomas who are either medically unable to undergo surgery or whose tumor is technically unresectable.

In patients unsuitable for an extended course of definitive RT, a short course of palliative RT can reduce symptoms for most patients with advanced inoperable cancer or with metastatic masses (e.g., pain, discharge, bleeding).

Cutaneous BCC and SCC are the most common malignancies in the world and occur at epidemic rates in countries such as Australia.[1] Collectively, these two carcinomas account for most (95%) patients with NMSC and are far more common than malignant melanomas (MM), which account for only 5% of all skin malignancies. BCC is the most common type of NMSC, with an incidence of more than twice that of SCC. Other NMSCs that are infrequently encountered include MCC, also known as primary cutaneous neuroendocrine carcinoma, a rare small cell carcinoma originally described by Toker in 1972,[2] adnexal carcinomas such as sebaceous gland carcinomas accounting for less than 1% of all skin cancers,[3] and eccrine carcinomas accounting for less than 0.01% of malignancies of the skin. NMSCs may be disfiguring and associated with local morbidity, and excluding MCC, are rarely lethal.

ETIOLOGY AND EPIDEMIOLOGY

Sun exposure is the main etiologic factor for NMSC particularly in Caucasians, whose skin is susceptible to the chronic carcinogenic effect of UV light.[4] Other, less common etiologic factors include exposure to chemical carcinogens (e.g., arsenic, tar, anthracene, and crude paraffin oil), chronic irritation or inflammation, and ionizing radiation.

The incidence and aggressiveness of SCC and MCC (both immunogenic carcinomas) are markedly increased in individuals with compromised immune function, including patients with non-Hodgkin's lymphoma, chronic lymphocytic leukemia,[5] and organ transplant recipients with iatrogenic immunosuppression.[6] In contrast, the incidence of BCC is not markedly increased and the outcome is similar as for patients who are immunocompetent.

Some genetic syndromes are also associated with a higher risk of developing skin carcinoma. Individuals with xeroderma pigmentosum are prone to developing BCC and SCC at a young age because of defective repair of UV light-induced DNA damage.[7] These patients usually die in their early 20s from disseminated SCC or melanoma. The basal cell nevus syndrome (or Gorlin's syndrome) is a genetic form of BCC inherited through an autosomal dominant gene.[8] Individuals with epidermodysplasia verruciformis tend to develop nodules of SCC within large verrucous plaques in the third and fourth decades of life.

PREVENTION AND SCREENING

Unprotected sun exposure, especially during the summer, is the main determinant for the subsequent development of skin cancer. Children and adolescents should be especially educated in regard to sun protection. The damage of excessive UV exposure is irreversible, but despite this, adults can still reduce their risk by avoiding further excessive UV exposure. Preventive measures to reduce skin cancer include avoidance of sunlight exposure—particularly limiting time spent outdoors between 10 AM and 3 PM—and wearing protective physical barriers, such as hats and clothing. If sun exposure cannot be limited because of occupational, cultural, or other factors, the use of sunscreens that are either opaque or that block UVA and UVB radiation is recommended. The use of tanning booths is also a factor in the risk of developing skin cancer, and guidelines regarding their appropriate use should be followed.

There is limited evidence that screening in the general population reduces the morbidity and mortality of skin cancers.[9] The American College of Preventive Medicine recommends periodic screening, consisting of a total cutaneous examination and a 2-minute to 3-minute visual inspection of the entire integument by an adequately trained physician for high-risk individuals. The risk factors include family history of skin cancer, fair skin, multiple nevi, immunosuppression, and a history of other skin cancers.

CLINICAL MANIFESTATIONS, PATHOBIOLOGY, AND PATHWAYS OF SPREAD

Basal Cell Carcinoma

Clinical Presentation and Pathology

BCC constitutes approximately 80% of all NMSC and is the most common malignancy worldwide. Most BCCs arise on the sun-exposed head and neck (80% to 85%); lesions occur less frequently on the trunk or extremities. Lesions may manifest as an asymptomatic nodule, a pruritic plaque, or a bleeding ulcer that characteristically waxes and wanes.[10,11] Many (up to 40% to 50%) patients treated for BCC develop at least one or more further BCC within 5 years.[12] Careful evaluation of sun-exposed skin should therefore be part of any follow-up examination.

BCC has numerous variants, each of which has distinctive clinical and histologic features and natural history. The characteristics of commonly occurring types are briefly summarized.

Nodular BCC, colloquially referred to as rodent ulcer, is the most frequently observed variant and accounts for approximately 50% of all lesions (Figure 41-1). It arises as a distinct papule that may develop central umbilication, progressing to central ulceration. The margins of this lesion appear pearly (pale and translucent) and contain enlarged capillaries (telangiectasia). Histologic features include the presence of large islands of monomorphous basaloid cells, varying in size and shape, embedded in a fibroblastic stroma in the dermis. The basaloid cells have large, oval hyperchromatic nuclei, scant cytoplasm, and no intercellular bridges. The peripheral cell layer of the aggregate frequently shows palisading, whereas central cells are less organized. Nodular BCC may show a varying degree of pigmentation (blue, brown, or black), depending on the number of melanocytes present in the lesion, and may be difficult to differentiate clinically from MM.[13]

Superficial BCC manifests as red, scaly macules with indistinct margins, usually located on the trunk. It enlarges into a crusted, erythematous patch without induration that may be difficult to differentiate clinically from solar keratosis, psoriasis, SCC in situ, or extramammary Paget's disease. Histologic examination shows multiple foci of buds of neoplastic cells with peripheral palisading originating from the undersurface of the epidermis.[10]

Figure 41-1 A 75-year-old white male with a long-standing nodular basal cell carcinoma occupying the left side of the lower nose with associated destruction and nostril retraction. The margins have a pearly appearance, and there are scattered telangiectasia. He was treated with definitive RT with the understanding that further retraction was likely to follow as the tumor regressed.

Morpheic (sclerosing) BCCs appear as single, flat, indurated, ill-defined macules. The lesions generally have a smooth, shiny surface that becomes depressed as it grows into a plaque. It is characterized histologically by the presence of small groups and narrow strands of basaloid cells embedded in a dense, fibrous connective tissue; there is little peripheral palisading.[14] Perineural invasion (PNI) is often reported to be present.

Infiltrative BCC has an opaque yellowish appearance and blends subtly with the surrounding skin.[14] Histologically, the lesion is characterized by poorly circumscribed spiky cell aggregates in the superficial portion and the main bulk, consisting of strands of neoplastic cells infiltrating the reticular dermis and subcutis.

Biology and Pattern of Spread

The biologic behavior of BCC varies with the histologic type. A superficial BCC may remain stable for a long time or enlarge gradually over many years to become a nodulo-ulcerative variant. Nodular BCC grow slowly over many years by peripheral and deep invasion, particularly along embryonal fusion planes, and PNI. Morpheic and infiltrative BCCs are more aggressive variants that may infiltrate deeper structures. The finding of PNI in BCC is uncommon (2% to 3% of patients), and generally occurs in the setting of recurrent disease or in morpheic histology.[15] Lesions located around the orbit with PNI present may gain access to the orbit via the first or second division of the trigeminal nerve.

High-risk BCC occur in the midface, or so-called H zone (Figure 41-2), which includes the periauricular region,

glabella, medial canthus, nose, nasolabial region, and columella, and contains embryonal fusion planes.[16] The depth of invasion of tumors in this region is frequently underestimated, leading to inadequate surgical excision, especially deep, and a higher rate of local recurrence. Histologic examination often reveals extensive infiltration of deeper structures by small nests of undifferentiated basal cells. This type of lesion may invade the orbit, nose, and maxilla, resulting in significant deformity (Figure 41-3). It should be readily recognized and treated promptly often necessitating extensive surgery with or without adjuvant RT.

BCCs rarely spread to the regional lymph nodes or distant organs with an overall incidence of metastasis less than 0.01%.[17] Most metastases occur in the regional lymph nodes with distant spread usually preceded by regional metastasis. Regional disease typically develops in association with large, ulcerated lesions in the head and neck that have recurred despite treatment.

Squamous Cell Carcinoma

Clinical Presentation and Pathology

SCC arises from epidermal keratinocytes and most commonly develops from skin exhibiting solar (or UV) damage. Actinic (or solar) keratosis (AK) is generally a precursor or premalignant lesion and at least 50% to 60% of all invasive SCCs arise from AK. Despite this, only a few (<5%) AK actually progress to invasive SCC. In a large study of 169 patients with 7784 documented AK, the risk of malignant progression was reported in 2.6% at 4 years.[18] Less frequently, SCC occurs from other preexisting skin lesions, such as arsenic keratosis, a thermal burn scar, or a chronic ulcer. Rarely, it arises from normal-appearing skin.[13]

Clinically, SCC in situ (Bowen's disease) manifests as a soft, erythematous, scaly, well-circumscribed red patch (Figure 41-4). Superficial SCC manifests as a scaly, crusted plaque or ulcer with a verrucous or papillate border, but invasive SCC can manifest as a firm, ulcerated mass with an elevated nodular border. Lesions can often be deeply invasive and progress rapidly in some patients (Figure 41-5).

Microscopically, SCC is composed of strands and sheets of atypical keratinocytes and referred to as SCC in situ when atypical keratinocytes are confined to the epidermis. Superficial SCC represents atypical keratinocyte proliferation

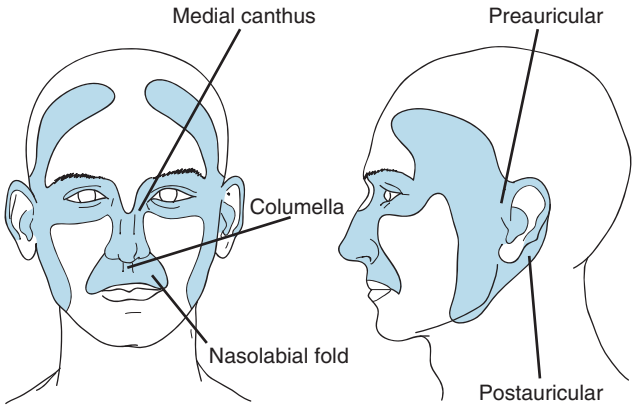

Figure 41-2 Diagram of H zone. Especially problematic areas are the medial canthus, glabella, nasolabial folds, and periauricular region.

Figure 41-4 A 75-year-old male with a large patch of biopsy proven in situ squamous cell carcinoma treated with local RT. Note the dashed green line delineating the RT treatment field with ~1.5-cm margins. The patient received 40 Gy in 10 fractions using superficial energy photons.

Figure 41-3 **A,** A 53-year-old male with a longstanding large and deeply invasive right temple basal cell carcinoma. **B,** He underwent wide local excision and free flap reconstruction and also required adjuvant RT because of a close deep margin.

Figure 41-5 **A,** A 68-year-old bed bound patient presenting with a rapidly enlarging left preauricular invasive squamous cell carcinoma that was poorly mobile over underlying structures. The patient was deemed medically inoperable and treated with wide field definitive RT (55 Gy in 25 fractions using high-energy electrons). Note the wide RT field margins to electively treat clinically uninvolved parotid and upper cervical nodes. **B,** Two months following RT the patient has experienced a complete clinical response to treatment.

confined to the upper reticular dermis, whereas infiltrating SCC denotes disease extension into and beyond the lower reticular epidermis.

Histologically, SCC is graded as well, moderately, or poorly differentiated, based on the degree of cellular polymorphism, keratinization, and mitosis. The spindle cell variant mimics other skin tumors, such as amelanotic melanoma, and may require a panel of immunohistochemical studies for complete characterization.

Biology and Pattern of Spread

SCC generally has a more aggressive course than BCC. SCC in situ (Bowen's disease) may evolve gradually into superficial (microinvasive) carcinoma in ~5% of cases.[19] Untreated, it may progress further into an infiltrating type that invades the surrounding and underlying structures. The rate of progression depends on the degree of cellular differentiation.

The risk of developing metastases, usually nodal, is markedly higher in SCC than in BCC. However, most patients who are immunocompetent with small (<2 cm), thin (<4 mm to 5 mm thick), nonrecurrent lesions are at low (<5%) risk of developing nodal metastases. Patients not meeting these criteria can be considered high-risk patients (>10% risk), and appropriate awareness and management are required.[20] Recurrent lesions in close proximity (forehead, temple, ear, cheek) to the parotid gland increase this risk. Data suggest that tumor thickness greater than 6 mm is a powerful, independent predictor of patients at risk for developing regional metastases.[21]

The most frequent sites for the development of metastatic cutaneous SCC are the parotid gland, the cervical lymph nodes, or both,[22] reflecting the high incidence of primary SCC in the head and neck region. In 20% to 25% of cases, an obvious index lesion is not identified. Invariably, these patients have a long-standing history of actinopathy and NMSC (Figure 41-6). The development of distant metastases (e.g., lung, liver) rarely occurs as a first site of relapse and is more often encountered after treatment for nodal relapse.

Metastatic SCC occurs less frequently in other nodal regions, such as the axilla and groin. Although difficult to quantify, the ratio of metastatic head and neck SCC to non–head and neck SCC is approximately 9:1. There are much fewer published data on the management of these patients, but analogous generalizations from the evidence on parotid and neck nodal metastases suggest operable patients should have surgical resection. Many will have unfavorable features, such as extranodal spread and incomplete margins, and should be recommended adjuvant RT.[23]

Figure 41-6 Elderly white male with a large metastatic lymph node containing metastatic squamous cell carcinoma located in his right upper neck in a parotid tail node. The patient had a long past history of skin cancers of the head and neck but did not have an obvious index lesion present or previously treated. He proceeded to surgery and adjuvant RT.

Merkel Cell Carcinoma

Clinical Presentation and Pathology

MCC is an aggressive cutaneous malignancy that often manifests as a rapidly enlarging firm, painless, pink-red, dermal-based nodule, frequently on the head and neck (50% to 60%) or extremities/trunk in older (>60 to 70 years old) individuals. In contrast to other types of NMSC, MCCs frequently occur in women (Figure 41-7). It is often misdiagnosed because it may resemble BCC or amelanotic melanoma. The median size of the primary lesion at diagnosis is approximately 2 cm, and the incidence of clinical nodal involvement at presentation is approximately 20% to 25%, although the risk of harboring occult nodal disease is high (30% to 40%).[24] Based on the U.S. Surveillance, Epidemiology, and End Results (SEER) database, the annual incidence in men is 0.34 per 100,000 with most patients older than 65 years and white (94%). In this study, slightly less than half (46%) of all lesions occurred in the head and neck, and at diagnosis, half of all patients had localized disease with nodal metastases present in approximately 25%.[25]

The cell of origin is thought to be the dermal neurotactile cell arising from the neural crest first described by Merkel.[26] Lesions usually involve the reticular dermis and subcutaneous tissues, with minimal extension to the papillary dermis and sparing of the epidermis. Vascular and lymphatic permeation is common, and clinically such permeation often manifests as in-transit metastasis. The neoplastic cells exhibit cytoplasmic extensions and small, uniform, membrane-bound neurosecretory granules on ultramicroscopic examination.[27] Several immunohistochemical markers have been identified in MCC. The neoplastic cells stain most consistently with polyclonal antisera to neuron-specific enolase and calcitonin, monoclonal antibody to neurofilament, and cytokeratin (CK 20 positive).[28]

Recent evidence suggests a possible viral association in the development of MCC. The Merkel cell polyomavirus (MCV) was first identified in 2008 and in some studies has been identified in around 80% of MCC tumors.[29] It is postulated that MCV in certain populations (e.g., Australians) may play less of a role compared to the mutagenic consequences of chronic UVB exposure, although this is controversial. The virus is considered part of normal human flora and is also present in healthy tissue from the general population. The prognosis of patients in the presence of MCV is also unclear with separate studies suggesting no difference, better or a worse outcome, respectively. In part this may explain some of the variation in outcome between different populations treated with MCC. Clinical management is currently unaltered whether a patient's tumor contains MCV or not.

Figure 41-7 Left cheek Merkel cell carcinoma (MCC) in an elderly white female. The lesion was asymptomatic, exophytic, rapidly growing with a reddish appearance all characteristics of a MCC. The patient underwent local excision followed by wide-field RT but subsequently developed liver metastases.

Biology and Pattern of Spread

MCC can exhibit an aggressive course characterized by a propensity for local recurrence even after wide surgical excision and a high incidence of nodal involvement (20% to 30% clinically present at diagnosis) with hematogenous dissemination a frequent site of relapse and death. Most series document a cancer-specific death rate of around 30%.[30] Patients may also present with metastatic nodal disease without an obvious index lesion. Such patients make up 10% to 20% of many series and have a better prognosis compared to patients with concomitant nodes and an index lesion.[31] MCC is a highly immunogenic carcinoma, and patients who are immunosuppressed (organ transplant recipients) and patients diagnosed with non-Hodgkin's lymphoma and chronic lymphocytic leukemia are at higher risk of developing MCC and having a poor outcome.[32] The role that the MCV plays in the pathogenesis of MCC may account for its higher incidence inpatients who are immunosuppressed.

Adnexal Carcinoma

Sebaceous Carcinoma

Clinical Presentation and Pathology

Sebaceous carcinomas are rare (approximately 400 reported) and arise most commonly (75% of cases) from the sebaceous glands of the ocular adnexa, the meibomian glands in the tarsus or glands of Zeis at the lid margin, and the caruncle. Extraocular locations, in decreasing frequency, are head and neck region, trunk and extremities, and external genitalia.[3]

For malignant neoplasms of the eyelids, sebaceous carcinomas are second only to BCC in frequency and second only to MM in lethality. The most common location of ocular sebaceous carcinomas is the upper eyelid, followed by the lower eyelid and caruncle. Sebaceous carcinomas predominantly affect individuals older than 60 years, and there is a slight preponderance for women. These lesions manifest clinically as slow-growing, nontender, deep-seated, firm nodules. They often produce a chalazion or manifestations suggestive of inflammatory processes, such as conjunctivitis, blepharitis, or tarsitis. Small primaries may be overlooked until orbital invasion or spread to preauricular or cervical nodes occurs.

The differential diagnosis includes sebaceous adenoma and BCC with sebaceous differentiation (basosebaceous epithelioma). Histologically, these carcinomas are composed of dermal-based lobules and cords of tumor cells, with varying

degrees of sebaceous differentiation and infiltration into the surrounding tissues. Differentiated cells contain foamy or vacuolated, slightly basophilic cytoplasm, whereas less differentiated cells contain more deeply basophilic cytoplasm. Clinical and pathologic features that indicate a poor prognosis include size of the primary lesion (>1 cm is associated with 50% mortality rate), vascular and lymphatic invasion, poor sebaceous differentiation, highly infiltrative growth pattern, and intraepithelial carcinomatous changes in the overlying epithelia.[33]

Biology and Pattern of Spread

Sebaceous carcinoma behaves more aggressively than SCC, with a propensity for nodal and hematogenous spread.[34] Of the 104 patients registered by the Ophthalmic Pathology of the Armed Forces Institute of Pathology, 23 patients (22%) experienced local recurrence once, and 11 patients experienced local recurrence two or more times. Metastatic disease was the cause of death in 23 patients.[33]

Eccrine Carcinoma

Clinical Presentation and Pathology

Sweat gland (eccrine, apocrine, apoeccrine) carcinomas are exceedingly rare, arise most frequently in the skin of the head and neck or the extremities, and manifest as painless papules or nodules that grow slowly. This type of neoplasm is usually diagnosed in individuals 50 to 70 years of age.

Histologically, eccrine or sweat gland carcinomas may resemble carcinomas of the breast, bronchus, and kidney and are difficult to differentiate from cutaneous metastases. Many histologic variants are reported and include ductal eccrine carcinoma, mucinous eccrine carcinoma, porocarcinoma, syringoid eccrine carcinoma, clear cell carcinoma, and microcystic adnexal carcinoma (MAC).[35]

Biology and Pattern of Spread

Eccrine carcinoma has a more aggressive behavior than BCC and SCC. In a series of 14 patients who underwent surgical excision with negative excision margins, 11 developed at least one local recurrence, and 5 relapsed at regional nodes or distant sites. One patient died of uncontrolled local relapse, and 4 died of distant metastasis 2 months to 10 years after diagnosis.[35] Apocrine carcinoma arises most commonly from apocrine glands of the axilla, but it can originate from apocrine glands of the vulva and eyelids and from ceruminal glands of the external auditory canal. It manifests clinically as a red-purple single or multinodular, firm or cystic dermal mass in elderly individuals. The natural history of apocrine carcinoma is not well documented but nodal and distant metastases have been reported.[36,37]

Microcystic Adnexal Carcinoma

Clinical Presentation and Pathology

MAC is a rare (~700 documented cases in the literature) locally aggressive carcinoma that belongs to the spectrum of adnexal carcinomas and most often arises on the mid face.[38] It usually grows slowly over years and often is deeply invasive when diagnosed. It arises equally in males and females and tends to occur in adults 55 to 60 years old and occasionally in children.

Histologically, the tumor is composed of keratin horn cysts, nests, or cords of basaloid cells that are usually more prominent in the superficial dermis. Tumor strands and cystically dilated tubules are arranged in sold islands and embedded in deeper desmoplastic stroma. The cells usually show no atypia or mitoses, and the differential diagnosis may include trichoadenoma, syringoma, desmoplastic trichoepithelioma, or morpheaform BCC.[39]

Biology and Pattern of Spread

Patients with MAC often present with advanced and deeply invasive lesions after years of slow growth and misdiagnosis. PNI is reported to be present in many cases particularly in the recurrent setting. Lymph node metastases rarely occur. MAC tends to be a locally recurrent tumor with morbidity related to local invasion and destruction.

PATIENT EVALUATION AND STAGING

Most patients with NMSC present with an asymptomatic skin lesion, and often have a history of other NMSCs. Symptoms suggestive of PNI, such as pain, tingling, and hypesthesia, should be specifically sought from the patient. Up to 60% of patients with PNI may be clinically asymptomatic (microscopic PNI), and a crawling sensation on the skin termed *formication* is suggestive for sensory nerve involvement.[40] The most common primary sites associated with PNI are the frontozygomatic (supraorbital nerve) and infraorbital (infraorbital nerve) regions. Patients occasionally present with cranial nerve palsy as the first sign of PNI. Facial nerve involvement is usually preceded by muscle fasciculations followed by frank paralysis.[41] Clinical evaluation of patients with NMSC should consist of inspection and palpation of the involved area and the draining lymph nodes.

Imaging studies (chest radiography, CT, or MRI) generally are not required in most patients with NMSC but should be obtained as indicated (e.g., clinically suspicious lymph nodes). Lymph node metastasis and bone involvement are best assessed with contrast-enhanced CT scan acquired with soft tissue and bone windows (Figure 41-8). MRI, with and without contrast enhancement and fat suppression, should be obtained for all patients in whom PNI is suspected, with the findings of an enlarged or abnormally enhancing nerve raising the possibility of PNI.[42] Patients may need to undergo biopsy of the suspected nerve to confirm the diagnosis.[43] PET-CT is generally not required to stage patients with NMSC.

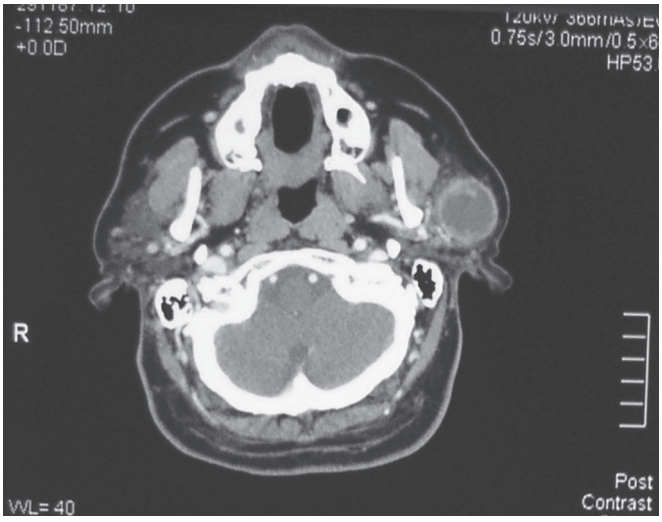

Figure 41-8 Axial CT scan showing metastatic cancer in the left parotid. There is concentric nodal enlargement, contrast enhancement of the rim, and central necrosis, all features consistent with a metastatic node from squamous cell carcinoma.

Staging of Basal and Squamous Cell Carcinoma

Previous staging systems have been criticized for lacking clinical and prognostic relevance, especially for patients with SCC.[44] More recent changes now include reporting of important pathologic high-risk features, such as tumor depth and the presence of PNI. The previous American Joint Committee on Cancer (AJCC) TNM (primary tumor, regional nodes, metastases) staging systems were based primarily on clinical findings and were of limited usefulness. The newer staging system (AJCC seventh edition) incorporates important clinicopathologic factors and does not rely purely on size as a T-category determinant.[45] High-risk features can now upstage a tumor, for example from T1 to T2, even if horizontal size is unchanged.

Similar to flaws in staging patients with the primary, or T-category, patients with nodal metastases from SCC were assigned an N-category via a flawed previous staging system with all patients indiscriminately assigned as N1 category regardless of metastatic nodal size, number, or presence of extranodal spread.[46] O'Brien et al[47] proposed a staging system for metastatic SCC to the parotid or neck that categorizes N (neck) and P (parotid) category based on the aforementioned variables. The new AJCC system now describes three nodal categories (N1-N3) based on the number and size of involved nodes.

Staging of Merkel Cell Carcinoma

A staging system developed by the Memorial Sloan Kettering Cancer Center separated patients with lesions less than, or greater than, 2 cm (stage I/II), with stage III representing those with nodal disease and stage IV those with distant disease.[48] In the current AJCC TNM seventh edition staging system, primary size and clinical and pathologic nodal status are incorporated into new group staging.[45] Of the stages documenting nondistant spread, stages I and II are classified by tumor size >2 cm and within each stage further categorized (A, B) depending on whether draining nodes have been evaluated as being uninvolved clinically (IA or IIA), or pathologically (IB, IIB) (e.g., by sentinel lymph node biopsy [SLNB]). Patients with stage III disease have pathologically confirmed nodal metastases and are further divided into those with micrometastases (i.e., occult) or macrometastases (clinically detectable).

PRIMARY TREATMENT AND RESULTS

Basal and Squamous Cell Carcinoma

Primary Tumor

The general strategy for managing most early NMSC is similar for either BCC or SCC. Various surgical and medical approaches are available, including curettage and electrodesiccation, Mohs's micrographic surgery, cryotherapy, surgical resection, and definitive RT. Numerous topical (e.g., 5FU, imiquimod) and intralesional (e.g., methotrexate, interferon) options as well as other modalities (e.g., photodynamic therapy [PDT]) are also available, often with ill-defined criteria for using them. Additionally the evidence to support topical or intralesional treatment is predominantly low level with long-term follow-up (up to 5 years) lacking and therefore clinicians need to consider various issues prior to any recommendation. Such treatments are essentially limited to select superficial NMSC and premalignant conditions (e.g., AK).[49]

With correct case selection the various surgical and medical approaches are similarly effective in curing most NMSC. The choice of treatment for individual patients is determined by factors such as the site and size of a lesion, anticipated functional and cosmetic results, treatment time and cost, patient age, occupation, and general condition. Carcinomas in the H zone or embryonic fusion planes may have extensive local spread, so treatment that ensures wide marginal (especially deep) coverage should be selected.

Overall, surgery is preferred for most patients. Simple procedures can yield high local control rates for patients with small lesions. Younger patients who have years of future exposure to sunlight are often better managed by surgery than by RT, although in certain cases RT may still be considered a better option. In numerous settings, especially in the setting of a close or positive margins or the presence of PNI, postoperative RT may be beneficial to reduce the risk of local recurrence. Other factors such high-grade histology, invasion of bone and cartilage and extensive skeletal muscle infiltration may also contribute to a decision to recommend adjuvant RT.

Local RT is an effective option when excision is incomplete and reexcision is not considered possible. In a study of 315 patients with primary cutaneous SCC of the head and neck undergoing wide local excision, patients undergoing surgery followed by adjuvant RT ($n = 52$) had a 92% reduced risk of recurrence (hazard ratio, 0.08; 95% CI 0.0 to 0.26; $p < 0.001$) compared to those treated with surgery alone.[50]

Primary (or definitive) RT is often recommended for lesions on and around the nose, lower eyelids, medial canthus, and ears, where it may yield better functional and cosmetic results than surgery[51] (Figure 41-9). Extensive lesions of the cheek, lip, and oral commissures that would require full-thickness resection may also be better irradiated. RT avoids the need for an operation and the surgical morbidity, scarring and requirement for reconstruction and has the benefit of being able to treat both wide (5 mm to 30+ mm) and deep margins, tissue that would otherwise require excision (with or without reconstruction). This particular advantage may result in improved cosmesis in situations in which a flap or graft is required. RT is particularly useful in areas of the midface, such as the periorbital region (especially the medial canthus), lower eyelid, nose (particularly the ala and tip), nasolabial fold, lip and chin, where excision and reconstruction could have a greater impact on form and function. Elderly patients with comorbid conditions are also often better approached with RT.

The lower lip is especially suited for RT when surgery may result in microstomia or require complex reconstruction for lesions occupying more than one third of the lips, and patients can be easily treated with orthovoltage RT after insertion of a lead oral cavity shield with expected cure rates similar to surgery. Patients may also benefit from postoperative RT if excision is incomplete and reexcision is not considered possible. In an Australian study of 217 patients with early lower lip SCC (considered as a sun-induced skin cancer), patients undergoing local adjuvant RT (50 Gy to 55 Gy in 20 to 25 fractions) in the setting of close (<2 mm) or positive margins had a significantly improved relapse free survival compared with similar patients not receiving RT (hazard ratio 0.36; 95% CI 0.17 to –0.77; $p = 0.008$). Of note, 57% of patients treated with excision alone developed a recurrence compared with 9% treated with surgery and RT, in the setting of close or positive margins.[52]

The overall local control rate of all sizes and types of cutaneous carcinoma treated with various modalities is 80% to 95%. RT is an excellent treatment option for patients in whom other modalities may have failed or are considered less optimal. In a series from M. D. Anderson Cancer Center of patients with SCC of the eyelid treated with definitive RT, an excellent 5-year local control of 89% was achieved.[53]

Figure 41-9 **A,** A 55-year-old white female with a 2.5-cm nodular basal cell carcinoma located on the right medial canthus. An internal eye shield has been inserted in preparation for RT markup. **B,** At markup, an RT field margin of approximately 1 cm *(solid line)* was applied. **C,** At completion of RT (55 Gy in 25 fractions using superficial energy photons), the tumor has almost completely regressed. At 3-year follow-up, she remained disease-free.

Patients with recurrent lesions (compared with de novo lesions) and with SCC (compared with BCC) have lower rates of local control. Similarly, as lesions increase in size, rates of local control decrease. In one study of patients with locally advanced (>T2) SCC and BCC, 4-year locoregional control rates were 86% and 58% for SCC and BCC, respectively.[54] Despite this, RT may still remain the best option.

One of the disadvantages of RT compared to surgery is the time required to undergo a course of treatment. The typical course of fractionated RT ranges from 10 to 25 daily 10-minute outpatient treatments (or fractions). However, fewer fractions (3 to 5) may be used in older patients with comorbid illnesses. Another disadvantage is that RT cannot be delivered a second time to the same site because of the risk of potential late complications such as soft-tissue and cartilage necrosis. Reirradiation is rarely ever considered an option but may be considered if surgical salvage is not possible. Although the initial cosmetic result after RT is excellent, fibrosis, soft-tissue or epidermal atrophy, and in-field pigmentation changes may become apparent over time (Figure 41-10). Unprotected sun exposure to irradiated sites is likely to exacerbate these changes, and patients should be warned to take appropriate measures. When RT is delivered to younger patients, daily fraction sizes of 2 Gy to 2.5 Gy are recommended (e.g., 55 Gy in 25 fractions) to minimize late changes. This should apply whether treatment is delivered in the definitive or adjuvant setting. The risk of developing a late in-field radiation-induced malignancy after RT is rare and poorly documented in the literature. Alternative treatments should be considered for younger patients, however, because many develop further skin cancers as they

Figure 41-10 Elderly male having 2 years previously received definitive RT (40 Gy in 10 fractions) to the tip of his nose in the setting of a nodular basal cell carcinoma. Note the well demarcated in-field hypopigmentation, scattered telangiectasia (small blood vessels), and epidermal atrophy.

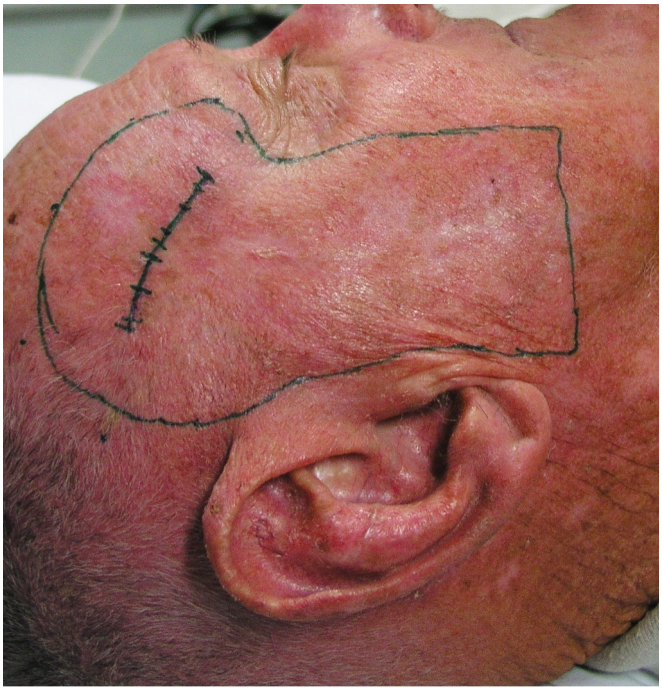

Figure 41-11 A 73-year-old white male had wide-field adjuvant RT to a high-risk squamous cell carcinoma (recurrent and positive deep margin) with the field electively encompassing his parotid lymph nodes. The patient received 50 Gy in 20 fractions using orthovoltage energy photons.

age. There is, however, no absolute contraindication for offering RT to younger patients if the patient and clinician agree this is the optimal modality.

Regional Nodes

Elective nodal treatment is not indicated for BCC or low-risk SCC because of the low incidence of lymphatic spread. However, select patients with high-risk SCC of the head and neck may warrant elective treatment (surgery or RT) of clinically node-negative regional nodes in conjunction with treatment of the primary, although consensus is lacking for this approach.[20,55] For example, a patient with a recurrent temple SCC in whom adjuvant RT is recommended in the setting of a positive deep margin may also be considered for the parotid nodes to be included electively en bloc in the RT field (Figure 41-11).

Patients who develop metastatic cutaneous SCC to the parotid or neck are optimally treated with surgery and adjuvant RT with few exceptions.[56] The aim of adjuvant RT is to reduce the risk of regional relapse because most patients have unfavorable features, such as multiple metastatic nodes, extranodal spread, close margins, or the presence of PNI. Despite combined treatment, 10% to 15% develop in-field recurrence, often in the parotid bed or skull-base region. Most will be inoperable and incurable. An ongoing study (Trans Tasman Radiation Oncology Group [TROG] 05.01) is evaluating the role of concurrent carboplatinum to adjuvant RT in improving regional control. With surgery and adjuvant RT, 5-year overall survival (OS) is 70% to 75%. Patients considered medically or technically inoperable can still be treated with RT alone, although the likelihood of cure is reduced. Patients of good performance status may also be considered suitable to receive concurrent platinum chemotherapy although this approach may also increase the toxicity of treatment and is experimental.

Perineural Invasion

The role of surgery and RT in patients with PNI is unclear. Patients with asymptomatic PNI, detected postoperatively, may benefit from wide field local RT without the need to treat neural pathways. Patients with symptomatic PNI may, however, require more extensive volumes irradiated to encompass involved neural pathways, including intracranial extension. Doses of 50 Gy to 60 Gy may be required and attention paid to the tolerance of structures such as the orbital contents and optic chiasm. Whether patients benefit from excision of involved nerves in addition to RT is controversial but recommended by some skull-base surgeons.[57]

Sentinel Lymph Node Biopsy

The role of SLNB in NMSC is unclear because the overall incidence of metastatic nodal disease is low. In contrast to patients with MM, there is limited evidence to guide clinicians with a meta-analysis (13 studies) reporting positive selective lymph nodes in 12.3% of high-risk patients.[58] In certain patients considered to have high-risk SCC, however, SLNB may be useful in guiding clinicians, provided that expertise in undertaking this investigation is available.

Merkel Cell Carcinoma

The initial treatment for MCC is usually surgery to establish tissue diagnosis. The role of RT in the management of MCC has been evaluated since the early 1980s because of the high rate of locoregional relapse in this radiosensitive disease.

With few exceptions, most studies report a marked benefit to locoregional control and survival with the addition of adjuvant RT. In the largest study ($n = 1665$) of its type, the addition of adjuvant RT significantly improved median survival in patients with lesions greater than 2 cm from 21 months to 50 months ($p = 0.0003$).[59] In a meta-analysis of 1254 patients, Lewis et al[60] reported a significant reduction in local (hazard ratio 0.27, $p < 0.001$) and regional (hazard ratio 0.34, $p < 0.001$) relapse and a benefit in overall survival (hazard ratio 0.63, $p = 0.04$) in patients treated with surgery and adjuvant RT compared with patients treated with surgery alone.

The routine use of adjuvant chemotherapy is unclear. In a Phase II single-arm study from Australia, 53 patients received concurrent and adjuvant chemotherapy (carboplatin and etoposide) with RT with 3-year OS, locoregional control, and distant control rates of 76%, 75%, and 76%, respectively.[61] These results add support for a randomized controlled trial to confirm the hypothesis that chemotherapy may benefit these patients.

With few exceptions, most patients with MCC should proceed to wide-field adjuvant RT when a diagnosis has been confirmed. Given the high risk of local recurrence, RT margins around a primary lesion (or excision site) of at least 3 cm to 4 cm are recommended, if possible, and as a guide treatment fields should encompass, as a minimum, the primary site, in-transit tissue, and first-echelon nodes (Figure 41-12).[61,62] RT should not be delayed by the need for further surgery if excision margins are involved. The risk of occult nodal metastases at presentation is 30% to 50%, and if left untreated, patients may develop clinical nodal metastases, which carries a poor prognosis.[62] Thus, all patients should have the draining lymph nodes either investigated with SLNB, or treated electively usually with RT in association with RT to the primary site. Patients who may be considered for close observation because of the relatively low risk of recurrence include those with small lesions (<10 mm) widely excised (5-mm to 10-mm margins), without the presence of lymphovascular invasion and SLNB negative.

Figure 41-12 A 49-year-old male undergoing wide-field adjuvant RT after excision of a 12-mm Merkel cell carcinoma from the right upper face. The large field encompasses the excision site, in-transit tissue, and parotid and upper neck lymph nodes. A dose of 55 Gy in 25 fractions using 9-MeV electrons was prescribed. The patient developed confluent brisk in-field erythema by the end of treatment.

Patients with small volume (<3 cm to 4 cm) nodal metastases can be treated adequately with RT without the need to undergo nodal resection. In the setting of inoperable disease, definitive RT to doses of 50 Gy to 55 Gy in 20 to 25 daily fractions still offers the likelihood of excellent in-field control (75%) and cure in a few patients.[63]

Adnexal Carcinoma

The standard treatment of sebaceous carcinoma is wide local excision and therapeutic nodal dissection if lymphadenopathy is present. Consideration may be given to excision with Mohs's micrographic surgery. The role of adjunctive modalities has not been explored systematically, but there is evidence that RT may be an effective modality in MAC in both the adjuvant and definitive setting and should therefore be considered in select patients.[64,65] Generally, postoperative irradiation is indicated when the surgical margins are positive or close, multiple lymph nodes are involved, or extracapsular nodal extension is present.

For eccrine and apocrine carcinomas, wide excision of the primary lesion is accepted as the standard treatment in patients with no lymphadenopathy at diagnosis. Postoperative RT to the surgical bed with 2-cm to 3-cm margins may be indicated.

The role of elective treatment of regional lymphatics is controversial in this rare disease. As most malignant skin adnexal neoplasms have a low rate of nodal metastasis, and there is little evidence in the literature regarding the use of SLNB, we do not generally recommend the routine use of SLNB in patients with malignant skin adnexal tumors. However, in select patients with high-risk eccrine porocarcinoma (tumor thickness >7 mm, lymphovascular invasion present) it may be of benefit.[66]

LOCALLY ADVANCED DISEASE AND PALLIATION

Patients with locally advanced (T4) primary skin cancers involving bone and cartilage, muscle, or nerves can still be treated and cured with definitive RT. In many cases, surgical salvage is an option if RT is unsuccessful. Al-Othman et al[67] documented an initial local control rate of 53% and an ultimate local control rate of 90% with surgical salvage in 85 patients with previously untreated (n = 43) and recurrent (n = 45) T4 skin carcinomas given RT to doses of 60 Gy to 75 Gy over 6 to 8 weeks. Bone invasion or PNI was found to reduce the likelihood of local control in this small series. Cause-specific survival at 5 years was 76%, and 15% developed severe late complications in the form of soft-tissue or bone and cartilage necrosis. In a study of 21 patients with T4 NMSC treated with megavoltage RT almost 60% achieved disease control with many treated with intensity-modulated RT (IMRT).[68] The utilization of newer technology such as IMRT in select patients with advanced NMSC may allow the delivery of higher doses of RT, yet minimize the side effects of treatment. Similarly, in 25 patients with an advanced NMSC and treated with helical tomotherapy (a form of IMRT) delivering doses between 50 Gy and 70 Gy, the authors documented complete clinical remission in 88%.[69]

Radiation can reduce symptoms (pain, bleeding, fungation, infection, and drainage) for most patients with advanced inoperable cancer or metastatic disease. Recommended dose-fractionation schedules depend on the tumor location and patient's life expectancy. The most frequently used regimens include the following:

- 20 Gy to 30 Gy in 5 to 10 fractions over 1 to 2 weeks for skeletal or cerebral metastasis or even a single fraction of 8 Gy, especially for skeletal metastases.
- 45 Gy to 50 Gy in 18 to 25 fractions over 4 to 5 weeks for patients with tumor deposits in the proximity of critical structures (e.g., parotid, axillary, or ilioinguinal region) but otherwise having a reasonable life expectancy. Alternative approaches include a QUAD SHOT schedule in which patients receive 4 fractions delivered over 2 days and repeated every 3 weeks to a total dose of approximately 42 Gy to 44 Gy (Figure 41-13).

In a study of 28 patients treated palliatively in the setting of advanced NMSC (5 cm median size) 24 Gy was delivered over 3 weeks. The authors report an alleviation of symptoms in 83% of assessable sites and a complete response recorded in 36% of patients.[70] Alternatively, large single fractions of 10 Gy to 15 Gy may also be appropriate in patients who are debilitated and in a nursing home with large neglected lesions that are often painful, bleeding, and infected.

Many SCCs express epidermal growth factor receptor and targeted treatment using monoclonal antibodies is an emerging option in select advanced cases. In some cases, dramatic results have been obtained using this relatively nontoxic treatment.[71] Similarly, a recent finding in patients with BCC has been genetic alterations resulting in up-regulation in the hedgehog signaling pathway. A new oral drug, Vismodegib, inhibits this pathway and may offer a potentially new treatment for patients with advanced (inoperable or previously treated) and metastatic BCC, and patients with Gorlin's syndrome (basal cell nevus syndrome). A recent study reported a complete response of 21% in eligible patients although the median duration of response was short (7.6 months) and serious adverse events and even death were reported. With further research it is likely that the outcome for these patients will improve with molecular inhibition of this and other pathways.[72]

Figure 41-13 **A,** Patient, 85 years old, unwell, with a rapidly growing left facial squamous cell carcinoma deemed inoperable. **B,** The patient underwent palliative RT (35 Gy in 10 fractions using orthovoltage photons) to the lesion and experienced an excellent regression in her cancer and an improved quality of life.

IRRADIATION TECHNIQUES

Carcinoma

As previously documented, definitive RT yields an excellent disease control rate with good functional and cosmetic results for lesions around the nostril, lower eyelids, ears, and lips. Patients who are poor surgical risks and patients with large lesions are also sometimes best treated with RT. Proper planning and execution of RT are essential to achieve the best outcome.

Target Volume

The RT target volume (or RT field) for a localized NMSC is determined by the size of the lesion, lesion location, and type of growth (infiltrative lesions require more generous field margins). The treatment field typically encompasses the visible or palpable tumor and 1 cm to 2 cm of surrounding normal-appearing skin. Margins may be tighter (1 cm) when treating areas close to the eye or when the primary lesion is 1 cm or smaller. More generous margins are appropriate for lesions with ill-defined borders to adequately encompass subclinical (i.e., microscopic) extension. In a study involving 159 NMSC in 150 patients the authors pathologically determined microscopic spread beyond gross lesions and made recommendations on RT field margins to achieve 95% coverage of subclinical spread. For BCC the margins ranged from 10 mm to 13 mm, and for SCC, from 11 mm to 14 mm. Clinicians should be aware that inadequate margins place a patient at risk of recurrence.[73]

Occasionally, in patients with SCC presenting with either low-volume lymphadenopathy and concomitant primary disease or high-risk primary lesions and a clinically negative nodal basin, the initial field may encompass the primary lesion and the regional lymphatics with the treatment field subsequently reduced to cover the areas of gross disease with adequate margins. A typical site is a temple primary with parotid metastases in which the initial RT field should receive a prescribed dose of 50 Gy, or equivalent, followed by an extra 10 Gy to 20 Gy to a reduced field (1 cm to 2 cm around macroscopic disease). In many cases, small treatment fields can be safely treated with hypofractionated schedules using 2.5-Gy to 4-Gy fractions, which reduces the overall duration of treatment.

In patients receiving postoperative RT in the setting of lymph node metastasis or PNI, the initial portal also may need to encompass the primary tumor bed, if technically feasible. However, if the time interval from primary site treatment exceeds 12 months, and there is no evidence of local recurrence, this may be omitted. Some clinicians may choose a longer period of time such as 24 months before omitting treatment of the primary site.

The clinical target volume in the setting of PNI depends on the primary site and the relevant cranial nerves involved and in many cases includes the skull base, cavernous sinus, and intracranial routes back to the brainstem.[74] IMRT may allow for the accurate treatment of neural pathways while limiting the dose to critical structures. Electively treating regional lymph nodes in patients with PNI is an option but probably unnecessary.

Setup, Field Arrangement, and Dose Fractionation Schedule

Patients are best immobilized in a position that gives optimal access to irradiate the tumor to ensure daily reproducibility. Preferably, the position is such that the plane of the skin to be treated is horizontal to facilitate the placement of a lead shield for skin collimation. Irradiation is delivered through a single appositional field, in most cases using superficial or orthovoltage energy photons (usually 75 kVp to 300 kVp) or electrons (usually 6 MeV to 9 MeV). Low-energy photons are preferable to using small field electrons when treating skin cancers. However, NMSC can still be treated effectively with electrons, provided that clinicians are aware of certain aspects of using electrons (e.g., skin sparing, dose constriction at depth, wide penumbra). In a large study of 434 NMSC in 333 patients all were treated with electrons (4 MeV to 12 MeV) receiving either 54 Gy in 18 fractions or 44 Gy in 11 fractions. With a median follow up of 43 months local control rates varied between 94% and 97% without a significant difference in outcome between BCC and SCC. Cosmetic outcome was also assessed in a small group without any significant difference between the two treatment schedules. These results suggest electrons are an effective treatment in departments that lack a superficial or orthovoltage machine.[75]

An alternative to external beam RT in select patients with superficial (<4 mm thick) well-circumscribed NMSC is brachytherapy (or contact therapy). In an Australian center 236

Figure 41-14 A patient undergoing RT to the left side of the nose. A lead mask is cut out to define the RT field receiving treatment. There is an extra layer of lead covering the eyes to reduce further any scattered dose.

NMSC (in 200 patients) were treated with high-dose rate brachytherapy using a surface applicator (max diameter 30 mm) and prescribed a dose of 36 Gy in 12 daily fractions taking ~10 minutes for each daily treatment. The outcome of these patients was excellent with local control achieved in 98% and a reported good or excellent cosmesis obtained in 88%. Centers with expertise in brachytherapy may consider this alternative in select patients, especially if the department lacks a superficial or orthovoltage machine.[76]

The energy of x-rays or electrons is chosen based on the thickness of the lesion to be treated. This decision is critical when using electrons, the energy of which should be selected such that the 90% isodose line including surface bolus is a few millimeters deeper than the base of the lesion. The treatment distance for x-rays also depends on the thickness of the lesion. A shorter 20-cm to 30-cm focus skin distance cone is appropriate for superficial tumors, but a 50-cm focus skin distance open field with skin collimation is preferable for thicker lesions to avoid a large dose gradient across the lesion. The focus skin distance for electrons is usually 100 cm.

Several techniques and devices are helpful in minimizing radiation exposure to the surrounding normal tissues and obtaining the desired dose distribution. A 3- to 4-mm-thick lead cutout is used for field shaping, conforming to the geometry of the lesion by skin collimation (Figure 41-14). The overall size of the cutout should be large enough so that the cone or collimator setting for electron beams is at least 4 × 4 cm in size for reliable dosimetry. Skin bolus or a scatter plate is used when treatment is given with electrons to ensure full surface dose. Additional shielding can be applied to protect tissues from "exit radiation." An internal eye shield is inserted when treating an eyelid lesion with orthovoltage x-rays or electrons of 8 MeV or less (see Figure 41-9, *B*). It is important to calibrate commercially available eye shields individually

Figure 41-15 A 45-year-old white male undergoing definitive RT for a T2 N0 lower lip squamous cell carcinoma. The patient received 55 Gy in 25 fractions using orthovoltage energy photons with the daily insertion of an oral cavity lead shield to limit exit dose to the mandible, teeth, and oral cavity.

with respect to their electron-attenuating properties because transmission through these shields can be considerable, even for a nominal 6-MeV beam. Similarly, lead oral cavity shields are used to shield the mandible, teeth, and oral cavity when treating a lip cancer (Figure 41-15).

Several fractionation schedules can be used and are effective in curing NMSC. Generally, more protracted fractionation schedules using lower dose (2 Gy to 2.5 Gy) per fraction give the best cosmetic results. The recommended radiation regimen for individual patients depends on patient age, lesion size, and site. For most skin cancers in older patients, a dose of 40 Gy in 10 fractions, 45 Gy in 15 fractions, or 50 Gy in 20 fractions is an appropriate and effective regimen. If the patient is in poor general condition, hypofractionation (e.g., 32 Gy in 4 fractions, 21 Gy in 3 fractions, 35 Gy in 5 fractions, or a single dose of 15 to 20 Gy) may be used. Delivering large fractions using superficial energy photons or orthovoltage energy photons can take 20 to 30 minutes, and an uncooperative patient may need to be lightly sedated.

The dose for treatment with x rays is specified at D_{max}. The dose for irradiation with electrons is prescribed at 90%. Prescription of electron doses at 90% versus D_{max} for superficial x-rays allows for the difference in relative biologic effectiveness between the two beam qualities.

After resection of a nodal basin (e.g., parotid or neck), patients with positive nodes (or a single node with extranodal spread) usually receive radiation in 2 Gy fractions to a dose of 60 Gy because of the large treatment volume. Similarly, for patients with inoperable nodal disease treated with RT alone, 2 Gy to 2.5 Gy fractions to a total dose of 60 Gy to 70 Gy with a shrinking field are used unless the intent is palliative.

Merkel Cell Carcinoma and Adnexal Carcinoma

Target Volume

The target volume for MCC consists of the excision site (with 3-cm to 4-cm margins), in-transit tissue, and at least the first echelon nodes (may consider next level as well). When a lesion is close to critical structures (e.g., orbit) narrower margins and appropriate shielding need to be considered.

The target volume for adnexal carcinoma consists of the surgical bed with margins of 2 cm to 3 cm and, depending on the site and size of the primary tumor, the draining lymphatics.

Figure 41-16 **A,** Multinodular Merkel cell carcinoma located on the distal foot of a 90-year-old male. **B,** The patient received 25 Gy in five fractions to the distal foot and experienced rapid disease regression by the end of treatment. **C,** At 2 months after RT, there was no evidence of disease; at 18-month follow-up, he remained disease free.

Setup, Field Arrangement, and Dose Fractionation Schedule

The general principles of patient setup and portal arrangement are as outlined for BCC and SCC. As primary treatment, RT is administered, preferably with electrons, in 2 to 2.5-Gy fractions to a cumulative dose of 45 to 55 Gy for elective irradiation, plus a boost dose of 10 Gy in 5 fractions to the gross disease. A cumulative dose of 60 to 66 Gy may be recommended for the treatment of bulky, inoperable primary tumors. Elderly patients of poor performance status who are unsuitable for an extended course of RT may still benefit from shorter palliative schedules, such as 25 Gy in 5 fractions (Figure 41-16).

Radiation regimens used for adnexal carcinoma are 60 Gy to 70 Gy in 30 to 35 fractions, depending on the site and target volume. The portal is generally reduced to encompass areas of known gross disease after 50 Gy to 54 Gy.

Patient Care During and after Radiotherapy

A tumoricidal dose of RT produces moist desquamation of the irradiated skin by the end of, and shortly after, treatment. The irradiated skin area should be protected from heat, cold, sunlight, friction, disinfectants, and other sources of irritation to avoid additional tissue injury. During RT, the daily application of a bland emollient is recommended. When moist desquamation occurs, the area should be kept clean to prevent secondary infection and may require the application of a burn-type dressing (e.g., silver sulfadiazine cream) for at least 2 to 3 weeks. Patients are instructed to use sunscreen over the irradiated area after completion of treatment.

Patients should also be informed about the specific acute and late side effects of treatment, such as mucositis of the nasal passages and upper lip, nasal dryness, synechiae (when treating nostril lesions), and conjunctivitis and loss of eyelashes (when treating eyelid cancers). After treatment involving the lacrimal canaliculi, irrigation of the ducts during the healing phase helps to prevent synechiae.

Regular follow-up examinations should include evaluation of the treated area for late complications and search for new lesions. The latter develop in up to 50% of treated patients occasionally in proximity to a previous treatment field. Late side effects include hypopigmentation, hyperpigmentation, telangiectasia, and skin atrophy. Skin retraction at the lower eyelid may result in ectropion. These are rarely serious after properly administered RT.

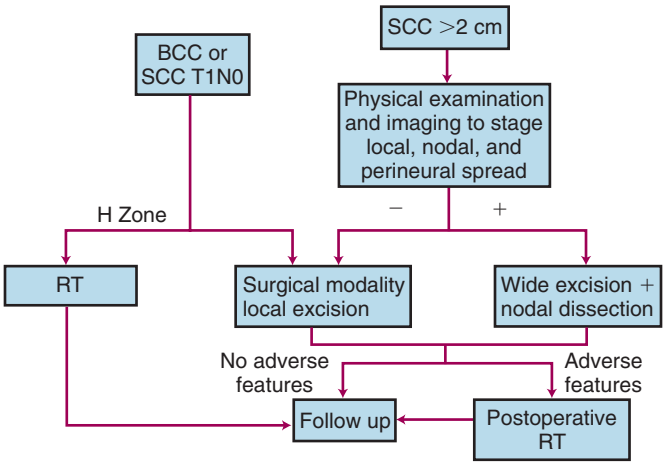

Figure 41-17 **Diagnostic and treatment algorithm for cutaneous basal cell carcinoma (BCC) and squamous cell carcinoma (SCC).** *RT,* Radiotherapy.

DIAGNOSTIC AND TREATMENT ALGORITHMS

Basal Cell Carcinoma and Squamous Cell Carcinoma

Figure 41-17 illustrates the diagnostic and treatment algorithm for BCC and SCC. The choice of treatment for individual patients is determined by factors such as the lesion site and size, anticipated functional and cosmetic results, treatment

time, treatment cost, and patient preference. Surgical approaches are preferred for most patients with resectable tumors, but RT may yield better functional and cosmetic results for lesions of the nose, lower eyelids, and ears. A combination of surgery and adjuvant RT is indicated in larger tumors or tumors with inadequate excision, PNI, invasion of bone or cartilage, extensive skeletal muscle infiltration, or nodal metastasis.

Merkel Cell Carcinoma and Adnexal Carcinoma

A combination of surgery (respecting form and function) and wide-field elective or adjuvant RT is recommended for most patients with MCC and adnexal carcinoma. In most situations, there should be elective treatment, usually RT, of first echelon lymph nodes. The role of adjuvant chemotherapy for the treatment of MCC is unclear without high-level supportive evidence to support a benefit. RT alone still offers a potential cure for inoperable patients or patients refusing surgery. More recent evidence suggests that PET/CT scanning in patients with MCC may alter management or prognosis, or both, in 30% to 40% of patients.[77]
